# Contents

## Part I: Background: The Elements of Brain Theory and Neural Networks 1

## Part II: Road Maps: A Guided Tour of Brain Theory and Neural Networks 25

## Part III: Articles 81

The articles in Part III are arranged alphabetically by title. To retrieve articles by author, turn to the contributors list, which begins on page 1241.

# Preface to the Second Edition

Like the first edition, which it replaces, this volume is inspired by two great questions: "How does the brain work?" and "How can we build intelligent machines?" As in the first edition, the heart of the book is a set of close to 300 articles in Part III which cover the whole spectrum of *Brain Theory and Neural Networks*. To help readers orient themselves with respect to this cornucopia, I have written Part I to provide the elementary background on the modeling of both brains and biological and artificial neural networks, and Part II to provide a series of road maps to help readers interested in a particular topic steer through the Part III articles on that topic. More on the motivation and structure of the book can be found in the Preface to the First Edition, which is reproduced after this. I also recommend reading the section "How to Use This Book"—one reader of the first edition who did not do so failed to realize that the articles in Part III were in alphabetical order, or that the Contributors list lets one locate each article written by a given author.

The reader new to the study of *Brain Theory and Neural Networks* will find it wise to read Part I for orientation before jumping into Part III, whereas more experienced readers will find most of Part I familiar. Many readers will simply turn to articles in Part III of particular interest at a given time. However, to help readers who seek a more systematic view of a particular subfield of *Brain Theory and Neural Networks*, Part II provides 22 Road Maps, each providing an essay linking most of the articles on a given topic. (I say "most" because the threshold is subjective for deciding when a particular article has more than a minor mention of the topic in a Road Map.) The Road Maps are organized into 8 groups in Part II as follows:

**Grounding Models of Neurons and Networks**
- Grounding Models of Neurons
- Grounding Models of Networks

**Brain, Behavior, and Cognition**
- Neuroethology and Evolution
- Mammalian Brain Regions
- Cognitive Neuroscience

**Psychology, Linguistics, and Artificial Intelligence**
- Psychology
- Linguistics and Speech Processing
- Artificial Intelligence

**Biological Neurons and Networks**
- Biological Neurons and Synapses
- Neural Plasticity
- Neural Coding
- Biological Networks

**Dynamics and Learning in Artificial Networks**
- Dynamic Systems
- Learning in Artificial Networks
- Computability and Complexity

**Sensory Systems**
- Vision
- Other Sensory Systems

**Motor Systems**
- Robotics and Control Theory
- Motor Pattern Generators
- Mammalian Motor Control

**Applications, Implementations, and Analysis**
Applications
Implementation and Analysis

The authors of the articles in Part III come from a broad spectrum of disciplines—such as biomedical engineering, cognitive science, computer science, electrical engineering, linguistics, mathematics, physics, neurology, neuroscience, and psychology—and have worked hard to make their articles accessible to readers across the spectrum. The utility of each article is enhanced by cross-references to other articles within the body of the article, and lists at the end of the article referring the reader to road maps, background material, and related reading.

To get some idea of how radically the new edition differs from the old, note that the new edition has 285 articles in Part III, as against the 266 articles of the first edition. Of the articles that appeared in the first edition, only 9 are reprinted unchanged. Some 135 have been updated (or even completely rewritten) by their original authors, and more than 30 have been written anew by new authors. In addition, there are over 100 articles on new topics. The primary shift of emphasis from the first edition has been to drastically reduce the number of articles on applications of artificial neural networks (from astronomy to steelmaking) and to greatly increase the coverage of models of fundamental neurobiology and neural network approaches to language, and to add the new papers which are now listed in the Road Maps on Cognitive Neuroscience, Neural Coding, and Other Sensory Systems (i.e., other than Vision, for which coverage has also been increased). Certainly, a number of the articles in the first edition remain worthy of reading in themselves, but the aim has been to make the new edition a self-contained introduction to brain theory and neural networks in all its current breadth and richness.

The new edition not only appears in print but also has its own web site.

## Acknowledgments

My foremost acknowledgment is again to Prue Arbib, who served as Editorial Assistant during the long and arduous process of eliciting and assembling the many, many contributions to Part III. I thank the members of the Editorial Advisory Board, who helped update the list of articles from the first edition and focus the search for authors, and I thank these authors not only for their contributions to Part III but also for suggesting further topics and authors for the *Handbook*, in an ever-widening circle as work advanced on this new edition. I also owe a great debt to the hundreds of reviewers who so constructively contributed to the final polishing of the articles that now appear in Part III. Finally, I thank the staff of P. M. Gordon Associates and of The MIT Press for once again meeting the high standards of copy editing and book production that contributed so much to the success of the first edition.

# Preface to the First Edition

This volume is inspired by two great questions: "How does the brain work?" and "How can we build intelligent machines?" It provides no simple, single answer to either question because no single answer, simple or otherwise, exists. However, in hundreds of articles it charts the immense progress made in recent years in answering many related, but far more specific, questions.

The term *neural networks* has been used for a century or more to describe the networks of biological neurons that constitute the nervous systems of animals, whether invertebrates or vertebrates. Since the 1940s, and especially since the 1980s, the term has been used for a technology of parallel computation in which the computing elements are "artificial neurons" loosely modeled on simple properties of biological neurons, usually with some adaptive capability to change the strengths of connections between the neurons.

Brain theory is centered on "computational neuroscience," the use of computational techniques to model biological neural networks, but also includes attempts to understand the brain and its function through a variety of theoretical constructs and computer analogies. In fact, as the following pages reveal, much of brain theory is not about neural networks per se, but focuses on structural and functional "networks" whose units are in scales both coarser and finer than that of the neuron. Computer scientists, engineers, and physicists have analyzed and applied artificial neural networks inspired by the adaptive, parallel computing style of the brain, but this *Handbook* will also sample non-neural approaches to the design and analysis of "intelligent" machines. In between the biologists and the technologists are the connectionists. They use artificial neural networks in psychology and linguistics and make related contributions to artificial intelligence, using neuron-like unites which interact "in the style of the brain" at a more abstract level than that of individual biological neurons.

Many texts have described limited aspects of one subfield or another of brain theory and neural networks, but no truly comprehensive overview is available. The aim of this *Handbook* is to fill that gap, presenting the entire range of the following topics: detailed models of single neurons; analysis of a wide variety of neurobiological systems; "connectionist" studies; mathematical analyses of abstract neural networks; and technological applications of adaptive, artificial neural networks and related methodologies. The excitement, and the frustration, of these topics is that they span such a broad range of disciplines, including mathematics, statistical physics and chemistry, neurology and neurobiology, and computer science and electrical engineering, as well as cognitive psychology, artificial intelligence, and philosophy. Much effort, therefore, has gone into making the book accessible to readers with varied backgrounds (an undergraduate education in one of the above areas, for example, or the frequent reading of related articles at the level of the *Scientific American*) while still providing a clear view of much of the recent specialized research.

The heart of the book comes in Part III, in which the breadth of brain theory and neural networks is sampled in 266 articles, presented in alphabetical order by title. Each article meets the following requirements:

1. It is authoritative within its own subfield, yet accessible to students and experts in a wide range of other fields.
2. It is comprehensive, yet short enough that its concepts can be acquired in a single sitting.
3. It includes a list of references, limited to 15, to give the reader a well-defined and selective list of places to go to initiate further study.
4. It is as self-contained as possible, while providing cross-references to allow readers to explore particular issues of related interest.

Despite the fourth requirement, some articles are more self-contained than others. Some articles can be read with almost no prior knowledge; some can be read with a rather general knowledge of a few key concepts; others require fairly detailed understanding of material covered in other articles. For example, many articles on applications will make sense only if one understands the “backpropagation” technique for training artificial neural networks; and a number of studies of neuronal function will make sense only if one has at least some idea of the Hodgkin-Huxley equation. Whenever appropriate, therefore, the articles include advice on background articles.

Parts I and II of the book provide a more general approach to helping readers orient themselves. Part I: Background presents a perspective on the “landscape” of brain theory and neural networks, including an exposition of the key concepts for viewing neural networks as dynamic, adaptive systems. Part II: Road Maps then provides an entrée into the many articles of Part III, with “road maps” for 23 different themes. The “Meta-Map,“ which introduces Part II, groups these themes under eight general headings which, in and of themselves, give some sense of the sweep of the *Handbook*:

Connectionism: Psychology, Linguistics, and Artificial Intelligence
Dynamics, Self-Organization, and Cooperativity
Learning in Artificial Neural Networks
Applications and Implementations
Biological Neurons and Networks
Sensory Systems
Plasticity in Development and Learning
Motor Control

A more detailed view of the structure of the book is provided in the introductory section “How to Use this Book.” The aim is to ensure that readers will not only turn to the book to get good brief reviews of topics in their own specialty, but also will find many invitations to browse widely—finding parallels amongst different subfields, or simply enjoying the discovery of interesting topics far from familiar territory.

## Acknowledgments

My foremost acknowledgment is to Prue Arbib, who served as Editorial Assistant during the long and arduous process of eliciting and assembling the many, many contributions to Part III; we both thank Paulina Tagle for her help with our work. The initial plan for the book was drawn up in 1991, and it benefited from the advice of a number of friends, especially George Adelman, who shared his experience as Editor of the *Encyclopedia of Neuroscience*. Refinement of the plan and the choice of publishers occupied the first few months of 1992, and I thank Fiona Stevens of The MIT Press for her support of the project from that time onward.

As can be imagined, the plan for a book like this has developed through a time-consuming process of constraint satisfaction. The first steps were to draw up a list of about 20 topic areas (similar to, but not identical with, the 23 areas surveyed in Part II), to populate these areas with a preliminary list of over 100 articles and possible authors, and to recruit the first members of the Editorial Advisory Board to help expand the list of articles and focus on the search for authors. A very satisfying number of authors invited in the first round accepted my invitation, and many of these added their voices to the Editorial Advisory Board in suggesting further topics and authors for the *Handbook*.

I was delighted, stimulated, and informed as I read the first drafts of the articles; but I have also been grateful for the fine spirit of cooperation with which the authors have responded to editorial comments and reviews. The resulting articles not only are authoritative and accessible in themselves, but also have been revised to match the overall style of the *Handbook* and to meet the needs of a broad readership. With this I express my sincere thanks to the editorial advisors, the authors, and the hundreds of reviewers who so constructively contributed to the final polishing of the articles that now appear in Part III; to Doug Gordon and the copy editors and typesetters who transformed the diverse styles of the manuscripts into the style of the *Handbook;* and to the graduate students who helped so much with the proofreading.

Finally, I want to record a debt that did not reach my conscious awareness until well into the editing of this book. It is to Hiram Haydn, who for many years was editor of *The American Scholar*, which is published for general circulation by Phi Beta Kappa. In 1971 or so, Phi Beta Kappa conducted a competition to find authors to receive grants for books to be written, if memory serves aright, for the Bicentennial of the United States. I submitted an entry. Although I was not successful, Mr. Haydn, who had been a member of the jury, wrote to express his appreciation of that entry, and to invite me to write an article for the *Scholar*. What stays in my mind from the ensuing correspondence was the sympathetic way in which he helped me articulate the connections that were at best implicit in my draft, and find the right voice in which to "speak" with the readers of a publication so different from the usual scientific journal. I now realize that it is his example I have tried to follow as I have worked with these hundreds of authors in the quest to see the subject of brain theory and neural networks whole, and to share it with readers of diverse interests and backgrounds.

# How to Use This Book

More than 90% of this book is taken up by Part III, which, in 285 separately authored articles, covers a vast range of topics in brain theory and neural networks, from language to motor control, and from the neurochemistry to the statistical mechanics of memory. Each article has been made as self-contained as possible, but the very breadth of topics means that few readers will be expert in a majority of them. To help the reader new to certain areas of the *Handbook*, I have prepared Part I: Background and Part II: Road Maps. The next few pages describe these aids to comprehension, as well as offering more information on the structure of articles in Part III.

### Part I: Background: The Elements of Brain Theory and Neural Networks

Part I provides background material for readers new to computational neuroscience or theoretical approaches to neural networks considered as dynamic, adaptive systems. Section I.1, "Introducing the Neuron," conveys the basic properties of neurons and introduces several basic neural models. Section I.2, "Levels and Styles of Analysis," explains the interdisciplinary nexus in which the present study of brain theory and neural networks is located, with historical roots in cybernetics and with current work going back and forth between brain theory, artificial intelligence, and cognitive psychology. We also review the different levels of analysis involved, with schemas providing the functional units intermediate between an overall task and neural networks. Finally, Section I.3, "Dynamics and Adaptation in Neural Networks," provides a tutorial on the concepts essential for understanding neural networks as dynamic, adaptive systems. We close by stressing that the full understanding of the brain and the improved design of intelligent machines will require not only improvements in the learning methods presented in Section I.3, but also fuller understanding of architectures based on networks of networks, with initial structures well constrained for the task at hand.

### Part II: Road Maps: A Guided Tour of Brain Theory and Neural Networks

The reader who wants to survey a major theme of brain theory and neural networks, rather than seeking articles in Part III one at a time, will find in Part II a set of 22 road maps that, among them, place every article in Part III in a thematic perspective. Section II.1 presents a Meta-Map, which briefly surveys all these themes, grouping them under eight general headings:

**Grounding Models of Neurons and Networks**
- Grounding Models of Neurons
- Grounding Models of Networks

**Brain, Behavior, and Cognition**
- Neuroethology and Evolution
- Mammalian Brain Regions
- Cognitive Neuroscience

**Psychology, Linguistics, and Artificial Intelligence**
- Psychology
- Linguistics and Speech Processing
- Artificial Intelligence

**Biological Neurons and Networks**
- Biological Neurons and Synapses
- Neural Plasticity
- Neural Coding
- Biological Networks

**Dynamics and Learning in Artificial Networks**
Dynamic Systems
Learning in Artificial Networks
Computability and Complexity
**Sensory Systems**
Vision
Other Sensory Systems
**Motor Systems**
Robotics and Control Theory
Motor Pattern Generators
Mammalian Motor Control
**Applications, Implementations, and Analysis**
Applications
Implementation and Analysis

This ordering of the themes has no special significance. It is simply one way to approach the richness of the *Handbook*, making it easy for you to identify one or two key road maps of special interest. By the same token, the order of articles in each of the 22 road maps that follow the Meta-Map is one among many such orderings. Each road map starts with an alphabetical listing of the articles most relevant to the current theme. The road map itself will provide suggestions for *interesting* traversals of articles, but this need not imply that an article provides *necessary* background for the articles it precedes.

## Part III: Articles

Part III comprises 285 articles. These articles are arranged in alphabetical order, both to make it easier to find a specific topic (although a Subject Index is provided as well, and the alphabetical list of Contributors on page 1241 lists all the articles to which each author has contributed) and because a given article may be relevant to more than one of the themes of Part II, a fact that would be hidden were the article to be relegated to a specific section devoted to a single theme. Most of these articles assume some prior familiarity with neural networks, whether biological or artificial, and so the reader new to neural networks is encouraged to master the material in Part I before tackling Part III.

Most articles in Part III have the following structure: The introduction provides a nontechnical overview of the material covered in the whole article, while the final section provides a discussion of key points, open questions, and linkages with other areas of brain theory and neural networks. The intervening sections may be more or less technical, depending on the nature of the topic, but the first and last sections should give most readers a basic appreciation of the topic, irrespective of such technicalities. The bibliography for each article contains about 15 references. People who find their favorite papers omitted from the list should blame my editorial decision, not the author's judgment. The style I chose for the *Handbook* was *not* to provide exhaustive coverage of research papers for the expert. Rather, references are there primarily to help readers who look for an *introduction* to the literature on the given topic, including background material, relevant review articles, and original research citations. In addition to formal references to the literature, each article contains numerous cross-references to other articles in the *Handbook*. These may occur either in the body of the article in the form THE TITLE OF THE ARTICLE IN SMALL CAPS, or at the end of the article, designated as "**Related Reading**." In addition to suggestions for related reading, the reader will find, just prior to the list of references in each article, a mention of the **road map(s)** in which the article is discussed, as well as **background** material, when the article is more advanced.

In summary, turn directly to Part III when you need information on a specific topic. Read sections of Part I to gain a general perspective on the basic concepts of brain theory and neural networks. For an overview of some theme, read the Meta-Map in Part II to choose road maps in Part II; read a road map to choose articles in Part III. A road map can also be used as an explicit guide for systematic study of the area under review. Then continue your exploration through further use of road maps, by following cross-references in Part III, by looking up terms of interest in the index, or simply by letting serendipity take its course as you browse through Part III at random.

# Part I: Background

## The Elements of Brain Theory and Neural Networks

Michael A. Arbib

# How to Use Part I

Part I provides background material, summarizing a set of concepts established for the formal study of neurons and neural networks by 1986. As such, it is designed to hold few, if any, surprises for readers with a fair background in computational neuroscience or theoretical approaches to neural networks considered as dynamic, adaptive systems. Rather, Part I is designed for the many readers—be they neuroscience experimentalists, psychologists, philosophers, or technologists—who are sufficiently new to *brain theory and neural networks* that they can benefit from a compact overview of basic concepts prior to reading the road maps of Part II and the articles in Part III. Of course, much of what is covered in Part I is also covered at some length in the articles in Part III, and cross-references will steer the reader to these articles for alternative expositions and reviews of current research. In this exposition, as throughout the *Handbook*, we will move back and forth between *computational neuroscience*, where the emphasis is on modeling biological neurons, and *neural computing*, where the emphasis shifts back and forth between biological models and artificial neural networks based loosely on abstractions from biology, but driven more by technological utility than by biological considerations.

Section I.1, "Introducing the Neuron," conveys the basic properties of neurons, receptors, and effectors, and then introduces several simple neural models, including the discrete-time McCulloch-Pitts model and the continuous-time leaky integrator model. References to Part III alert the reader to more detailed properties of neurons which are essential for the neuroscientist and provide interesting hints about future design features for the technologist.

Section I.2, "Levels and Styles of Analysis," is designed to give the reader a feel for the interdisciplinary nexus in which the present study of brain theory and neural networks is located. The selection begins with a historical fragment which traces our federation of disciplines back to their roots in cybernetics, the study of control and communication in animals and machines. We look at the way in which the research addresses brains, machines, and minds, going back and forth between brain theory, artificial intelligence, and cognitive psychology. We then review the different levels of analysis involved, whether we study brains or intelligent machines, and the use of schemas to provide intermediate functional units that bridge the gap between an overall task and the neural networks which implement it.

Section I.3, "Dynamics and Adaptation in Neural Networks," provides a tutorial on the concepts essential for understanding neural networks as dynamic, adaptive systems. It introduces the basic dynamic systems concepts of stability, limit cycles, and chaos, and relates Hopfield nets to attractors and optimization. It then introduces a number of basic concepts concerning adaptation in neural nets, with discussions of pattern recognition, associative memory, Hebbian plasticity and network self-organization, perceptrons, network complexity, gradient descent and credit assignment, and backpropagation. This section, and with it Part I, closes with a cautionary note. The basic learning rules and adaptive architectures of neural networks have already illuminated a number of biological issues and led to useful technological applications. However, these networks must have their initial structure well constrained (whether by evolution or technological design) to yield approximate solutions to the system's tasks—solutions that can then be efficiently and efficaciously shaped by experience. Moreover, the full understanding of the brain and the improved design of intelligent machines will require not only improvements in these learning methods and their initialization, but also a fuller understanding of architectures based on networks of networks. Cross-references to articles in Part III will set the reader on the path to this fuller understanding. Because Part I focuses on the basic concepts established for the formal study of neurons and neural networks by 1986, it differs hardly at all from Part I of the first edition of the *Handbook*. By contrast, Part II, which provides the road maps that guide readers through the radically updated Part III, has been completely rewritten for the present edition to reflect the latest research results.

# I.1. Introducing the Neuron

We introduce the *neuron*. The dangerous word in the preceding sentence is *the*. In biology, there are radically different types of neurons in the human brain, and endless variations in neuron types of other species. In brain theory, the complexities of real neurons are abstracted in many ways to aid in understanding different aspects of neural network development, learning, or function. In *neural computing* (technology based on networks of "neuron-like" units), the artificial neurons are designed as variations on the abstractions of brain theory and are implemented in software, or VLSI or other media. There is no such thing as a "typical" neuron, yet this section will nonetheless present examples and models which provide a starting point, an essential set of key concepts, for the appreciation of the many variations on the theme of neurons and neural networks presented in Part III.

An analogy to the problem we face here might be to define *vehicle* for a handbook of transportation. A vehicle could be a car, a train, a plane, a rowboat, or a forklift truck. It might or might not carry people. The people could be crew or passengers, and so on. The problem would be to give a few key examples of form (such as car versus plane) and function (to carry people or goods, by land, air, or sea, etc.). Moreover, we would find interesting examples of co-evolution: for example, modern highway systems would not have been created without the pressure of increasing car traffic; most features of cars are adapted to the existence of sealed roads, and some features (e.g., cruise control) are specifically adapted to good freeway conditions. Following a similar procedure, Part III offers diverse examples of neural form and function in both biology and technology.

Here, we start with the observation that a brain is made up of a network of cells called neurons, coupled to receptors and effectors. Neurons are intimately connected with glial cells, which provide support functions for neural networks. New empirical data show the importance of glia in regeneration of neural networks after damage and in maintaining the neurochemical milieu during normal operation. However, such data have had very little impact on neural modeling and so will not be considered further here. The input to the network of neurons is provided by *receptors*, which continually monitor changes in the external and internal environment. Cells called *motor neurons* (or *motoneurons*), governed by the activity of the neural network, control the movement of muscles and the secretion of glands. In between, an intricate network of neurons (a few hundred neurons in some simple creatures, hundreds of billions in a human brain) continually combines the signals from the receptors with signals encoding past experience to barrage the motor neurons with signals that will yield adaptive interactions with the environment. In animals with backbones (vertebrates, including mammals in general and humans in particular), this network is called the *central nervous system* (CNS), and the brain constitutes the most headward part of this system, linked to the receptors and effectors of the body via the spinal cord. Invertebrate nervous systems (neural networks) provide astounding variations on the vertebrate theme, thanks to eons of divergent evolution. Thus, while the human brain may be the source of rich analogies for technologists in search of "artificial intelligence," both invertebrates and vertebrates provide endless ideas for technologists designing neural networks for sensory processing, robot control, and a host of other applications. (A few of the relevant examples may be found in the Part II road maps, **Vision**, **Robotics and Control Theory**, **Motor Pattern Generators**, and **Neuroethology and Evolution**.)

The brain provides far more than a simple stimulus-response chain from receptors to effectors (although there are such reflex paths). Rather, the vast network of neurons is interconnected in loops and tangled skeins so that signals entering the net from the receptors interact there with the billions of signals already traversing the system, not only to yield the signals that control the effectors but also to modify the very properties of the network itself, so that future behavior will reflect prior experience.

## The Diversity of Receptors

Rod and cone receptors in the eyes respond to light, hair cells in the ears respond to pressure, and other cells in the tongue and the mouth respond to subtle traces of chemicals. In addition to touch receptors, there are receptors in the skin that are responsive to movement or to temperature, or that signal painful stimuli. These external senses may be divided into two classes: (1) the proximity senses, such as touch and taste, which sense objects in contact with the body surface, and (2) the distance senses, such as vision and hearing, which let us sense objects distant from the body. Olfaction is somewhere in between, using chemical signals "right under our noses" to sense nonproximate objects. Moreover, even the proximate senses can yield information about nonproximate objects, as when we feel the wind or the heat of a fire. More generally, much of our appreciation of the world around us rests on the unconscious fusion of data from diverse sensory systems.

The appropriate activity of the effectors must depend on comparing where the system should be—the current target of an ongoing movement—with where it is now. Thus, in addition to the external receptors, there are receptors that monitor the activity of muscles, tendons, and joints to provide a continual source of feedback about the tensions and lengths of muscles and the angles of the joints, as well as their velocities. The vestibular system in the head monitors gravity and accelerations. Here, the receptors are hair cells monitoring fluid motion. There are also receptors to monitor the chemical level of the bloodstream and the state of the heart and the intestines. Cells in the liver monitor glucose, while others in the kidney check water balance. Receptors in the *hypothalamus*, itself a part of the brain, also check the balance of water and sugar. The hypothalamus then integrates these diverse messages to direct behavior or other organs to restore the balance. If we stimulate the hypothalamus, an animal may drink copious quantities of water or eat enormous quantities of food, even though it is already well supplied; the brain has received a signal that water or food is lacking, and so it instructs the animal accordingly, irrespective of whatever contradictory signals may be coming from a distended stomach.

## Basic Properties of Neurons

To understand the processes that intervene between receptors and effectors, we must have a closer look at "the" neuron. As already emphasized, *there is no such thing as a typical neuron*. However, we will summarize properties shared by many neurons. The "basic neuron" shown in Figure 1 is abstracted from a motor neuron of mammalian spinal cord. From the *soma* (cell body) protrudes a number of ramifying branches called *dendrites*; the soma and dendrites constitute the input surface of the neuron. There also extrudes from the cell body, at a point called the *axon hillock* (abutting the initial segment), a long fiber called the *axon*, whose branches form the *axonal arborization*. The tips of the branches of the axon, called *nerve terminals* or *boutons*, impinge on other neurons or on effectors. The locus of interaction between a bouton and the cell on which it impinges is called a *synapse*, and we say that the cell with the bouton *synapses upon* the cell with which the connection is made. In fact, axonal branches of some neurons can have many varicosities, corresponding to synapses, along their length, not just at the end of the branch.

We can imagine the flow of information as shown by the arrows in Figure 1. Although "conduction" can go in either direction on the axon, most synapses tend to "communicate" activity to the dendrites or soma of the cell they synapse upon, whence activity passes to the axon hillock and then down the axon to the terminal arbo-

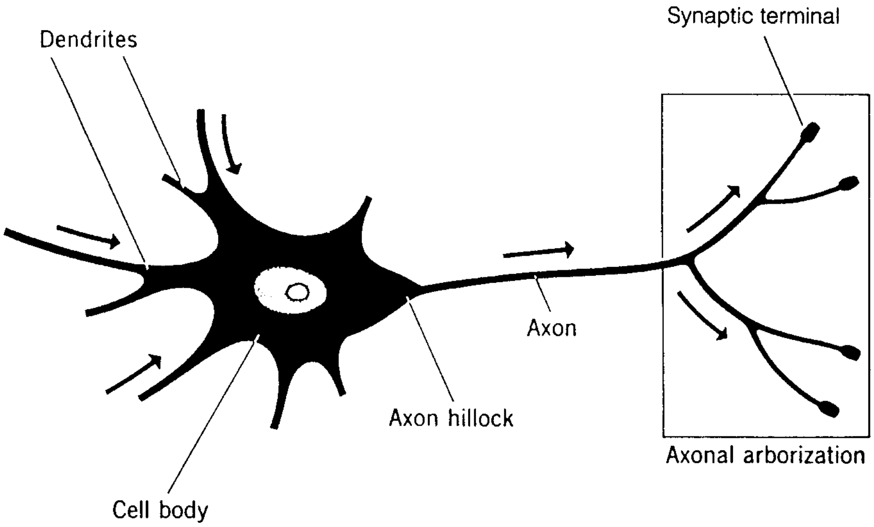

**Figure 1.** A "basic neuron" abstracted from a motor neuron of mammalian spinal cord. The dendrites and soma (cell body) constitute the major part of the input surface of the neuron. The axon is the "output line." The tips of the branches of the axon form synapses upon other neurons or upon effectors (although synapses may occur along the branches of an axon as well as at the ends). (From Arbib, M. A., 1989, *The Metaphorical Brain 2: Neural Networks and Beyond*, New York: Wiley-Interscience, p. 52. Reproduced with permissions. Copyright © 1989 by John Wiley & Sons, Inc.)

rization. The axon can be very long indeed. For instance, the cell body of a neuron that controls the big toe lies in the spinal cord and thus has an axon that runs the complete length of the leg. We may contrast the immense length of the axon of such a neuron with the very small size of many of the neurons in our heads. For example, amacrine cells in the retina have branchings that cannot appropriately be labeled dendrites or axons, for they are short and may well communicate activity in either direction to serve as local modulators of the surrounding network. In fact, the propagation of signals in the "counter-direction" on dendrites away from the soma has in recent years been seen to play an important role in neuronal function, but this feature is not included in the account of the "basic neuron" given here (see DENDRITIC PROCESSING—titles in SMALL CAPS refer to articles in Part III).

To understand more about neuronal "communication," we emphasize that the cell is enclosed by a membrane, across which there is a difference in electrical charge. If we change this potential difference between the inside and outside, the change can propagate in much the same passive way that heat is conducted down a rod of metal: a normal change in potential difference across the cell membrane can propagate in a passive way so that the change occurs later, and becomes smaller, the farther away we move from the site of the original change. This passive propagation is governed by the *cable equation*

$$\frac{\partial V}{\partial t} = \frac{\partial^2 V}{\partial x^2}$$

If the starting voltage at a point on the axon is $V_0$, and no further conditions are imposed, the potential will decay exponentially, having value $V_{(x)} = V_0 e^{-x}$ at distance $x$ from the starting point, where the length unit, the *length constant*, is the distance in which the potential changes by a factor of $1/e$. This length unit will differ from axon to axon. For "short" cells (such as the rods, cones, and bipolar cells of the retina), passive propagation suffices to signal a potential change from one end to the other; but if the axon is long, this mechanism is completely inadequate, since changes at one end will decay almost completely before reaching the other end. Fortunately, most nerve cells have the further property that if the change in potential difference is large enough (we say it exceeds a *threshold*), then in a cylindrical configuration such as the axon, a pulse can be generated that will actively propagate at full amplitude instead of fading passively.

If propagation of various potential differences on the dendrites and soma of a neuron yields a potential difference across the membrane at the axon hillock which exceeds a certain threshold, then a regenerative process is started: the electrical change at one place is enough to trigger this process at the next place, yielding a *spike* or *action potential*, an undiminishing pulse of potential difference propagating down the axon. After an impulse has propagated along the length of the axon, there is a short *refractory period* during which a new impulse cannot be propagated along the axon.

The propagation of action potentials is now very well understood. Briefly, the change in membrane potential is mediated by the flow of ions, especially sodium and potassium, across the membrane. Hodgkin and Huxley (1952) showed that the *conductance* of the membrane to sodium and potassium ions—the ease with which they flow across the membrane—depends on the transmembrane voltage. They developed elegant equations describing the voltage and time dependence of the sodium and potassium conductances. These equations (see the article AXONAL MODELING in Part III) have given us great insight into cellular function. Much mathematical research has gone into studying Hodgkin-Huxley-like equations, showing, for example, that neurons can support rhythmic pulse generation even without input (see OSCILLATORY AND BURSTING PROPERTIES OF NEURONS), and explicating triggered long-distance propagation. Hodgkin and Huxley used curve fitting from experimental data to determine the terms for conductance change in their model. Subsequently, much research has probed the structure of complex molecules that form *channels* which selectively allow the passage of specific ions through the membrane (see ION CHANNELS: KEYS TO NEURONAL SPECIALIZATION). This research has demonstrated how channel properties not only account for the terms in the Hodgkin-Huxley equation, but also underlie more complex dynamics which may allow even small patches of neural membrane to act like complex computing elements. At present, most artificial neurons used in applications are very simple indeed, and much future technology will exploit these "subneural subtleties."

An impulse traveling along the axon from the axon hillock triggers new impulses in each of its branches (or *collaterals*), which in turn trigger impulses in their even finer branches. Vertebrate axons come in two varieties, myelinated and unmyelinated. The myelinated fibers are wrapped in a sheath of *myelin* (Schwann cells in the periphery, oligodendrocytes in the CNS—these are glial cells, and their role in axonal conduction is the primary role of glia considered in neural modeling to date). The small gaps between successive segments of the myelin sheath are called *nodes of Ranvier*. Instead of the somewhat slow active propagation down an unmyelinated fiber, the nerve impulse in a myelinated fiber jumps from node to node, thus speeding passage and reducing energy requirements (see AXONAL MODELING).

Surprisingly, at most synapses, the direct cause of the change in potential of the postsynaptic membrane is not electrical but chemical. When an impulse arrives at the presynaptic terminal, it causes the release of *transmitter* molecules (which have been stored in the bouton in little packets called vesicles) through the presynaptic membrane. The transmitter then diffuses across the very small *synaptic cleft* to the other side, where it binds to receptors on the postsynaptic membrane to change the conductance of the postsynaptic cell. The effect of the "classical" transmitters (later we shall talk of other kinds, the neuromodulators) is of two basic kinds: either *excitatory*, tending to move the potential difference across the postsynaptic membrane in the direction of the threshold (*depolarizing* the membrane), or *inhibitory*, tending to move the polarity away from the threshold (*hyperpolarizing* the membrane). There are some exceptional cell appositions that are so large or have such tight coupling (the so-called gap junctions) that the impulse affects the postsynaptic membrane without chemical mediation (see NEOCORTEX: CHEMICAL AND ELECTRICAL SYNAPSES).

Most neural modeling to date focuses on the excitatory and inhibitory interactions that occur on a fast time scale (a millisecond, more or less), and most biological (as distinct from technological) models assume that all synapses *from* a neuron have the same "sign." However, neurons may also secrete transmitters that modulate the function of a circuit on some quite extended time scale. Modeling that takes account of this *neuromodulation* (see SYNAPTIC INTERACTIONS and NEUROMODULATION IN INVERTEBRATE NERVOUS SYSTEMS) will become increasingly important in the future, since it allows cells to change their function, enabling a neural network to switch dramatically its overall mode of activity.

The excitatory or inhibitory effect of the transmitter released when an impulse arrives at a bouton generally causes a subthreshold change in the postsynaptic membrane. Nonetheless, the cooperative effect of many such subthreshold changes may yield a potential change at the axon hillock that exceeds threshold, and if this occurs at a time when the axon has passed the refractory period of its previous firing, then a new impulse will be fired down the axon.

Synapses can differ in shape, size, form, and effectiveness. The geometrical relationships between the different synapses impinging on the cell determine what patterns of synaptic activation will yield the appropriate temporal relationships to excite the cell (see

Dendritic Processing). A highly simplified example (Figure 2) shows how the properties of nervous tissue just presented would indeed allow a simple neuron, by its very dendritic geometry, to compute some useful function (cf. Rall, 1964, p. 90). Consider a neuron with four dendrites, each receiving a single synapse from a visual receptor, so arranged that synapses A, B, C, and D (from left to right) are at increasing distances from the axon hillock. (This is not meant to be a model of a neuron in the retina of an actual organism; rather, it is designed to make vivid the potential richness of single neuron computations.) We assume that each receptor reacts to the passage of a spot of light above its surface by yielding a generator potential which yields, in the postsynaptic membrane, the same time course of depolarization. This time course is propagated passively, and the farther it is propagated, the later and the lower is its peak. If four inputs reached A, B, C, and D simultaneously, their effect may be less than the threshold required to trigger a spike there. However, if an input reaches D before one reaches C, and so on, in such a way that the peaks of the four resultant time courses at the axon hillock coincide, the total effect could well exceed threshold. This, then, is a cell that, although very

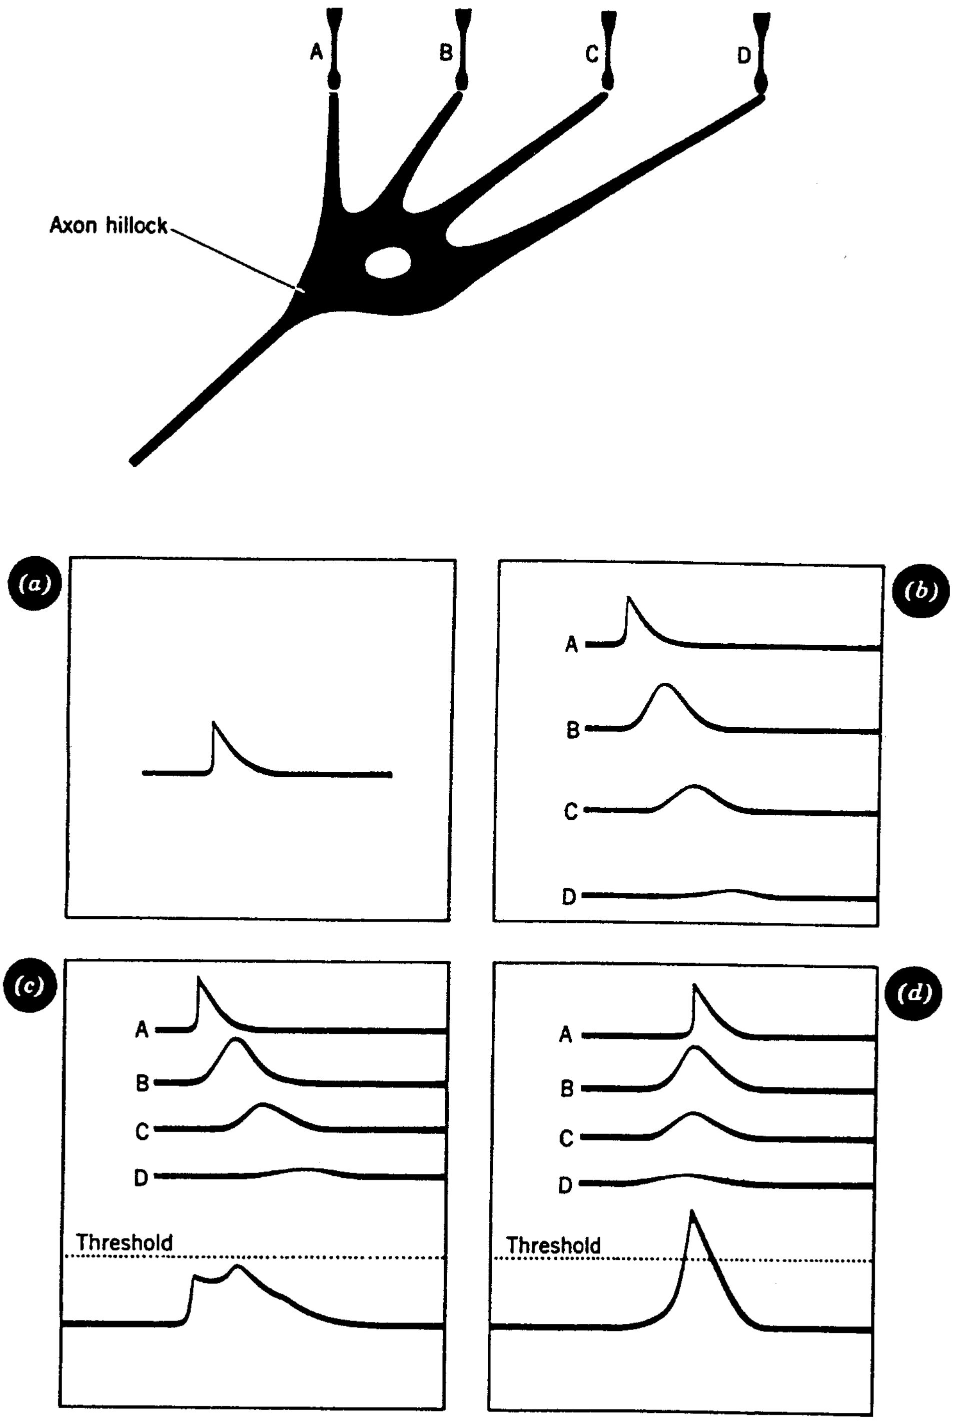

**Figure 2.** An example, conceived by Wilfrid Rall, of the subtleties that can be revealed by neural modeling when dendritic properties (in this case, length-dependent conduction time) are taken into account. As shown in Part *C*, the effect of simultaneously activating all inputs may be subthreshold, yet the cell may respond when inputs traverse the cell from right to left (*D*). (From Arbib, M. A., 1989, *The Metaphorical Brain 2: Neural Networks and Beyond*, New York: Wiley-Interscience, p. 60. Reproduced with permission. Copyright © 1989 by John Wiley & Sons, Inc.)

simple, can detect direction of motion across its input. It responds only if the spot of light is moving from right to left, and if the velocity of that motion falls within certain limits. Our cell will not respond to a stationary object, or one moving from left to right, because the asymmetry of placement of the dendrites on the cell body yields a preference for one direction of motion over others (for a more realistic account of biological mechanisms, see DIRECTIONAL SELECTIVITY). This simple example illustrates that the *form* (i.e., the geometry) of the cell can have a great impact on the *function* of the cell, and we thus speak of *form-function* relations. When we note that neurons in the human brain may have 10,000 or more synapses upon them, we can understand that the range of functions of single neurons is indeed immense.

## Receptors and Effectors

On the "input side," receptors share with neurons the property of generating potentials, which are transmitted to various synapses upon neurons. However, the input surface of a receptor does not receive synapses from other neurons, but can transduce environmental energy into changes in membrane potential, which may then propagate either actively or passively. (Visual receptors do not generate spikes; touch receptors in the body and limbs use spike trains to send their message to the spinal cord.) For instance, the rods and cones of the eye contain various pigments that react chemically to light in different frequency bands, and these chemical reactions, in turn, lead to local potential changes, called generator potentials, in the membrane. If the light falling on an array of rods and cones is appropriately patterned, then their potential changes will induce interneuron changes to, in turn, fire certain ganglion cells (retinal output neurons whose axons course toward the brain). Properties of the light pattern will thus be signaled farther into the nervous system as trains of impulses (see RETINA).

At the receptors, increasing the intensity of stimulation will increase the generator potential. If we go to the first level of neurons that generate pulses, the axons "reset" each time they fire a pulse and then have to get back to a state where the threshold and the input potential meet. The higher the generator potential, the shorter the time until they meet again, and thus the higher the frequency of the pulse. Thus, at the "input" it is a useful first approximation to say that intensity or quantity of stimulation is coded in terms of pulse frequency (more stimulus ≈ more spikes), whereas the quality or type of stimulus is coded by different lines carrying signals from different types of receptors. As we leave the periphery and move toward more "computational" cells, we no longer have such simple relationships, but rather interactions of inhibitory cells and excitatory cells, with each inhibitory input moving a cell away from, and each excitatory input moving it toward, threshold.

To discuss the "output side," we must first note that a muscle is made up of many thousands of muscle fibers. The motor neurons that control the muscle fibers lie in the spinal cord or the brainstem, whence their axons may have to travel vast distances (by neuronal standards) before synapsing upon the muscle fibers. The smallest functional entity on the output side is thus the *motor unit*, which consists of a motor neuron cell body, its axon, and the group of muscle fibers the axon influences.

A muscle fiber is like a neuron to the extent that it receives its input via a synapse from a motor neuron. However, the response of the muscle fiber to the spread of depolarization is to contract. Thus, the motor neurons which synapse upon the muscle fibers can determine, by the pattern of their impulses, the extent to which the whole muscle comprised of those fibers contracts, and can thus control movement. (Similar remarks apply to those cells that secrete various chemicals into the bloodstream or gut, or those that secrete sweat or tears.)

Synaptic activation at the *motor end-plate* (i.e., the synapse of a motor neuron upon a muscle fiber) yields a brief "twitch" of the muscle fiber. A low repetition rate of action potentials arriving at a motor end-plate causes a train of twitches, in each of which the mechanical response lasts longer than the action potential stimulus. As the frequency of excitation increases, a second action potential will arrive while the mechanical effect of the prior stimulus still persists. This causes a mechanical summation or fusion of contractions. Up to a point, the degree of summation increases as the stimulus interval becomes shorter, although the summation effect decreases as the interval between the stimuli approaches the refractory period of the muscle, and maximum tension occurs. This limiting response is called a *tetanus*. To increase the tension exerted by a muscle, it is then necessary to recruit more and more fibers to contract. For more delicate motions, such as those involving the fingers of primates, each motor neuron may control only a few muscle fibers. In other locations, such as the shoulder, one motor neuron alone may control thousands of muscle fibers. As descending signals in the spinal cord command a muscle to contract more and more, they do this by causing motor neurons with larger and larger thresholds to start firing. The result is that fairly small fibers are brought in first, and then larger and larger fibers are recruited. The result, known as Henneman's Size Principle, is that at any stage, the increment of activation obtained by recruiting the next group of motor units involves about the same percentage of extra force being applied, aiding smoothness of movement (see MOTONEURON RECRUITMENT).

Since there is no command that a neuron may send to a muscle fiber that will cause it to lengthen—all the neuron can do is stop sending it commands to contract—the muscles of an animal are usually arranged in pairs. The contraction of one member of the pair will then act around a pivot to cause the expansion of the other member of the pair. Thus, one set of muscles *extends* the elbow joint, while another set *flexes* the elbow joint. To extend the elbow joint, we do not signal the *flexors* to lengthen, we just stop signaling them to contract, and then they will be automatically lengthened as the *extensor* muscles contract. For convenience, we often label one set of muscles as the "prime mover" or *agonist*, and the opposing set as the *antagonist*. However, in such joints as the shoulder, which are not limited to one degree of freedom, many muscles, rather than an agonist-antagonist pair, participate. Most real movements involve many joints. For example, the wrist must be fixed, holding the hand in a position bent backward with respect to the forearm, for the hand to grip with its maximum power. *Synergists* are muscles that act together with the main muscles involved. A large group of muscles work together when one raises something with one's finger. If more force is required, wrist muscles may also be called in; if still more force is required, arm muscles may be used. In any case, muscles all over the body are involved in maintaining posture.

## Neural Models

Before presenting more realistic models of the neuron (see PERSPECTIVE ON NEURON MODEL COMPLEXITY; SINGLE-CELL MODELS), we focus on the work of McCulloch and Pitts (1943), which combined neurophysiology and mathematical logic, using the all-or-none property of neuron firing to model the neuron as a binary discrete-time element. They showed how excitation, inhibition, and threshold might be used to construct a wide variety of "neurons." It was the first model to tie the study of neural nets squarely to the idea of computation in its modern sense. The basic idea is to divide time into units comparable to a refractory period so that, in each time period, at most one spike can be generated at the axon hillock of a given neuron. The McCulloch-Pitts neuron (Figure 3*A*) thus operates on a discrete-time scale, $t = 0, 1, 2, 3, \ldots$, where the

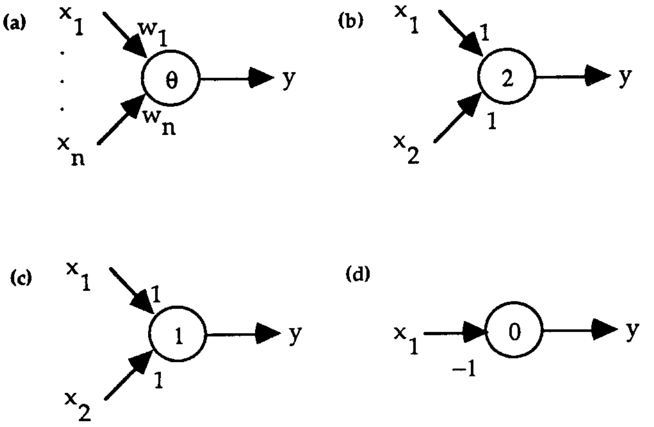

**Figure 3.** *a*, A McCulloch-Pitts neuron operating on a discrete-time scale. Each input has an attached weight $w_i$, and the neuron has a threshold $\theta$. The neuron "fires" at time $t + 1$ just in case the weighted values of its inputs at time $t$ is at least $\theta$. *b*, Settings of weights and threshold for neurons that function as an AND gate (i.e., the output fires if $x_1$ and $x_2$ both fire). *c*, An OR gate (the output fires if $x_1$ or $x_2$, or both fire). *d*, A NOT gate (the output fires if $x_1$ does NOT fire).

time unit is (in biology) on the order of a millisecond. We write $y(t) = 1$ if a spike does appear at time $t$, and $y(t) = 0$ if not. Each connection, or *synapse*, from the output of one neuron to the input of another has an attached *weight*. Let $w_i$ be the weight on the $i$th connection onto a given neuron. We call the synapse *excitatory* if $w_i > 0$, and *inhibitory* if $w_i < 0$. We also associate a *threshold* $\theta$ with each neuron, and assume exactly one unit of delay in the effect of *all* presynaptic inputs on the cell's output, so that a neuron "fires" (i.e., has value 1 on its output line) at time $t + 1$ if the weighted value of its inputs at time $t$ is at least $\theta$. Formally, if at time $t$ the value of the $i$th input is $x_i(t)$ and the output one time step later is $y(t + 1)$, then

$$y(t + 1) = 1 \quad \text{if and only if} \quad \sum_i w_i x_i(t) \geq \theta$$

Parts *b* through *d* of Figure 3 show how weights and threshold can be set to yield neurons that realize the logical functions AND, OR, and NOT. As a result, McCulloch-Pitts neurons are sufficient to build networks that can function as the control circuitry for a computer carrying out computations of arbitrary complexity; this discovery played a crucial role in the development of automata theory and in the study of learning machines. Although the McCulloch-Pitts neuron no longer plays an active part in *computational neuroscience*, it is still widely used in *neural computing*, especially when it is generalized so that the input and output values can lie anywhere in the range [0, 1] and the function $f(\Sigma_i w_i x_i(t))$, which yields $y(t + 1)$, is a continuously varying function rather than a step function. However, it is one thing to define model neurons with sufficient logical power to subserve any discrete computation; it is quite another to understand how the neurons in actual brains perform their tasks. More generally, the problem is to select just which units to model, and to decide how such units are to be represented. Thus, when we turn from neural computing to computational neuroscience, we must turn to more realistic models of neurons. On the other hand, we may say that neural computing cannot reach its full power without applying new mechanisms based on current and future study of biological neural networks (see the road map **Biological Neurons and Synapses**).

Modern brain theory no longer uses the binary model of the neuron, but instead uses continuous-time models that either represent the variation in average firing rate of the neuron or actually capture the time course of membrane potentials. It is only through such correlates of measurable brain activity that brain models can really feed back to biological experiments. Such models also require the brain theorist to know a great deal of detailed anatomy and physiology as well as behavioral data. Hodgkin and Huxley (1952) have shown us how much can be learned from analysis of membrane properties about the propagation of electrical activity along the axon: Rall (1964; cf. Figure 2) was a leader in showing that the study of membrane properties in a variety of connected "compartments" of membrane in dendrite, soma, and axon can help us understand small neural circuits, as in the Olfactory Bulb (q.v.) or for Dendritic Processing (q.v.). Nonetheless, in many cases, the complexity of compartmental analysis makes it more insightful to use a more lumped representation of the individual neuron if we are to assemble the model neurons to analyze large networks. A computer simulation of the response of a whole brain region which analyzed each component at the finest level of detail available would be too large to run on even a network of computers. In addition to the importance of detailed models of single neurons in themselves, such studies can also be used to fine-tune more economical models of neurons, which can then serve as the units in models of large networks, whether to model systems in the brain or to design artificial neural networks which exploit subtle neural capabilities.

We may determine units in the brain *physiologically*, e.g., by electrical recording, and *anatomically*, e.g., by staining. In many regions of the brain, we have an excellent correlation between physiological and anatomical units; that is, we know which anatomical entity yields which physiological response. Unfortunately, this is not always the case. We may have data on the electrophysiological correlates of animal behavior, and anatomical data as well, yet not know which specific cell, defined anatomically, yields an observed electrophysiological response. Another problem that we confront in modeling is that we have both too much and too little anatomical detail: too much in that there are many synapses that we cannot put into our model without overloading our capabilities for either mathematical analysis or computer simulation, and too little in that we often do not know which details of synaptology may determine the most important modes of behavior of a particular region of the brain. Judicious choices from available data, and judicious hypotheses concerning missing data, must thus be made in setting up a model, leading to the design of experiments whose results may either confirm these hypotheses or lead to their modification. An important point of good modeling methodology is thus to set up simulations in such a way that we can use different connectivity on different simulations, both to test alternative hypotheses and to respond to new data as they become available.

The simplest "realistic" model consonant with the above material is the *leaky integrator* model. Although some biological neurons communicate by the passive propagation (cable equation) of membrane potential down their (necessarily short) axons, most communicate by the active propagation of "spikes." The generation and propagation of such spikes has been described in detail by the Hodgkin-Huxley equations. However, the leaky integrator model omits such details. It is a continuous-time model based on using the *firing rate* (e.g., the number of spikes traversing the axon in the most recent 20 ms) as a continuously varying *output* measure of the cell's activity, in which the *internal state* of the neuron is described by a single variable, the membrane potential at the spike initiation zone. The firing rate is approximated by a simple, sigmoid function of the membrane potential. That is, we introduce a function $\sigma$ of the membrane potential $m$ such that $\sigma(m)$ increases from 0 to some maximum value as m increases from $-\infty$ to $+\infty$ (e.g., the sigmoidal function $k/[l + \exp(-m/\theta)]$, increasing from 0 to its maximum $k$). Then the firing rate $M(t)$ of the cell is given by the equation:

$$M(t) = \sigma(m(t))$$

The time evolution of the cell's membrane potential is given by a differential equation. Consider first the simple equation

$$\tau \frac{dm(t)}{dt} = -m(t) + h \qquad (1)$$

We say that $m(t)$ is in an *equilibrium* if it does not change under the dynamics described by the differential equation. However, $dm(t)/dt = 0$ if and only if $m(t) = h$, so that $h$ is the *unique* equilibrium of Equation 1. To get more information, we now integrate Equation 1 to get

$$m(t) = e^{-t/\tau}m(0) + (1 - e^{-t/\tau})h$$

which tends to the *resting level* $h$ with *time constant* $\tau$ with increasing $t$ so long as $\tau$ is positive. We now add synaptic inputs to obtain

$$\tau \frac{dm(t)}{dt} = -m(t) + \sum_i w_i X_i(t) + h \qquad (2)$$

where $X_i(t)$ is the firing rate at the $i$th input. Thus, an excitatory input ($w_i > 0$) will be such that increasing it will increase $dm(t)/dt$, while an inhibitory input ($w_i < 0$) will have the opposite effect. A neuron described by Equation 2 is called a *leaky integrator neuron*. This is because the equation

$$\tau \frac{dm(t)}{dt} = \sum_i w_i X_i(t) \qquad (3)$$

would simply integrate the inputs with scaling constant $\tau$,

$$m(T) = m(0) + \frac{1}{\tau}\int_0^T \sum_i w_i X_i(t)dt \qquad (4)$$

but the $-m(t)$ term in Equation 3 opposes this integration by a "leakage" of the potential $m(t)$ as it tries to return to its input-free equilibrium $h$.

It should be noted that, even at this simple level of modeling, there are alternative models. In the foregoing model, we have used subtractive inhibition. But there are inhibitory synapses which seem better described by *shunting* inhibition which, applied at a given point on a dendrite, serves to divide, rather than subtract from, the potential change passively propagating from more distal synapses. Again, the "lumped frequency" model cannot model the relative timing effects crucial to our motion detector example (see Figure 2). These might be approximated by introducing appropriate delay terms

$$\tau \frac{dm(t)}{dt} = -m(t) + \sum_i w_i X_i(t - t_i) + h$$

Another class of neuron models—spiking neurons, including integrate-and-fire neurons—are intermediate in complexity between leaky integrator models in which the output is the average firing rate (see RATE CODING AND SIGNAL PROCESSING) and detailed biophysical models in which the fine details of action potential generation are modeled using the Hodgkin-Huxley equation. In these intermediate models, the output is a spike whose timing is continuously variable as a result of cellular interactions, but the spike is represented simply by its time of occurrence, with no internal structure. For example, one may track the continuous variable (4), then generate a spike each time this quantity reaches threshold, while simultaneously resetting the integral to some baseline value (see INTEGRATE-AND-FIRE NEURONS AND NETWORKS). Such models include the ability to transmit information very rapidly through small temporal differences between the spikes sent out by different neurons (see SPIKING NEURONS, COMPUTATION WITH).

All this reinforces the observation that there is no modeling approach that is automatically appropriate. Rather, we seek to find the simplest model adequate to address the complexity of a given range of problems. The articles in Part III of the *Handbook* will provide many examples of the diversity of neural models appropriate to different tasks.

## More Detailed Properties of Neurons

In Section I.3, the only details we will add to the neuron models just presented will be various, relatively simple, rules of synaptic plasticity. This level of detail (though with many variations) will suffice for a fair range of models of biological neural networks, and for a range of current work on artificial neural networks (ANNs). The road map **Biological Neurons and Synapses** in Part II surveys a set of articles that demonstrate that biological neurons are vastly more complex than the present models suggest. Other road maps show the special structures revealed in "special-purpose" neural circuitry in different species of animals. Table 1 lists some of the relevant articles on such circuits, together with the specific animal types on which the studies were based. The point is that much is to be learned from features specific to many different types of nervous systems, as well as from studies in humans, monkeys, cats, and rats that focus on commonalities with the human nervous system.

An appreciation of this complexity is necessary for the computational neuroscientist wishing to address the increasingly detailed database of experimental neuroscience, but it should also prove important for the technologist looking ahead to the incorporation of new capabilities into the next generation of ANNs. Nonetheless, much can be accomplished with simple models, as we shall see in Section I.3.

**Table 1.** A Sampling of Articles Showing the Lessons to be Learned from the Study of Nervous Systems Very Different from Those of Humans

# I.2. Levels and Styles of Analysis

Many articles in this book show the benefits of interplay between biology and technology. Nonetheless, it is essential to distinguish between studying the brain and building an effective technology for intelligent systems and computation, and to distinguish among the various levels of investigation that exist (from the molecular to the system level) in these related, but by no means identical, disciplines. The present section provides a fuller sense of the disciplines that come together in brain theory and neural networks, and of the different levels of analysis involved in the study of complex biological and technological systems.

## A Historical Fragment

Perhaps the simplest history of brain theory and neural networks would restrict itself to just three items: studies by McCulloch and Pitts (1943), Hebb (1949), and Rosenblatt (1958). These publications introduced the first model of neural networks as "computing machines," the basic model of network self-organization, and the model of "learning with a teacher," respectively. (Section I.3 provides a semitechnical introduction to this work and a key set of currently central ideas that build upon it.) The present historical fragment is designed to take us up to 1948, the year preceding the publication of Hebb's book, to reveal our present federation of disciplines as the current incarnation of what emerged in the 1940s and is aptly summed up in the title of the book, *Cybernetics: Or Control and Communication in the Animal and the Machine* (Wiener, 1948). But whereas Wiener's view of cybernetics was dominated by concepts of control and communication, our subject is dominated by notions of parallel and distributed computation, with special attention to learning in neural networks. On the other hand, notions of information and statistical mechanics championed by Wiener have reemerged as a strong strand in the study of neural networks today (see, e.g., the articles Feature Analysis and Statistical Mechanics of Neural Networks in Part III). The articles in Part III will make abundantly clear how far we have come since 1948, and also how many problems remain. My intent in the present "fragment" is to enrich the reader's understanding of current contributions by using a selective historical tour to place them in context.

Noting that the Greek word *cybernetics* (*κυβερνετεσ*) means the helmsman of a ship (cf. the Latin word *gubernator*, which gives us the word "governor" in English), Wiener (1948) used the term for a subject in which feedback played a central role. Feedback is the process whereby, e.g., the helmsman notes the "error," the extent to which he is off course, and "feeds it back" to decide which way to move the rudder. We can see the importance of this concept in endowing automata ("self-moving" machines) with flexible behavior. Two hundred years earlier, in *L'Homme machine*, La Mettrie had suggested that such automata as the mechanical duck and flute player of Vaucanson indicated the possibility of one day building a mechanical man that could talk. While these clockwork automata were capable of surprisingly complex behavior, they lacked a crucial aspect of animal behavior, let alone human intelligence: they were unable to adapt to changing circumstances. In the following century, machines were built that could automatically counter disturbances to restore desired performance. Perhaps the best-known example of this is Watt's governor for the steam engine, which would let off excess steam if the velocity of the engine became too great. This development led to Maxwell's (1868) paper, "On Governors," which laid the basis for both the theory of negative feedback and the study of system stability (both of which are discussed in Section I.3). Negative feedback was feedback in which the error (in Watt's case, the amount by which actual velocity exceeded desired velocity) was used to counteract the error; stability occurred if this feedback was apportioned to reduce the error toward zero. Bernard (1878) brought these notions back to biology with his study of what Cannon (1939) would later dub *homeostasis*, observing that physiological processes often form circular chains of cause and effect that could counteract disturbances in such variables as body temperature, blood pressure, and glucose level in the blood. In fact, following publication of Wiener's 1948 book, the Josiah Macy, Jr., Foundation conferences, in which many of the pioneers of cybernetics were involved, became referred to as the Cybernetics Group, with the proceedings entitled *Cybernetics: Circular Causal and Feedback Mechanisms in Biological and Social Systems,* (see Heims, 1991, for a history of the conferences and their participants).

The nineteenth century also saw major developments in the understanding of the brain. At an overall anatomical level, a major achievement was the understanding of localization in the cerebral cortex (see Young, 1970, for a history). Magendie and Bell had discovered that the dorsal roots of the spinal cord were sensory, carrying information from receptors in the body, while the ventral roots (on the belly side) were motor, carrying commands to the muscles. Fritsch and Hitzig, and then Ferrier, extended this principle to the brain proper, showing that the rear of the brain contains the primary receiving areas for vision, hearing, and touch, while the motor cortex is located in front of the central fissure. All this understanding of localization in the cerebral cortex led to the nineteenth century neurological doctrine, perhaps best exemplified in Lichtheim's (1885) development of the insights of Broca and Wernicke into brain mechanisms of language, which viewed different mental "faculties" as being localized in different regions of the brain. Thus, neurological deficits were to be explained as much in terms of lesions of the connections linking two such regions as in terms of lesions to the regions themselves. We may also note a major precursor of the connectionism of this volume, where the connections are those between neuron-like units rather than anatomical regions: the associationist psychology of Alexander Bain (1868), who represented associations of ideas by the strengths of connections between "neurons" representing those ideas.

Around 1900, two major steps were taken in revealing the finer details of the brain. In Spain, Santiago Ramón y Cajal (e.g., 1906) gave us exquisite anatomical studies of many regions of the brain, revealing the particular structure of each as a network of neurons. In England, the physiological studies of Charles Sherrington (1906) on reflex behavior provided the basic physiological understanding of synapses, the junction points between the neurons. Somewhat later, in Russia, Ivan Pavlov (1927), extending associationist psychology and building on the Russian studies of reflexes by Sechenov in the 1860s, established the basic facts on the modifiability of reflexes by conditioning (see Fearing, 1930, for a historical review).

A very different setting of the scene for cybernetics came from work in mathematical logic in the 1930s. Kurt Gödel published his famous *Incompleteness Theorem* in 1931 (see Arbib, 1987, for a proof as well as a debunking of the claim that Gödel's theorem sets limits on machine intelligence). The "formalist" program initiated by David Hilbert, which sought to place all mathematical truth within a single formal system, had reached its fullest expression in the *Principia Mathematica* of Whitehead and Russell. But Gödel showed that, if one used the approach offered in *Principia Mathematica* to set up consistent axioms for arithmetic and prove theorems by logical deduction from them, the theory *must* be incomplete, no matter which axioms ("knowledge base") one started with—there would be true statements of arithmetic that could not be deduced from the axioms.

Following Gödel's 1931 study, many mathematical logicians sought to formalize the notion of an effective procedure, of what could *and could not* be done by explicitly following an algorithm or set of rules. Kleene (1936) developed the theory of partial recursive functions; Turing (1936) developed his machines; Church (1941) developed the lambda calculus, the forerunner of McCarthy's list processing language, LISP, a one-time favorite of artificial intelligence (AI) workers; while Emil Post (1943) introduced systems for rewriting strings of symbols, of which Chomsky's early formalizations of grammars in 1959 were a special case. Fortunately, these methods proved to be equivalent. Whatever could be computed by one of these methods could be computed by any other method if it were equipped with a suitable "program." It thus came to be believed (Church's thesis) that if a function could be computed by any machine at all, it could be computed by each one of these methods.

Turing (1936) helped chart the limits of the computable with his notion of what is now called a *Turing machine*, a device that followed a fixed, finite set of instructions to read, write, and move upon a finite but indefinitely extendible tape, each square of which bore a symbol from some finite alphabet. As one of the ingredients of Church's thesis, Turing offered a "psychology of the computable," making plausible the claim that any effectively definable computation, that is, anything that a human could do in the way of symbolic manipulation by following a finite and completely explicit set of rules, could be carried out by such a machine equipped with a suitable program. Turing also provided the most famous example of a noncomputable problem, "the unsolvability of the Halting Problem." Let $p$ be the numerical code for a Turing machine program, and let $x$ be the code for the initial contents of a Turing machine's tape. Then the halting function $h(p, x) = 1$ if Turing machine $p$ will eventually halt if started with data $x$; otherwise it is 0. Turing showed that there was no "computer program" that could compute $h$.

And so we come to 1943, the key year for bringing together the notions of control mechanism and intelligent automata.

In "A Logical Calculus of the Ideas Immanent in Nervous Activity," McCulloch and Pitts (1943) united the studies of neurophysiology and mathematical logic. Their formal model of the neuron as a threshold logic unit (see Section I.1) built on the neuron doctrine of Ramón y Cajal and the excitatory and inhibitory synapses of Sherrington, using notation from the mathematical logic of Whitehead, Russell, and Carnap. McCulloch and Pitts provided the "physiology of the computable" by showing that the control box of any Turing machine, the essential formalization of symbolic computation, could be implemented by a network (with loops) of their formal neurons. The ideas of McCulloch and Pitts influenced John von Neumann and his colleagues when they defined the basic architecture of stored program computing. Thus, as electronic computers were built toward the end of World War II, it was understood that whatever they could do could be done by a network of neurons.

Craik's (1943) book, *The Nature of Explanation*, viewed the nervous system "as a calculating machine capable of modeling or paralleling external events," suggesting that the process of forming an "internal model" that paralleled the world is the basic feature of thought and explanation. In the same year, Rosenblueth, Wiener, and Bigelow published "Behavior, Purpose and Teleology." Engineers had noted that if feedback used in controlling the rudder of a ship were too brusque, the rudder would overshoot, compensatory feedback would yield a larger overshoot in the opposite direction, and so on and so on as the system wildly oscillated. Wiener and Bigelow asked Rosenblueth whether there was any corresponding pathological condition in humans and were given the example of intention tremor associated with an injured cerebellum. This evidence for feedback within the human nervous system (see MOTOR CONTROL, BIOLOGICAL AND THEORETICAL) led the three scientists to advocate that neurophysiology move beyond the Sherringtonian view of the CNS as a reflex device adjusting itself in response to sensory inputs. Rather, setting reference values for feedback systems could provide the basis for analysis of the brain as a purposive system explicable only in terms of circular processes, that is, from nervous system to muscles to the external world and back again via receptors.

Such studies laid the basis for the emergence of cybernetics, which in turn gave birth to a number of distinct new disciplines, such as AI, biological control theory, cognitive psychology, and neural modeling, which each went their separate ways in the 1970s. The next subsection introduces a number of these disciplines and the relations between them; this analysis will continue in many articles in Part III of the *Handbook*.

## Brains, Machines, and Minds

*Brains.* *Brain theory* comprises many different theories as to how the structures of the brain can subserve such diverse functions as perception, memory, control of movement, and higher mental function. As such, it includes both attempts to extend notions of computing, as well as applications of modern electronic computers to explore the performance of complex models. An example of the former is the study of *cooperative computation* between different structures in the brain which seeks to offer a new paradigm for computing that transcends classical notions associated with serial execution of symbolic programs. For the latter, *computational neuroscience* makes systematic use of mathematical analysis and computer simulation to provide ever better models of the structure and function of living brains, building on earlier work in both neural modeling and biological control theory.

*Machines.* *Artificial intelligence* studies how computers may be programmed to yield "intelligent" behavior without necessarily attempting to provide a correlation between structures in the program and structures in the brain. *Robotics* is related to AI but emphasizes the flexible control of machines (robots) which have receptors (e.g., television cameras) and effectors (e.g., wheels, legs, arms, grippers) that allow them to interact with the world.

Brain theory has spawned a companion field of *neural computing*, which involves the design of machines with circuitry inspired by, but which need not faithfully emulate, the neural networks of brains. Many technologists usurp the term "neural networks" for this latter field, but we will use it as an umbrella term which may, depending on context, describe biological nervous systems, models thereof, and the artificial networks which (sometimes at great remove) they inspire. When the emphasis is on "higher mental functions," neural computing may be seen as a new branch of AI (see the road map **Artificial Intelligence** in Part II), but it also contributes to robotics (especially to those robot designs inspired by analysis of animal behavior), and to a wide range of technologies, including those based on image analysis, signal processing, and control (see the road map **Applications**).

For the latter work, many people emphasize adaptive neural networks which, without specific programming, can adjust their connections through self-organization or to meet specifications given by some teacher. There are also significant contributions to the systematic design, rather than emergence through learning, of neural networks, especially for applications in low-level vision (such as stereopsis, optic flow, and shape-from-shading). However, complex problems cannot, in general, be solved by the tuning or the design of a single unstructured network. For example, robot control may integrate a variety of low-level vision networks with a set of competing and cooperating networks for motor control and its planning. Brain theory and neural computing thus have to address the analysis and design, respectively, of networks of networks (see, e.g., Hybrid Connectionist/Symbolic Systems and Modular and Hierarchical Learning Systems).

*Minds.* Here, I want to distinguish the brain from the mind (the realm of the "mental"). In great part, brain theory seeks to analyze how the brain guides the behaving organism in its interactions with the dynamic world around it, but much of the control of such interactions is not mental, and much of what is mental is subsymbolic and/or unconscious (see Philosophical Issues in Brain Theory and Connectionism and Consciousness, Neural Models of). Without offering a precise definition of "mental," let me just say that many people can agree on examples of mental activity (perceiving a visual scene, reading, thinking, etc.) even if they take the diametrically opposite philosophical positions of dualism (mind and brain are separate) or monism (mind is a function of brain). They would then agree that some mental activity (e.g., contemplation) need not result in overt "interactions with the dynamic real world," and that much of the brain's activity (e.g., controlling normal breathing) is not mental. Face recognition seems to be a mental activity that we do not carry out through symbol manipulation. Indeed, even psychologists who reject Freud's particular psychosexual theories accept his notion that much of our mental behavior is shaped by unconscious forces (for an assessment of Freud and an account of consciousness, see Arbib and Hesse, 1986).

*Cognitive psychology* attempts to explain the mind in terms of "information processing" (a notion which is continuing to change). It thus occupies a middle ground between brain theory and AI in which the model must explain psychological data (e.g., what tasks are hard for humans, people's ability at memorization, the development of the child, patterns of human errors, etc.) but in which the units of the model need not correspond to actual brain structures. In the 1960s and 1970s, the majority of cognitive psychologists formulated their theories in terms of information theory and/or symbol manipulation, while theories of biological organization were ignored. However, workers in both AI and cognitive psychology now pay increasing attention to the cooperative computation paradigm. The term *connectionism* has come to be used for studies that model human thought and behavior in terms of parallel distributed networks of neuron-like units, with learning mediated by changes in strength of the connections between these elements (see Cognitive Modeling: Psychology and Connectionism).

The study of brain theory and neural networks thus has a twofold aim: (1) to enhance our understanding of human thought and the neural basis of human and animal behavior (brain theory), and (2) to learn new strategies for building "intelligent" machines or adaptive robots (neural computing). In either case, we seek organizational principles that will help us understand how neurons (whether biological or artificial) can work together to yield complex patterns of behavior. *Brain theory* requires empirical data to shape and constrain modeling, but in return provides concepts and hypotheses to shape and constrain experimentation. In *neural computing*, the criterion for success is the design of a machine that can perform a task cheaply, reliably, and effectively, even if, in the process of making the best use of available (e.g., silicon) technology, the final design departs radically from the biological neural network that inspired it. It will be important in reading this *Handbook*, then, to be clear as to whether a particular study is an exercise in brain theory/computational neuroscience or in AI/neural computing. What will not be in doubt is that the influence of these subjects works both ways: not only can brain mechanisms inspire new technology, but new technologies provide metaphors to drive new theories of brain function. To this it must be added that most workers in ANNs know little of brain function, and relatively few neuroscientists have a deep understanding of brain theory or know much of neural computing beyond the basic ideas of Hebbian plasticity and, perhaps, backpropagation (see Section I.3). However, the level of interchange has increased since the first edition of this *Handbook* appeared, and this new edition is designed to further increase the flow of information between these scientific communities.

## Levels of Analysis

Whether the emphasis is on humans, animals, or machines, it becomes clear that we can seek insight at many different levels of analysis; from large information processing blocks down to the finest details of molecular structure. Much of psychology and linguistics looks at human behavior "from the outside," whether studying overall competence or attending to details of performance. Neuropsychology relates behavior to the interaction of various brain regions. Neurophysiology studies the activity of neurons, both to understand the intrinsic properties of the neurons and to help understand their role in the subsystems dissected out by the neuropsychologist, such as networks for pattern recognition or for visuomotor coordination. Molecular and cell biology and biophysics correlate the structure and connectivity of the membranes and subcellular systems which constitute cells with the way these cells transform incoming patterns or subserve memory by changing function with repeated interactions.

These differing levels make it possible to focus individual research studies, but they are ill-defined, and a scientist who works on any one level needs to make occasional forays, both downward to find mechanisms for the functions studied, and upward to understand what role the studied function can play in the overall scheme of things. *Top-down* modeling starts from some overall behavior and explains it in terms of the interaction of high-level functional units, while *bottom-up* modeling starts from the interaction of individual neurons (or even smaller units) to explain network properties. It requires a judicious blend of the two to connect the clear overview of crucial questions to the hard data of neuroscience or, in the case of neural engineering, to the details of implementation. Most successful modeling will be purely bottom-up or top-down only in its initial stages, if at all—constraints on an initial top-down model will be given, for example, by the data on regional localization offered by the neurologist, or the circuit-cell-synapse studies of much current neuroscience.

We must now distinguish the brain's computation from connectionist computation "in the *style* of the brain." If a connectionist model succeeds in describing some psychological input/output behavior, it may become an important hypothesis that its internal structure is "real" (see Recurrent Networks: Neurophysiological Modeling). In general, however, much additional work will be required to find and assimilate neurophysiological data to provide brain models in which the neurons are not mere formal units but actually represent biological neurons in the brain.

Much study of the brain is guided by evolutionary and comparative studies of animal behavior and brain function (cf. Evolution of the Ancestral Vertebrate Brain and related articles in the road map **Neuroethology and Evolution**). The information about the function of the human brain that is gained in the neurological clinic or during neurosurgery can thus be supplemented by humane experimentation on animals. (However, as evidenced by Table 1 of Section I.1, we can learn a great deal by studying the *differences*, as well as the similarities, between the brains of different species.) We learn by stimulating, recording from, or excising portions of an animal's brain and seeing how the animal's behavior changes. We may then compare such results with observations using such techniques as positron emission tomography (PET) or functional magnetic resonance imaging (fMRI) of the relative activity of different parts of the human brain during different tasks (see Imaging the Grammatical Brain, Imaging the Motor

BRAIN, and IMAGING THE VISUAL BRAIN). The grand aim of *cognitive neuroscience* (as neuropsychology has now become; see the **Cognitive Neuroscience** road map) is to use clinical data and brain imaging to form a high-level view of the involvement of various brain regions in human cognition, using single-cell activity recorded from animals engaged in analogous behaviors to suggest the neural networks underlying this involvement (see SYNTHETIC FUNCTIONAL BRAIN MAPPING). The catch, of course, is that the "analogous behaviors" of animals are not very analogous at all when it comes to such symbolic activities as language and reasoning. In Part III, we will see that "higher mental functions" tend to be modeled more in connectionist terms constrained (if at all) by psychological or psycholinguistic data (cf. the Part II road maps **Psychology** and **Linguistics and Speech Processing**), while the greatest successes in seeking the neural underpinnings of human behavior have come in areas such as vision, memory, and motor control, where we can make neural network models of animal analogues of human capabilities (cf. the road maps **Vision**, **Other Sensory Systems**, **Neural Plasticity**, **Biological Networks**, **Motor Pattern Generators**, and **Mammalian Motor Control**).

We also learn from the attempt to reproduce various aspects of human behavior in a robot, even though human action, memory, learning, and perception are far richer than those of any machine yet built or likely to be built in the near future (see BIOLOGICALLY INSPIRED ROBOTICS). Thus, when we suggest that the brain can be thought of in some ways as a (highly distributed) computer, we are not trying to reduce humans to the level of extant machines, but rather to understand ways in which machines give us insight into human attributes. This type of study has been referred to as *cybernetics*, extending the concept of Norbert Wiener, who, as we have seen, defined the subject as "the study of control and communication in man and machine."

To the extent that they address "higher mental function," the studies presented in this *Handbook* suggest that there is no single "thing" called *intelligence*, but rather a plexus of properties that, taken one at a time, may be little cause for admiration, but any sizable collection of which will yield behavior that we would label as intelligent. Turing (1950) argued that we would certainly regard a machine as intelligent if it could pass the following test: An experimenter sits in a room with two teletypes by which she conducts a "conversation" with two systems. One is a human, the other is a machine, but the experimenter is not told which is which. If, after asking many questions, she is likely to have much doubt about which is human and which is machine, we should, says Turing, concede intelligence to the machine. However, unless one dogmatically insists that being intelligent entails behaving in a human way, it is "harder" for a machine to pass this *Turing test* than to be intelligent. For instance, whereas a computer can answer problems in arithmetic quickly and correctly, a much more complex program would be required to ensure that it answered as slowly and erratically as a human. Turing's aim was not to find a necessary set of conditions to ensure intelligence, but rather to devise a test which, if passed by a machine, would convince most skeptics that the machine had intelligence.

## Schema Theory

The analysis of complex systems, whether they subserve natural or artificial intelligence, requires a coarser grain of analysis to complement that of neural networks. To make sense of the brain, we often divide it into functional systems—such as the motor system, the visual system, and so on—as well as into structural subsystems—from the spinal cord and the hippocampus to the various subdivisions of the prefrontal cortex. Similarly, in distributed AI (see MULTIAGENT SYSTEMS), the solution of a task may be distributed over a complex set of interacting *agents*, each with their dedicated processors for handling the information available to them locally. Thus, both neuroscience and artificial intelligence require a language for expressing the distribution of function across units intermediate between overall function and the final units of analysis (e.g., neurons or simple instructions).

Since the "units of thought" or the subfunctions of a complex behavior may be quite high-level compared to the fine-grain computation of the myriad neurons in the human brain, SCHEMA THEORY (q.v.; see also Arbib, 1981; Arbib, Érdi, and Szentágothai, 1998, chap. 3) complements connectionism by providing a bridging language between functional description and neural networks. It is based on a theory of the concurrent activity of interacting functional units called *schemas*. Perceptual schemas are those used for perceptual analysis, while motor schemas are those which provide the control systems that can be coordinated to effect a wide variety of movement. Other schemas compete and cooperate to meld action, internal state, and perception in an ongoing action-perception cycle.

Figure 4*A* represents brain theory, while Figure 4*B* offers a similar but distinct picture for distributed AI. We may model the brain either functionally, analyzing some behavior in terms of interacting schemas, or structurally, through the interaction of anatomically defined units, such as brain regions (cf. the examples in the road map **Mammalian Brain Regions**) or substructures of these regions, such as layers or columns. In brain theory, we ultimately seek an explanation in terms of neural networks, since the neuron may be considered the basic unit of function as well as of structure, and much further work in computational neuroscience seeks to explain the complex functionality of real neurons in terms of "subneural" units, such as membrane compartments, channels, spines, and synapses. What makes the story more subtle is that, in general, a functional analysis proceeding "top-down" from some overall behavior need not map directly into a "bottom-up" analysis proceeding upward from the neural circuitry (brain theory) or basic set of processors (distributed AI), and that several iterations from the "middle out" may be required to bring the structural and functional accounts into consonance. Brain theory may then seek to replace an initially plausible schema analysis with one whose schemas may be constituted by an assemblage of schemas which can each be embodied in one structure (without denying that a given brain region may support the activity of multiple schemas). The schemas that serve as the functional units in our initial hypotheses about the decomposition of some overall function may well differ from the more refined hypotheses which provide an account of structural correlates as well. On the other hand, distributed AI may adopt any schema analysis that is technologically effective, and the schemas may be implemented in whatever medium is appropriate, whether as conventional computer programs, ANNs, or special-purpose devices. These different approaches then rest on effective design of VLSI "chips" or other computing materials (cf. the road map **Implementation and Analysis**).

For brain theory, the top-level schemas must be "large" enough to allow an analysis of behavior at or near the psychological level, yet also be subject to successive decomposition down to a level that may, in certain cases, be implemented in specific neural networks. We again distinguish a schema as a *functional* unit from a neural network as a *structural* unit. A given schema may be distributed across several neural networks; a given neural network may be involved in the implementation of several different schemas. The same will be true for relating connectionist units to single biological neurons. If there is to be a fuller rapprochement between connectionism and neuropsychology, it will be important to use a vocabulary (or context) that allows one to make the necessary distinctions between connectionist and biological neurons.

A top-down analysis (decomposing a function) may suggest that a certain schema is embedded in a certain part of the brain; we can then marshal the available data from anatomy and neurophysiology

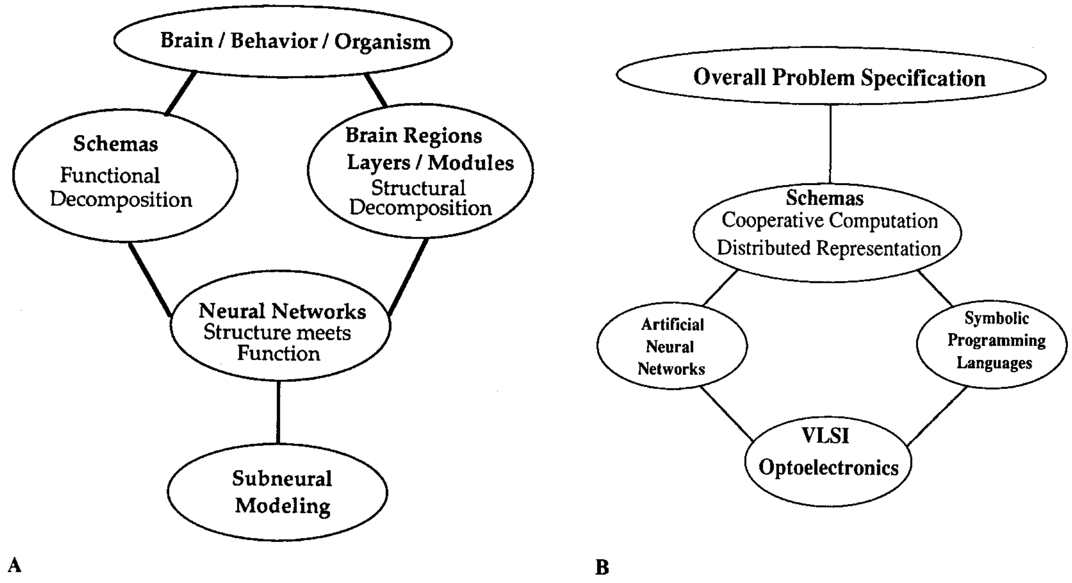

**Figure 4.** Views of level of analysis of brain and behavior (*A*) and a distributed technological system (*B*), highlighting the role of schemas as an intermediate level of functional analysis in each case.

to assess whether the circuitry can, indeed, subserve an instance of that schema. It often happens that the empirical data are inadequate. We then make hypotheses for experimental confirmation. Alternatively, bottom-up analysis of a brain region (assembling its constituents) may suggest that it subserves a different schema from that originally hypothesized, and we must then conduct a new top-down analysis in the light of these newfound constraints.

To illuminate the notion of experimental insight modifying an initial top-down analysis, we consider an example from *Rana computatrix*, a set of models of visuomotor coordination in the frog and toad (cf. VISUOMOTOR COORDINATION IN FROG AND TOAD). Frogs and toads snap at small moving objects and jump away from large ones (to oversimplify somewhat). Thus, a simple schema-model of the frog brain might simply postulate four schemas: two perceptual schemas (processes for recognizing objects or situations) and two motor schemas (processes for controlling some structured behavior). One perceptual schema would recognize small moving objects and activate a motor schema for approaching the prey; the other would recognize large moving objects and activate a motor schema for avoiding the predator. Lesion experiments can put such a model to the test if it is enhanced by hypotheses on the localization of each schema in the brain. It was thought that the tectum (a key visual region in the animal's midbrain) was the locus for recognizing small moving objects, while the pretectum (a region just in front of the tectum) was the locus for recognizing large moving objects. Based on these localization hypotheses, the model described would predict that an animal with a lesioned pretectum would be unresponsive to large objects, but would respond normally to small objects. However, the facts are quite different. A pretectum-lesioned toad will approach moving objects, both large and small, and does not exhibit avoidance behavior. This has led to a new schema model in which a perceptual schema to recognize large moving objects is still localized in the pretectum, but the tectum now contains a perceptual schema for *all* moving objects. We then add that activity of the pretectal schema not only triggers the avoidance motor schema but also inhibits approach. This new schema model still yields the normal behavior to large and small moving objects, but also fits the lesion data, since removal of the pretectum removes inhibition, meaning that the animal will now approach any moving object (Ewert and von Seelen, 1974).

We have thus seen how schemas may be used to provide falsifiable models of the brain, using lesion experiments to test schema models of behavior, and leading to new functional models that better match the structure of the brain. Note again that, in different species, the map from function to brain structure may be different, while in distributed AI the constraints are not those of analysis but rather those of design—namely, for a given function and a given set of processors, a schema decomposition must be found that will map most efficiently onto a network of processors of a certain kind.

While the brain may be considered a network of interacting "boxes" (anatomically distinguishable structures), there is no reason to expect each such box to mediate a single function that is well-defined from a behavioral standpoint. We have just seen that the frog tectum is implicated in both approach and (when modulated by pretectum) avoidance behavior. The language of schemas lets us express hypotheses about the various functions that the brain performs without assuming localization of any one function in any one region, but also allows us to express the way in which many regions participate in a given function, or a given region participates in many functions.

The style of *cooperative computation* (see COOPERATIVE PHENOMENA) exhibited in both schema theory and connectionism is far removed from serial computation and the symbol-based ideas that have dominated conventional AI. As we shall see in example after example in Part III, the brain has many specialized areas, each with a partial representation of the world. It is only through the interaction of these regions that the unity of behavior of the animal emerges, and the human is no different in this regard. The representation of the world is *the pattern of relationships between all its partial representations*. Much work in AI contributes to schema theory, even when it does not use this term. For example, Brooks (1986) builds robot controllers using layers made up of asynchronous modules that can be considered to be a version of schemas (see REACTIVE ROBOTIC SYSTEMS). This work shares with schema theory, with its mediation of action through a network of schemas, the point that no single, central, logical representation of the world needs link perception and action. It is also useful to view cooperative computation as a social phenomenon. A schema is a self-contained computing agent (object) with the ability to communicate with other agents, and whose function is specified by some behavior. Whereas schema theory was motivated in great part by the study of interacting brain regions (other influences are reviewed in Schema Theory), much early work in distributed AI was motivated by a social analogy in which the schemas were thought of as "agents" analogous to people interacting in a social setting to compete or cooperate in solving some overall problem, a theme elaborated on by Minsky (1985) and whose current status is reviewed in Multiagent Systems.

# I.3. Dynamics and Adaptation in Neural Networks

Section I.1 introduced a number of key concepts from the biological study of neurons, stressing the diversity of neurons both within the human CNS and across species. It presented several simple models of neurons, noting that computational neuroscience has gone on to produce more subtle and complicated neuronal models, while neural computing tends to use simple neurons augmented by "learning rules" for changing connection strengths on the basis of "experience." The purpose of this section is to introduce two key approaches that dominate the modern study of neural networks: (1) the study of neural networks as dynamic systems (developed more fully in the road map **Dynamic Systems**), and (2) the study of neural networks as adaptive systems (see **Learning in Artificial Networks**). To make this section essentially self-contained, we start by recalling the definitions of the McCulloch-Pitts and leaky integrator neurons from Section I.1, but we do this in the context of a general, semiformal, introduction to dynamic systems.

## Dynamic Systems

We motivate the notion of dynamic systems by considering how to abstract the interaction of an organism (or a machine) with its environment. The organism will be influenced by aspects of the current environment—the *inputs* to the organism—while the activity of the environment will be responsive in turn to aspects of the current activity of the organism, the *outputs* of the organism. The inputs and outputs that actually enter into a *theory* of the organism (or machine) are a small sampling of the flux of its interactions with the rest of the universe. There is essentially no limit to how many variables one could include in the analysis; a crucial task in any theory building is to pick the "right" variables.

Depending on the context, we will use the word *system* to denote either the physical reality (which we cannot know in its entirety) or the abstraction with which we approximate it. Inputs and outputs do not constitute a complete description of a system. We cannot predict how someone will answer a question unless we know her state of knowledge; nor can we tell how a computer will process its data unless we know the instructions controlling its computation. In short, we must include a description of the *internal state* of the system which determines what it will extract from its current stimulation in determining its current actions and modifying its internal state. Our abstraction of any real system contains five elements:

1. The set of *inputs*: those variables of the environment which we believe will affect the system behavior of interest to us.
2. The set of *outputs*: those variables of the system which we choose to observe, or which we believe will significantly affect the environment.
3. The set of *states*: those internal variables of the system (which may or may not also be output variables) which determine the relationship between input and output. Essentially, the state of a system is the system's "internal residue of the past": when we know the state of a system, no further information about the past behavior of the system will enable us to refine predictions of the way in which future inputs and outputs of the system will be related.
4. The *state-transition function*: that function which determines how the state will change when the system obtains various inputs.
5. The *output function*: that function which determines what output the system will yield with a given input when in a given state.

Any system in which the state-transition function and output function uniquely determine the new state and output from a specification of the initial state and subsequent inputs is called a *deterministic* system. If, no matter how carefully we specify subsequent inputs to a system, we cannot specify exactly what will be the subsequent states and outputs, we say the system is *probabilistic* or *stochastic*. A stochastic treatment may be worthwhile, either because we are analyzing systems, which are "inescapably" stochastic (e.g., at the quantum level), or because we are analyzing macroscopic systems, which lend themselves to a stochastic description by ignoring "fine details" of microscopic variables. For example, it is usually more reasonable to describe a coin in terms of a 0.5 probability of coming up heads than to measure the initial placement of the coin on the finger and the thrust of the thumb in sufficient detail to determine whether the coin will come up heads or tails.

### *Continuous-Time Systems*

In Newtonian mechanics, the state of the system comprises the positions of its components, which are directly observable, and their velocities, which can be estimated from the observed trajectory over a period of time. Time is continuous (i.e., characterized by the set $\mathbb{R}$ of real numbers), and the way in which the state changes is described by a differential equation: classical mechanics provides the basic example of *continuous-time* systems in which the present state and input determine *the rate at which the state changes*. This requires that the input, output, and state spaces be continuous spaces in which such continuous changes can occur. Consider the simple example of a point mass undergoing rectilinear motion. At any time, its position $y(t)$ is the observable output of the system, and the force $u(t)$ acting upon it is the input applied to the system. Newton's third law says that the force applied to the system equals the mass times the acceleration $\ddot{y}(t) = mu(t)$, where the acceleration $\ddot{y}(t)$ is the second derivative of $y(t)$. According to Newton's laws, the state of the system is given by the position and velocity of the particle. We call the position-velocity pair, at any time, the *instantaneous state* $q(t)$ of the system. In fact, the earlier equation gives us enough information to deduce the rate of change $dq(t)/dt$ of this state. Using standard matrix formalism, we thus have

$$\frac{d}{dt}\begin{bmatrix} y(t) \\ \dot{y}(t) \end{bmatrix} = \begin{bmatrix} \dot{y}(t) \\ \ddot{y}(t) \end{bmatrix} = \begin{bmatrix} \dot{y}(t) \\ mu(t) \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}\begin{bmatrix} y(t) \\ \dot{y}(t) \end{bmatrix} + \begin{bmatrix} 0 \\ m \end{bmatrix} u(t)$$

while

$$y(t) = \begin{bmatrix} 1 \\ 0 \end{bmatrix} q(t)$$

This is an example of a *linear* system in which the rate of change of state depends linearly on the present state and input, and the present output depends linearly on the present state. That is, there are matrices $F$, $G$, and $H$ such that

$$\frac{dq(t)}{dt} = Fq(t) + Gu(t);\ y(t) = Hq(t)$$

More generally, a physical system can be expressed by a pair of equations:

$$\frac{dq(t)}{dt} = f(q(t), u(t))$$

$$y(t) = g(q(t))$$

The first expresses the rate of change $dq(t)/dt$ of the state as a function of both the state $q(t)$ and the input or control vector $u(t)$ applied at any time $t$; the second reads the output from the current state.

We now present the definition of a *leaky integrator neuron* as a continuous-time system. The internal state of the neuron is its membrane potential, $m(t)$, and its output is the firing rate, $M(t)$. The *state transition function* of the cell is expressed as

$$\tau\frac{dm(t)}{dt} = -m(t) + \sum_i w_i X_i(t) + h \qquad (1)$$

while the *output function* of the cell is given by the equation

$$M(t) = \sigma(m(t)) \qquad (2)$$

Thus, if there are $m$ inputs $X_i(t)$, $i = 1, \ldots, m$, then the *input space* of the neuron is $\mathbb{R}^m$, with current value $(X_1(t), \ldots, X_m(t))$, while the *state* and *output* spaces of the neuron both equal $\mathbb{R}$, with current values $m(t)$ and $M(t)$, respectively.

Let us now briefly (and semiformally) see how a neural network comprised of leaky integrator neurons can also be seen as a continuous-time system. As typified in Figure 5, we characterize a neural network by selecting $N$ neurons (each with specified input weights and resting potential) and by taking the axon of each neuron, which may be split into several branches carrying identical output signals, and either connecting each line to a unique input of another neuron or feeding it outside the net to provide one of the $K$ network output lines. Then every input to a given neuron must be connected either to an output of another neuron or to one of the (possibly split) $L$ input lines of the network. Thus the input set $X = \mathbb{R}^L$, the state set $Q = \mathbb{R}^N$, and the output set $Y = \mathbb{R}^K$. If the $i$th output line comes from the $j$th neuron, then the *output function* is determined by the fact that the $i$th component of the output at time $t$ is the firing rate $M_j(t) = \sigma_j(M_j(t))$ of the $j$th neuron at time $t$. The state transition function for the neural network follows from the state transition functions of each of the $N$ neurons

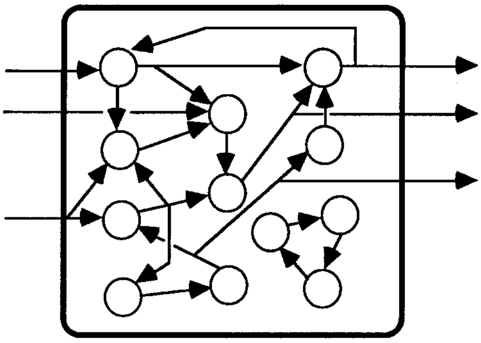

**Figure 5.** A neural network viewed as a system. The input at time $t$ is the pattern of firing on the input lines, the output is the pattern of firing on the output lines; and the internal state is the vector of firing rates of all the neurons of the network.

$$\tau\frac{dm_i(t)}{dt} = -m_i(t) + \sum_j w_{ij} X_{ij}(t) + h_i \qquad (3)$$

as soon as we specify whether $X_{ij}(t)$ is the output $M_k(t)$ of the $k$th neuron or the value $x_l(t)$ currently being applied on the $l$th input line of the overall network.

### *Discrete-Time Systems*

In contrast to continuous-time systems, which *must* have continuous state spaces on which the differential equations for the state transition function can be defined, *discrete-time* systems may have either continuous or discrete state spaces. (A *discrete* state space is just a set with no specific metric or topological structure.) For example, a McCulloch-Pitts neuron is considered to operate on a discrete-time scale, $t = 0, 1, 2, 3, \ldots$, and has connection weights $w_i$ and threshold $\theta$. If at time $t$ the value of the $i$th input is $x_i(t)$, then the output one time step later, $y(t + 1)$, equals 1 if and only if $\Sigma_i w_i x_i(t) \geq \theta$. If there are $m$ inputs $(x_1(t), \ldots, x_m(t))$, then, since inputs and outputs are binary, such a neuron has input set $= \{0, 1\}^m$, state set $=$ output set $\{0, 1\}$ (we treat the current state and output as being identical). On the other hand, the important learning scheme known as backpropagation (defined later) is based on neurons which operate on discrete time, but with both input and output taking continuous values in some range, say [0, 1].

In computer science, an *automaton* is a discrete-time system with discrete input, output, and state spaces. Formally, we describe an automaton by the sets $X$, $Y$, and $Q$ of inputs, outputs, and states, respectively, together with the *next-state function* $\delta$: $Q \times X \to Q$ and the *output function* $\beta$: $Q \to Y$. If the automaton is in state $q$ and receives input $x$ at time $t$, then its next state will be $\delta(q, x)$ and its next output will be $\beta(q)$. It should be clear that a McCulloch-Pitts neural network (i.e., a network like that shown in Figure 5, but a discrete-time network with each neuron a McCulloch-Pitts neuron) functions like a finite automaton, as each neuron changes state synchronously on each tick of the time scale $t = 0, 1, 2, 3, \ldots$. Conversely, it can be shown (see Arbib, 1987; the result was essentially, though inscrutably, due to McCulloch and Pitts, 1943) that any finite automaton can be simulated by a suitable McCulloch-Pitts neural network.

### *Stability, Limit Cycles, and Chaos*

With the previous discussion, we now have more than enough material to understand the crucial dynamic systems concept of *stability* and the related concepts of limit cycles and chaos (see COMPUTING WITH ATTRACTORS and CHAOS IN NEURAL SYSTEMS). We want to know what happens to an "unperturbed" system, i.e., one for which the input is held constant (possibly with some specific "null input," usually denoted by 0, the "zero" input in $X$). An *equilibrium* is a state $q$ in which the system can stay at rest, i.e., such that $\delta(q, 0) = q$ (discrete time) or $dq/dt = f(q, 0) = 0$ (continuous time). The study of stability is concerned with the issue of whether or not this rest point will be maintained in the face of slight disturbances. To see the variety of equilibria, we use the image of a sticky ball rolling on the "hillside" of Figure 6. We say that point $A$ on the "hillside" in this diagram is an *unstable equilibrium* because a slight displacement from $A$ will tend to increase over time. Point $B$ is in a region of *neutral equilibrium* because slight displacements will tend not to change further, while $C$ is a point of *stable equilibrium*, since small displacements will tend to decrease over time. Note the word "small": in a nonlinear system like that of Figure 6, a large displacement can move the ball from the *basin of attraction* of $C$ (the set of states whose dynamics tends toward $C$) to another one. Clearly, the ball will not tend to return to $C$ after a massive displacement that moves the ball to the far side of $A$'s hilltop.

Many nonlinear systems have another interesting property: they may exhibit *limit cycles*. These are closed trajectories in the state space, and thus may be thought of as "dynamic equilibria." If the state of a system follows a limit cycle, we may also say it oscillates or exhibits periodic behavior. A limit cycle is *stable* if a small displacement will be reduced as the trajectory of the system comes closer and closer to the original limit cycle. By contrast, a limit cycle is *unstable* if such excursions do not die out. Research in nonlinear systems has also revealed what are called *strange attractors*. These are attractors which, unlike simple limit cycles, describe such complex paths through the state space that, although the system is deterministic, a path that approaches the strange attractor gives every appearance of being random. The point here is that very small differences in initial state may be amplified with the passage of time, so that differences that at first are not even noticeable will yield, in due course, states that are very different indeed. Such a trajectory has become the accepted mathematical model of *chaos*, and it is used to describe a number of physical phenomena, such as the onset of turbulence in a weather system, as well as a number of phenomena in biological systems (see CHAOS IN BIOLOGICAL SYSTEMS; CHAOS IN NEURAL SYSTEMS).

### *Hopfield Nets*

Many authors have treated neural networks as dynamical systems, employing notions of equilibrium, stability, and so on, to classify their performance (see, e.g., Grossberg, 1967; Amari and Arbib, 1977; see also COMPUTING WITH ATTRACTORS). However, it was a paper by John Hopfield (1982) that was the catalyst in attracting the attention of many physicists to this field of study. In a McCulloch-Pitts network, every neuron processes its inputs to determine a new output at each time step. By contrast, a *Hopfield net* is a net of such units with (1) *symmetric* weights ($w_{ij} = w_{ji}$) and no self-connections ($w_{ii} = 0$), and (2) asynchronous updating. For instance, let $s_i$ denote the state (0 or 1) of the $i$th unit. At each time step, pick just one unit at random. If unit $i$ is chosen, $s_i$ takes the value 1 if and only if $\Sigma w_{ij}s_j \geq \theta_i$. Otherwise $s_i$ is set to 0. Note that this is an *autonomous* (input-free) network: there are no inputs (although instead of considering $\theta_i$ as a threshold we may consider $-\theta_i$ as a constant input, also known as a bias).

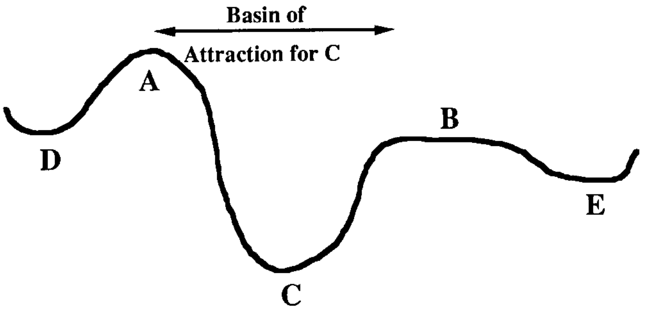

**Figure 6.** An energy landscape: For a ball rolling on the "hillside," point $A$ is an *unstable equilibrium*, point $B$ lies in a region of *neutral equilibrium*, and point $C$ is a point of *stable equilibrium*. Point $C$ is called an attractor: the basin of attraction of $C$ comprises all states whose dynamics tend toward $C$.

Hopfield defined a measure called the *energy* for such a net (see ENERGY FUNCTIONALS FOR NEURAL NETWORKS)

$$E = -\tfrac{1}{2} \sum_{ij} s_i s_j w_{ij} + \sum_i s_i \theta_i \tag{1}$$

This is not the physical energy of the neural net but a mathematical quantity that, in some ways, does for neural dynamics what the potential energy does for Newtonian mechanics. In general, a mechanical system moves to a state of lower potential energy just as, in Figure 6, the ball tends to move downhill. Hopfield showed that his symmetrical networks with asynchronous updating had a similar property.

For example, if we pick a unit and the foregoing firing rule does not change its $s_i$, it will not change $E$. However, if $s_i$ initially equals 0, and $\Sigma w_{ij}s_j \geq \theta_i$, then $s_i$ goes from 0 to 1 with all other $s_j$ constant, and the "energy gap," or change in $E$, is given by

$$\begin{aligned}\Delta E &= -\tfrac{1}{2} \sum_j (w_{ij}s_j + w_{ji}s_j) + \theta_i \\ &= -\sum_j w_{ij}s_js_j + \theta_i, \text{ by symmetry} \\ &\leq 0 \text{ since } \sum w_{ij}s_j \geqslant \theta_i\end{aligned}$$

Similarly, if $s_i$ initially equals 1, and $\Sigma w_{ij}s_j < \theta_i$, then $s_i$ goes from 1 to 0 with all other $s_j$ constant, and the energy gap is given by

$$\Delta E = \sum w_{ij}s_j - \theta_i < 0$$

In other words, with every asynchronous updating, we have $\Delta E \leq 0$. Hence the dynamics of the net tends to move $E$ toward a minimum. We stress that there may be different such states—they are *local* minima, just as, in Figure 6, both $D$ and $E$ are local minima (each of them is lower than any "nearby" state) but not global minima (since $C$ is lower than either of them). Global minimization is not guaranteed.

The expression just presented for $\Delta E$ depends on the symmetry condition, $w_{ij} = w_{ji}$, for without this condition, the expression would instead be $\Delta E = -(\tfrac{1}{2})\Sigma_j(w_{ij}s_j + w_{ji}s_j) + \theta_i$ and in this case, Hopfield's updating rule need not yield a passage to energy minimum, but might instead yield a limit cycle, which could be useful in, e.g., controlling rhythmic behavior (see, e.g., RESPIRATORY RHYTHM GENERATION). In a control problem, a link $w_{ij}$ might express the likelihood that the action represented by $i$ would precede that represented by $j$, in which case $w_{ij} = w_{ji}$ is normally inappropriate.

The condition of *asynchronous* update is crucial, too. If we consider the simple "flip-flop" with $w_{12} = w_{21} = 1$ and $\theta_1 = \theta_2 = 0.5$, then the McCulloch-Pitts network will *oscillate* between the states (0, 1) and (1, 0) or will sit in the states (0, 0) or (1, 1); in other words, there is no guarantee that it will converge to an equilibrium. However, with $\mathrm{E} = -(\tfrac{1}{2})\Sigma_{ij}s_is_jw_{ij} + \Sigma_i s_i\theta_i$, we have $E(0, 0) = 0$, $E(0, 1) = E(1, 0) = 0.5$, and $E(1, 1) = 0$, and the Hopfield network will *converge* to the global minimum at either (0, 0) or (1, 1).

Hopfield also aroused much interest because he showed how a number of optimization problems could be "solved" using neural networks. (The quotes around "solved" acknowledge the fact that the state to which a neural network converges may represent a local, rather than a global, optimum of the corresponding optimization problem.) Such networks were similar to the "constraint satisfaction" networks that had already been studied in the computer vision community. (In most vision algorithms—see, e.g., STEREO CORRESPONDENCE—constraints can be formulated in terms of symmetric weights, so that $w_{ij} = w_{ji}$ is appropriate.) The aim, given a "constraint satisfaction" problem, is to so choose weights for a neural network so that the energy $E$ for that network is a measure of the overall constraint violation. A famous example is the Traveling Salesman Problem (TSP): There are $n$ cities, with a road of length $l_{ij}$ joining city $i$ to city $j$. The salesman wishes to find a way to visit the cities that is optimal in two ways: each city is visited only once, and the total route is as short as possible. We express this as a constraint satisfaction network in the following way: Let the activity of neuron $N_{ij}$ express the decision to go straight from city $i$ to city $j$. The cost of this move is simply $l_{ij}$, and so the total "transportation cost" is $\Sigma_{ij}l_{ij}N_{ij}$. It is somewhat more challenging to express the cost of violating the "visit a city only once" criterion, but we can reexpress it by saying that, for city $j$, there is one and only one city $i$ from which $j$ is directly approached. Thus, $\Sigma_j(\Sigma_i N_{ij} - 1)^2 = 0$ just in case this constraint is satisfied; a non-zero value measures the extent to which this constraint is violated. This can then be mapped into the setting of weights and thresholds for a Hopfield network. Hopfield and Tank (1986) constructed chips for this network which do indeed settle very quickly to a local minimum of $E$. Unfortunately, there is no guarantee that this minimum is globally optimal. The article OPTIMIZATION, NEURAL presents this and a number of other neurally based approaches to optimization. The article SIMULATED ANNEALING AND BOLTZMANN MACHINES shows how noise may be added to "shake" a system out of a local minimum and let it settle into a global minimum. (Consider, for example, shaking that is strong enough to shake the ball from $D$ to $A$, and thus into the basin of attraction of $C$, in Figure 6, but not strong enough to shake the ball back from $C$ toward $D$.)

## Adaptation in Dynamic Systems

In the previous discussion of neural networks as dynamic systems, the dynamics (i.e., the state transition function) has been fixed. However, just as humans and animals learn from experience, so do many important applications of ANNs depend on the ability of these networks to adapt to the task at hand by, e.g., changing the values of the synaptic weights to improve performance. We now introduce the general notion of an adaptive system as background to some of the most influential "learning rules" used in adaptive neural networks. The key motivation for using learning networks is that it may be too hard to program explicitly the behavior that one sees in a black box, but one may be able to drive a network by the actual input/output behavior of that box, or by some description of its trajectories, to cause it to adapt itself into a network which approximates that given behavior. However, as we will stress at the end of this section, a learning algorithm may not solve a problem within a reasonable period of time unless the initial structure of the network is suitable.

### Adaptive Control

A key problem of technology is to control a complex system so that it behaves in some desired way, whether getting a space probe on course to Mars or a steel mill to produce high-quality steel. A common situation that complicates this *control problem* is that the controlled system may not be known accurately; it may even change its character somewhat with time. For example, as fuel is depleted, the mass and moments of inertia of the probe may change in unpredicted ways. The *adaptation problem* involves determining, on the basis of interaction with a given system, an appropriate "model" of the system which the controller can use in solving the control problem.

Suppose we have available an *identification procedure* which can find an adequate parametric representation of the controlled system (see IDENTIFICATION AND CONTROL). Then, rather than build a controller specifically designed to control this one system, we may instead build a general-purpose controller which can accommodate to any reasonable set of parameters. The controller then uses the parameters which the identification procedure provides as the best estimate of the controlled system's parameters at that time. If the identification procedure can make accurate estimates of the system's parameters as quickly as they actually change, the controller will be able to act efficiently despite fluctuations in controlled system dynamics. The controller, when coupled to an identification procedure, is an *adaptive controller*; that is, it adapts its control strategy to changes in the dynamics of the controlled system. However, the use of an explicit identification procedure is only one way of building an adaptive controller. Adaptive neural nets may be used to build adaptive procedures which may directly modify the parameters in some control rule, or identify the system *inverse* so that desired outputs can be automatically transformed into the inputs that will achieve them. (See SENSORIMOTOR LEARNING for the distinction between forward and inverse models.)

### Pattern Recognition

In the setup shown in Figure 7, the *preprocessor* extracts from the environment a set of "confidence levels" for various input features (see FEATURE ANALYSIS), with the result represented by a vector of $d$ real numbers. In this formalization, any pattern x is represented by a point $(x_1, x_2, \ldots, x_d)$ in a $d$-dimensional Euclidean space $\mathbb{R}^d$ called the *pattern space*. The pattern recognizer then takes the pattern and produces a response that may have one of $K$ distinct values where there are $K$ categories into which the patterns must be sorted; points in $\mathbb{R}^d$ are thus grouped into at least $K$ different sets (see CONCEPT LEARNING and PATTERN RECOGNITION). However, a

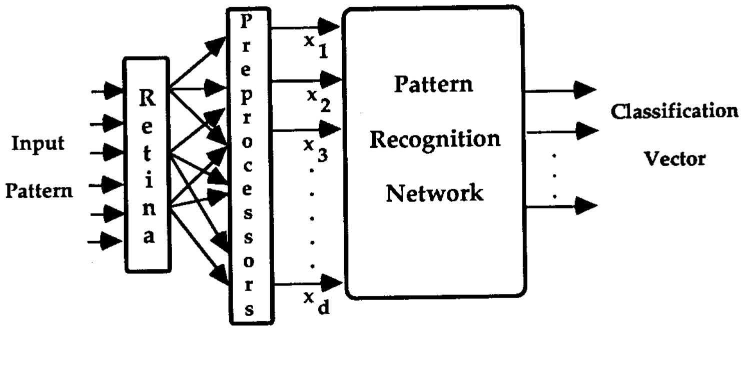

**Figure 7.** One strategy in pattern recognition is to precede the adaptive neural network by a fixed layer of "preprocessors" or "feature extractors" which replace the image by a finite vector for further processing. In other approaches, the functions defined by the early layers of the network may themselves be subject to training.

category might be represented in more than one region of $\mathbb{R}^d$. To take an example from visual pattern recognition (although the theory of pattern recognition networks applies to any classification of $\mathbb{R}^d$), *a* and *A* are members of the category of the first letter of the English alphabet, but they would be found in different connected regions of a pattern space. In such cases, it may be necessary to establish a hierarchical system involving a separate apparatus to recognize each subset, and a further system that recognizes that the subsets all belong to the same set (a related idea was originally developed by Selfridge, 1959; for adaptive versions, see MODULAR AND HIERARCHICAL LEARNING SYSTEMS). Here we avoid this problem by concentrating on the case in which the decision space is divided into exactly two connected regions.

We call a function f: $\mathbb{R}^d \rightarrow \mathbb{R}$ a *discriminant function* if the equation $f(x) = 0$ gives the *decision surface* separating two regions of a pattern space. A basic problem of pattern recognition is the specification of such a function. It is virtually impossible for humans to "read out" the function they use (not to mention *how* they use it) to classify patterns. Thus, a common strategy in pattern recognition is to provide a classification machine with an adjustable function and to "train" it with a set of patterns of known classification that are typical of those with which the machine must ultimately work. The function may be linear, quadratic, polynomial, or even more subtle yet, depending on the complexity and shape of the pattern space and the necessary discriminations. The experimenter chooses a class of functions with parameters which, it is hoped, will, with proper adjustment, yield a function that will successfully classify any given pattern. For example, the experimenter may decide to use a linear function of the form

$$f(x) = w_1x_1 + w_2x_2 + \ldots + w_dx_d + w_{d+1}$$

(i.e., a McCulloch-Pitts neuron!) in a two-category pattern classifier. The equation $f(x) = 0$ gives a hyperplane as the decision surface, and training involves adjusting the coefficients ($w_1$, $w_2$, . . . , $w_d$, $w_{d+1}$) so that the decision surface produces an acceptable separation of the two classes. We say that two categories are *linearly separable* if an acceptable setting of such linear weights exists. Thus, pattern recognition poses (at least) the following challenges to neural networks:

(a) Find a "good" set of preprocessors. Competitive learning based on Hebbian plasticity (see COMPETITIVE LEARNING, as well as the following text) provides one way of finding such features by extracting statistically significant patterns from a set of input patterns. For example, if such a network were exposed to many, but only, letters of the Roman alphabet, then it would find that certain line segments and loops occurred repeatedly, even if there were no teacher to tell it how to classify the patterns.

(b) Given a set of preprocessors and a set of patterns which have already been classified, adjust the connections of a neural network so that it acts as an effective pattern recognizer. That is, its response to a preprocessed pattern should usually agree well with the classification provided by a teacher.

(c) Of course, if the neural network has multiple layers with adaptable synaptic weights, then the early layers can be thought of as preprocessors for the later layers, and we have a case of supervised, rather than Hebbian, formation of these "feature detectors"—emphasizing features which are not only statistically significant elements of the input patterns but which also serve to distinguish usefully to which class a pattern belongs.

### *Associative Memory*

In pattern recognition, we associate a pattern with a "label" or "category." Alternatively, an associative memory takes some "key" as input and returns some "associated recollection" as output (see ASSOCIATIVE NETWORKS). For example, given the sound of a word, we may wish to recall its spelling. Given a misspelled word, we may wish to recall the correctly spelled word of which it is most plausibly a "degraded image." There are two major approaches to the use of neural networks as associative memories:

In *nonrecurrent* neural networks, there are no loops (i.e., we cannot start at any neuron and "follow the arrows" to get back to that neuron). We use such a network by fixing the pattern of inputs as the key, and holding them steady. Since the absence of loops ensures that the input pattern uniquely determines the output pattern (after the new inputs have time to propagate their effects through the network), this uniquely determined output pattern is the recollection associated with the key.

In *recurrent* networks, the presence of loops implies that the input alone may not determine the output of the net, since this will also depend on the initial state of the network. Thus, recurrent networks are often used as associative memories in the following way. The inputs are only used transiently to establish the initial state of the neural network. After that, the network operates autonomously (i.e., uninfluenced by any inputs). If and when it reaches an equilibrium state, that state is read out as the recollection associated with the key.

In either case, the problem is to set the weights of the neural network so that it associates keys as accurately as possible with the appropriate recollections.

## Learning Rules

Most learning rules in current models of "lumped neurons" (i.e., those that exclude detailed analysis of the fine structure of the neuron or the neurochemistry of neural plasticity) take the form of schemes for adjusting the synaptic weights, the "*w*s." The two classic learning schemes for McCulloch-Pitts-type formal neurons are due to Hebb (see HEBBIAN SYNAPTIC PLASTICITY) and Rosenblatt (the perceptron, see PERCEPTRONS, ADALINES, AND BACKPROPAGATION), and we now introduce these in turn.

### *Hebbian Plasticity and Network Self-Organization*

In Hebb's (1949) learning scheme (see HEBBIAN SYNAPTIC PLASTICITY), the connection between two neurons is strengthened if both neurons fire at the same time. The simplest example of such a rule is to increase $w_{ij}$ by the following amount:

$$\Delta w_{ij} = ky_ix_j$$

where synapse $w_{ij}$ connects a presynaptic neuron with firing rate $x_j$ to a postsynaptic neuron with firing rate $y_i$. The trouble with the original Hebb model is that every synapse will eventually get stronger and stronger until they all saturate, thus destroying any selectivity of association. Von der Malsburg's (1973) solution was to normalize the synapses impinging on a given neuron. To accomplish this, one must first compute the Hebbian "update" $\Delta w_{ij} = kx_iy_j$ and then divide this by the total putative synaptic weights to get the final result which replaces $w_i$ by

$$\frac{w_{ij} + \Delta w_{ij}}{\sum_k (w_{kj} + \Delta w_{kj})}$$

where the summation $k$ extends over all inputs to the neuron. This new rule not only increases the strengths of those synapses with inputs strongly correlated with the cell's activity, but also decreases the synaptic strengths of other connections in which such correlations did not arise.

Von der Malsburg was motivated by the pattern recognition problem and was concerned with how individual cells in his network might come to be tuned so as to respond to one particular input "feature" rather than another (see OCULAR DOMINANCE AND ORIENTATION COLUMNS for background as well as a review of more recent approaches). This exposed another problem with Hebb's rule: a lot of nearby cells may, just by chance, all have initial random connectivity which makes them easily persuadable by the same stimulus; alternatively, the same pattern might occur many times before a new pattern is experienced by the network. In either case, many cells would become tuned to the same feature, with not enough cells left to learn important and distinctive features. To solve this, von der Malsburg introduced *lateral inhibition* into his model. In this connectivity pattern, activity in any one cell is distributed laterally to reduce (partially inhibit) the activity of nearby cells. This ensures that if one cell—call it A—were especially active, its connections to nearby cells would make them less active, and so make them less likely to learn, by Hebbian synaptic adjustment, those features that most excite A.

In summary, then, when the Hebbian rule is augmented by a normalization rule, it tends to "sharpen" a neuron's predisposition "without a teacher," getting its firing to become better and better correlated with a cluster of stimulus patterns. This performance is improved when there is some competition between neurons so that if one neuron becomes adept at responding to a pattern, it inhibits other neurons from doing so (COMPETITIVE LEARNING). Thus, the final set of input weights to the neuron depends both on the initial setting of the weights and on the pattern of clustering of the set of stimuli to which it is exposed (see DATA CLUSTERING AND LEARNING). Other "post-Hebbian" rules, motivated both by technological efficiency and by recent biological findings, are discussed in several articles in Part III, including HEBBIAN LEARNING AND NEURONAL REGULATION and POST-HEBBIAN LEARNING ALGORITHMS.

In the adaptive architecture just described, the inputs are initially randomly connected to the cells of the processing layer. As a result, none of these cells is particularly good at pattern recognition. However, by sheer statistical fluctuation of the synaptic connections, one will be slightly better at responding to a particular pattern than others are; it will thus slightly strengthen those synapses which allow it to fire for that pattern and, through lateral inhibition, this will make it harder for cells initially less well tuned for that pattern to become tuned to it. Thus, without any teacher, this network automatically organizes itself so that each cell becomes tuned for an important cluster of information in the sensory inflow. This is a basic example of the kind of phenomenon treated in SELF-ORGANIZATION AND THE BRAIN.

### *Perceptrons*

Perceptrons are neural nets that change with "experience," using an *error-correction rule* designed to change the weights of each response unit when it makes erroneous responses to stimuli that are presented to the network. We refer to the judge of what is correct as the "teacher," although this may be another neural network, or some environmental input, rather than a signal supplied by a human teacher in the usual schoolroom sense. Consider the case in which a set **R** of input lines feeds a Pitts-McCulloch neural network whose neurons are called *associator units* and which in turn provide the input to a single McCulloch-Pitts neuron (called the *output unit* of the perceptron) with adjustable weights ($w_1, \ldots, w_d$) and threshold $\theta$. (In the case of visual pattern recognition, we think of **R** as a rectangular "retina" onto which patterns may be projected.) A *simple perceptron* is one in which the associator units are not interconnected, *which means that it has no short-term memory*. (If such connections are present, the perceptron is called *cross-coupled*. A cross-coupled perceptron may have multiple layers and loops back from an "earlier" to a "later" layer.) If the associator units feed the pattern $x = (x_1, \ldots, x_d)$ to the output unit, then the response of that unit will be to provide the pattern discrimination with discriminant function $f(x) = w_1x_1 + \ldots + w_dx_d - \theta$. In other words, the simple perceptron can only compute a *linearly separable* function of the pattern as provided by the associator units. The question asked by Rosenblatt (1958) and answered by many others since (cf. Nilsson, 1965) was, "Given a simple perceptron (i.e., only the synaptic weights of the output unit are adjustable), can we 'train' it to recognize a given linearly separable set of patterns by adjusting the 'weights' on various interconnections on the basis of feedback on whether or not the network classifies a pattern correctly?" The answer was "Yes: if the patterns are linearly separable, then there is a learning scheme which will eventually yield a satisfactory setting of the weights." The best-known perceptron learning rule strengthens an active synapse if the efferent neuron fails to fire when it should have fired, and weakens an active synapse if the neuron fires when it should not have done so:

$$\Delta w_{ij} = k(Y_i - y_i)x_j$$

As before, synapse $w_{ij}$ connects a presynaptic neuron with firing rate $x_j$ to a postsynaptic neuron with firing rate $y_i$, but now $Y_i$ is the "correct" output supplied by the "teacher." (This is similar to the Widrow-Hoff [1960] least mean squares model of adaptive control; see PERCEPTRONS, ADALINES, AND BACKPROPAGATION.) Notice that the rule does change the response to $x_j$ "in the right direction." If the output is correct, $Y_i = y_i$ and there is no change, $\Delta w_j = 0$. If the output is too small, then $Y_i - y_i > 0$, and the change in $w_j$ will add $\Delta w_j x_j = k(Y_i - y_i)x_j x_j > 0$ to the output unit's response to $(x_1, \ldots, x_d)$. Similarly, if the output is too large, then $Y_i - y_i < 0$, $\Delta w_j$ will add $k(Y_i - y_i)x_j x_j < 0$ to the output unit's response. Thus, there is a sense in which the new setting $w' = w + \Delta w$ classifies the input pattern $x$ "more nearly correctly" than $w$ does. Unfortunately, in classifying $x$ "more correctly" we run the risk of classifying another pattern "less correctly." However, the *perceptron convergence theorem* (see Arbib, 1987, pp. 66–69, for a proof) shows that Rosenblatt's procedure does not yield an endless seesaw, but will eventually converge to a correct set of weights if one exists, albeit perhaps after many iterations through the set of trial patterns.

## Network Complexity

The perceptron convergence theorem states that, if a linear separation exists, the perceptron error-correction scheme will find it. Minsky and Papert (1969) revivified the study of perceptrons (although some AI workers thought they had killed it!) by responding to such results with questions like, "Your scheme works when a weighting scheme exists, but *when* does there exist such a setting of the weights?" More generally, "Given a pattern-recognition problem, how much of the retina must each associator unit 'see' if the network is to do its job?" Minsky and Papert studied when it was possible for a McCulloch-Pitts neuron (no matter how trained) to combine information in a single preprocessing layer to perform a given pattern recognition task, such as recognizing whether a pattern $X$ of 1s on the retina (the other retinal units having output 0) is *connected*, that is, whether a path can be drawn from any 1 of $X$ to another without going through any 0s. Another question was to determine whether $X$ is of *odd parity*, i.e., whether $X$ contains an odd number of 1s. The question is, "How many inputs are required for the preprocessing units of a simple perceptron to successfully implement $f$?" We can get away with using a single element, computing an arbitrary Boolean function, and connecting it to all the units of the retina. So the question that really interests us is whether we can get away with a response unit connected to proprocessors, each of which receives inputs from a limited set of retinal units to make a global decision by synthesizing an array of local views.

We convey the flavor of Minsky and Papert's approach by the example of XOR, the simple Boolean operation of addition modulo

2, also known as the exclusive-or. If we imagine the square with vertices (0, 0), (0, 1), (1, 1), and (1, 0) in the Cartesian plane, with $(x_1, x_2)$ being labeled by $x_1 \oplus x_2$, we have 0s at one diagonally opposite pair of vertices and 1s at the other diagonally opposite pair of vertices. It is clear that there is no way of interposing a straight line such that the 1s lie on one side and the 0s lie on the other side. However, we shall prove it mathematically to gain insight into the techniques used by Minsky and Papert.

Consider the claim that we wish to prove wrong: that there actually exists a neuron with threshold $\theta$ and weights $\alpha$ and $\beta$ such that $x_1 \oplus x_2 = 1$ if and only if $\alpha x_1 + \beta x_2 \geq \theta$. The crucial point is to note that the function of addition modulo 2 is symmetric; therefore, we must also have $x_1 \oplus x_2 = 1$ if and only if $\beta x_1 + \alpha x_2 \geq \theta$, and, so, adding together the two terms, we have $x_1 \oplus x_2 = 1$ if and only if $(\frac{1}{2})(\alpha + \beta)(x_1 + x_2) \geq \theta$. Writing $(\frac{1}{2})(\alpha + \beta)$ as $\gamma$, we see that we have reduced three putative parameters $\alpha$, $\beta$, and $\theta$ to just two, namely $\gamma$ and $\theta$.

We now set $t = x_1 + x_2$ and look at the polynomial $\gamma t - \theta$. It is a degree 1 polynomial, but note: at $t = 0$, $\gamma t - \theta$ must be less than zero ($0 \oplus 0 = 0$); at $t = 1$, it is greater than or equal to zero ($0 \oplus 1 = 1 \oplus 0 = 1$); and at $t = 2$, it is again less than zero ($1 \oplus 1 = 0$). This is a contradiction—a polynomial of degree 1 cannot change sign from positive to negative more than once. We conclude that there is no such polynomial, and thus that there is no threshold element which will add modulo 2.

We now understand a general method used again and again by Minsky and Papert: start with a pattern-classification problem. Observe that certain symmetries leave it invariant. For instance, for the parity problem (is the number of active elements even or odd?), which includes the case of addition modulo 2 when the retina has only two units, any permutation of the points of the retina would leave the classification unchanged. Use this to reduce the number of parameters describing the circuit. Then lump items together to get a polynomial and examine actual patterns to put a lower bound on the degree of the polynomial, fixing things so that this degree bounds the number of inputs to the response unit of a simple perceptron.

Minsky and Papert provide many interesting theorems (for the proof of an illustrative sample, see Arbib, 1987, pp. 82–84). As just one example, we may note that they prove that the parity function requires preprocessors big enough to scan the whole retina if the preprocessors can only be followed by a single McCulloch-Pitts neuron. By contrast, to tell whether the number of active retinal inputs reaches a certain threshold only requires two inputs per neuron in the first layer. (For other complexity results, see the articles listed in the road map **Computability and Complexity**.)

## Gradient Descent and Credit Assignment

The implication of the results on "network complexity" is clear: if we limit the complexity of the units in a neural network, then in general we will need many layers, rather than a single layer, if the network is to have any chance of being trained to realize many "interesting" functions. This conclusion motivates the study of training rules for multilayer perceptrons, of which the most widely used is *backpropagation*. Before describing this method, we first discuss two general notions of which it is an important exemplar: *gradient descent* and *credit assignment*.

In discussing Hopfield networks, we introduced the metaphor of an "energy landscape" (see Figure 6). The asynchronous updates move the state of the network (the vector of neural activity levels) "downhill," tending toward a local energy minimum. Our task now is to realize that the metaphor works again on a far more abstract level when we consider learning. In learning, the dynamic variable is not the network state, but rather the vector of synaptic weights (or whatever other set of network parameters is adjusted by the learning rules). We now conduct *gradient descent in weight space*. At each step, the weights are adjusted in such a way as to improve the performance of the network. (As in the case of the simple perceptron, the improvement is a "local" one based on the current situation. It is, in this case, a matter for computer simulation to prove that the cumulative effect of these small changes is a network which solves the overall problem.)

But how do we recognize which "direction" in weight space is "downhill"? Suppose success is achieved by a complex mechanism after operating over a considerable period of time (for example, when a chess-playing program wins a game). To what particular decisions made by what particular components should the success be attributed? And, if failure results, what decisions deserve blame? This is closely related to the problem known as the "mesa" or "plateau" problem (Minsky, 1961). The performance evaluation function available to a learning system may consist of large level regions in which gradient descent degenerates to exhaustive search, so that only a few of the situations obtainable by the learning system and its environment are known to be desirable, and these situations may occur rarely.

One aspect of this problem, then, is the *temporal* credit assignment problem. The utility of making a certain action may depend on the sequence of actions of which it is a part, and an indication of improved performance may not occur until the entire sequence has been completed. This problem was attacked successfully in Samuel's (1959) learning program for playing checkers. The idea is to interpret predictions of future reward as rewarding events themselves. In other words, neutral stimulus events can themselves become reinforcing if they regularly occur before events that are intrinsically reinforcing. Such *temporal difference learning* (see REINFORCEMENT LEARNING) is like a process of erosion: the original uninformative mesa, where only a few sink holes allow gradient descent to a local minimum, is slowly replaced by broader valleys in which gradient descent may successfully proceed from many different places on the landscape.

Another aspect of credit assignment concerns structural factors. In the simple perceptron, only the weights to the output units are to be adjusted. This architecture can only support maps which are linearly separable as based on the patterns presented by the preprocessors, and we have seen that many interesting problems require preprocessing units of undue complexity to achieve linear separability. We thus need multiple layers of preprocessors, and, since one may not know a priori the appropriate set of preprocessors for a given problem, these units should be trainable too. This raises the question, "How does a neuron deeply embedded within a network 'know' what aspect of the outcome of an overall action was 'its fault'?" This is the *structural* credit assignment problem. In the next section, we shall study the most widely used solution to this problem, called *backpropagation*, which propagates back to a hidden unit some measure of its responsibility.

Backpropagation is an "adaptive architecture": it is not just a local rule for synaptic adjustment; it also takes into account the position of a neuron in the network to indicate how the neuron's weights are to change. (In this sense, we may see the use of lateral inhibition to improve Hebbian learning as the first example of an adaptive architecture in these pages.) This adaptive architecture is an example of "neurally inspired" modeling, not modeling of actual brain structures; and there is no evidence that backpropagation represents actual brain mechanisms.

## Backpropagation

The task of backpropagation is to train a *multilayer* (feedforward) *perceptron* (or MLP), a loop-free network which has its units arranged in layers, with a unit providing input only to units in the next layer of the sequence. The first layer comprises fixed input units; there may then be several layers of trainable "hidden units" carrying an internal representation, and finally, there is the layer of output units, also trainable. (A simple perceptron then corresponds to the case in which we view the input units as fixed associator units, i.e., they deliver a preprocessed, rather than a "raw," pattern which connect directly to the output units without any hidden units in between.) For what follows, it is crucial that each unit *not* be binary: it has both input and output taking continuous values in some range, say [0, 1]. The response is a sigmoidal function of the weighted sum. Thus, if a unit has inputs $x_k$ with corresponding weights $w_{ik}$, the output $x_i$ is given by $x_i = f_i(\Sigma w_{ik}x_k)$, where $f_i$ is a sigmoidal function, say

$$f_i(x) = \frac{1}{1 + e^{-(x + \theta_i)}}$$

with $\theta_i$ being a bias or threshold for the unit.

The environment only evaluates the output units. We are given a training set of input patterns $p$ and corresponding desired target patterns $t^p$ for the output units. With $o^p$ the actual output pattern elicited by input $p$, the aim is to adjust the weights in the network to minimize the error

$$E = \sum_{\text{patterns } p} \; \sum_{\text{output neurons } k} (t_k^p - o_k^p)^2$$

Rumelhart, Hinton, and Williams (1986) were among those who devised a formula for propagating back the gradient of this evaluation from a unit to its inputs. This process can continue by backpropagation through the entire net. The scheme seems to avoid many false minima. At each trial, we fix the input pattern $p$ and consider the corresponding "restricted error"

$$E = \sum_k (t_k - o_k)^2$$

where $k$ ranges over designated "output units." The net has many units interconnected by weights $w_{ij}$. The learning rule is to change $w_{ij}$ so as to reduce $E$ by *gradient descent*:

$$\Delta w_{ij} = -\frac{\partial E}{\partial w_{ij}} = 2 \sum_k (t_k - o_k) \frac{\partial o_k}{\partial w_{ij}}$$

Consider a net divided into $m + 1$ layers, with nets in layer $g + 1$ receiving all their inputs from layer $g$; with layer 0 comprising the input units; and layer $m$ comprising the output units. If $i$ is an output unit (remember, $w_{ij}$ connects from $j$ to $i$) then the only nonzero term in the last equation has $k = i$. Now $o_k = \Sigma w_{il}o_l$ where $w_{il} \neq 0$ only for $o_1$ which are outputs from the previous layer. We thus have

$$\Delta w_{ij} = 2(t_i - o_i) \frac{\partial f_i\left(\sum w_{i1}o_{m1}\right)}{\partial w_{ij}} = 2(t_i - o_i)f'_i o_j$$

where $f'_i$ is the derivative of the activation function evaluated at the activation level $in_i = \Sigma w_{il}o_l$ to unit $i$. Thus $\Delta w_{ij}$ for an output unit $i$ is proportional to $\delta_i o_j$, where $\delta_i = (t_i - o_i)f'_i$.

Next, suppose that $i$ is a hidden unit whose output drives only output units:

$$\Delta w_{ij} = 2 \sum_k (t_k - o_k) \frac{\partial f_k\left(\sum w_{kl}o_l\right)}{\partial w_{ij}}$$

However, the only $o_l$ that depends on $w_{ij}$ is $o_i$, and so

$$\frac{\partial f_k\left(\sum w_{kl}o_l\right)}{\partial w_{ij}} = \frac{\partial f_k\left(\sum w_{kl}o_l\right)}{\partial o_i} \frac{\partial o_i}{\partial w_{ij}} = [f'_k w_{ki}] \cdot [f'_i o_j]$$

so that $\Delta w_{ij} = 2\Sigma_k(t_k - o_k)[f'_k w_{ki}] \cdot [f'_i o_j]$.

Recalling that $\delta_k = (t_k - o_k)f'_k$ for an output unit $k$, we may rewrite this as

$$\Delta w_{ij} = 2\left(\sum_k \delta_k w_{ki}\right)f'_i o_j$$

Thus, $\Delta w_{ij}$ is proportional to $\delta_i o_j$, with $\delta_i = (\Sigma_k \delta_k w_{ki})f'_i$, where $k$ runs over all units which receive unit i's output. More generally, we can prove the following, by induction on how many layers back we must go to reach a unit:

***Proposition.*** Consider a layered loop-free net with error $E = \Sigma_k(t_k - o_k)^2$, where $k$ ranges over designated "output units," and let the weights $w_{ij}$ be changed according to the gradient descent rule

$$\Delta w_{ij} = -\partial E/\partial w_{ij} = 2 \sum_k (t_k - o_k) \frac{\partial o_k}{\partial w_{ij}}$$

Then the weights may be changed inductively, working back from the output units, by the rule

$$\Delta w_{ij} \text{ is proportional to } \delta_i o_j$$

where:

*Basis Step*: $\delta_i = (t_i - o_i)f'_i$ for an output unit.

*Induction Step*: If $i$ is a hidden unit, and if $\delta_k$ is known for all units that receive unit $i$'s output, then $\delta_i = (\Sigma_k \delta_k w_{ki})f'_i$, where $k$ runs over all units which receive unit $i$'s output.

Thus the "error signal" $\delta_i$ *propagates* back layer by layer from the output units. In $\Sigma_k \delta_k w_{ki}$, unit $i$ receives error propagated back from a unit $k$ to the extent to which $i$ affects $k$. For output units, this is essentially the *delta rule* given by Widrow and Hoff (1960) (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION).

The theorem just presented tells us how to compute $\Delta w_{ij}$ for gradient descent. It does not guarantee that the above step-size is appropriate to reach the minimum, nor does it guarantee that the minimum, if reached, is global. The backpropagation rule defined by this proposition is, thus, a heuristic rule, not one guaranteed to find a global minimum, but is still perhaps the most diversely used adaptive architecture. Many other approaches to learning, including some which are "neural-like" in at best a statistical sense, rather than being embedded in adaptive neural networks, may be found in the road map **Learning in Artificial Networks** (not just neural networks).

## A Cautionary Note

The previous subsections have introduced a number of techniques that can be used to make neural networks more adaptive. In a typical training scenario, we are given a network **N** which, in response to the presentation of any $x$ from some set of input patterns, will eventually settle down to produce a corresponding $y$ from the set $Y$ of the network's output patterns. A training set is then a sequence of pairs $(x_k, y_k)$ from $X \times Y$, $1 \leq k \leq n$. The foregoing results say that, in many cases (and the bounds are not yet well defined), if we train the net with repeated presentations of the various $(x_k, y_k)$, it will converge to a set of connections which cause $N$ to compute a function $f$: $X \rightarrow Y$ with the property that, over the set of $k$'s from 1 to $n$, the $f(x_k)$ "correlate fairly well" with the $y_k$. Of course, there are many other functions $g$: $X \rightarrow Y$ such that the $g(x_k)$ "correlate fairly well" with the $y_k$, and they may differ wildly on those "tests" $x$ in $X$ that do not equal an $x_k$ in the training set. The view that one may simply present a trainable net with a few examples of solved problems, and it will then adjust its connections to be able to solve all problems of a given class, glosses over three main issues:

(a) *Complexity*: Is the network complex enough to encode a solution method?

(b) *Practicality*: Can the net achieve such a solution within a feasible period of time? and
(c) *Efficacy*: How do we guarantee that the generalization achieved by the machine matches our conception of a useful solution?

Part III provides many "snapshots" of the research underway to develop answers to these problems (for the "state of play" see, for example, LEARNING AND GENERALIZATION: THEORETICAL BOUNDS; PAC LEARNING AND NEURAL NETWORKS; and VAPNIK-CHERVONENKIS DIMENSION OF NEURAL NETWORKS). Nonetheless, it is clear that these training techniques will work best when training is based on an adaptive architecture and an initial set of weights appropriate to the given problem. Future work on the neurally inspired design of intelligent systems will involve many domain-specific techniques for system design, such as those exemplified in the road maps **Vision** and **Robotics and Control Theory**, as well as general advances in adaptive architectures.

## Envoi

With this, our tour of some of those basic landmarks of *Brain Theory and Neural Networks* established by 1986 is complete. I now invite each reader to follow the suggestions of the section "How to Use this Book" of the *Handbook* to begin exploring the riches of Part III, possibly with the guidance of a number of the road maps in Part II.

**Acknowledgments.** All of Part I is a lightly edited version of Part I as it appeared in the first edition of the *Handbook*. Section I.1 is based in large part on material contained in Section 2.3 of Arbib (1989), while Section I.3 is based on Sections 3.4 and 8.2.

# Part II: Road Maps

## A Guided Tour of Brain Theory and Neural Networks

Michael A. Arbib

# How to Use Part II

Part II provides a guided tour of our subject in the form of 22 **road maps**, each of which provides an overview of a single theme in brain theory and neural networks and offers a précis of Part III articles related to that theme. The road maps are grouped under eight general headings:

**Grounding Models of Neurons and Networks**
**Brain, Behavior, and Cognition**
**Psychology, Linguistics, and Artificial Intelligence**
**Biological Neurons and Networks**
**Dynamics and Learning in Artificial Networks**
**Sensory Systems**
**Motor Systems**
**Applications, Implementations, and Analysis**

Part II starts with the **meta-map** (Section II.1), which is designed to give some sense of the diversity yet interconnectedness of the themes taken up in this *Handbook* by quickly surveying the 22 different road maps. We then offer eight sections, one for each of the above headings, that comprise the 22 road maps. In the road maps, we depart from the convention used elsewhere in this text whereby titles in capitals and small capitals are used for cross-references to all other articles. In the road maps, we reserve capitals and SMALL CAPITALS for articles on the tour, and we use titles in quotation marks to refer to related articles that are not primary to the current road map. We will use **boldface** type to refer to road maps and other major sections in Part II.

Every article in Part III occurs in at least one road map, and a few articles appear in two or even three road maps. Clearly, certain articles unequivocally have a place in a given road map, but as I considered articles that were less central to a given theme, my decisions on which articles to include became somewhat arbitrary. Thus, I invite you to read each road map to get a good overview of the main themes of each road map, and then continue your exploration by browsing Part III and using the articles listed under Related Reading and the index of the *Handbook* to add your own personal extensions to each map.

# II.1. The Meta-Map

There is no one best path for the study of brain theory and neural networks, and you should use the meta-map simply to get a broad overview that will help you choose a path that is pleasing, or useful, to you.

## Grounding Models of Neurons and Networks

Grounding Models of Neurons
Grounding Models of Networks

The articles surveyed in these two road maps can be viewed as continuing the work of Part I, providing the reader with a basic understanding of the models of both biological and artificial neurons and neural networks that are developed in the 285 articles in Part III. The road maps will help each reader decide which of these articles provide necessary background for their own reading of the *Handbook*.

## Brain, Behavior, and Cognition

Neuroethology and Evolution
Mammalian Brain Regions
Cognitive Neuroscience

The road map **Neuroethology and Evolution** places the following road map, **Mammalian Brain Regions**, in a dual perspective. First, by reviewing work on modeling neural mechanisms of the behavior of a variety of nonmammalian animals, it helps us understand the wealth of subtle neural computations available in other species, enriching our study of nervous systems that are closer to that of humans. When we focus on ethology (animal behavior), we often study the integration of perception and action, thus providing a useful complement to the many articles that focus on a subsystem in relative isolation. Second, by offering a number of articles on both biological and artificial evolution, we take the first steps in understanding the ways in which different neural architectures may emerge across many generations. Turning to the mammalian brain, we first look at **Mammalian Brain Regions**. We will also study the role of these brain regions in other road maps as we analyze such functions as vision, memory, and motor control. We shall see that every such function involves the "cooperative computation" of a multiplicity of brain regions. However, **Mammalian Brain Regions** reviews those articles that focus on a single brain region and give some sense of how we model its contribution to key neural functions. The road map **Cognitive Neuroscience** then pays special attention to a range of human cognitive functions, including perception, action, memory, and language, with emphasis on the range of data now available from imaging of the active human brain and the challenges these data provide for modeling.

## Psychology, Linguistics, and Artificial Intelligence

Psychology
Linguistics and Speech Processing
Artificial Intelligence

Our next three road maps–**Psychology, Linguistics and Speech Processing**, and **Artificial Intelligence**—are focused more on the effort to understand human psychology than on the need to understand the details of neurobiology. For example, the articles on **Psychology** may overlap those on **Cognitive Neuroscience**, but overall the emphasis shifts to "connectionist" models in which the "neurons" rarely correspond to the actual biological neurons of the human brain (the underlying structure). Rather, the driving idea is that the functioning of the human mind (the functional expression of the brain's activity) is best explored through a parallel, adaptive processing methodology in which large populations of elements are simultaneously active, pass messages back and forth between each other, and can change the strength of their connections as they do so. This is in contrast to the serial computing methodology, which is based on the computing paradigm that was dominant from the 1940s through the 1970s and that now is complemented in mainstream computer science by work in grid-based computing, embedded systems, and teams of intelligent agents.

In short, connectionist approaches to psychology and linguistics use "neurons" that are more like the artificial neurons used to build new applications for parallel processing than they are like the real neurons of the living brain.

In dividing this introduction to connectionism into three themes, I have first distinguished those aspects of connectionist psychology that relate to perception, memory, emotion, and other aspects of cognition in general from those specifically involved in connectionist linguistics before turning to artificial intelligence. The road map **Psychology** also contains articles that address philosophical issues in brain theory and connectionism, including the notion of consciousness, as well as articles that approach psychology from a developmental perspective. The road map **Linguistics and Speech Processing** presents connectionist models of human language performance as well as approaches (some more neural than others) to technologies for speech processing. The central idea in connectionist linguistics is that rich linguistic representations can emerge from the interaction of a relatively simple learning device and a structured linguistic environment, rather than requiring the details of grammar to be innate, captured in a genetically determined universal grammar. The road map **Artificial Intelligence** presents articles whose themes are similar to those in **Psychology** in what they explain, but are part of artificial intelligence (AI) because the attempt is to get a machine to exhibit some intelligent-like behavior, without necessarily meeting the constraints imposed by experimental psychology or psycholinguistics. "Classical" symbolic AI is contrasted with a number of methods in addition to the primary concentration on neural network approaches. The point is that, whereas brain theory seeks to know "how the brain does it," AI must weigh the value of artificial neural networks (ANNs) as a powerful technology for parallel, adaptive computation against that of other technologies on the basis of efficacy in solving practical problems on available hardware. The reader will, of course, find a number of models that are of equal interest to psychologists and to AI researchers.

The articles gathered in these three road maps will not exhaust the scope of their subject matter, for at least two reasons. First, in addition to connectionist models of psychological phenomena, there are many biological models that embody genuine progress in relating the phenomena to known parts of the brain, perhaps even grounding a phenomenon in the behavior of identifiable classes of biological neurons. Second, while **Artificial Intelligence** will focus on broad thematic issues, a number of these also appear in applying neural networks in computer vision, speech recognition, and elsewhere using techniques elaborated in articles of the road map **Learning in Artificial Networks**.

## Biological Neurons and Networks

Biological Neurons and Synapses
Neural Plasticity
Neural Coding
Biological Networks

The next four road maps, **Biological Neurons and Synapses**, **Neural Plasticity**, **Neural Coding**, and **Biological Networks**, are ones that, for many readers, may provide the appropriate entry point for the book as a whole, namely, an understanding of neural networks from a biological point of view. The road map **Biological Neurons and Synapses** gives us some sense of how sophisticated real biological neurons are, with each patch of membrane being itself a subtle electrochemical structure. An appreciation of this complexity is necessary for the computational neuroscientist wishing to address the increasingly detailed database of experimental neuroscience on how signals can be propagated, and how individual neurons interact with each other. But such complexity may also provide an eye opener for the technologist planning to incorporate new capabilities into the next generation of ANNs. The road map **Neural Plasticity** then charts from a biological point of view a variety of specific mechanisms at the level of synapses, or even finer-grained molecular structures, which enable the changes in the strength of connections that underlie both learning and development. A number of such mechanisms have already implied a variety of learning rules for ANNs (see **Learning in Artificial Networks**), but they also include mechanisms that have not seen technological use. This road map includes articles that analyze mechanisms that underlie both development and regeneration of neural networks and learning in biological systems. However, I again stress to the reader that one may approach the road maps, and the articles in Part III of this *Handbook*, in many different orders, so that some readers may prefer to study the articles described in the road map **Learning in Artificial Networks** before or instead of studying those on neurobiological learning mechanisms.

Two more road maps round out our study of **Biological Neurons and Networks**. The simplest models of neurons either operate on a discrete-time scale or measure neural output by the continuous variation in firing rate. The road map **Neural Coding** examines the virtues of other alternatives, looking at both the possible gains in information that may follow from exploiting the exact timing of spikes (action potentials) as they travel along axonal branches from one neuron to many others, and the way in which signals that may be hard to discern from the firing of a single neuron may be reliably encoded by the activity of a whole population of neurons. We then turn to articles that chart a number of the basic architectures whereby biological neurons are combined into **Biological Networks**—although clearly, this is a topic expanded upon in many articles in Part III which are not explicitly presented in this road map.

## Dynamics and Learning in Artificial Networks

Dynamic Systems
Learning in Artificial Networks
Computability and Complexity

The next three road maps—**Dynamic Systems**, **Learning in Artificial Networks**, and **Computability and Complexity**—provide a broad perspective on the dynamics of neural networks considered as general information processing structures rather than as models of a particular biological or psychological phenomenon or as solutions to specific technological problems. Our study of **Dynamic Systems** is grounded in studying the dynamics of a neural network with fixed inputs: does it settle down to an equilibrium state, and to what extent can that state be seen as the solution of some problem of optimization? Under what circumstances will the network exhibit a dynamic pattern of oscillatory behavior (a limit cycle), and under what circumstances will it undergo chaotic behavior (traversing what is known as a strange attractor)? This theme is expanded by the study of cooperative phenomena. In a gas or a magnet, we do not know the behavior of any single atom with precision, but we can infer the overall "cooperative" behavior—the pressure, volume, and temperature of a gas, or the overall magnetization of a magnet—through statistical methods, methods which even extend to the analyses of such dramatic phase transitions as that of a piece of iron from an unmagnetized lump to a magnet, or of a liquid to a gas. So, too, can statistical methods provide insight into the large-scale properties of neural nets, abstracting away from the detailed function of individual neurons, when our interest is in statistical patterns of behavior rather than the fine details of information processing. This leads us to the study of self-organization in neural networks, in which we ask for ways in which the interaction between elements in a neural network can lead to the spontaneous expression of pattern; whether this pattern is constituted by the pattern of activity of the individual neurons or by the pattern of synaptic connections which records earlier experience.

With this question of earlier experience, we have fully made the transition to the study of learning, and we turn to the road map which focuses on **Learning in Artificial Networks**, complementing the road map **Neural Plasticity**. (This replaces two road maps from the first edition–Learning in Artificial Neural Networks, Deterministic, and Learning in Artificial Neural Networks, Statistical—for two reasons: (1) the use of statistical methods in the study of learning in ANNs is so pervasive that the attempt to distinguish deterministic and statistical approaches to learning is not useful, and (2) the statistical analysis of learning in ANNs has spawned a variety of statistical methods that are less closely linked to neurobiological inspiration, and we wish these, too, to be included in our road map.) The study of **Computability and Complexity** then provides a rapprochement between neural networks and a number of ideas developed within the mainstream of computer science, especially those arising from the study of complexity of computational structures. Indeed, it takes us back to the very foundations of the theory of neural networks, in which the study of McCulloch-Pitts neurons built on earlier work on computability to inspire the later development of automata theory.

### Sensory Systems

Vision
Other Sensory Systems

**Vision** has been the most widely studied of all sensory systems, both in brain theory and in applications and analysis of ANNs, and thus has a special road map of its own. **Other Sensory Systems**, treated at less length in the next road map, include audition, touch, and pain, as well a number of fascinating special systems such as electrolocation in electric fish and echolocation in bats.

### Motor Systems

Robotics and Control Theory
Motor Pattern Generators
Mammalian Motor Control

The next set of road maps—**Robotics and Control Theory**, **Motor Pattern Generators**, and **Mammalian Motor Control**—addresses the control of movement by neural networks. In the study of **Robotics and Control Theory**, the adaptive properties of neural networks play a special role, enabling a control system, through experience, to become better and better suited to solve a given repertoire of control problems, guiding a system through a desired trajectory, whether through the use of feedback or feedforward. These general control strategies are exemplified in a number of different approaches to robot control. The articles in the road map **Motor Pattern Generators** focus on subconscious functions, such as breathing or locomotion, in vertebrates and on a wide variety of pattern-generating activity in invertebrates. The reader may wish to turn back to the road map **Neuroethology and Evolution** for other studies in animal behavior (neuroethology) which show how sensory input, especially visual input, and motor behavior are integrated in a cycle of action and perception. **Mammalian Motor Control** places increased emphasis on the interaction between neural control and the kinematics or dynamics of limbs and eyes, and also looks at various forms of motor-related learning. In showing how the goals of movement can be achieved by a neural network through the time course of activity of motors or muscles, this road map overlaps some of the issues taken up in the more applications-oriented road map, **Robotics and Control Theory**. Much of the material on biological motor control is of general relevance, but the road map also includes articles on primate motor control that examine a variety of movements of the eyes, head, arm, and hand which are studied in a variety of mammals but are most fully expressed in primates and humans. Of course, as many readers will be prepared to notice by now, **Mammalian Motor Control** will, for some readers, be an excellent starting place for their study, since, by showing how visual and motor systems are integrated in a number of primate and human behaviors, it motivates the study of the specific neural network mechanisms required to achieve these behaviors.

### Applications, Implementations, and Analysis

Applications
Implementation and Analysis

We then turn to a small set of **Applications** of neural networks, which include signal processing, speech recognition, and visual processing (but exclude the broader set of applications to astronomy, speech recognition, high-energy physics, steel making, telecommunications, etc., of the first edition, since *The Handbook of Neural Computation* [Oxford University Press, 1996] now provides a large set of articles on ANN applications). Since a neural network cannot be applied unless it is implemented, whether in software or hardware, we close with the road map **Implementation and Analysis**. The implementation methodologies include simulation on a general-purpose computer, emulation on specially designed neurocomputers, and implementation in a device built with electronic or photonic materials. As for analysis, we present articles in the nascent field of neuroinformatics which combines database methodology, visualization, modeling, and data analysis in an attempt to master the explosive growth of neuroscience data. (In Europe, the term *neuroinformatics* is used to encompass the full range of computational approaches to brain theory and neural networks. In the United States, some people use *neuroinformatics* to refer solely to the use of databases in neuroscience. Here we focus on the middle ground, where the analysis of data and the construction of models are brought together.)

# II.2. Grounding Models of Neurons and Networks

The first two road maps expand the exposition of Part I by presenting basic models of neurons and networks that provide the building blocks for many of the articles in Part III.

### Grounding Models of Neurons

Axonal Modeling
Dendritic Processing
Hebbian Synaptic Plasticity
Perceptrons, Adalines, and Backpropagation
Perspective on Neuron Model Complexity
Reinforcement Learning
Single-Cell Models
Spiking Neurons, Computation with

This road map introduces classes of neuron models of increasing complexity and attention to detail. The point is that much can be learned even at high degrees of abstraction, while other phenomena can be understood only by attention to subtle details of neuronal function. The reader of this *Handbook* will find many articles exploring biological phenomena and technological applications at different levels of complexity. The implicit questions will always be, "Do all the details matter?" and "Is the model oversimplified?" The answers will depend both on the phenomena under question and on the current subtlety of experimental investigations. After introducing articles that present neuron models across the range of model complexity, the road map concludes with a brief look at the most widely analyzed forms of synaptic plasticity.

Classes of neuron models can be defined by how they treat the train of action potentials issued by a neuron (see the road map **Neural Coding**). Many models assume that information is carried in the average rate of pulses over a time much longer than a typical pulse width, with the occurrence times of particular pulses simply treated as jitter on an averaged analog signal. A neural model in such a theory might be a mathematical function which produces a real-valued output from its many real-valued inputs; that function could be linear or nonlinear, static or adaptive, and might be instantiated in analog silicon circuits or in digital software. Examples given of such models in SINGLE-CELL MODELS are the McCulloch-Pitts model, the perceptron model, Hopfield neurons, and polynomial neurons. However, some models assume that each single neural pulse carries reliable, precisely timed information. A neural model in such a theory fires only upon the exact coincidence of several input pulses, and quickly "forgets" when it last fired, so that it is always ready to fire upon another coincidence. The simplest such models are the integrate-and-fire models. The article concludes by briefly introducing the Hodgkin-Huxley model of squid axon, based on painstaking analysis (without benefit of electronic computers) of data from the squid giant axon, and then introduces modified single-point models, compartmental models, and computation with both passive dendrites and active dendrites. SPIKING NEURONS, COMPUTATION WITH provides more detail on those neuron models of intermediate complexity in which the output is a spike whose timing is continuously variable as a result of cellular interactions, providing a model of biological neurons that offers more details than firing rate models but without the details of biophysical models. The virtues of such models include the ability to transmit information very quickly through small temporal differences between the spikes sent out by different neurons. Information theory can be used to quantify how much more information about a stimulus can be extracted from spike trains if the precise timing is taken into account. Moreover, computing with spiking neurons may prove of benefit for technology.

AXONAL MODELING is centered on the Hodgkin and Huxley model, arguably the most successful model in all of computational neuroscience. The article shows how the Hodgkin-Huxley equations extend the cable equation to describe the ionic mechanisms underlying the initiation and propagation of action potentials. The vast majority of contemporary biophysical models use a mathematical formalism similar to that introduced by Hodgkin and Huxley, even though their model of the continuous, deterministic, and macroscopic permeability changes of the membrane was achieved without any knowledge of the underlying all-or-none, stochastic, and microscopic ionic channels. The article also describes the differences between myelinated and nonmyelinated axons; and briefly discusses the possible role of heavily branched axonal trees in information processing.

PERSPECTIVE ON NEURON MODEL COMPLEXITY then shows how this type of modeling might be extended to the whole cell. The key point is that one neuron with detailed modeling of dendrites (especially with nonuniform distributions of synapses and ion channels) can perform tasks that would require a network of many simple binary units to duplicate. The point is not to choose the most complex model of a neuron but rather to seek an intermediate level of complexity which preserves the most significant distinctions between different "compartments" of the neuron (soma, various portions of the dendritic tree, etc.). The challenge is to demonstrate a useful computation or discrimination that can be accomplished with a particular choice of compartments in a neuron model, and then show that this useful capacity is lost when a coarser decomposition of the neuron is used. DENDRITIC PROCESSING especially emphasizes developments in compartmental modeling of dendrites, arguing that we are in the midst of a "dendritic revolution" that has yielded a much more fascinating picture of the electrical behavior and chemical properties of dendrites than one could have imagined only a few years ago. The dendritic membrane hosts a variety of nonlinear voltage-gated ion channels that endow dendrites with potentially powerful computing capabilities. Moreover, the classic view of dendrites as carrying information unidirectionally, from synapses to the soma, has been transformed: dendrites of many central neurons also carry information in the "backward" direction, via active propagation of the action potentials from the axon to the dendrites. These "reversed" signals can trigger plastic changes in the dendritic input synapses. Moreover, it is now known that the fine morphology as well as the electrical properties of dendrites change dynamically, in an activity-dependent manner.

If the most successful model in all of computational neuroscience is the Hodgkin-Huxley model, then the second most successful is Hebb's model of "unsupervised" synaptic plasticity. The former was based on rigorous analysis of empirical data; the latter was initially the result of theoretical speculation on how synapses might behave if assemblies of cells were to work together to store and reconstitute thoughts and associations. HEBBIAN SYNAPTIC PLASTICITY notes that predictions derived from Hebb's postulate can be generalized for different levels of integration (synaptic efficacy, functional coupling, adaptive change in behavior) by simply adjusting the variables derived from various measures of neural activity and the time-scale over which it operates. The article addresses five major issues: Should the definition of "Hebbian" plasticity refer to a simple positive correlational rule of learning, or are there biological justifications for including additional "pseudo-Hebbian" terms (such as synaptic depression due to disuse or competition) in a generalized phenomenological algorithm? What are the spatiotemporal constraints (e.g., input specificity, temporal associativity) that characterize the induction process? Do the predictions of Hebbian-based algorithms account for most forms of activity-dependent dynamics in synaptic transmission throughout phylogenesis? On which time-scales (perception, learning, epigenesis) and at which stage of development of the organism (embryonic, "critical" postnatal developmental periods, adulthood) are activity-dependent changes in functional links predicted by Hebb's rule? Are there examples of correlation-based plasticity that contradict the predictions of Hebb's postulate (termed anti-Hebbian modifications)? The article thus frames many important issues to be developed in the articles of the road map **Neural Plasticity** but that are also implicit, for example, in articles reviewed in the road maps **Psychology** and **Linguistics and Speech Processing**, in which Hebbian (and other) learning rules are used for "formal neurons" that are psychological abstractions rather than representation of real neurobiological neurons or even biological neuron pools. Two other articles serve to introduce the basic learning rules that have been most central in both biological analysis and connectionist modeling. Supervised learning adjusts the weights in an attempt to respond to explicit error signals provided by a "teacher," which may be external, or another network in the same "brain." This model was introduced in the perceptron model, which is reviewed in PERCEPTRONS, ADALINES, AND BACKPROPAGATION (of which more details in the next road map, **Grounding Models of Networks**). On the other hand, REINFORCEMENT LEARNING (of which more details in the road map **Learning in Artificial Networks**) shows how networks can improve their performance when given general reinforcement ("that was good," "that was bad") by a critic, rather than the explicit error information offered by a teacher.

### Grounding Models of Networks

Associative Networks
Computing with Attractors
Perceptrons, Adalines, and Backpropagation
Radial Basis Function Networks
Self-Organizing Feature Maps
Spiking Neurons, Computation with

The mechanisms and implications of association—the linkage of information with other information—have a long history in psychology and philosophy. Associative Networks discusses association as realized in neural networks as well as association in the more traditional senses. Many neural networks are designed as pattern associators, which link an input pattern with the "correct" output pattern. Learning rules are designed to construct useful linkages between input and output patterns whether in feedforward neural network architectures or in a network whose units are recurrently interconnected. Special attention is given to the critical importance of data representation at all levels of network operation. Perceptrons, Adalines, and Backpropagation introduces the perceptron rule and the LMS (least-mean-squares) algorithm for training feedforward networks with multiple adaptive elements, where each element can be seen as an adaptive linear combiner of its inputs followed by a nonlinearity which produces the output. It then presents the major extension provided by the backpropagation algorithm for training multilayer neural networks—which can be viewed as dividing the input space into regions bounded by hyperplanes, one for the thresholded output of each neuron of the output layer—and shows how this technique has been used to attack problems requiring neural networks with high degrees of nonlinearity and precision.

Computing with Attractors shows how neural networks (often seen now as operating in continuous time) may be viewed as dynamic systems (a theme developed in great detail by the articles of the road map **Dynamic Systems**). This article describes how to compute with networks with feedback, with the input of a computation being set as an initial state for the system and the result read off a suitably chosen set of units when the network has "settled down." The state a dynamical system settles into is called an *attractor*, so this paradigm is called *computing with attractors*. It is possible to settle down into an equilibrium state, or into periodic or even chaotic patterns of activity. (An interesting possibility, not considered in this article, is to perform computations based on the transient approach to the attractor, rather than on the basis of the attractor alone.) The Hopfield model for associative memory is used as the key example, showing its dynamic behavior as well as how the connections necessary to embed desired patterns can be learned and how the paradigm can be extended to time-dependent attractors.

Self-Organizing Feature Maps (SOFMs) introduces a famous version of competitive learning based on a layer of adaptive "neurons" that gradually develops into an array of feature detectors. The learning method is an augmented Hebbian method in which learning by the element most responsive to an input pattern is "shared" with its neighbors. The result is that the resulting "compressed image" of the (usually higher-dimensional) input space forms a "topographic map" in which distance relationships in the input space (expressing, e.g., pattern similarities) are approximately preserved as distance relationships between corresponding excitation sites in the map, while clusters of similar input patterns tend to become mapped to areas in the neural layer whose size varies in proportion to the frequency of the occurrence of their patterns. From a statistical point of view, the SOFM provides a nonlinear generalization of principal component analysis.

Spiking Neurons, Computation with discusses both the use of spiking neurons as a useful approximation to biological neurons and the study of networks of spiking neurons as a formal model of computation for which the assumptions need not be biological (see also "Integrate-and-Fire Neurons and Networks"). If the spiking neurons are not subject to significant amounts of noise, then one can carry out computations in networks of spiking neurons where every spike matters, and some finite network of spiking neurons can simulate a universal Turing machine. Spiking neurons can also be used as computational units that function like radial basis functions in the temporal domain. Another code uses the order of firing of different neurons as the relevant signal conveyed by these neurons. Firing rates of neurons in the cortex are relatively low, making it hard for the postsynaptic neuron to "read" the firing rate of a presynaptic neuron. However, networks of spiking neurons can carry out complex analog computations if the inputs of the computation are presented in terms of a space rate or population code.

The last article in this road map gives an example of the utility of studying networks in which the response properties of the individual units are designed not as abstractions from biological neurons, but rather because their response functions have mathematically desirable properties. A multilayer perceptron can be viewed as dividing the input space into regions bounded by hyperplanes, one for the thresholded output of each neuron of the output layer. Radial Basis Function Networks describes an alternative approach to decomposition of a pattern space into regions, describing the clusters of data points in the space as if they were generated according to an underlying probability density function. Thus the perceptron method concentrates on class boundaries, while the radial basis function approach focuses on regions where the data density is highest, constructing global approximations to functions using combinations of basis functions centered around weight vectors. The article shows that this approach not only has a range of useful theoretical properties but also is practically useful, having been applied efficiently to problems in discrimination, time-series prediction, and feature extraction.

# II.3. Brain, Behavior, and Cognition

### Neuroethology and Evolution

Command Neurons and Command Systems
Crustacean Stomatogastric System
Echolocation: Cochleotopic and Computational Maps
Electrolocation
Evolution and Learning in Neural Networks
Evolution of Artificial Neural Networks
Evolution of Genetic Networks
Evolution of the Ancestral Vertebrate Brain
Hippocampus: Spatial Models

Language Evolution and Change
Language Evolution: The Mirror System Hypothesis
Locomotion, Vertebrate
Locust Flight: Components and Mechanisms in the Motor
Motor Primitives
Neuroethology, Computational
Olfactory Cortex
Scratch Reflex
Sensorimotor Interactions and Central Pattern Generators
Sound Localization and Binaural Processing
Spinal Cord of Lamprey: Generation of Locomotor Patterns
Visual Course Control in Flies
Visuomotor Coordination in Frog and Toad
Visuomotor Coordination in Salamander

Many readers will come to the *Handbook* with one of two main motivations: to understand the human brain, or to explore the potential of ANNs as a technology for adaptive, parallel computation. The present road map emphasizes a third motivation: to study neural mechanisms in creatures very different from humans and their mammalian cousins—for the intrinsic interest of discovering the diverse neural architectures that abound in nature, for the suggestions these provide for future technology, and for the novel perspective on human brain mechanisms offered by seeking to place them in an evolutionary perspective.

Ethology is the study of animal behavior, in which our concern is with the circumstances under which a particular motor pattern will be deployed as an appropriate part of the animal's activity. Neuroethology, then, is the study of neural mechanisms underlying animal behavior. The emphasis is thus on an integrative, systems approach to the neuroscience of the animal being studied, as distinct from a reductionist approach to, for example, the neurochemistry of synaptic plasticity. Of course, a major aim of this *Handbook* is to create a context in which the reader can see both approaches to the study of nervous systems and ponder how best to integrate them. In particular, the reader will find many examples of the neuroethology of mammalian systems in a wide variety of other road maps, such as **Cognitive Neuroscience**, **Vision**, **Other Sensory Systems**, and **Mammalian Motor Control**. However, the present road map is designed to guide the reader to articles on a number of fascinating nonmammalian systems—as well as a few "exotic" mammalian systems—as a basis for a brief introduction of the evolutionary approach to biological and artificial neural networks.

Neuroethology, Computational suggests that *computational* neuroethology applies not only to animals but also to nonbiological autonomous agents, such as some types of robots and simulated embodied agents operating in virtual worlds (see also "Embodied Cognition"). The key element is the use of sophisticated computer-based simulation and visualization tools to study the neural control of behavior within the context of "agents" that are both embodied and situated within an environment. Other examples include specific neuroethological modeling directed toward specific animals (the computational frog *Rana computatrix* and the computational cockroach *Periplaneta computatrix*) and their implications for the rebirth of ideas first introduced by Grey Walter in his 1950s design of *Machina speculatrix* and later developed in the book *Vehicles* by Valentino Braitenberg.

If a certain interneuron is stimulated electrically in the brain of a marine slug, the animal then displays a species-specific escape swimming behavior, although no predator is present. If in a toad a certain portion of the optic tectum is stimulated in this manner, snapping behavior is triggered, although no prey is present. In both cases, a stimulus produces a rapid ballistic response. Such command functions provide the sensorimotor interface between sensory pattern recognition and localization, on the one side, and motor pattern generation on the other. Command Neurons and Command Systems analyzes the extent to which a motor pattern generator (MPG) may be activated alone or in concert with others through perceptual stimuli mediated by a single "command neuron" (as in the marine slug) or by more diffuse "command systems" (as in the toad). Three articles then focus specifically on visuomotor coordination. Visual Course Control in Flies explains the mechanisms underlying the extraction of retinal motion patterns in the fly, and their transformation into the appropriate motor activity. Rotatory large-field motion can signal unintended deviations from the fly's course and initiate a compensatory turn; image expansion can signal that the animal approaches an obstacle and initiates a landing or avoidance response; and discontinuities in the retinal motion field indicate nearby stationary or moving objects. Since many of the cells responsible for motion extraction are large and individually identifiable, the fly is quite amenable to an analysis of sensory processing. Similarly, the small number of muscles and motor neurons used to generate flight maneuvers facilitates studies of motor output. Visuomotor Coordination in Salamander shows how low-level mechanisms add up to produce complicated behaviors, such as the devious approach of salamanders to their prey. Coarse coding models demonstrate how the location of an object may be encoded with high accuracy using only a few neurons with large, overlapping receptive fields. (This fits with the fact that the brains of salamanders are anatomically the simplest among vertebrates, containing only about 1 million neurons—frogs have up to 10 times and humans 10 million times as many neurons.) The models have been extended to the case where several objects are presented to the animal by linking a segmentation network and a winner-take-all-like object selection network to the coarse coding network in a biologically plausible way. Compensation of background movement, selection of an object, saccade generation, and approach and snapping behavior in salamanders have also been modeled successfully, in line with behavioral and neurobiological findings. Again, Visuomotor Coordination in Frog and Toad stresses that visuomotor integration implies a complex transformation of sensory data, since the same locus of retinal activation might release behavior directed toward the stimulus (as in prey catching) or toward another part of the visual field (as in predator avoidance). The article also shows how the efficacy of visual stimuli to release a response is determined by many factors, including the stimulus situation, the motivational state of the organism itself, and previous experience with the stimulus (learning and conditioning), and the physical condition of the animal's CNS (e.g., brain lesions). In addition, other types of sensory signals can modulate frogs' and toads' response to certain moving visual stimuli. For example, the efficacy of a visual stimulus may be greatly enhanced by the presence of prey odor.

Motor Primitives and Scratch Reflex are two of the articles on nonmammalian animal behaviors that are described more fully in the road map **Motor Pattern Generators**. These articles examine the behavior elicited in frogs and turtles, respectively, by an irritant applied to the animal's skin. The former article examines the extent to which motor behaviors can be built up through a combination of a small set of basic elements; the latter emphasizes how the form of the scratch reflex changes dramatically, depending on the locus of the irritant. Other articles in the road map **Motor Pattern Generators** describe mechanisms underlying a variety of forms of locomotion (swimming, walking, flying).

Sound Localization and Binaural Processing uses data from owls, which are exquisitely skillful in using auditory signals to locate their prey, even in the dark, to anchor models which explain how information from the two ears is brought together to localize the source of a sound. The article focuses on the use of interaural time difference (ITD) as one way to estimate the azimuthal angle of a sound source. It describes one biological model (ITD detection in the barn owl's brainstem) and two psychological models. The underlying idea is that the brain attempts to match the sounds in the two ears by shifting one sound relative to the other, with the shift that produces the best match assumed to be the one that just balances the "real" ITD.

Echolocation: Cochleotopic and Computational Maps explores the highly specialized auditory system used by mustached bats to analyze the return signals from the biosonar pulses they emit for orientation and for hunting flying insects. Each biosonar pulse consists of a long constant-frequency (CF) component followed by a short frequency-modulated (FM) component. The CF components constitute an ideal signal for target detection and the measurement of target velocity (relative motion in a radial direction and wing beats of insects), whereas the short FM components are suited for ranging, localizing, and characterizing a target. The article shows how different parameters of echoes received by the bat carry different types of information about a target and how these may be structured in computational maps via parallel-hierarchical processing of different types of biosonar signals. These maps guide the bat's behavior. Electrolocation discusses another "exotic" sensory system related to behavior, this time the electrosensory systems of weakly electric fish. Animals with active electrosensory systems generate an electrical field around their body by means of an electrical organ located in the trunk and tail, and measure this field via electroreceptors embedded in the skin. Distortions of the electrical field due to animate or inanimate targets in the environment or signals generated by other fish provide inputs to the system, and several distinct behaviors can be linked to patterns of electrosensory input. The article focuses on progress in understanding electrolocation behavior and on the neural implementation of an adaptive filter that attenuates the effects of the fish's own movements.

We now turn to motor systems. Crustacean Stomatogastric System shows that work on the rhythmic motor patterns of the four areas of the crustacean stomach, the esophagus, cardiac sac, gastric mill, and pylorus, has identified four widely applicable properties. First, rhythmicity in these highly distributed networks depends on both network synaptic connectivity and slow active neuronal membrane properties. Second, modulatory influences can induce individual networks to produce multiple outputs, "switch" neurons between networks, or fuse individual networks into single larger networks. Third, modulatory neuron terminals receive network synaptic input. Modulatory inputs can be sculpted by network feedback and become integral parts of the networks they modulate. Fourth, network synaptic strengths can vary as a function of pattern cycle period and duty cycle.

The lamprey is a very primitive form of fish whose spinal cord supports a traveling wave of activity that yields the swimming movements of the animal's body, yet also persists ("fictive swimming") when the spinal cord is isolated from the body and kept alive in a dish. Spinal Cord of Lamprey: Generation of Locomotor Patterns reviews the data which ground a circuit diagram for the spinal cord circuitry, then shows how the lamprey locomotor network has been simulated. There are a number of neuromodulators present in the lamprey spinal cord that alter the output of the locomotor network. These substances, such as serotonin, dopamine, and tachykinins, offer good opportunities to test our knowledge of the locomotor system by combining the cellular and synaptic actions of the modulators into detailed network models. However, models that do not depend on details of individual cells have also proved useful in advancing our understanding of lamprey locomotion such as the control of turning. Other models probe the nature of the coupling among the rhythm generators, explaining how it may be that the speed of the head-to-tail propagation of the rhythmic activity down the spinal cord can vary with the speed of swimming even though conduction delays in axons are fixed. Locust Flight: Components and Mechanisms in the Motor stresses that locust flight motor patterns are generated by an interactive mixture of the intrinsic properties of flight neurons, the operation of complex circuits, and phase-specific proprioceptive input. These mechanisms are subject to the concentrations of circulating neuromodulators and are also modulated according to the demands of a constantly changing sensory environment to produce adaptive behaviors. The system is flexible and able to operate despite severe ablations, and then to recover from these lesions. Sensorimotor Interactions and Central Pattern Generators analyzes basic properties of the biological systems performing sensorimotor integration. The article discusses both the impact of sensory information on central pattern generators and the less well-understood influence of motor systems on sensory activity. Interaction between motor and sensory systems is pervasive, from the first steps of sensory detection to the highest levels of processing. While there is no doubt that cortical systems contribute to sensorimotor integration, the article questions the view that motor cortex sends commands to a passively responsive spinal cord. Motor commands are only acted upon as spinal circuits integrate their intrinsic activity with all incoming information.

Turning to evolution, we find two classes of articles. We first look at those which focus on simulated evolution in ANNs, with emphasis on the role of evolution as an alternative learning mechanism to fit network parameters to yield a network better adapted to a given task. We then turn to articles more closely related to comparative and evolutionary neurobiology.

When neural networks are studied in the broader biological context of artificial life (i.e., the attempt to synthesize lifelike phenomena within computers and other artificial media), they are sometimes characterized by genotypes and viewed as members of evolving populations of networks in which genotypes are inherited from parents to offspring. Evolution of Artificial Neural Networks shows how ANNs can be evolved by using evolutionary algorithms (also known as genetic algorithms). An initial population of different artificial genotypes, each encoding the free parameters (e.g., the connection strengths and/or the architecture of the network and/or the learning rules) of a corresponding neural network, is created randomly. (An important challenge for future research is to study models in which the genotypes are more "biological" in nature, and less closely tied to direct description of the phenotype.) The population of networks is evaluated in order to determine the performance (fitness) of each individual network. The fittest networks are allowed to reproduce by generating copies of their genotypes, with the addition of changes introduced by genetic operators such as mutations (i.e., the random change of a few genes that are selected randomly) or crossover (i.e., the combination of parts of the genotype derived from two reproducing networks). This process is repeated for a number of generations until a network that satisfies the performance criterion set by the experimenter is obtained. Locomotion, Vertebrate shows that the combination of neural models with biomechanical models has an important role to play in addressing the evolutionary challenge of seeing what modifications may have occurred in the locomotor circuits between the generation of traveling waves for swimming (the most ancestral vertebrates were close to the lamprey), the generation of standing waves for walking, and the generation of multiple gaits for quadruped locomotion, and on to biped locomotion. One example uses "genetic algorithms" to model the transition from a lamprey-like spinal cord that supports traveling waves to a salamander-like spinal cord that supports both traveling waves for swimming and "standing waves" for terrestrial locomotion, and then shows how vision may modulate spinal activity to yield locomotion toward a goal (see also Visuomotor Coordination in Salamander).

Evolution and Learning in Neural Networks then extends the analysis of ANN evolution to networks that are able to adapt to the environment as a result of some form of lifetime learning. Where evolution is capable of capturing relatively slow environmental changes that might encompass several generations, learning allows an individual to adapt to environmental changes that are unpredictable at the generational level. Moreover, while evolution operates on the genotype, learning affects the phenotype, and phenotypic changes cannot directly modify the genotype. The article shows how ANNs subjected both to an evolutionary and a lifetime learning process have been studied to look at the advantages, in terms of performance, of combining two different adaptation techniques and also to help understand the role of the interaction between learning and evolution in natural organisms. Continuing this theme, Language Evolution and Change offers another style of "connectionist evolution," placing a number of connectionist models of basic forms of language processing in an evolutionary perspective. In some cases, connectionist networks are used as simulated agents to study how social transmission via learning may give rise to the evolution of structured communication systems. In other cases, the specific properties of neural network learning are enlisted to help illuminate the constraints and processes that may have been involved in the evolution of language. The article surveys this connectionist research, starting from the emergence of early syntax, to the role of social interaction and constraints on network learning in the subsequent evolution of language, to linguistic change within existing languages.

With this we turn to the study of evolution in the sense of natural selection in biological systems, building on the insights of Charles Darwin. Since brains do not leave fossils, evolutionary work is more at the level of comparative neurobiology, looking at the nervous systems of currently extant species, then trying to build a "family tree" of possible ancestors. The idea is that we may gain deeper insights into the brains of animals of a given species if we can compare them with the brains of other species, make plausible inferences about the brain structure of their common ancestor, and then seek to relate differences between the current brains and the putative ancestral brains by relating these changes to the possible evolutionary pressures that caused each species to adapt to a specific range of environments. Evolution of the Ancestral Vertebrate Brain notes that efforts to understand how the evolving brain has adapted to specific environmental constraints are complicated because there are always several ways to implement a certain function within existing connections using molecular and cellular mechanisms. In any case, adult diversity is viewed as the outcome of divergent genetic developmental mechanisms. Thus, study of adult structures is aided by placing adult structures within their developmental history as structured by the genes that guide such development. The article introduces a possible prototype of the ancestral vertebrate brain, followed by a scenario for mechanisms that may have diversified the ancestral vertebrate brain. Evolution of the brainstem oculomotor system is used as a focal case study.

The study of gene expression patterns is playing an increasingly important role in the empirical study of brains and neurons, and the pace of innovation in this area has greatly accelerated with the publication of two maps of the human genome as well as genome maps for more and more other species. As of 2002, however, the impact of "genomic neuroscience" on computational neuroscience is still small. To help readers think about the promise of increasing this impact, we not only have the discussion in Evolution of the Ancestral Vertebrate Brain of how during development the CNS becomes polarized and then subdivides into compartments, each characterized by specific pattern of gene expression, but also a companion article, Evolution of Genetic Networks, which outlines some of the computational problems in modeling genetic networks that can direct the establishment of a diversity of neuronal networks in the brain. Since neuronal networks are composed of a wide variety of different cell types, the final fate or end-stage of each cell type represents the outcome of a dynamic amalgamation of gene networks. Genetic networks not only determine the cell fate acquisition from the original stem cell, they also govern contact formation between the cell populations of a given neuronal network. There are intriguing parallels between the establishment and functioning of genetic networks with those of neuronal networks, which can range from simple (on-off switch) to complex. To give some sense of the complexity of organismic development, the article outlines how intracellular as well as cell-cell interactions modify the complexity of gene interactions involved in genetic networks to achieve an altered status of cell function and, ultimately, the connection alterations in the formation of neuronal networks.

Olfactory Cortex describes how, during phylogeny, the paleocortex and archicortex develop in extent and complexity but retain their three-layered character, whereas neocortex emerges in mammals as a five- to six-layered structure. It stresses the evolutionary significance of the olfactory cortex and includes an account for brain theorists interested in principles of cortical organization of the early appearance of the olfactory cortex in phylogeny. Certainly, the cerebral cortex is a distinctive evolutionary feature of the mammalian brain (which does not mean that it is "better" than structures in other genera to which it may be more or less related), and the next articles give two perspectives on its structure. "Grasping Movements: Visuomotor Transformations" presents the interactions of visual areas of parietal cortex with the F5 area of premotor cortex in the monkey brain in serving the visual control of hand movements. The companion article, Language Evolution: The Mirror System Hypothesis, starts from the observations that monkey F5 contains a special set of "mirror neurons" active not only when the monkey performs a specific grasp, but also when the monkey sees others perform a similar task; that F5 is homologous to human Broca's area, an area of cortex usually thought of as related to speech production; but that Broca's area also seems to contain a mirror system for grasping. These facts are used to ground a new theory of the evolution of the human brain mechanisms that support language. It adds a neurological "missing link" to the long-held view that imitation and communication based on hand signs may have preceded the emergence of human mechanisms for extensive vocal communication. With this example to hand, the reader is invited to look through the book for articles that study specific brain mechanisms or specific behaviors in a number of species more or less related to the human. The challenge then is to chart what aspects are common to human brains and the brains more generally of primates, mammals, or even vertebrates; and then, having done so, to see what, if any, distinctive properties human brain and behavior possess. One can then seek an evolutionary account which illuminates these human capacities. For example, it is well known that the human hippocampus is crucial for the creation of episodic memories, our memories of episodes located in specific contexts of space and time (though these memories are eventually consolidated outside hippocampus). On the other hand, Hippocampus: Spatial Models emphasizes the role of the hippocampus and related brain regions in building a map of spatial relations in the rat's world. To what extent can we come to better understand human episodic memory by looking for the generalization from a spatial graph of the environment to one whose nodes are linked in both space and time?

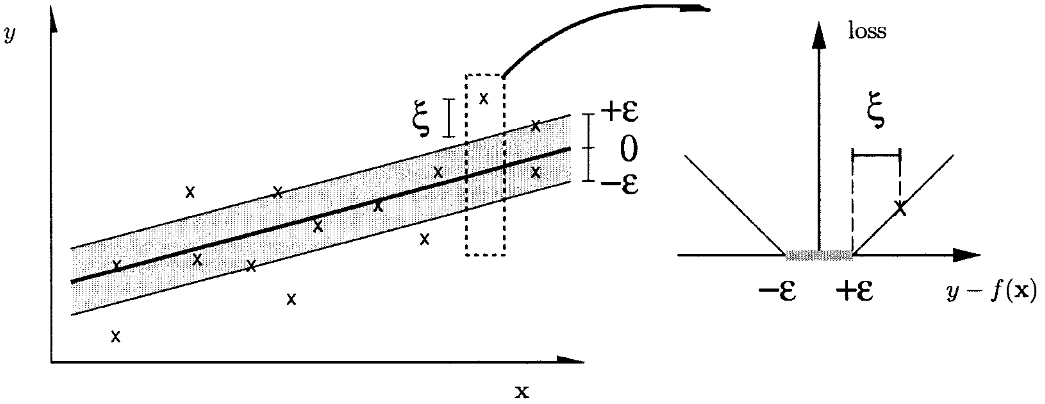

**Figure 5.** In support vector regression, a tube with radius $\varepsilon$ is fitted to the data. The trade-off between model complexity and points lying outside of the tube (with positive slack variables $\zeta$) is determined by minimizing Equation 39. (From Schölkopf, B., and Smola, A. J., 2002, *Learning with Kernels*, Cambridge, MA: MIT Press. Reprinted with permission.):

## Kernel Principal Component Analysis

The kernel trick can be used to develop nonlinear generalizations of any algorithm that can be cast in terms of dot products, such as Principal Component Analysis (PCA) (q.v.).

PCA in feature space leads to an algorithm called *kernel PCA*. It is derived as follows. We wish to find eigenvectors **v** and eigenvalues $\lambda$ of the so-called *covariance matrix* **C** in the feature space, where

$$\mathbf{C} := \frac{1}{m} \sum_{i=1}^{m} \Phi(x_i)\Phi(x_i)^{\top} \tag{43}$$

In the case when $\mathcal{H}$ is very high-dimensional, the computational costs of doing this directly are prohibitive. Fortunately, one can show that all solutions to

$$\mathbf{Cv} = \lambda \mathbf{v} \tag{44}$$

with $\lambda \neq 0$ must lie in the span of $\Phi$-images of the training data. Thus, we may expand the solution **v** as

$$\mathbf{v} = \sum_{i=1}^{m} \alpha_i \Phi(x_i) \tag{45}$$

thereby reducing the problem to that of finding the $\alpha_i$. It turns out that this leads to a dual eigenvalue problem for the expansion coefficients,

$$m\lambda\boldsymbol{\alpha} = K\boldsymbol{\alpha} \tag{46}$$

where $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_m)^{\top}$ is normalized to satisfy $\|\boldsymbol{\alpha}\|^2 = 1/\lambda$.

To extract nonlinear features from a test point $x$, we compute the dot product between $\Phi(x)$ and the $n$th normalized eigenvector in feature space,

$$\langle \mathbf{v}^n, \Phi(x) \rangle = \sum_{i=1}^{m} \alpha_i^n k(x_i, x) \tag{47}$$

**Figure 6.** Architecture of SVMs and related kernel methods. The input $x$ and the expansion patterns (SVs) $x_i$ (we assume that we are dealing with handwritten digits) are nonlinearly mapped (by $\Phi$) into a feature space $\mathcal{H}$ where dot products are computed. Through the use of the kernel $k$, these two layers are in practice computed in one step. The results are linearly combined using weights $v_i$, found by solving a quadratic program (in pattern recognition, $v_i = y_i\alpha_i$; in regression estimation, $v_i = \alpha_i^* - \alpha_i$) or an eigenvalue problem (kernel PCA). The linear combination is fed into the function $\sigma$ (in pattern recognition, $\sigma(x) = \operatorname{sgn}(x + b)$; in regression estimation, $\sigma(x) = x + b$; in kernel PCA, $\sigma(x) = x$). (From Schölkopf, B., and Smola, A. J., 2002, *Learning with Kernels*, Cambridge, MA: MIT Press. Reprinted with permission.)

A toy example is given in Figure 7. As in the case of SVMs, the architecture can be visualized by Figure 6.

## Implementation and Empirical Results

An initial weakness of SVMs was that the size of the quadratic programming problem scaled with the number of SVs. This was due to the fact that in Equation 32, the quadratic part contained at least all SVs—the common practice was to extract the SVs by going through the training data in chunks while regularly testing for the possibility that patterns initially not identified as SVs become SVs at a later stage. This procedure is referred to as *chunking.* Note that without chunking, the size of the matrix in the quadratic part of the objective function would be $m \times m$, where $m$ is the number of all training examples.

What happens if we have a high-noise problem? In this case, many of the slack variables $\xi_i$ become non-zero, and all the corresponding examples become SVs. For this case, decomposition algorithms were proposed, based on the observation that not only can we leave out the non-SV examples (the $x_i$ with $\alpha_i = 0$) from the current chunk, but also some of the SVs, especially those that hit the upper boundary ($\alpha_i = C$). The chunks are usually dealt with using quadratic optimizers. Several public domain SV packages and optimizers are listed on the web page http://www.kernel-machines.org.

Modern SVM implementations made it possible to train on some rather large problems. Success stories include the 60,000 example top of the layer. However, this discrepancy led to new experiments and related changes in the model which resulted in a good replication of the actual physiological data and required only feedforward excitation. The article continues by analyzing the anatomical substrates for orientation specificity and for surround modulation of visual responses, and concludes by discussing the origins of patterned anatomical connections. VISUAL SCENE PERCEPTION moves beyond V1 to chart the bifurcation of V1 output in monkeys and humans into a pathway that ascends to the parietal cortex (the dorsal "where/how" system involved in object location and setting of parameters for action) and a pathway that descends to inferotemporal cortex (the ventral "what" system involved in object recognition) (see also "Dissociations Between Visual Processing Modes").

SOMATOSENSORY SYSTEM argues that the tactile stimulus representation changes from an original form (more or less isomorphic to the stimulus itself) to a completely distributed form (underlying perception) in a series of partial transformations in successive subcortical and cortical networks. At the level of primary somatosensory cortex, the neural image of the stimulus is sensitive to shape and temporal features of peripheral stimuli, rather than simply reflecting the overall intensity of local stimulation. The processing of somatosensory information is seen as modular on two different scales: macrocolumnar in terms of "segregates" such as the cortical barrels seen in rodent somatosensory cortex, each of which receives its principal input from one of the facial whiskers; and minicolumnar, with each minicolumn in a segregate receiving afferent connections from a unique subset of the thalamic neurons projecting to that segregate. The article argues that the causal factors involved in body/object interactions are represented by the pyramidal cells of somatosensory cortical areas in such a way that their ascending, lateral, and feedback connections develop an internal working model of mechanical interactions of the body with the outside world. Such an internal model can endow the somatosensory cortex with powerful interpretive and predictive capabilities that are crucial for haptic perception (i.e., tactile perception of proximal surroundings) and for control of object manipulation.

The auditory system is introduced in two articles. AUDITORY PERIPHERY AND COCHLEAR NUCLEUS spells out how the auditory periphery transforms a very high information rate acoustic stimulus into a series of lower information rate auditory nerve firings, with the incoming acoustic information split across hundreds of nerve fibers to avoid loss of information. The transformation involves complex mechanical-to-electrical transformations. The cochlear nucleus continues this process of parallelization by creating multiple representations of the original acoustic stimulus, with each representation presumably emphasizing different acoustic features that are fed to other brainstem structures, such as the superior olivary complex, the nuclei of the lateral lemniscus, and the inferior colliculus. These parallel pathways are believed to be specialized for the processing of different auditory features used for sound source classification and localization. From the inferior colliculus, auditory information is passed via the medial geniculate body in the thalamus to the auditory cortex. AUDITORY CORTEX stresses the crucial role that auditory cortex plays in the perception and localization of complex sounds. Although recent studies have expanded our knowledge of the neuroanatomical structure, the subdivisions, and the connectivities of all central auditory stages, relatively little is known about the functional organization of the central auditory system. Nevertheless, a few auditory tasks have been broadly accepted as vital for all mammals, such as sound localization, timbre recognition, and pitch perception. The article discusses a few of the functional and stimulus feature maps that have been found or postulated, and relates them to the more intuitive and better understood case of the echolocating bats (cf. "Echolocation: Cochleotopic and Computational Maps").

The olfactory system is distinctive in that paths from periphery to cortex do not travel via a thalamic nucleus. The olfactory pathway begins with the olfactory receptor neurons in the nose, which project their axons to the olfactory bulb. The function of the olfactory bulb is to perform the initial stages of sensory processing of the olfactory signals before sending this information to the olfactory cortex. The study of the olfactory system offers prime examples of seeking a "basic circuit" that defines the irreducible minimum of neural components necessary for a model of the functions carried out by a region. OLFACTORY BULB offers examples of information processing without impulses and of output functions of dendrites (dendrodendritic synapses). The olfactory cortex is defined as the region of the cerebral cortex that receives direct connections from the olfactory bulb and is subdivided into several areas that are distinct in terms of details of cell types, lamination, and sites of output to the rest of the brain. The main area involved in olfactory perception is the piriform (also called prepyriform) cortex, which projects to the mediodorsal thalamus, which in turn projects to the frontal neocortex. This is often regarded as the main olfactory cortex, and is the subject of the article OLFACTORY CORTEX. Olfactory cortex is the earliest cortical region to differentiate in the evolution of the vertebrate forebrain and is the only region within the forebrain to receive direct sensory input. Models of olfactory cortex emphasize the importance of cortical dynamics, including the interactions of intrinsic excitatory and inhibitory circuits and the role of oscillatory potentials in the computations performed by the cortex.

We now introduce motor cortex, then turn to three systems related to motor control and to visuomotor coordination in mammals (cf. the road map **Mammalian Motor Control**): cortical areas involved in grasping, the basal ganglia, and cerebellum. MOTOR CORTEX: CODING AND DECODING OF DIRECTIONAL OPERATIONS spells out the relation between the direction of reaching and changes in neuronal activity that have been established for several brain areas, including the motor cortex. The cells involved each have a broad tuning function, the peak of which is viewed as the "preferred" direction of the cell. A movement in a particular direction will engage a whole population of cells. It is found that the weighted vector sum of their neuronal preferences is a "population vector" which points in (close to) the direction of the movement for discrete movements in 2D and 3D space. GRASPING MOVEMENTS: VISUOMOTOR TRANSFORMATIONS shows the tight coupling between (specific subregions of) parietal and premotor cortex in controlling grasping. The AIP region of inferior parietal lobe appears to play a fundamental role in extracting intrinsic visual properties ("affordances") from the object for organizing grasping movements. The extracted visual information is then sent to the F5 region of premotor cortex, there activating neurons that code grip types congruent to the size, shape, and orientation of the object. In addition to visually activated neurons in AIP, there are AIP cells whose activity is linked to motor activity, possibly reflecting corollary discharges sent by F5 back to the parietal cortex. (For the possible relation of grasping to language, and the homology between F5 and Broca's area, see "Language Evolution: The Mirror System Hypothesis.")

The basal ganglia include the striatum, the globus pallidus, the substantia nigra, and the subthalamic nucleus. BASAL GANGLIA stresses that all of these structures are functionally subdivided into skeletomotor, oculomotor, associative, and limbic territories. The basal ganglia can be viewed as a family of loops, each taking its origin from a particular set of functionally related cortical fields, passing through the functionally corresponding portions of the basal ganglia, and returning to parts of those same cortical fields by way of specific zones in the dorsal thalamus. The article reviews models of the basal ganglia that attempt to incorporate appropriate anatomical or physiological data, but not those that use only generic neural network architectures. Some models work at a comparatively low level of detail (membrane properties of individual neurons and microanatomical features) and restrict themselves to a single component of the basal ganglia nucleus; others work at the system level with the basal ganglia as a whole and with their interactions with related structures (e.g., thalamus and cortex). Since dopamine neurons discharge in relation to conditions involving the probability and imminence of behavioral reinforcement, dopamine neurons have been seen as playing a role in striatal information processing analogous to that of an “adaptive critic” in connectionist networks (cf. “Reinforcement Learning” and “Dopamine, Roles of”).

The division of function between cerebellum and basal ganglia remains controversial. One view is that the basal ganglia play a role in determining when to initiate one phase of movement or another, and that the cerebellum adjusts the metrics of movement, tuning different movements and coordinating them into a graceful whole. Cerebellum and Motor Control reviews a number of models for cerebellar mechanisms underlying the learning of motor skills. Cerebellum can be decomposed into cerebellar nuclei and a cerebellar cortex. The only output cells of the cerebellar cortex are the Purkinje cells, and their only effect is to provide varying levels of inhibition on the cerebellar nuclei. Each Purkinje cell receives two types of input—a single climbing fiber, and many tens of thousands of parallel fibers. The most influential model of cerebellar cortex has been the Marr-Albus model of the formation of associative memories between particular patterns on parallel fiber inputs and Purkinje cell outputs, with the climbing fiber acting as “training signal.” Later models place more emphasis on the relation between the cortex and nuclei, and on the way in which the subregions of this coupled cerebellar system can adapt and coordinate the activity of specific motor pattern generators. The plasticity of the cerebellum is approached from a different direction in Cerebellum and Conditioning. Many experiments indicate that the cerebellum is involved in learning and performance of classically conditioned reflexes. The article reviews a number of models of the role of cerebellum in rabbit eye blink conditioning, providing a useful complement to models of the role of cerebellum in motor control.

The hippocampus has been implicated in a variety of memory functions, both as working memory and as basis for long-term memory. It was also the site for the discovery of long-term potentiation (LTP) in synapses (see “Hebbian Synaptic Plasticity”). Structurally, hippocampus is the simplest form of cortex. It contains one projection cell type, whose cell bodies are confined to a single layer, and receives inputs from all sensory systems and association areas. Hippocampus: Spatial Models builds on the finding that single-unit recordings in freely moving rats have revealed “place cells” in subfields of the hippocampus whose firing is restricted to small portions of the rat’s environment (the corresponding “place fields”). These data underlie the seminal idea of the hippocampus as a spatial map (cf. “Cognitive Maps”). The article reviews the data and describes some models of hippocampal place cells and of their role in circuits controlling the rat’s navigation through its environment. Hippocampal Rhythm Generation provides data and models on theta and other rhythms as well as epileptic discharges, and also introduces the key cell types of the hippocampus and a number of interconnections between the hippocampus that seem to play a key role in the generation of these patterns of activity.

Finally, we turn to prefrontal cortex, the association cortex of the frontal lobes. It is one of the cortical regions to develop last and most in the course of both primate evolution and individual ontogeny. Prefrontal Cortex in Temporal Organization of Action suggests that the late morphological development of this cortex in both cases is related to its support of higher cognitive functions involving the capacity to execute novel and complex actions, which reaches its maximum in the adult human brain. The lateral region of prefrontal cortex is involved in the representation and temporal organization of sequential behavior. This article emphasizes the physiological functions of the lateral prefrontal cortex in the temporal organization of behavior. Temporal integration of sensory and motor information, through active short-term memory (working memory) and prospective set, supports the goal-directed performance of the perception-action cycle. This role extends to the temporal organization of higher cognitive operations, including, in the human, language and reasoning.

Synthetic Functional Brain Mapping

Cognitive neuroscience has been boosted tremendously in the last decade by the rapid development and increasing use of techniques to image the active human brain. The road map thus starts with several articles on ways of observing activity in the human brain and then examines various human cognitive functions.

The organization of large masses of neurons into synchronized waves of activity lies at the basis of phenomena such as the electroencephalogram (EEG) and evoked potentials, as well as the magnetoencephalogram (MEG). The EEG consists of the electrical activity of relatively large neuronal populations that can be recorded from the scalp, while the MEG can be recorded using very sensitive transducers arranged around the head. EEG and MEG Analysis reviews methods of quantitative analysis that have been applied to extract information from these signals, providing an indispensable tool for sleep and epilepsy research. Epilepsy is a neurological disorder characterized by the occurrence of seizures, sudden changes in neuronal activity that interfere with the normal functioning of neuronal networks, resulting in disturbances of sensory or motor activity and of the flow of consciousness. During an epileptic seizure, the neuronal network exhibits typical oscillations that usually propagate throughout the brain, involving progressively more brain systems. These oscillations are revealed in the EEG (see also “Hippocampal Rhythm Generation”). In general, the same brain sources account for the EEG and the MEG, with the reservation that the MEG reflects magnetic fields perpendicular to the skull that are caused by tangential current dipolar fields, whereas the EEG/MEG reflects both radial and tangential fields. This property can be used advantageously to disentangle radial sources lying in the convexity of cortical gyri from tangential sources lying in the sulci.

Event-Related Potentials shows how cortical event-related potentials (ERPs) arise from synchronous interactions among large numbers of participating neurons. These include dense local interactions involving excitatory pyramidal neurons and inhibitory interneurons, as well as long-range interactions mediated by axonal pathways in the white matter. Depending on the types of interaction that occur in a specific behavioral condition, cortical networks may display different states of synchrony, causing their ERPs to oscillate in different frequency bands, designated delta (0–4 Hz), theta (5–8 Hz), alpha (9–12 Hz), beta (13–30 Hz), and gamma (31–100 Hz). Depending on the location and size of the recording and reference electrodes, recorded cortical field potentials integrate neural activity over a range of spatial scales: from the intracortical local field potential (LFP) to the intracranial electrocorticogram (ECoG) to the extracranial electroencephalogram (EEG). ERP studies have shown that local cortical area networks are able to synchronize and desynchronize their activity rapidly with changes in cognitive state. When incorporated into ANNs, the result could be a metastable large-scale neural network design that recruits and excludes subnetworks according to their ability to reach consensual local patterns, with the ability to implement behavioral schemas and adapt to changing environmental conditions.

Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) provide means for seeing which brain regions are significantly more active in one task rather than another. Functional neuroimaging is generally used to make inferences about functional anatomy on the basis of evoked patterns of cortical activity. Functional anatomy involves an understanding of what each part of the brain does, and how different brain systems interact to support various sensorimotor and cognitive functions. Large-scale organization can be inferred from techniques that image the hemodynamic and metabolic sequelae of evoked neuronal responses. PET measures regional cerebral blood flow (rCBF) and fMRI measures oxygenation changes. Their spatial resolution is on the order of a few millimeters. Because PET uses radiotracers, its temporal resolution is limited to a minute or more by the half-life of the tracers employed. However, fMRI is limited only by the biophysical time constants of hemodynamic responses themselves (a few seconds).

Statistical Parametric Mapping of Cortical Activity Patterns considers the neurobiological motivations for different designs and analyses of functional brain imaging studies, noting that the principles of *functional specialization* and *integration* serve as the motivation for most analyses. Statistical parametric mapping (SPM) is used to identify functionally specialized brain regions that respond selectively to experimental cognitive or sensorimotor changes, irrespective of changes elsewhere. SPM is a voxel-based approach (a voxel is a volume element of a 3D image) employing standard inferential statistics. SPM is a *mass-univariate* approach, in the sense that each data sequence, from every voxel, is treated as a univariate response. The massive numbers of voxels are analyzed in parallel, and dependencies among them are dealt with using random field theory (see "Markov Random Field Models in Image Processing").

One approach to systems-level neural modeling aims at determining the network of brain regions mediating a specific cognitive task. This means finding the nodes of the network (i.e., the brain regions), and determining the task-dependent functional strengths of their interregional anatomical linkages. Covariance Structural Equation Modeling describes techniques applied to the correlations between PET- or fMRI-determined regional brain activities. These correlations are viewed as "functional connectivities." They thus vary from task to task, as different patterns of excitation and inhibition are routed through the anatomical connections of these regions. Examples of questions that can be answered using this approach are: (1) As one learns a task, do the functional links between specific brain regions change their values? (2) In cases of similar performance, are the same brain networks being used by normals and patients? The method is illustrated with studies of object and spatial vision showing cross-talk between the dorsal and ventral streams (see "Visual Scene Perception"), which implies that they need not be functionally independent. The article stresses the concept of a *neural context*, where the functional relevance of a particular region is determined by its interactions with other areas. Because the pattern of interactions with other connected areas differs from task to task, the resulting cognitive operations may vary within a single region as it engages in different tasks.

Synthetic Functional Brain Mapping analyzes ways in which models of neural networks grounded in primate neurophysiology can be used as the basis for predictions of the results of human brain imaging. This is crucial for furthering our understanding of the neural basis of behavior. Covariance structural equation modeling helps identify the nodes of the region-by-region network corresponding to a cognitive task, especially when there is little or no nonhuman data available (e.g., most language tasks). Synthetic functional brain mapping uses primate data to form hypotheses about the neural mechanisms whereby cognitive tasks are implemented in humans, with PET and fMRI data providing constraints on the possible ways in which these neural systems function. This is illustrated in relation to the mechanisms underlying saccadic eye movements and working memory.

The next three articles focus on what we are learning about vision, motor activity, and language from functional brain imaging. Imaging the Visual Brain addresses functional brain imaging of visual processes, with emphasis on limits in spatial and temporal resolution; constraints on subject participation; and trade-offs in experimental design. The articles focuses on retinotopy, visual motion perception, visual object representation, and voluntary modulation of attention and visual imagery, emphasizing some of the areas where modeling and brain theory might be testable using current imaging tools. Imaging the Motor Brain shows that the behavioral form and context of a movement are important determinants of functional activity within cortical motor areas and the cerebellum, stressing that functional imaging of the human motor system requires one to study the interaction of neurological and cognitive processes with the biomechanical characteristics of the effectors. Multiple neural systems must interact to successfully perform motor tasks, encode relevant information for motor learning, and update behavioral performance in real time. The article discusses how evidence from functional imaging studies provides insight into motor automaticity as well as the role of internal models in movement. The article also discusses novel mathematical techniques that extend the scope of functional imaging experimentation.

Imaging the Grammatical Brain reviews brain imaging results that support the author's view that linguistic rules are neurally real and form a constitutive element of the human language faculty. The focus is on linguistic combinations at the sentence level; but an analysis of cerebral representation of phonological units and of word meaning in its isolated and compositional aspects is provided as background. The study of brain mechanisms supporting language is further advanced in Neurolinguistics. Neurolinguistics began as the study of the language deficits occurring after brain injuries, and is rooted in the conceptual model of Broca's aphasia, Wernicke's aphasia, and other aphasic syndromes established over a hundred years ago. The article presents data and analyses for between-stage information flow, dynamics of within-stage processing, unitary representations and activation, and processing by constraint satisfaction. (For more background on these two articles, see the road map **Linguistics and Speech Processing**.)

Prefrontal Cortex in Temporal Organization of Action emphasizes the physiological functions of the lateral prefrontal cortex in the temporal organization of behavior, highlighting active short-term memory (working memory) and prospective set. The two cooperate toward temporally integrating sensory and motor information by mediating cross-temporal contingencies of behavior (see also "Competitive Queuing for Planning and Serial Performance"). This temporal integration supports the goal-directed performance of the perception-action cycle. It is a role that extends to the temporal organization of higher cognitive operations, including language and reasoning in humans. CORTICAL MEMORY stresses that some components of memory are localized in discrete domains of cortex, while others are more widely distributed. It outlines a view of network memory in the neocortex that is supported by empirical evidence from neuropsychology, behavioral neurophysiology, and neuroimaging. Its essential features are the acquisition of memory by the formation and expansion of networks of neocortical neurons through changes in synaptic transmission; and the hierarchical organization of memory networks, with a hierarchy of networks in posterior cortex for perceptual memory and another in frontal cortex for executive memory. SEQUENCE LEARNING characterizes behavioral sequences in terms of their serial, temporal, and abstract structure, and analyzes the associated neural processing systems (see also "Temporal Pattern Processing"). Temporal structure is defined in terms of the durations of elements (and the possible pauses that separate them), and intuitively corresponds to the familiar notion of rhythm. Abstract structure is defined in terms of generative rules that describe relations between repeating elements within a sequence. Thus, the two sequences A-B-C-B-A-C and D-E-F-E-D-F are both generated from the same abstract structure 123-213. The article focuses on how the different dimensions of sequence structure can be encoded in neural systems, citing behavioral studies in different patient and control groups and related simulation studies. A recurrent network for manipulating abstract structural relations is implemented in a distributed network that potentially includes the perisylvian cortex in and around Broca's area. It is argued that both transfer of sequence knowledge between domains and abstract rule representation are likely to be neurophysiological realities.

Complementing sequence learning is the study of imitation, the ability to recognize and reproduce others' actions. Imitation is also related to fundamental capabilities for social cognition such as the recognition of conspecifics, the attribution of others' intentions, and the ability to deceive and to manipulate others' states of mind. IMITATION bridges between biology and engineering, reviewing the cognitive and neural processes behind the different forms of imitation seen in animals and showing how studies of biological processes influence the design of robot controllers and computational algorithms. Theoretical models have been proposed to, e.g., distinguish between purely associative imitation (low-level) and sequential imitation (high-level). It is argued that modeling of imitation will lead to a better understanding of the neural mechanisms at the basis of social cognition and will offer new perspectives on the evolution of animal abilities for social representation (see "Language Evolution: The Mirror System Hypothesis" for more on evolution and imitation).

EMOTIONAL CIRCUITS stresses the distinction between emotional experiences and the underlying processes that lead to emotional experiences. (See also "Motivation" for a discussion of the motivated or goal-directed behaviors that are often accompanied by emotion or affect.) The article is grounded in studies of how the brain detects and evaluates emotional stimuli and how, on the basis of such evaluations, appropriate responses are produced, treating emotion as a function that allows the organism to respond in an adaptive manner to challenges in the environment rather than being inextricably compounded with the subjective experience of emotion. The amygdala is shown to play a major role in the evaluation process. It is argued that fearful stimuli follow two main routes. The fast route involves the thalamo-amygdala pathway and responds best to simple stimulus features, while the slow route involves the thalamo-cortical-amygdala pathway and carries more complex features (such as context). The expression of fear is mediated by the outputs of the amygdala to brainstem and hypothalamus, while the experience of fear involves the prefrontal cortex.

One cerebral hemisphere may perform better than the other for such diverse tasks as language, handedness, visuospatial processing, emotion and its facial expression, olfaction, and attention. Behavioral lateralization has not only been demonstrated in people, but also in rodents, birds, primates, and other animals in areas such as vocalization and motor preferences. Many anatomical, biochemical, and physiological asymmetries exist in the brain, but it is generally unclear which, if any, of these asymmetries actually contribute to hemispheric specialization. Pathways such as the corpus callosum connecting the hemispheres appear to mediate both excitatory and longer-term inhibitory interactions between the hemispheres. HEMISPHERIC INTERACTIONS AND SPECIALIZATION first considers models of hemispheric interactions that do not incorporate hemispheric differences, and conversely, models examining the effects of hemispheric differences that do not incorporate hemispheric interactions. It then looks in more detail at recent studies demonstrating how both hemispheric interactions and differences influence the emergence of lateralization in models where lateralization is not initially present.

As we already saw in, e.g., NEUROLINGUISTICS, cognitive neuropsychology uses neurological data on the performance of brain-damaged patients to constrain models of normal cognitive function. LESIONED NETWORKS AS MODELS OF NEUROPSYCHOLOGICAL DEFICITS surveys how connectionist techniques have been employed to model the operation and interaction of "modules" inferred from the neurological data. The advantage over "box-and-arrow" models is that removing neurons or connections in connectionist models leads to natural analogues of real brain damage. Moreover, such models let one explore the possibility that processing is actually more distributed and interactive than the older models implied. The article discusses the effects of simulated lesioning on various models, constructed either as feedforward networks or as attractor networks, paying special attention to the misleading artifacts that may arise when large brains are modeled by small ANNs. Continuing with this theme, NEUROPSYCHOLOGICAL IMPAIRMENTS cautions that the inferences that link a neuropsychological impairment to a particular theory in cognitive neuroscience are not as direct as one might at first assume. The brain is a distributed and highly interactive system, such that local damage to one part can unleash new modes of functioning in the remaining parts of the system. The article emphasizes neural network models of cognition and the brain that provide a framework for reasoning about the effects of local lesions in distributed, interactive systems. In many cases a model's behavior after lesioning is somewhat counterintuitive and so can lead to very different interpretations regarding the nature of the normal system. A model of neglect dyslexia shows how an impairment in a prelexical attentional process could nevertheless show a lexicality effect. Prosopagnosia is an impairment of face recognition that can occur relatively independently of impairments in object recognition. The behavior of some prosopagnosic patients seems to suggest that that recognition and awareness depend on dissociable and distinct brain systems. However, a model of covert face recognition demonstrates how dissociation may occur without separate systems. NEUROLOGICAL AND PSYCHIATRIC DISORDERS shows how neural modeling may be harnessed to investigate the pathogenesis and potential treatment of brain disorders by studying the relation between the "microscopic" pathological alterations of the underlying neural networks and the "macroscopic" functional and behavioral disease manifestations that characterize the network's function. The article reviews computational studies of the neurological disorders of Alzheimer's disease, Parkinson's disease, and stroke, and the psychiatric disorders of schizophrenia and affective disorders.

Philosophical Issues in Brain Theory and Connectionism
Schema Theory
Systematicity of Generalizations in Connectionist Networks

Much classical psychology was grounded in notions of association—of ideas, or of stimulus and response—which were well developed in the philosophy of Hume, but with roots going back as far as Aristotle. Associative Networks shows how these old ideas gain new power because neural networks can provide mechanisms for the formation of associations that automatically yield many further properties. One of these is that neural networks will in many cases have similar responses to similar inputs, a property that is exploited in the study of Analogy-Based Reasoning and Metaphor. Analogy and metaphor have been characterized as comparison processes that permit one domain to be seen in terms of another. Indeed, many of the advantages suggested for connectionist models—representation completion, similarity-based generalization, graceful degradation, and learning—also apply to analogy, yet analogical processing poses significant challenges for connectionist models. Analogy and metaphor involve structured pattern matching, structured pattern completion, and a focus on common *relational structure* rather than on common object descriptions. The article analyzes current connectionist models of analogy and metaphor in terms of representations and associated processes, not in terms of brain function. Challenges for future research include building analogical models that can preserve structural relations over incrementally extended analogies and that can be used as components of a broader cognitive system such as one that would perform problem solving. Indeed, people continually deal with composite structures whether they result from aggregation of symbols in a natural language into syllables, words, and sentences or aggregation of visual features into contour and regions, objects, and complete scenes. Compositionality in Neural Systems addresses the question of what sort of neural dynamics allows composite structures to emerge, with the grouping and binding of parts into interpretable wholes. To this day it is still disputed whether ANNs are capable of adequately handling compositional data, and if so, which type of network is most suitable. Basic results have been obtained with simple recurrent networks, but some researchers argue that more complicated dynamics (see, e.g., "Synchronization, Binding and Expectancy") or dynamics similar to classical symbolic processing mechanisms are necessary for successful modeling of compositionality. In a related vein, Systematicity of Generalizations in Connectionist Networks presents the current "state of play" for Fodor and Pylyshyn's critique of connectionist architecture. They claimed that human cognitive abilities "come in clumps" (i.e., the abilities are systematically related), and that this systematic relationship does not hold in connectionist networks. The present article examines claims and counterclaims concerning the idea that learning in connectionist architectures can engender systematicity, with special attention paid to studies based on simple recurrent networks (SRNs) and recursive auto-associative memory (RAAM). The conclusion is that, for now, evidence for systematicity in such simple networks is rather limited. (One may ponder the fact that animal brains are vastly more complex than a single SRN or RAAM.)

The "units of thought" afforded by connectionist "neurons" are quite high level compared to the fine-grain computation of the myriad neurons in the human brain, and their properties may hence be closer to those of entire neural networks than to single biological neurons. Moreover, future connectionist accounts of cognition will certainly involve the coordination of connectionist modules (see, e.g., "Hybrid Connectionist/Symbolic Systems"). Schema Theory complements neuroscience's well-established terminology for levels of structural analysis (brain region, neuron, synapse) with a functional vocabulary, a framework for analysis of behavior with no necessary commitment to hypotheses on the localization of each schema (unit of functional analysis), but which can be linked to a structural analysis whenever appropriate. The article focuses on two issues: structuring perceptual and motor schemas to provide an action-oriented account of behavior and cognition (as relevant to the roboticist as the ethologist), and how schemas describing animal behavior may be mapped to interacting regions of the brain. Schema-based modeling becomes part of neuroscience when constrained by data provided by, e.g., human brain mapping, studies of the effects of brain lesions, or neurophysiology. The resulting model may constitute an adequate explanation in itself or may provide the framework for modeling at the level of neural networks or below. Such a neural schema theory provides a functional/structural decomposition, in strong contrast to models that employ learning rules to train a single neural network to respond as specified by some training set.

Connectionism can apply many different types of ANN techniques to explain psychological phenomena, and the article Cognitive Modeling: Psychology and Connectionism places a sample of these in perspective. The general idea is that much of psychology is better understood in terms of parallel networks of adaptive units than in terms of serial symbol processing, and that connectionism gains much of its power from using very simple units with explicit learning rules. The article points out that connectionist models of cognition can be used both to model cognitive processes and to simulate the performance of tasks and that, unlike many traditional computational models, they are not explicitly programmed by the investigator. However, important aspects of the performance of a connectionist net are controlled by the researcher, so that the achievement of a good fit to the psychological data depends both on the way in which analogs to the data are derived and on the results of "extensional programming," such as decisions about the selection and presentation of training data. The article also notes the work of "cognitive connectionists," whose computational experiments have demonstrated the ability of connectionist representations to provide a promisingly different account of important characteristics of cognition (compositionality and systematicity), previously assumed to be the exclusive province of the classical symbolic tradition. Philosophical Issues in Brain Theory and Connectionism asks the following questions: (1) Do neural systems exploit classical compositional and systematic representations, distributed representations, or no representations at all? (2) How do results emerging from neuroscience help constrain cognitive scientific models? (3) In what ways might embodiment, action, and dynamics matter for understanding the mind and the brain? There is a growing emphasis on the computational economies afforded by real-world action and the way larger structures (of agents and artifacts) both scaffold and transform the shape of individual reason. However, rather than seeing representations as opposed to interactive dynamics, the article advocates a broader vision of the inner representational resources themselves, stressing the benefits of converging influences from robotics, systems-level neuroscience, cognitive psychology, evolutionary theory, AI, and philosophical analysis. This philosophical theme is further developed in CONSCIOUSNESS, NEURAL MODELS OF, which reviews the basic ways in which consciousness has been defined, relevant neuropsychological data, and preliminary progress in neural modeling. Among the characteristics needed for consciousness are temporal duration, attentional focus, binding, bodily inputs, salience, past experience, and inner perspective. Brain imaging, as well as insights into single-cell activity and the effects of brain deficits, is leading to a clearer picture of the neural correlates of consciousness. The article presents a specific attention control model of the emergence of awareness in which experience of the prereflective self is identified with the corollary discharge of the attention movement control signal. This signal is posited to reside briefly in its buffer until the arrival of the associated attended input activation at its own buffer. The article concludes by reviewing other neural models of consciousness.

Much of the early work on ANNs was inspired by the problem of "Pattern Recognition" (q.v.). CONCEPT LEARNING provides a general introduction to recent work, placing such ideas in a psychological perspective. Concepts are mental representations of kinds of objects, events, or ideas. The article focuses on learning mental representations of new concepts from experience and how mental representations of concepts are used to make categorization decisions and other kinds of judgments. The article reviews five types of concept learning models: rule models, prototype models, exemplar models, mixed models, and neuroscientific models. The mechanisms discussed briefly here are developed at greater length in many articles in the road map **Learning in Artificial Networks**. The psychology of concept learning receives special application in the study of FACE RECOGNITION: PSYCHOLOGY AND CONNECTIONISM, which relates connectionist approaches to face recognition to psychological theories for the subtasks of representing faces and retrieving them from memory, comparing human and model performance along these dimensions.

Many of the concepts of connectionist psychology are strongly related to work in behaviorism, but neural networks provide a stronger "internal structure" than stimulus-response probabilities. Connectionist research has enriched a number of concepts that seemed "anticognitive" by embedding them in mechanisms, namely, neural nets, which can both support internal states and yield stimulus-response pairs as part of a general input-output map. This is shown in CONDITIONING. During conditioning, animals modify their behavior as a consequence of their experience of the contingencies between environmental events. This article presents formal theories and neural network models that have been proposed to describe classical and operant conditioning. During *classical conditioning*, animals change their behavior as a result of the contingencies between the conditioned stimulus (CS) and the unconditioned stimulus (US). Contingencies may vary from very simple to extremely complex ones. For example, in Pavlov's proverbial experiment, dogs were exposed to the sound of a bell (CS) followed by food (US). At the beginning of training, animals salivated (generated an unconditioned response, UR) only when the US was presented. With an increasing number of CS-US pairings, CS presentations elicited a conditioned response (CR). The article discusses variations in the effectiveness of the CS, the US, and the CS and US together, as well as attentional models. During *operant* (or *instrumental*) *conditioning*, animals change their behavior as a result of a triple contingency between its responses (R), discriminative stimuli (SD), and the reinforcer (US). Animals are exposed to the US in a relatively close temporal relationship with the SD and R. As in "Reinforcement Learning" (q.v.), during operant conditioning animals learn by trial and error from feedback that evaluates their behavior but does not indicate the correct behavior. The article discusses positive reinforcement and negative reinforcement. Such ideas are further developed in COGNITIVE MAPS. Tolman introduced the notion of a *cognitive map* to explain animals' capacity for place learning, latent learning, detours, and shortcuts. In some models, Tolman's vicarious trial-and-error behavior has been regarded as reflecting the animal's comparison of different expectancies: at choice points, animals make a decision after sampling the intensity of the activation elicited by the various alternative paths. Other models still use Tolman's stimulus-approach view and assume that animals approach the place with the strongest appetitive activation, thereby performing a gradient ascent toward the goal. In addition to storing the representation of the environment in the terms of the contiguity between places, cognitive maps can store information about differences in height and the type of terrain between adjacent places, contain a priori knowledge of the space to be explored, distinguish between roads taken and those not taken, and keep track of which places have been examined. Neural networks with more than two layers can also be used to represent both the contiguity between places and the relative position of those places. Hierarchical cognitive maps can represent the environment at multiple levels. In contrast to their nonhierarchical counterparts, hierarchical maps can plan navigation in large environment, use a smaller number of connections in their networks, and have shorter decision times.

Learning in neural nets can be either supervised or unsupervised, and supervision can be in terms of a specific error signal or some general reinforcement. However, in real animals, these signals seem to have some "heat" to them, which brings us to the issues of motivation and emotion. Motivated or goal-directed behaviors are sets of motor actions that direct an animal toward a particular goal object. Interaction with the goal either promotes the survival of an individual or maintains the species. Motivated behaviors include sleep/wake, ingestive, reproductive, thermoregulatory, and aggressive/defensive behaviors (see also "Pain Networks"). They are often accompanied by emotion or affect. Given the difficulty of defining the terms *drive*, *instinct*, and *motivation* with respect to the neural substrates of behavior, MOTIVATION adopts a neural systems approach that discusses what and how particular parts of the brain contribute to the expression of behaviors that have a motivated character. The approach is based on Hullian incentive models of motivation, where the probability of a particular behavior depends on the integration of information from systems that control circadian timing and regulate arousal state, inputs derived from interosensory information that encode internal state (e.g., hydration state, plasma glucose, leptin, etc.), modulatory hormonal inputs such as gonadal steroids that mediate sexual behavior, and inputs derived from classic sensory modalities. EMOTIONAL CIRCUITS analyzes the nature of emotion, emphasizing its role in behavior rather than the subjective feelings that accompany human emotions, then examines the role of brain structures such as the amygdala, the interaction of body and cognitive states, and the status of neural modeling. The expression of fear is seen as mediated by the outputs of the amygdala to lower brain centers (brainstem, hypothalamus), while the experience of fear involves the prefrontal cortex.

Finally, we turn to development, a theme of special concern in connectionist linguistics (see the next road map). COGNITIVE DEVELOPMENT reviews connectionist models of the origins of knowledge, the mechanisms of change, and the task-dependent nature of developing knowledge across a variety of domains. In each case, the models provided explicit instantiations and controlled tests of specific theories of development, and allowed the exploration of complex, emergent phenomena. However, most connectionist models are "fed" their input patterns regardless of what they output, whereas even very young children shape their environments based on how they behave. Moreover, most connectionist models are designed for and tested on a single task within a single domain, whereas children face a multitude of tasks across a range of domains each day. Capturing such features of development will require future models to take in a variety of types of information and learn how to perform successfully across a number of tasks. Developmental Disorders uses the comparison of different abnormal phenotypes to explore further the modeling of the developing mind/brain. The article reviews recent examples of connectionist models of developmental disorders. Autism is a developmental disorder characterized primarily by deficits in social interaction, communication, and imagination, but also by a range of secondary deficits. One hypothesis suggests that these structural deficits are consistent with too few neurons in some brain areas, such as the cerebellum, and too many neurons in other areas, such as the amygdala and hippocampus. This grounds a simple connectionist model trained on categorization tasks linking such differences in neurocomputational constraints to some of the secondary deficits found in autism. Other models relate disordered feature maps or hidden unit numbers to higher-level cognitive deficits that characterize autism. Developmental dyslexia has been modeled by changing parameters in models of the normal processes of reading. Another model captures some features of specific language impairment, specifically the difficulty of affected patients in learning rule-based inflectional morphology in verbs, using an attractor network mapping between semantic codes and phonological codes. The article also reports new empirical findings on Williams syndrome patients which reveal a deficit in generalizing knowledge of inflectional patterns to novel forms. Alterations in the initial computational constraints of a connectionist model of past tense development are shown to account for some of the patterns seen in such data, demonstrating how different computational constraints interact in the process of development. Connectionist models thus provide a powerful tool with which to investigate the role of initial computational constraints in determining the trajectory of both typical and atypical development, ensuring that selective deficits in developmental disorders are seen in terms of the outcome of the developmental process itself.

## Linguistics and Speech Processing

Constituency and Recursion in Language

Speech Processing: Psycholinguistics
Speech Production
Speech Recognition Technology

The traditional grounding of linguistics is in grammar, a systematic set of rules for structuring the sentences of a particular language. Much modern work in linguistics has been dominated by the ideas of Noam Chomsky, who placed the notion of grammar in a mathematical framework. His ideas have gone through successive stages in which the formulation of grammars has changed radically. However, two themes have remained stable in the "generative linguistics" that has grown from his work:

- There is a *universal grammar* which defines what makes a language human, and each human language has a grammar that is simply a parametric variation of the universal grammar.
- Language is too complicated for a child to learn from scratch; instead a child has universal grammar as an innate mental capacity. When the child hears example sentences of a language, they set parameters in the universal grammar so that the child can then acquire the grammar of the particular language.

Connectionist linguistics attacks this reasoning on two fronts:

- It says that language processing is better understood in terms of connectionist processing, which, as a performance model (i.e., a model of behavior, as distinct from a competence model, which gives a static representation of a body of knowledge), can give an account of errors as well as regularities in language use.
- It notes that connectionism has powerful learning tools that Chomsky has chosen to ignore. With those tools, connectionism can model how children could acquire language on the basis of far less specific mental structures than those posited in universal grammar.

Language Processing reviews many application of connectionist modeling. Despite the insights gained into syntactic structure across languages, the formal study of language has revealed relatively little about learning and development. Thus, as we shall see later in this road map, the connectionist program for understanding language has concentrated on the process of *change*, exploring topics such as language development, language breakdown, the dynamics of representation in complex systems which themselves may be receiving changing input, and even the evolution of language. The article briefly reviews models of lexical processing (reading single words, recognizing spoken words, and word production) as well as higher-level processing. It concludes that there has been important progress in many areas of connectionist-based research into language processing, and this modeling influences both psychological and neuropsychological experimentation and observation. However, it concedes that the major debates on top-down feedback, on the capacity of connectionist models to capture the productivity and systematicity of human language, and on the degree of modularity in language processing remain to be settled.

Constituency and Recursion in Language then provides more detail on connectionist approaches to syntax. Words group together to form coherent building blocks, *constituents*, within a sentence, so that "The girl liked a boy" decomposes into "the girl" and "liked a boy," forming a subject noun phrase (NP) and a verb phrase (VP), respectively. In linguistics, grammar rules such as Sentence S → NP VP determine how constituents can be put together to form sentences. To capture the full generativity of human language, *recursion* needs to be introduced into the grammar. For example, if we add the rules NP → (det) N(PP) (noun with optional determiner and prepositional phrase) and PP → Preposition NP, then the rules are recursive, because in this case, NP can invoke rules that eventually call for another instance of NP. This article discusses how constituency and recursion may fit into a connectionist framework, and the possible implications this may have for linguistics and psycholinguistics.

Language Acquisition presents models used by developmental connectionists to support the claim that rich linguistic representations can emerge from the interaction of a relatively simple learning device and a structured linguistic environment. The article reviews connectionist models of lexical development, inflectional morphology, and syntax acquisition, stressing that these models use similar learning algorithms to solve diverse linguistic problems. Past Tense Learning then presents issues in word morphology as a backdrop for a detailed discussion of the prime debate between a rule-based and a connectionist account of language processing, over the forming of regular and irregular past tenses of verbs in English. The dual mechanism model—use the general rule "add-*ed*" unless an irregular past tense is found in a table of exceptions—was opposed by the view that all past tenses, even for regular verbs, are formed by a connectionist network. The article concludes that most researchers now agree that the mental processing of irregular inflections is not rule governed but rather works much like a connectionist network. Certainly, rules provide an intuitively appealing explanation for regular behavior. Indeed, people are clearly able to consciously identify regularities and describe them with explicit rules that can then be deliberately followed, but this does not imply that a neural encoding of these rules, rather than a connectionist network which yields rule-like behavior, is the better account of "mental reality." The matter is subtle because the brain is composed of neurons. Thus the issue is not "Does the brain's language processing use neural networks?" but whether or not the activity of those networks is best described as explicitly encoding a set of rules.

Reading covers connectionist models of reading and associated processes, including the reading disorder known as dyslexia. Where a skilled reader can recognize many thousands of printed words, each in a fraction of a second, with no noticeable effort, a dyslexic child may need great effort to recognize a printed word as a particular word. Most connectionist networks for reading are models of word recognition. However, word recognition is more than an analytic letter-by-letter process that translates spelling into phonology, and so the synthetic-analytic debate provides the organizing theme for this article. The authors argue that, rather than see modeling word recognition as a distinct, separable component of reading, it may be better to investigate more integrative, nonlinear iterative network models. However, Speech Processing: Psycholinguistics reviews attempts to capture psycholinguistic data using connectionist models, with the primary focus on speech segmentation and word recognition. This article analyzes how far the problem of segmenting speech into words occurs independently of word recognition; considers the interplay of connectionist models of word recognition with empirical research and theory; and assesses the gap that remains between psycholinguistic studies of speech processing and modeling of the human brain. Although data from neuropsychology and functional imaging are becoming increasingly important (see Imaging the Grammatical Brain and Neurolinguistics), the main empirical constraints on psycholinguistic models are derived from laboratory studies of human language processing that are unrelated to neural data. The article suggests that connectionist modeling helps bridge the gulf between psycholinguistics and neuroscience by employing computational models that embody at least some of the computational principles of the brain.

Imaging the Grammatical Brain notes that there is little agreement on the best way to analyze language. Contrary to the connectionist approach (see, e.g., Past Tense Learning), the author sees inventories of combinatorial rules, and stores of complex objects of several types over which these rules operate, as being at the core of language. The "language faculty," in this view, inheres in a cerebrally represented knowledge base (rule system) and in algorithms that instantiate it. It is divided into levels for the identification and segmentation of speech sounds (universal phonetics), a system that enables the concatenation of phonetic units into sequences (phonology), then into words (morphology, where word structure is computed), sentences (syntax), and meaning (lexical and compositional semantics). The article reviews results emanating from brain imaging that support the neural reality of linguistic rules as a constitutive element of the human language faculty. The focus is on linguistic combinations at the sentence level, but an analysis of cerebral representation of phonological units and of word meaning in its isolated and compositional aspects is provided as background. The study of brain mechanisms supporting language is further advanced in Neurolinguistics. Neurolinguistics began as the study of the language deficits occurring after brain injuries and is rooted in the conceptual model of Broca's aphasia, Wernicke's aphasia, and other aphasic syndromes established over a hundred years ago. However, thanks to recent research, critical details are now seen differently, and finer details have been added. Speech and language are now recognized as the products of interacting dynamic systems, with major implications for modeling normal and abnormal performance and for understanding their neural substrates. The article analyzes between-stage information flow, dynamics of within-stage processing, unitary representations and activation, and processing by constraint satisfaction. How the cognitive elements (nodes) of psychological theorizing correspond to actual neuronal activity is not known for certain. However, the article suggests that the attractor states that can occur in recurrent networks are viable candidates for behaving as nodes. Indeed, many modeling efforts in neurolinguistics have been concerned with the consequences of relatively large-scale assumptions about stages and connections (see "Lesioned Networks as Models of Neuropsychological Deficits").

On the output side, Speech Production focuses on work in motor control, dynamical systems and neural networks, and linguistics that is critical to understanding the functional architecture and characteristics of the speech production system. The central point is that spoken word forms are not unstructured wholes but rather are composed from a limited inventory of phonological units that have no independent meaning but that can be (relatively freely) combined and organized in the construction of word forms. The production of speech by the lips, tongue, vocal folds, velum, and respiratory system can thus be understood as arising from choreographed linguistic action units. However, when phonological units are made manifest in word and sentence production, their spatiotemporal realization by the articulatory system, and consequent acoustic character presented to the auditory system, is highly variable and context dependent. The speech production system is sometimes viewed as having two components, one (traditionally referred to as phonology) concerned with categorical and linguistically contrastive information, and the other concerned with gradient, noncontrastive information (traditionally referred to as phonetics). However, current work in connectionist and dynamical systems models blurs this dichotomy. Motor Theories of Perception reviews reasons why speech scientists have doubted the claim that the speech motor system participates in speech perception and then argues against such doubts, showing that the theory accrues credibility when it is set in the larger context of investigations of perception, action, and their coupling. The mirror neurons in primates (see Language Evolution: The Mirror System Hypothesis) are seen as providing an existence proof of neuronal perceptuomotor couplings. The article further argues that, although the motor theory of speech perception was motivated by requirements of speaking and listening, real-world functional perception-action coupling is central to the "design" of animals more generally.

We have already contrasted connectionism with rule-based frameworks that account for linguistic patterns through the sequential application of transformations to lexical entries. Optimality Theory in Linguistics introduces optimality theory (OT) as a framework for linguistic analysis that has largely supplanted rule-based frameworks within phonology; it has also been applied to syntax and semantics, though not as widely. Generation of utterances in OT involves two functions, *Gen* and *Eval*. *Gen* takes an input and returns a (possibly infinite) set of output candidates. Some candidates might be identical to the input, others modified somewhat, others unrecognizable. *Eval* chooses the candidate that best satisfies a set of ranked constraints; this optimal candidate becomes the output. The constraints can conflict, so the constraints' ranking, which differs from language to language, determines the outcome. One language might eliminate consonant clusters by deleting consonants; another might retain all input consonants. OT was partly inspired by neural networks, employing as it does the ideas of optimization, parallel evaluation, competition, and soft, conflicting constraints. OT can be implemented in a neural network with constraints that are implemented as connection weights. The network implements a Lyapunov function that maximizes "harmony" ($\Sigma_{ij}a_iw_{ij}a_j$: the sum, for all pairs $i$, $j$ of neurons, of the product of the neurons' activations and their connection weight). Hierarchically structured representations (e.g., consonants and vowels grouped into syllables) can be represented as matrices of neurons, where each matrix is the tensor product of a vector for a linguistic unit and a vector for its position in the hierarchy.

An approach to language that emphasizes the learning processes of each new speaker rather than the existence of a set of immutable rules shared by all humans seems well equipped to approach the issue of how a language changes from generation to generation. Computational modeling has been used to test competing theories about specific aspects of language evolution under controlled circumstances. Connectionist networks have been used as simulated agents to study how social transmission via learning may give rise to the evolution of structured communication systems. In other cases, properties of neural network learning are enlisted to help illuminate the constraints and processes that may have been involved in the evolution of language. Language Evolution and Change surveys this connectionist research, starting from the emergence of early syntax and continuing on to the role of social interaction and constraints on network learning in subsequent evolution of language. It also discusses linguistic change within existing languages, showing how the inherent generalization ability of neural networks makes certain errors in language transmission from one generation to the next more likely than others. (However, such models say more about the simplification of grammars than about how language complexity arises in the first place.) Where this article stresses computational efficacy of various models proposed for the emergence of features characteristic of current human languages, Language Evolution: The Mirror System Hypothesis focuses on brain mechanisms shared by humans with other primates, and seeks to explain how these generic mechanisms might have become specialized during hominid evolution to support language. It is argued that imitation and pantomime provide a crucial bridging capability between general primate capabilities for action recognition and the language readiness of the human brain.

At present, the state of play may be summarized as follows: generative linguistics has shown how to provide grammatical rules that explain many subtle sentence constructions of English and many other languages, revealing commonalities and differences between languages, with the differences in some cases being reduced to very elegant and compact formulations in terms of general rules with parametric variations. However, in offering the notion of universal grammar as the substrate for language acquisition, generative linguistics ignores issues of learning that must, in any case, be faced in explaining how children acquire the large and idiosyncratic vocabulary of their native tongue. Connectionist linguistics, on the other hand, has made great strides in bringing learning to the center, not only showing how specific language skills (e.g., use of the past tense) may be acquired, but also providing insight into psycholinguistics, the study of language behavior. However, connectionist linguistics still faces two major hurdles: it lacks the systematic overview of language provided by generative linguistics, and little progress has been made in developing a neurolinguistic theory of the contributions of specific brain regions to language capabilities. It is one thing to train an ANN to yield a convincing model of performance on the past tense; it is quite another to offer an account of how this skill interfaces with all the other aspects of language, and what neural substrates are necessary for their acquisition by the human child.

The remaining articles look at speech processing from a technological perspective rather than in relation to human psycholinguistic data. Speech Recognition Technology introduces the way computer systems that transcribe speech waveforms into words rely on digital signal processing and statistical modeling methods to analyze and model the speech signal. Although commercial technology is typically not based on connectionist methods, neural network processing is commonly seen as a promising alternative to some of the current algorithms, and the article focuses on speech recognizers that process large-vocabulary continuous speech and that use multilayer feedforward neural networks. Traditional speech recognition systems follow a hierarchical architecture. A grammar specifies the sentences allowed by the application. (Alternatively, for very large vocabulary systems, a statistical language model may be used to define the probabilities of various word sequences in the domain of application.) Each word allowed by the grammar is listed in a dictionary that specifies its possible pronunciations in terms of sequences of phonemes which are further decomposed into smaller units whose acoustic realizations are represented by statistical acoustic models. When a speech waveform is input to a recognizer, it is first processed by a front-end unit that extracts a sequence of observations, or "features," from the raw signal. This sequence of observations is then decoded into the sequence of speech units whose acoustic models best fit the observations and that respect the constraints imposed by the dictionary and language model. Hidden Markov models (HMMs) have been an essential part of the toolkit for continuous speech recognition, as well as other complex temporal pattern recognition problems such as cursive (handwritten) text recognition, time-series prediction, and biological sequence analysis. Hidden Markov Models describes the use of deterministic and stochastic finite state automata for sequence processing, with special attention to HMMs as tools for the processing of complex piecewise stationary sequences. It also describes a few applications of ANNs to further improve these methods. HMMs allow complex learning problems to be solved by assuming that the sequential pattern can be decomposed into piecewise stationary segments, with each stationary segment parameterized in terms of a stochastic function. The HMM is called "hidden" because there is an underlying stochastic process (i.e., the sequence of states) that is not directly observable but that nonetheless affects the observed sequence of events. Convolutional Networks for Images, Speech, and Time Series shows how shift invariance is obtained in convolutional networks by forcing the replication of weight configurations across space. This takes the topology of the input into account, enabling such networks to force the extraction of local features by restricting the receptive fields of hidden units to be local, and enforcing a built-in invariance with respect to translations, or local distortions of the inputs.

Structured Connectionist Models
Systematicity of Generalizations in Connectionist Networks

In the 1950s, the precursors of today's fields of artificial intelligence and neural networks were still subsumed under the general heading of *cybernetics*. Much of the work in the 1960s sought to distance artificial intelligence (AI) from its cybernetic roots, emphasizing models of, e.g., logical inference, game playing, and problem solving that were based on explicit symbolic representations manipulated by serial computer programs. However, work in computer vision and in robotics (discussed in the road maps **Vision** and **Robotics and Control Theory**, respectively) showed that this distinction was never entirely convincing, since these were areas of AI that made use of parallel computation and numerical transformations. For a while, a case could be made that the use of parallelism might be appropriate for peripheral sensing and motor control but not for the "central" processes involved in "real" intelligence. However, work from at least the mid-1970s onward has made this fallback position untenable. For example, in the HEARSAY system, speech understanding was achieved not by serial manipulation of symbolic structures but by the action (implicitly distributed, though in the 1970s still implemented on a serial computer) of knowledge sources (what we would now call "agents") to update numerical confidence levels of multiple hypotheses distributed across a set of "levels" in a data structure known as a blackboard. Multiagent Systems introduces the methodology that has grown out of such beginnings. What constitutes an "individual" can be highly subjective: an individual to one researcher can, to another, be a complex distributed system comprised of finer-grained agents. Research in brain theory has dealt with different levels, from neurons to brain regions to humans whereas AI work in multi-agent systems has focused on coarse-grained levels of individuality and interaction, where the goal is to draw upon sociological, political, and economic insights. The article is designed to survey enough of this work on multi-agent systems to foster comparisons between the ANN, brain theory, and multi-agent approaches. A crucial notion is that agents either have or learn models of the agents with which they interact. These models allow agents to avoid dealing with malicious or broken agents. Agents may even build nested models of the other agents that include an agent's models of other agents, and so on. By using their models of each other, the agents loosely organize themselves into self-reinforcing communities of trust, avoiding unproductive future interactions with other agents. In another branch of AI, work on *expert systems*—information systems that represent expert knowledge for a particular problem area as a set of rules, and that perform inferences when new data are entered—provided an important application success in which numerical confidence values played a role, but with the emphasis still on manipulation of hypotheses through the serial application of explicit rules. As shown in Decision Support Systems and Expert Systems, we now see many cases in which the application of separate rules is replaced by transformations effected in parallel by (trainable) neural networks. A *decision system* is either a decision support system or an expert system in the classic AI sense. The article reviews results on connectionist-based decision systems. In particular, trainable knowledge-based neural networks can be used to accumulate both knowledge (rules) and data, building adaptive decision systems with incremental, on-line learning.

As the general overview article Artificial Intelligence and Neural Networks makes clear, there are many problems for which the (not necessarily serial) manipulation of symbolic structures can still outperform connectionist approaches, at least with today's software running on today's hardware. Nonetheless, if we define AI by the range of problems it is to solve—or the "packets of intelligence" it is to implement—then it is no longer useful to define it in opposition to connectionism. In general, the technologist facing a specific problem should choose between, or should combine, connectionist and symbolic approaches on the basis of efficacy, not ideology. On occasion, for rhetorical purposes, authors will use the term AI for a serial symbolic methodology distinct from connectionism. However, we will generally use it in an extended sense of a technology that seeks to realize aspects of intelligence in machines by whatever methods work best. The term *symbolic AI* will then be used for the "classical" approach. The article examines the relative merits of symbolic AI systems and neural networks, and ways of attempting to bridge between the two. In brain theory, everything, whether symbolic or not, is, in the final analysis, implemented in a neural network. But even here, an analysis of the brain will often best be conducted in terms of interacting subsystems that are not all fully explicated in neural network terms. Schema Theory complements neuroscience's well-established terminology for levels of structural analysis (brain region, neuron, synapse) with a framework for analysis of behavior with no necessary commitment to hypotheses on the localization of each schema (unit of functional analysis), but which can be linked to a structural analysis whenever appropriate. The article focuses on two issues: structuring perceptual and motor schemas to provide an action-oriented account of behavior and cognition (as relevant to the roboticist as the ethologist), and how schemas describing animal behavior may be mapped to interacting regions of the brain. Schema-based modeling becomes part of neuroscience when constrained by data provided by, e.g., human brain mapping, studies of the effects of brain lesions, or neurophysiology. The resulting model may constitute an adequate explanation in itself or may provide the framework for modeling at the level of neural networks or below. Such a neural schema theory provides a functional/structural decomposition, in strong contrast to models that employ learning rules to train a single, otherwise undifferentiated, neural network to respond as specified by some training set. Hybrid Connectionist/Symbolic Systems reviews work on hybrid systems that integrate neural (ANN) and symbolic processes. Cognitive processes are not homogeneous, and so some are best captured by symbolic models and others by connectionist models. Correspondingly, from a technological viewpoint, AI systems for practical applications can benefit greatly from a proper combination of different techniques combining, e.g., symbolic models (for capturing explicit knowledge) and connectionist models (for capturing implicit knowledge).

Use of the term *systematicity* in relation to connectionist networks originated with Fodor and Pylyshyn's critique of connectionist architecture. They claimed that human cognitive abilities are systematically related in a way that does not hold in connectionist networks, unlike formal systems akin to propositional logic. Systematicity of Generalizations in Connectionist Networks starts by noting that this critique made no reference to learning-based generalization, and then proceeds to examine claims and counterclaims concerning the claim that learning in connectionist architectures can engender systematicity. Special attention is paid to studies based on simple recurrent networks (SRNs) and recursive auto-associative memory (RAAM). The article suggests that, for now, evidence for systematicity in such simple networks is rather limited. Perhaps this is not so surprising, given that there is little evidence of systematicity in most animals, and animal brains are vastly more complex than SRNs or RAAMs. Compare "Language Evolution: The Mirror System Hypothesis" for a discussion of how evolution may have shaped the human brain to extend capabilities shared with other species to yield novel human cognitive abilities.

The notion of representation plays a central role in AI. As discussed in SEMANTIC NETWORKS, one classic form of representation in AI is the *semantic network*, in which nodes represent concepts and links represent relations between them. Semantic networks were originally developed for couching "semantic" information, either in the psychologist's sense of static information about concepts or in the semanticist's sense of the meanings of natural language sentences. However, they are also used as a general knowledge representation tool. The more elaborate types of semantic networks are similar in their representational abilities to sophisticated forms of symbolic logic. The article discusses various ways of implementing or emulating semantic networks in neural networks, and of forming hybrid semantic network-neural network systems. STRUCTURED CONNECTIONIST MODELS emphasizes those neural networks in which the translation from symbolic to neural is fairly direct: nodes become "neurons," but now processing is done by neural interactions rather than by an "inference engine" acting on a passive representation. At the other extreme, certain neural networks (connectionist, rather than biological) may transform input "questions" to output "answers" via the distributed activity of neurons whose firing conditions have no direct relationship to the concepts that might normally arise in a logical analysis of the problem (cf. "Past Tense Learning"). In the fully distributed version of the latter approach, each "item" (concept or mental object) is represented as a pattern of activity distributed over a common pool of nodes. However, if "John" and "Mary," for example, are represented as patterns of activity over the entire network such that each node in the network has a specific value in the patterns for "John" and "Mary," respectively, then how can the network represent "John" and "Mary" at the same time? To address such problems, the structured approach often employs small clusters of nodes that act as "focal" nodes for concepts and provide access to more elaborate structures that make up the detailed encoding of concepts (cf. "Localized Versus Distributed Representations"). The discussion of these varying styles of representation is continued in CONNECTIONIST AND SYMBOLIC REPRESENTATIONS. In symbolic representations, the heart of mathematics and many models of cognition, symbols are meaningless entities to which arbitrary significance may be assigned. Composing ordered tuples from symbols and other tuples allows us to create an infinitude of complex structures from a finite set of tokens and combination rules. Inference in the symbolic framework is founded on structural comparison and rule-governed manipulation of these objects. However, AI makes extensive use of nondeductive reasoning methods. Symbolists have moved to more complex formalizations of cognitive processes, using heuristic and unsound inference rules. Connectionists explore a radical alternative: that cognitive processes are mere epiphenomena of a completely different type of underlying system, whose operations can never be adequately formalized in symbolic language. The article examines representation and processing issues in the connectionist move from classical discrete, set-theoretic semantics to a continuous, statistical, vector-based semantics.

In symbolic AI, two concepts can be linked by providing a pointer between them. In a neural net, the problem of "binding" the two patterns of activity that represent the concepts is a more subtle one, and several models address the use of rapidly changing synaptic strengths to provide temporary "assemblages" of currently related data. This theme is developed not only in STRUCTURED CONNECTIONIST MODELS, but also in the articles COMPOSITIONALITY IN NEURAL SYSTEMS (how can inferences about a structure be based on the way it is composed of various elements?), and "Object Structure, Visual Processing" (combining visual elements of an object into a recognizable whole). DYNAMIC LINK ARCHITECTURE, the basic methodology, views the brain's data structure as a graph composed of nodes connected by links. Both units and links bear activity variables changing on the rapid time scale of fractions of a second. The nodes play the role of symbolic elements. The intensity of activity measures the degree to which a node is active in a given time interval, signifying the degree to which the meaning of the node is alive in the mind of the animal, while correlations of activity between nodes quantify the degree to which the signal of one node is related to that of others. The strength of links can change on two time scales, represented by two variables called temporary weight and permanent weight. The permanent weight corresponds to the usual synaptic weight, can change on the slow time scale of learning, and represents permanent memory. The temporary weight can change on the same time scale as the node activity—it is what makes the link dynamic. On this view, dynamic links constitute the glue by which higher data structures are built up from more elementary ones.

Complementing the theme of representation in symbolic AI has been that of planning, going from (representations of) the current state and some desired state to a sequence of operations that will transform the former to the latter. COMPETITIVE QUEUING FOR PLANNING AND SERIAL PERFORMANCE presents neural network studies based on two assumptions: that more than one plan representation can be simultaneously active in a planning layer, and that which plan to enact next is chosen as the most active plan representation by a competition in a second neural layer. Once a plan wins the competition and is used to initiate a response, its representation is deleted from the field of competitors in the planning layer, and the competition is re-run. This iteration allows the two-layer network to transform an initial activity distribution across plan representations into a serial performance. Such models provide a very different basis for control of serial behavior than that given by recurrent neural networks. The article suggests that such a system was probably an ancient invention in the evolution of animals yet may still serve as a viable core for the highest levels of planning and skilled sequencing exhibited by humans.

The final articles in this road map are not on neural nets per se, but instead provide related methods that add to the array of techniques extending AI beyond the serial, rule-based approach. BAYESIAN NETWORKS provides an explicit method for following chains of probabilistic inference such as those appropriate to expert systems, extending Bayes's rule for updating probabilities in the light of new evidence. The nodes in a Bayesian network represent propositional variables of interest and the links represent informational or causal dependencies among the variables. The dependencies are quantified by conditional probabilities for each node given its parents in the network. The network supports the computation of the probabilities of any subset of variables given evidence about any other subset, and the reasoning processes can operate on Bayesian networks by propagating information in any direction. GRAPHICAL MODELS: PROBABILISTIC INFERENCE introduces the graphical models framework, which has made it possible to understand the relationships among a wide variety of network-based approaches to computation, and in particular to understand many neural network algorithms and architectures as instances of a broader probabilistic methodology. Graphical models use graphs to represent and manipulate joint probability distributions. The graph underlying a graphical model may be directed, in which case the model is often referred to as a belief network or a Bayesian network, or the graph may be undirected, in which case the model is generally referred to as a Markov random field. The articles Graphical Models: Structure Learning and Graphical Models: Parameter Learning present learning algorithms that build on these inference algorithms and allow parameters and structures to be estimated from data. (A fuller précis of the three articles on graphical models can be found in the road map **Learning in Artificial Networks**.) Finally, Memory-Based Reasoning applies massively parallel computing to answer questions about a new situation by searching for data on the most similar stored instances. Memory-based reasoning (MBR) refers to a family of nearest-neighbor-like methods for making decisions or classifications. Where nearest-neighbor methods generally use a simple overlap distance metric, MBR uses variants of the value distance metric. MBR and neural nets form decision surfaces differently, and so will perform differently. MBR can become arbitrarily accurate if large numbers of cases are available, and if these cases are well behaved and properly categorized, whereas neural nets cannot respond well to isolated cases but tend to be good at smooth extrapolation. For each article reviewed in this paragraph, the reader may ponder whether these methods are alternatives to connectionist AI, or whether they can contribute to the emergence of a technologically efficacious hybrid. As stated before, where brain theory seeks to know "how the brain does it," AI must weigh the value of ANNs as a powerful technology for parallel, adaptive computation against that of other technologies on the basis of efficacy in solving practical problems on available hardware.

Synaptic Transmission
Temporal Dynamics of Biological Synapses

Nearly all the articles in the road maps **Psychology**, **Linguistics and Speech Processing**, and **Artificial Intelligence** discuss networks made of very simple neurons describable by a single internal variable, either binary or real-valued (the "membrane potential") and that communicate with other neurons by a simple (generally nonlinear) function of that variable, sometimes referred to as the firing rate. Incoming signals are usually summed linearly via "synaptic weights," and these weights in turn may be adjusted by simple learning rules, such as the Hebbian rule, the perceptron rule, or a reinforcement learning rule. Such simplifications remain valuable both for technological application of ANNs and for approximate models of large biological networks. Nonetheless, biological neurons are vastly more complex than these single-compartment models suggest. An appreciation of this complexity is necessary for the computational neuroscientist wishing to address the increasingly detailed database of experimental neuroscience. It is also important for the technologist looking ahead to the incorporation of new capabilities into the next generation of ANNs.

The neocortex is functionally parcellated into vertical columns (~0.5 mm in diameter) traversing all six layers. These columns have no obvious anatomical boundaries, and the topographic mapping of afferent and efferent pathways probably determines their locations and dimensions as well as their functions. Neocortex: Basic Neuron Types shows that these apparently stereotypical microcircuits are composed of a daunting variety of precisely and intricately interconnected neurons and argues that this neuronal diversification may provide a foundation for maximizing the computational abilities of the neocortex. All anatomical cell types can display multiple discharge patterns and molecular expression profiles. Different cell types are synaptically interconnected according to complex organizational principles to form intricate stereotypical microcircuits. The article challenges neural network modelers to incorporate and account for this cellular diversity and the role of different cells in the computational capability of cortical microcircuits. Neocortex: Chemical and Electrical Synapses summarizes the diverse functional properties of synapses in neocortex. These synapses tend to be small, but their structure and biochemistry are complex. Both chemical and electrical synapses exist in neocortex. *Chemical synapses* are the "usual synapses" of neural network models, and are far more abundant. They use a chemical neurotransmitter that is packaged presynaptically into vesicles, released in quantized (vesicle-multiple) amounts, and binds to postsynaptic receptors that either open an ion channel directly (voltage-dependent ion channels) or modulate the channel through an intracellular molecule that links the activated receptor to the opening or closing of the channel. The latter molecule is called a "second messenger," to contrast it with the case in which the transmitter itself provides a "primary message" that acts directly on the channel, in this case called "ligand-gated." Second-messenger-based synaptic interaction occurs on a slower time scale than ligand-gated interaction and is called *neuromodulation*, since it may modulate the behavior of the postsynaptic neuron over a time scale of seconds or minutes rather than milliseconds (cf. "Neuromodulation in Invertebrate Nervous Systems" and "Neuromodulation in Mammalian Nervous Systems"). The essential element of an *electrical synapse* is a protein called a connexin; 12 connexins form a single intercytoplasmic ion channel, and a cluster of such channels constitutes a gap junction. Electrical synapses provide a direct pathway that allows ionic current or small organic molecules to flow from the cytoplasm of one cell to that of another. Short-term dynamics allow synapses to serve as temporal filters of neural activity. Long-term synaptic plasticity provides specific, localized substrates for various forms of memory. Modulation of synaptic function by neurotransmitters (see "Neuromodulation in Mammalian Nervous Systems") provides a mechanism for globally altering the properties of a neural circuit during changes of behavioral state. Each of these functions has diverse forms that vary between synapses, depending on their site within the cortical circuit (and elsewhere in the brain).

Perspective on Neuron Model Complexity discusses the wide range of model complexity, from very simple to rather complex neuron models. Which model to choose depends, in each case, on the context, such as how much information we already have about the neurons under consideration and what questions we wish to answer. The use of more realistic neuron models when seeking functional insights into biological nervous systems does not mean choosing the most complex model, at least in the sense of including all known anatomical and physiological details. Rather, the key is to preserve the most significant distinctions between regions (soma, proximal dendritic, distal dendritic, etc.), using "compartmental modeling," whereby one compartment represents each functionally distinct region. SINGLE-CELL MODELS starts by reviewing the "simple" models of Part I (the McCulloch-Pitts, perceptron, and Hopfield models) and the slightly more complex polynomial neuron. It then turns to more realistic biophysical models, most of which are explored in further detail in this road map. These include the Hodgkin-Huxley model of squid axon, integrate-and-fire models, modified single-point models, cable and compartmental models, and models of synaptic conductances.

Before turning to a detailed analysis of mechanisms of neuronal function, we first consider an article that offers a high-level view of the neuron, but this time a stochastic one. Most nerve cells encode their output as a series of action potentials, or spikes, that originate at or close to the cell body and propagate down the axon at constant velocity and amplitude. DIFFUSION MODELS OF NEURON ACTIVITY studies the membrane potential of a single neuron as engaged in a stochastic process that will eventually bring it to the threshold for spike initiation. This leads to the first-passage-time problem, inferring the distribution of neuronal spiking based on the "first passage" of the membrane potential from its resting value to threshold. In addition to using stochastic differential equations, the article shows how the Wiener and Ornstein-Uhlenbeck neuronal models can be obtained as the limit of a Markov process with discrete state spaces. Besides these models, characterized by additive noise terms appearing in the corresponding stochastic differential equations, the article also reviews diffusion models with multiplicative noise, showing that these can be used not only for the description of steady-state firing under constant stimulation, but also for effects of periodic stimulation.

Now for the details of neuronal function. The ionic mechanisms underlying the initiation and propagation of action potentials were elucidated in the squid giant axon by a number of workers, most notably Hodgkin and Huxley. Variations on the Hodgkin-Huxley equation underlie the vast majority of contemporary biophysical models. AXONAL MODELING describes this model and its assumptions, introduces the two classes of axons (myelinated and nonmyelinated) found in most animals, and concludes by briefly commenting on the possible functions of axonal branching in information processing. The Hodgkin-Huxley equation was brilliantly inferred from detailed experiments on conduction of nerve impulses. Much research since then has revealed that the basis for these equations is provided by "channels," structures built from a few macromolecules and embedded in the neuron which, in a voltage-dependent way, can selectively allow different ions to pass through the cell membrane to change the neuron's membrane potential. Similarly, channels (also known in this case as receptors) in the postsynaptic membrane can respond to neurotransmitters, chemicals released from the presynaptic membrane, to change the neuron's local membrane potential in response to presynaptic input. These changes, local to the synapse, must propagate down the dendrites and across the cell body to help determine whether or not the axon will "pass threshold" and generate an action potential. ION CHANNELS: KEYS TO NEURONAL SPECIALIZATION notes that channels not only produce action potentials but can set a particular firing pattern, latency, rhythm, or oscillation for the firing of these spikes. Each neuronal class is endowed with a different set of channels, and the diversity of channels between different types of neurons explains the functional classes of neurons found in the brain. Some neurons fire spontaneously, some show adaptation, some fire in bursts, and so on. Therefore, a channel-based cellular physiology is relevant to questions about the role of different brain regions in overall function.

Biophysically detailed compartmental models of single neurons typically aim to quantitatively reproduce membrane voltages and currents in response to some sort of "synaptic" input. We may think of them as "Hodgkin-Huxley-Rall" models, based on the hypothesis of the neuron as a dynamical system of nonlinear membrane channels distributed over an electrotonic cable skeleton. Such models can incorporate as much biophysical detail as desired (or practical), but in general, all include some explicit assortment of voltage-dependent and transmitter-gated (synaptic) membrane channels. BIOPHYSICAL MECHANISMS IN NEURONAL MODELING first presents general issues regarding model formulations and data interpretation. It then describes the modeling of various features of Hodgkin-Huxley-Rall models, including Hodgkin-Huxley and Markov kinetic descriptions of voltage- and second-messenger-dependent ion channels as well as methods for describing intracellular calcium dynamics and the associated buffer systems and membrane pumps. The models for each of these mechanisms are at an intermediate level of biophysical detail, appropriate for describing macroscopic variables (e.g., membrane currents, ionic concentrations) on the scale of the entire cell or anatomical compartments thereof. Similar models of synaptic mechanisms are covered in SYNAPTIC INTERACTIONS, which provides kinetic models of how synaptic currents arise from ion channels whose opening and closing are controlled (gated) directly or indirectly by the release of neurotransmitter. The article compares several models of synaptic interaction, focusing on simple models based on the kinetics of postsynaptic receptors, and shows how these models capture the time courses of postsynaptic currents of several types of synaptic responses, as well as synaptic summation, saturation, and desensitization.

The membrane potential of central neurons undergoes synaptic noise, fluctuations that depend on both the summed firing of action potentials by neurons presynaptic to the investigated cell and the spontaneous release of transmitter. SYNAPTIC NOISE AND CHAOS IN VERTEBRATE NEURONS argues that, despite its random appearance, synaptic noise may be a true signal associated with neural coding, possibly a chaotic one. In addition to reviewing tools for detecting chaotic behavior, the article pays special attention to Mauthner cells, a pair of identified neurons in the hindbrain of teleost fishes. When the fish is subjected to an unexpected stimulus, one of the cells triggers an escape reaction. Their excitability is controlled by powerful inhibitory presynaptic interneurons that continuously generate an intense synaptic noise. While it is still an open question whether this synaptic noise exhibits deterministic chaos or is truly random, it is worth stressing that the "noise" has adaptive value for the fish: the variability along output pathways introduces uncertainty in the expression of the reflex, and therefore enhances the fish's success in evading predators.

TEMPORAL DYNAMICS OF BIOLOGICAL SYNAPSES complements the many studies of synaptic plasticity in the *Handbook* that focus on long-term changes in synaptic strength by showing how synaptic function can be profoundly influenced by activity over time scales of milliseconds to seconds. Synapses that exhibit such short-term plasticity are powerful computational elements that can have profound impact on cortical circuits (cf. "Dynamic Link Architecture"). Short-term plasticity includes both synaptic depression and a number of components of short-term enhancement (facilitation, augmentation, and posttetanic potentiation) acting over increasingly longer periods of time. Synaptic facilitation appears to result from enhanced transmitter release due to elevated presynaptic calcium levels, while depression is believed to result, in part, from depletion of a readily releasable pool of vesicles. Depression appears to be a particularly prominent feature of transmission at excitatory synapses onto pyramidal cells. In addition to having complex short-term dynamics, synapses are stochastic, and it is argued that constructive roles for unreliable transmission become apparent when short-term plasticity is considered in connection with stochastic transmission, with synapses acting as stochastic temporal filters of their presynaptic spike trains. Indeed, Synaptic Transmission is concerned with the uncertainties introduced by noise and their relation to synaptic plasticity. The probability that a single activated synapse will release neurotransmitter has a broad distribution, well fitted by a gamma function, with a mean near 0.3. The dynamic regulation of synaptic strength depends on a complicated set of mechanisms that record the history of synaptic use over many time scales, and serve to filter the incoming spike train in a way that reflects the past use of the synapse. The article provides equations which describe how synaptic use determines the number of vesicles available for release, and for the release probability in turn.

Oscillatory and Bursting Properties of Neurons offers a dynamic systems analysis of the linkage between a fascinating variety of endogenous oscillations (neuronal rhythms) and appropriate sets of channels. However, membrane potential oscillations with apparently similar characteristics can be generated by different ionic mechanisms, and a given cell type may display several different firing patterns under different neuromodulatory conditions. Here, membrane dynamics are described by coupled differential equations, the behavior modes by attractors (cf. "Computing with Attractors"), and the transitions between modes by bifurcations. The rest state is represented by a time-independent steady state, and repetitive firing is represented by a limit cycle. ("Silicon Neurons" shows how such differential equations can be directly mapped into an electronic circuit built using analog VLSI, to allow real-time exploration of the behavior of quite realistic neural models.)

Roughly a dozen different types of ion channels contribute to the membrane conductance of a typical neuron. Activity-Dependent Regulation of Neuronal Conductances takes as its starting point the fact that the electrical characteristics of a neuron depend on the number of channels of each type active within the membrane and on how these channels are distributed over the surface of the cell. A complex array of biochemical processes controls the number and distribution of ion channels by constructing and transporting channels, modulating their properties, and inserting them into and removing them from the neuron's membrane. The point to note here is that channels are small groupings of large molecules, and they are assembled on the basis of genetic instructions in the cell nucleus. Thus, changing which genes are active (i.e., regulating gene expression) can change the set of channels in a cell, and thus the characteristics of the cell. In fact, electrical activity in the cell can affect a range of processes, from activity-induced gene expression to activity-dependent modulation of assembled ion channels. Channel synthesis, insertion, and modulation are much slower than the usual voltage- and ligand-dependent processes that open and close channels. Thus, consideration of activity-dependent regulation of conductances introduces a dynamics acting on a new, slower time scale into neuronal modeling, a feedback mechanism linking a neuron's electrical characteristics to its activity. A similar theme is developed in Biophysical Mosaic of the Neuron, which is structured around the metaphor of the mosaic neuron. A mosaic is a collection of discrete parts, each with unique properties, that are fitted together in such a way that an image emerges from the whole in a nonobvious way. Similarly, the neuronal membrane is packed with a diversity of receptors and ion channels and other proteins with a recognizable distribution. In addition, the cytoplasm is not just water with ions, but a mosaic of interacting molecular systems that can directly affect the functional properties of membrane proteins. The argument is that, just as a mosaic painting provokes perception of a complete image out of a maze of individually diversified tiles, so a given neuron performs a well-defined computational role that depends not only on the network of cells in which it is embedded, but also to a large extent on the dynamic distribution of macromolecules throughout the cell.

Dendritic Processing focuses on dendrites as electrical input-output devices that operate on a time scale range of several to a few hundred milliseconds. (See "Dendritic Learning" for modeling of the plasticity of dendritic function and the assertion that the concept of "overall connection strength between two neurons" is ill-defined, since it is the distribution of synapses in relation to dendritic geometry that proves crucial.) The input to a dendrite consists of temporal patterns of synaptic inputs spatially distributed over the dendritic surface, whereas the output is (except, for example, in the case of dendrodendritic interactions) an ionic current delivered to the soma for transformation there, via a threshold mechanism, to a train of action potentials at the axon. The article discusses how the morphology, electrical properties, and synaptic inputs of dendrites interact to perform their input-output operation. It uses cable theory and compartmental modeling to model the spread of electric current in dendritic trees. The variety of excitable (voltage-gated) channels that are found in many types of dendrites enrich the computational capabilities of neurons, with interaction proceeding in both directions, away from and toward the soma. Computer modeling methods for neurons offer numerical methods for solving the equations describing branched cables. Dendritic Spines are short appendages found on the dendrites of many different cell types. They are composed of a bulbous "head" connected to the dendrite by a thin "stem." An excitatory synapse is usually found on the spine head, and some spines also have a second, usually inhibitory, synapse located on or near the spine stem. Models in which the spine is represented as a passive electrical circuit show that the large resistance of a thin spine stem can attenuate a synaptic input delivered to the spine head. Other models address calcium diffusion and plasticity in spines. Current research focuses on the hypothesis that the spine stem provides a diffusional resistance that allows calcium to become concentrated in the spine head and calcium-dependent reactions to be localized to the synapse. This could be very important for plasticity changes, such as those that occur with long-term potentiation.

Temporal Dynamics of Biological Synapses

Most studies of learning in ANNs involve a variety of learning rules, inspired in great part by the psychological hypotheses of

Hebb and Rosenblatt (cf. Section I.3) about ways in which synaptic connections may change their strength as a result of experience. In recent years, much progress has been made in tracing the processes that underlie the plasticity of synapses of biological neurons. The present road map samples this research together with related modeling. Although the emphasis will be on synaptic plasticity, several articles stress the role of axonal growth in forming new connections, and the road map closes with an article suggesting that changes in location of synapses may be just as important as changes in synaptic strength.

Hebb's idea was that a synapse (what we would now call a Hebbian synapse) strengthens when the presynaptic and postsynaptic elements tend to be coactive. The plausibility of this hypothesis has been enhanced by the neurophysiological discovery of a synaptic phenomenon in the hippocampus known as long-term potentiation (LTP), which is induced by a Hebbian mechanism. Hebb's postulate has received various modifications to address, e.g., the saturation problem.

Hebbian Synaptic Plasticity shows that a variety of experimental networks ranging from the abdominal ganglion in the invertebrate *Aplysia* to visual cortex and the CA1 region of hippocampus offer converging validation of Hebb's postulate on strengthening synapses by (more or less) coincident presynaptic and postsynaptic activity. In these networks, similar algorithms of potentiation can be implemented using different cascades of second messengers triggered by activation of synaptic and/or voltage-dependent conductances. Most cellular data supporting Hebb's predictions have been derived from electrophysiological measurements of composite postsynaptic potentials or synaptic currents, or of short-latency peaks in cross-correlograms, which cannot always be interpreted simply at the synaptic level. The basic conclusion of these experiments is that covariance between pre- and postsynaptic activity upregulates and downregulates the "effective" connectivity between pairs of functionally coupled cells. The article thus suggests that what changes according to a correlational rule is not so much the efficacy of transmission at a given synapse, but rather a more general coupling term mixing the influence of polysynaptic excitatory and inhibitory circuits linking the two cells, modulated by the diffuse network background activation. Replacing this composite interaction by a single coupling term defines an ideal Hebbian synapse.

The crucial role played in the CA1 form of LTP by channels called NMDA receptors in the synapses is further explained in NMDA Receptors: Synaptic, Cellular, and Network Models. NMDA receptors are subtypes of receptors for the excitatory neurotransmitter glutamate and are involved in diverse physiological as well as pathological processes. They mediate a relatively "slow" excitatory postsynaptic potential, and act as coincidence detectors of presynaptic and postsynaptic activity. The interactions between the slow NMDA-mediated and fast AMPA-mediated currents provide the basis for a range of dynamic properties that contribute to diverse neuronal processes. NMDA receptors have attracted much interest in neuroscience because of their role in learning and memory. Their ability to act as coincidence detectors make them an ideal molecular device for producing Hebbian synapses. The article reviews data related to the biological characteristics of NMDA receptors and models that have been used to describe their function in isolated membrane patches, in neurons, and in complex circuits.

A classic problem with Hebb's original rule is that it only strengthens synapses. But this means that all synapses would eventually saturate, depriving the cell of its pattern separation ability. A number of biologically inspired responses to this problem are described in the next two articles. Hebbian Learning and Neuronal Regulation stresses that, for both computational and biological reasons, Hebbian plasticity will involve many synapses of the same neuron. Biologically, synaptic interactions are inevitable as synapses compete for the finite resources of a single neuron. Computationally, neuron-specific modifications of synaptic efficacies are required in order to obtain efficient learning, or to faithfully model biological systems. Hence neuronal regulation, a process modulating all synapses of a postsynaptic neuron, is a general phenomenon that complements Hebbian learning. The article shows that neuronal regulation may answer important questions, such as: What bounds the positive feedback loop of Hebbian learning and guarantees some normalization of the synaptic efficacies of a neuron? How can a neuron acquire specificity to particular inputs without being prewired? How can memories be maintained throughout life while synapses suffer degradation due to metabolic turnover? In unsupervised learning, neuronal regulation allows for competition between the various synapses on a neuron and leads to normalization of their synaptic efficacies. In supervised learning, neuronal regulation improves the capacity of associative memory models and can be used to guarantee the maintenance of biological memory systems. Our basic tour of Hebbian learning concludes with Post-Hebbian Learning Algorithms. This article starts by observing that Hebb's original postulate was a verbally described phenomenological rule, without specification of detailed mechanisms. Subsequent work has shown the computational usefulness of many variations of the original learning rule. This article presents background material on conditioning, neural development, and physiologically realistic cellular-level learning phenomena as a prelude to a review of several families of rules providing computational implementations of Hebbian-inspired rules.

Cerebellum and Motor Control reviews a number of models for cerebellar mechanisms underlying the learning of motor skills. Cerebellum can be decomposed into cerebellar nuclei and a cerebellar cortex. The only output cells of the cerebellar cortex are the Purkinje cells, and their only effect is to provide varying levels of inhibition on the cerebellar nuclei. Each Purkinje cell receives two types of input: a single climbing fiber, and many tens of thousands of parallel fibers. The most influential model of cerebellar cortex has been the Marr-Albus model of the formation of associative memories between particular patterns on parallel fiber inputs and Purkinje cell outputs, with the climbing fiber acting as "training signal." Later models place more emphasis on the relation between the cortex and nuclei, and on the way in which the subregions of this coupled cerebellar system can adapt and coordinate the activity of specific motor pattern generators. The plasticity of the cerebellum is approached from a different direction in Cerebellum and Conditioning. Many experiments indicate that the cerebellum is involved in learning and performance of classically conditioned reflexes; the present article reviews a number of models of the role of cerebellum in rabbit eyelid conditioning. (A more general perspective on conditioning is given in Conditioning and described more fully in the road map **Psychology**, which describes several formal theories and neural network models for classical and operant conditioning.) Inspired by the Marr-Albus hypothesis, neurophysiological research eventually showed that coincidence of climbing fiber and parallel fiber activity on a Purkinje cell led to long-term depression (LTD) of the synapse from parallel fiber to Purkinje cell. Cerebellum: Neural Plasticity offers readers an exhaustive overview of the data on the neurochemical mechanisms underlying this form of plasticity. The authors conclude that the timing conditions for LTD induction may account for the temporal specificity of cerebellar motor learning, and suggest that an important future development in the field will be to study developmental aspects of LTD in relation to acquisition of motor skills. However, the article cites only one model of LTD. It is clear that there are immense challenges to neural modelers in exploring the implications of the plethora of neurochemical interactions swirling about this single class of synaptic plasticity and, by implication, the variety of different mechanisms expressed elsewhere in the nervous system.

There is now strong evidence for a process of short-term memory (STM) involved in performing tasks requiring temporary storage and manipulation of information to guide appropriate actions. Short-Term Memory addresses three issues: What are the different types of STM traces? How do intrinsic and synaptic mechanisms contribute to the formation of STM traces? How do STM traces translate into long-term memory representation of temporal sequences? The stress is on the computational mechanisms underlying these processes, with the suggestion that these mechanisms may well underlie a wide variety of seemingly different biological processes. The article examines both the short-term preservation of patterns of neural firing in a circuit and ways in which short-term maintained activity may be transferred into long-term memory traces.

There is no hard and fast line between the cellular mechanisms underlying the development of the nervous system and those involved in learning. Nonetheless, the former emphasizes the questions of how one part of the brain comes to be connected to another and how overall patterns of connectivity are formed, while the latter tends to regard the connections as in place, and asks how their strengths can be modified to improve the network's performance. Studies of regeneration—the reforming of connections after damage to neurons or cell tracts—are thus associated more with developmental mechanisms than with learning per se. Another significant area of research that complements development is that of aging, but there is still too little work relating aging to neural modeling.

Study of the regeneration of retinotopic eye-brain maps in frogs (i.e., neighboring points in the frog retina map, in a one-to-many fashion, to neighboring points in the optic tectum) has been one of the most fruitful areas for theory-experiment interaction in neuroscience. Following optic nerve section, optic nerve fibers tended to regenerate connections with those target neurons to which they were connected before surgery, even after eye rotation. This suggests that each cell in both retina and tectum has a unique chemical marker signaling 2D location, and that retinal axons seek out tectal cells with the same positional information. However, in experiments in which lesions were made in goldfish retina or tectum, it was found that topographic maps regenerated in conformance with whatever new boundary conditions were created by the lesions; e.g., the remaining half of a retina would eventually connect in a retinotopic way to the whole of the tectum, rather than just to the half to which it was originally connected. Although there is wide variation between species in the degree of order existing in the optic nerve, it is almost always the case that the final map in the tectum is ordered to a greater extent than is the optic nerve. Theory and experiment paint a subtle view in which genetics sets a framework for development, but the final pattern of connections depends both on boundary conditions and on patterns of cellular activity. This view is now paradigmatic for our understanding of how patterns of neural connectivity are determined. The development of such maps appears to proceed in two stages: the first involves axon guidance independent of neural activity; the second involves the refinement of initially crude patterns of connections by processes dependent on neural activity. Axonal Path Finding focuses on the former events, while Development of Retinotectal Maps discusses the latter. Understanding the molecular basis of retinotectal map formation has been transformed since the appearance of the first edition of the *Handbook* by discoveries centering on ephrins and the corresponding Eph receptors. The Eph/ephrins come in two families, A and B, with the A family important for mapping along the rostral-caudal axis of the tectum, while the B family may be important for mapping along the dorsal-ventral axis. Most models of development of retinotectal maps take synaptic strengths as their primary variable between arrays of retinal and tectal locations, with initial synaptic strengths then updated according to rules that depend in various ways on correlated activity, competition for tectal space, molecular gradients, and fiber-fiber interactions. However, actual movement or branching of axons to find their correct targets is rarely considered. Thus, future computational models of retinotectal map formation should take into account data on Eph receptors and ephrin ligands, data on the guidance of retinal axons that enter the tectum by ectopic routes, and the results of retinal and tectal ablation and transplantation experiments. Up to now, the great majority of theoretical work in the neural network tradition has focused on changes in synaptic strengths within a fixed connectional architecture, but how axons chart their initial path toward the correct target structure has generally not been addressed. Axonal Path Finding reviews recent experimental work addressing how retinal ganglion cell axons find the optic disk, how they then exit the retina, why they grow toward the optic chiasm, why some then cross at the midline while others do not, and so on—a body of knowledge that now has the potential to be framed and interpreted in terms of theoretical models. Whereas work in neural networks has usually focused on processes such as synaptic plasticity that are dependent on neural activity, models for axon guidance must generally be phrased in terms of activity-independent mechanisms, particularly guidance by molecular gradients. Many fundamental questions remain unresolved, for which theoretical models have the potential to make an important contribution. What is the minimum gradient steepness detectable by a growth cone, and how does this vary with the properties of the receptor-ligand interaction and the internal state of the growth cone? How is a graded difference in receptor binding internally converted into a signal for directed movement? And, how do axons integrate multiple cues?

Ocular Dominance and Orientation Columns studies two issues that go beyond basic map formation to provide further insight into activity-dependent development. When cells in layer IVc of visual cortex are tested to see which eye drives them more strongly, it is found that ocular dominance takes the form of a zebra-stripe-like pattern of alternating dominance. Model and experiment support the view that the stripes are not genetically specified but instead form through network self-organization. Another classic example is the formation of orientation specificity. A number of models are reviewed in light of current data, both theoretical analysis based on the idea that leading eigenvectors dominate (cf. "Pattern Formation, Biological" and "Pattern Formation, Neural") and computer simulations.

Temporal Dynamics of Biological Synapses complements the many studies of synaptic plasticity in the *Handbook* that focus on long-term changes in synaptic strength by showing the importance of fast synaptic changes over time scales of milliseconds to seconds. Short-term plasticity includes both synaptic depression and a number of components of short-term enhancement (facilitation, augmentation, and posttetanic potentiation) acting over increasingly longer periods of time. In addition to having complex short-term dynamics, synapses are stochastic (see "Synaptic Transmission"), and it is argued that constructive roles for unreliable transmission become apparent when short-term plasticity is considered in connection with stochastic transmission, with synapses acting as stochastic temporal filters of their presynaptic spike trains. Dynamic Link Architecture develops the theme of fast synaptic changes at the level of network function, viewing the brain's data structure as a graph composed of nodes connected by links whose strength can change on two time scales, represented by two variables called temporary weight and permanent weight. The permanent weight corresponds to the usual synaptic weight, can change on the slow time scale of learning, and represents permanent memory. The temporary weight can change on the same time scale as the node activity, providing the dynamic links that, according to this model, constitute the glue by which higher data structures are built up from more elementary ones.

Information Theory and Visual Plasticity demonstrates some features of information theory that are relevant to the relaying of information in cortex and presents cases in which information theory led people to seek methods for Gaussianizing the input distribution and, in other cases, to seek learning goals for non-Gaussian distributions. The MDL principle (see "Minimum Description Length Analysis") was presented as a learning goal which takes into account the complexity of the decoding network. In particular, the article connects entropy-based methods, projection pursuit, and extraction of simple cells in visual cortex.

As can be seen from the above, neural network models of development and regeneration have been dominated by studies of the visual system. The next article, however, takes us to the somatosensory system. Research in the past decade has demonstrated plastic changes at all levels of the adult somatosensory system in a wide range of mammalian species. Changes in the relative levels of sensory stimulation as a result of experience or injury produce modifications in sensory maps. Somatotopy: Plasticity of Sensory Maps discusses which features of somatotopic maps change and under what conditions, the mechanisms that may account for these changes, and the functional consequences of sensory map changes.

Just as the giant squid axon provided invaluable insights into the active properties of neural membrane summarized in the Hodgkin-Huxley equation, so have invertebrates provided many insights into other basic mechanisms (see "Neuromodulation in Invertebrate Nervous Systems" and "Crustacean Stomatogastric System" for two examples). Invertebrate Models of Learning: *Aplysia* and *Hermissenda* does the same for basic learning mechanisms. A ganglion (localized neural network) of these invertebrates can control a variety of different behaviors, yet a given behavior such as a withdrawal response may be mediated by 100 neurons or less. Moreover, many neurons are relatively large and can be uniquely identified, functional properties of an individual cell can be related to a specific behavior, and changes in cellular properties during learning can be related to specific changes in behavior. Biophysical and molecular events underlying the changes in cellular properties can then be determined and mathematically modeled. The present article illustrates this with studies of two gastropod mollusks: associative and nonassociative modifications of defensive siphon and tail withdrawal reflexes in *Aplysia* and associative learning in *Hermissenda*.

Habituation describes one of the simplest forms of learning, the progressive decrement in a behavioral response with repeated presentations of the eliciting stimulus, and reveals the complexity in this apparent simplicity. This article reviews the fundamental characteristics of habituation and describes experimental preparations in which the neural basis of habituation has been examined as well as attempts to model habituation. Experimental studies have identified at least two important neural mechanisms of habituation, homosynaptic depression within the reflex circuit and extrinsic descending modulatory input. A number of systems are put forward as good candidates for future modeling. Habituation of defensive reflexes was among the first types of learning explained successfully at the cellular level. Habituation in the crayfish tail-flip reflex, due to both afferent depression as well as descending inhibition, offers the opportunity to analyze the interaction and cooperativity of mechanisms intrinsic and extrinsic to the reflex circuit. The nematode *C. elegans* offers the possibility of a genetic analysis of habituation.

As shown in "Dendritic Processing," dendrites are highly complex structures, both anatomically and physiologically, and are the principal substrates for information processing within the neuron. Dendritic Learning assesses the consequences of axodendritic structural plasticity for learning and memory, countering the view that neural plasticity is limited to the strengthening and weakening of existing synaptic connections. In particular, the article supports the view that long-term storage may involve the correlation-based sorting of synaptic contacts onto the many separate dendrites of a target neuron. In the models offered in this article, the output of the cell represents the sum of a moderately large set of separately thresholded dendritic subunits, so that a single neuron as modeled here is equivalent to a conventional ANN built from two layers of point neurons. As a result, the concept of "overall connection strength between two neurons" is no longer well defined, for it is the distribution of synapses in relation to dendritic geometry that proves crucial.

Sensory Coding and Information Transmission
Sparse Coding in the Primate Cortex
Synchronization, Binding and Expectancy
Synfire Chains

In the McCulloch-Pitts neuron, the output is binary, generated on a discrete-time scale; at the other extreme, the Hodgkin-Huxley equations can create a dazzling array of patterns of axonal activity in which the shape as well as the timing of each spike is continuously variable. In between, we have models such as the leaky integrator model, in which only the rate of firing of a cell is significant, while in the spiking neuron model the timing but not the shape of spikes is continuously variable. This raises the question of how sensory inputs and motor outputs, let alone "thoughts" and other less mental intervening variables, are coded in neural activity. In answering this question, we must not only seek to understand the significance of the firing pattern of an individual neuron but also probe how variables may be encoded in patterns of firing distributed across a whole population of neurons.

Retinotopic feature maps are the norm near the visual periphery and up into the early stages of the visual cortex. Here, the firing of a cell peaks for stimuli that fall on a specific patch of the retina and also for a specific feature. Perhaps the most famous example of this is provided by the simple cells discovered in visual cortex by Hubel and Wiesel, which are edge-sensitive cells tuned both for the retinal position and orientation of the edge. In such studies, the cell is characterized by its firing rate during presentation of the stimulus. Similar results are seen for other feature types (see "Feature Analysis") and other sensory systems. The issue of how other information may be coded by activity in the nervous systems of animals is addressed in a number of articles. Localized Versus Distributed Representations asks whether the final neural encoding of visual recognition of one's grandmother, say, involves neurons that respond selectively to "grandmother"—so-called "grandmother cells"—or whether the sight of grandmother is never made explicit at the single neuron level, with the representation instead distributed across a large number of cells, none of which responds selectively to "grandmother" alone. Few neuroscientists argue that individual neurons might explicitly represent particular objects, but many connectionists have used localist representations to model phenomena that include word and letter perception, although they generally insist that the units in their models are not real neurons. The article examines neurophysiological evidence that both distributed and local coding are used in high-order visual areas and then goes "against the stream" by forwarding computational reasons for preferring representations that are more localist in some parts of the brain, before examining how work on temporal coding schemes has changed the nature of the local versus distributed debate. SPARSE CODING IN THE PRIMATE CORTEX marshals theoretical reasons and experimental evidence suggesting that the brain adopts a compromise between distributed and local representations that is often referred to as *sparse coding*. This thesis is illustrated with data on object recognition and face recognition in inferotemporal cortex (the "what" pathway) in monkey.

Perhaps the best-known example of motor coding is that described in MOTOR CORTEX: CODING AND DECODING OF DIRECTIONAL OPERATIONS for the relation between the direction of reaching and changes in neuronal activity that have been established for several brain areas, including the motor cortex. The cells involved each have a broad tuning function the peak of which is considered to be the "preferred" direction of the cell. A movement in a particular direction will engage a whole population of cells. It is found that, during discrete movements in 2D and 3D space, the weighted vector sum of these neuronal preferences is a "population vector" which points in (close to) the direction of the movement. Such examples underlie the more general analysis given in POPULATION CODES. Population codes are computationally appealing both because the overlap among the neurons' tuning curves allows precise encoding of values that fall between the peaks of two adjacent tuning curves and because many cortical functions, such as sensorimotor transformations, can be easily modeled with population codes. The article focuses on decoding, or reading out, population codes. Neuronal responses are noisy, leading to the need for good estimators for the encoded variables. The article reviews the various estimators that have been proposed, and considers their neuronal implementations. Moreover, there are cases where it is reasonable to assume that population activity codes for more than just a single value, and could even code for a whole probability distribution. The goal of decoding is then to recover an estimate of this probability distribution.

INTEGRATE-AND-FIRE NEURONS AND NETWORKS shows how these models offer potential principles of coding and dynamics. At the single neuron level, it is shown that coherent input is more efficient than incoherent spikes in driving a postsynaptic neuron. Questions discussed for homogeneous populations include conditions under which it is possible, in the absence of an external stimulus, to stabilize a population of spiking neurons at a reasonable level of spontaneous activity, and the relation of frequency of collective oscillations to neuronal parameters, and how rapidly population activity responds to changes in the input. An extension to mixed excitatory/inhibitory populations as found in the cortex is also discussed. SYNCHRONIZATION, BINDING AND EXPECTANCY argues that the "binding" of cells that correspond to features of a given visual object may exploit another dimension of cellular firing, namely, the phase at which a cell fires within some overall rhythm of firing. The article presents data consistent with the proposal that the synchronization of responses on a time scale of milliseconds provides an efficient mechanism for response selection and binding of population responses. Synchronization also increases the saliency of responses because it allows for effective spatial summation in the population of neurons receiving convergent input from synchronized input cells. SYNFIRE CHAINS were introduced to account for the appearance of precise firing sequences with long interspike delays, dealing with the ways in which such chains might be generated, activity propagation along the chain, how synfire chains can be used to compute, and how they might be detected in electrophysiological recordings. A synfire chain is composed of many pools (or layers) of neurons connected in a feedforward fashion. In a random network with moderate connectivity, many synfire chains can be found by chance, but such random synfire chains may not function reproducibly unless the synaptic connections are strengthened by some appropriate learning rule. A given neuron can participate in more than one synfire chain. The extent to which such repeated membership can take place without compromising reproducibility is known as the *memory capacity* of synfire chains. Synfire chains may be considered a special case of the "cell assembly" suggested by Hebb. However, in Hebb's concepts the cell assembly was a network with multiple feedback connections, whereas the synfire chain is a feedforward net. This allows for much faster computations by synfire chains. While noting that there have also been criticisms of the theory, the article argues that classical anatomy and physiology of the cortex sustain the idea that activity may be organized in synfire chains and that one can create compositional systems from synfire chains.

RATE CODING AND SIGNAL PROCESSING investigates ways in which the sequence of spike occurrence times may encode the information that a neuron communicates to its targets. Spike trains are often quite variable under seemingly identical stimulation conditions. Does this variability carry information about the stimulus? The term *rate coding* is applied in situations where the precise timing of spikes is thought not to play a significant role in carrying sensory information. The article analyzes the sensory information conveyed by two types of rate codes, mean firing rate codes and instantaneous firing rate codes, by adapting classical methods of statistical signal processing to the analysis of neuronal spike trains. While focusing on various examples of rate coding, such as that of neurons of weakly electric fish sensitive to electrical field amplitude, the article also notes cases in which spike timing plays a crucial role.

Recent years have seen an increasing number of quantitative studies of neuronal coding based on Shannon's information theory, in which the "information" or "entropy" of a message is a purely statistical measure based on the probability of the message within an ensemble: the less likely the message is to occur, the greater its information content. SENSORY CODING AND INFORMATION TRANSMISSION reviews two recent approaches to measuring transmitted information. The first is based on direct estimation of the spike train entropies in terms of which transmitted information is defined; the second is based on an expansion to second order in the length of the spike trains. The meaning of any signal that we receive from our environment is modulated by the context within which it appears. ADAPTIVE SPIKE CODING explores the analysis of "context" as the statistical ensemble in which the signal is embedded. Interpreting a message requires both registering the signal itself and knowing something about this statistical ensemble. The relevant temporal or spatial ensemble depends on the task. Information theoretically, representations that appropriately take into account the statistical properties of the incoming signal are more efficient (see OPTIMAL SENSORY ENCODING and "Information Theory and Visual Plasticity"). The article focuses on neural adaptation, reversible change in the response properties of neurons on short time scales. Since the first observations of adaptation in spiking neurons, it had been suggested that adaptation serves a useful function for information processing, preventing a neuron from continuing to transmit redundant information, viewing both the filtering and the threshold function of a neuron as adaptive functions of the input that may implement the goal of increasing information transmission. Issues include adaptation to the stimulus distribution, with the information about the ensemble read off from the statistics of spike time differences; the separation of different time scales in adaptation; and adaptation of receptive fields. The article also explores the role of calcium and of channel dynamics in providing adaptation mechanisms.

OPTIMAL SENSORY ENCODING focuses on the visual system, seeking to understand what type of data encoding for signals passing from retina to cerebral cortex could reduce the data rate without significant information loss, exploiting the fact that nearby image pixels tend to convey similar signals and thus carry redundant information. One strategy is to transform the original redundant signal (e.g., in photoreceptors) to nonredundant signals in the retinal ganglion cells or cortical neurons, as in the Infomax proposal. The article presents different coding schemes with different advantages. The retinal code has the advantage of small and identical receptive field (RF) shapes, involving shorter neural wiring and easier specifications. The cortical multiscale code is preferred when invariance is needed for objects moving in depth. Again, whereas the Infomax principle applies well to explain the RFs of the more numerous class of retinal ganglion cells, the P cells in monkeys or X cells in cats, another class of ganglion cells, M cells in monkeys or Y cells in cats, have RFs that are relatively larger, color unselective, and tuned to higher temporal frequencies. These M cells do not extract the maximum information possible (Infomax) about the input but can serve to extract the information as quickly as possible. It is argued that information theory is more likely to find its application in the early stages of the sensory processing, before information is selected or discriminated for any specific cognitive task, and that optimal sensory coding in later stages of sensory pathways will depend on cognitive tasks that require applications of alternative theories.

Temporal Integration in Recurrent Microcircuits

We turn now to studies of biological neural networks, a study complemented by articles in the road map **Mammalian Brain Regions** and in other road maps on sensory systems, memory, and motor control.

Cortical Hebbian Modules models the activity seen in cortical networks during the delay period following the presentation of the stimulus in a delay match-to-sample or delay eye-movement task. The rates observed are in the range of about 10–20 spikes/s, with the subset of neurons that sustain elevated rates being selective of the sample stimulus and concentrated in localized columns in associative cortex. The article shows how to model these selective activity distributions through the autonomous local dynamics in the column. The model presents neural elements and synaptic structures that can reproduce the observed neuronal spike dynamics; showing how Hebbian synaptic dynamics can give rise, in a process of training, to a synaptic structure in the local module capable of sustaining selective activity during the delay period. The mathematical framework for the analysis is provided by the mean field theory of statistical mechanics.

Layered Computtion in Neural Networks abstracts from the biology to present a general framework for modeling computations performed in layered structures (which occur in many parts of the vertebrate and invertebrate brain, including the optic tectum, the avian visual wulst, and the cephalopod optic lobe, as well as the mammalian cerebral cortex). A general formalism is presented for the connectivity between layers and the dynamics of typical units of each layer. Information processing capabilities of neural layers include filter operations; lateral cooperativity and competition that can be used in, e.g., stereo vision and winner-take-all; topographic mapping that underlies the allocation of cortical neurons to different parts of the visual field (fovea/periphery), or the processing of optic flow patterns; and feature maps and population coding, which may be applied both to sensory systems and to "motor fields" of neurons so that the flow of activity in motor areas can predict initiated movements. In a related vein, Cortical Population Dynamics and Psychophysics describes cortical population dynamics in the form of structurally simple differential equations for the neurons' firing activities, using a model class introduced by Wilson and Cowan. The Wilson-Cowan model is powerful enough to reproduce a variety of cortical phenomena and captures the dynamics of neuronal populations seen in a variety of experiments, yet simple enough to allow for analytical treatment that yields an understanding of the mechanisms leading to the observed behavior. The model is applied here to explain dynamical properties of the primate visual system on different levels, reaching from single neuron properties like selectivity for the orientation of a stimulus up to higher cognitive functions related to the binding and processing of stimulus features in psychophysical discrimination experiments.

Hippocampal Rhythm Generation notes that global brain states in both normal and pathological situations may be associated with spontaneous rhythmic activities of large populations of neurons. This article presents data and models on the main such states associated with the hippocampus: the two main normally occurring states—the theta rhythm with the associated gamma oscillation, and the irregular sharp waves (SPW) with the associated high-frequency (ripple) oscillation—and a pathological brain state associated with epileptic seizures. Several different modeling strategies are compared in studying rhythmicity in the hippocampal CA3 region.

Sleep Oscillations analyzes cortical and thalamic networks at multiple levels, from molecules to single neurons to large neuronal assemblies, with techniques ranging from intracellular recordings to computer simulations, to illuminate the generation, modulation, and function of brain oscillations. Sleep is characterized by synchronized events in billions of synaptically coupled neurons in thalamocortical systems. The early stage of quiescent sleep is associated with EEG spindle waves, which occur at a frequency of 7 to 14 Hz; as sleep deepens, waves with slower frequencies appear on the EEG. The other sleep state, associated with rapid eye movements (REM sleep) and dreaming, is characterized by abolition of low-frequency oscillations and an increase in cellular excitability, very much like wakefulness, although motor output is markedly inhibited. Activation of a series of neuromodulatory transmitter systems during arousal blocks low-frequency oscillations, induces fast rhythms, and allows the brain to recover full responsiveness.

It is a truism that similarity of input-output behavior is no guarantee of similarity of internal function in two neural networks. In particular, a recurrent neural network trained by backpropagation to mimic some biological function may have little internal resemblance to the neural networks responsible for that function in the living brain. Nonetheless, Recurrent Networks: Neurophysiological Modeling demonstrates that dynamic recurrent network models (see "Recurrent Networks: Learning Algorithms" for the formal background) can provide useful tools to help systems neurophysiologists understand the neural mechanisms mediating behavior. Biological experiments typically involve bits of the system; neural network models provide a method of generating working models of the complete system. Confidence in such models is increased if they not only simulate dynamic sensorimotor behavior but also incorporate anatomically appropriate connectivity. The utility of such models is illustrated in the analysis of four types of biological function: oscillating networks, primate target tracking, short-term memory tasks, and the construction of neural integrators.

As is evident in the road map **Biological Neurons and Synapses**, not all neurons are alike: they show a rich variety of conductances that endow them with different functional properties. These properties and hence the collective activity of interacting groups of neurons are not fixed, but are instead subject to modulation. The term *neuromodulation* usually refers to the effect of neurochemicals such as acetylcholine, dopamine, norepinephrine, and serotonin, and other substances, including neuropeptides. By contrast with the rapid transmission of information through the nervous system by excitatory and inhibitory synaptic potentials, neuromodulators primarily activate receptor proteins, which do not contain an ion channel (metabotropic receptors). These receptors in turn activate enzymes, which change the internal concentration of substances called second messengers. Second messengers cause slower and longer-lasting changes in the physiological properties of neurons, resulting in changes in the processing characteristics of the neural circuit. NEUROMODULATION IN INVERTEBRATE NERVOUS SYSTEMS stresses that the sensory information an animal needs depends on a number of factors, including its activity patterns and motivational state. The modulation of the sensitivities of many sensory receptors is shown for a stretch receptor in crustaceans. Modulators can activate, terminate, or modify rhythmic pattern-generating networks. One example of such "polymorphism" is that neuromodulation can reconfigure the same network to produce either escape swimming or reflexive withdrawal in the nudibranch mollusk *Tritonia*. Mechanisms and sites of neuromodulation include alteration of intrinsic properties of neurons, alteration of synaptic efficacy by neuromodulators, and modulation of neuromuscular junctions and muscles. All this makes clear the subtlety of neuronal function that must be addressed by computational neuroscience and that may inspire the design of a new generation of artificial neurons. Turning to the mammalian brain, we find that the anatomical distribution of fibers releasing neuromodulatory substances in the brain is usually very diffuse, with the activity of a small number of neuromodulatory neurons influencing the functional properties of broad regions of the brain. NEUROMODULATION IN MAMMALIAN NERVOUS SYSTEMS starts by summarizing physiological effects of neuromodulation, including effects on resting membrane potential of pyramidal cells and interneurons, spike frequency adaptation, synaptic transmission, and long-term potentiation. It is stressed that the effect of a neurochemical is receptor dependent: a single neuromodulator such as serotonin can have dramatically different effects on different neurons, depending on the type of receptor it activates. Indeed, a chemical may function as a neurotransmitter for one receptor and as a neuromodulator for another. The second half of the article reviews neural network models that help us understand how neuromodulatory effects that appear small at the single neuron level may have a significant effect on dynamical properties when distributed throughout a network. The article reviews several different models of the function of modulatory influences in neural circuits, including noradrenergic modulation of attentional processes (strangely, noradrenergic neurons are those sensitive to norepinephrine), dopaminergic modulation (by dopamine) of working memory, cholinergic modulation (by acetylcholine) of input versus internal processing, and modulation of oscillatory dynamics in cortex and thalamus. DOPAMINE, ROLES OF then focuses specifically on roles of dopamine in both neuromodulation and in synaptic plasticity. Dopamine is a neuromodulator that originates from small groups of neurons in the ventral tegmental area, the substantia nigra, and in the diencephalon. Dopaminergic projections are in general very diffuse and reach large portions of the brain. The time scales of dopamine actions are diverse, from a few hundred milliseconds to several hours. The article focuses on the mesencephalic dopamine centers because they are the most studied, and because they are thought to be involved in diseases such as Tourette's syndrome, schizophrenia, Parkinson's disease, Huntington's disease, drug addiction, and depression. These centers are also involved in such normal brain functions as working memory, reinforcement learning, and attention. The article discusses the biophysical effects of dopamine, how dopamine levels influence working memory, the ways in which dopamine responses resemble the reward prediction signal of the temporal difference model of reinforcement learning, and the role of dopamine in allocation of attention.

INTEGRATE-AND-FIRE NEURONS AND NETWORKS presents relatively simple models that take account of the fact that most biological neurons communicate by action potentials, or spikes (see also "Spiking Neurons, Computation with"). In contrast to the standard neuron model used in ANNs, integrate-and-fire neurons do not rely on a temporal average over the pulses. Instead, the pulsed nature of the neuronal signal is taken into account and considered as potentially relevant for coding and information processing. However, integrate-and-fire models do not explicitly describe the form of an action potential. Integrate-and-fire and similar spiking neuron models are phenomenological descriptions on an intermediate level of detail. Compared to other single-cell models, they allow coding principles to be discussed in a transparent manner. Moreover, the dynamics in networks of integrate-and-fire neurons can be analyzed mathematically, and large systems with thousands of neurons can be simulated rather efficiently.

TEMPORAL INTEGRATION IN RECURRENT MICROCIRCUITS hypothesizes that the ability of neural computation in behaving organisms to produce a response at any time that depends appropriately on earlier sensory inputs and internal states rests on a common principle by which neural microcircuits operate in different cortical areas and species. The article argues that, while tapped delay lines, finite state machines, and attractor neural networks are suitable for modeling specific tasks, they appear to be incompatible with results from neuroanatomy (highly recurrent diverse circuitry) and neurophysiology (fast transient dynamics of firing activity with few attractor states). The authors thus view the transient dynamics of neural microcircuits as the main carrier of information about past inputs, from which specific information needed for a variety of different tasks can be read out in parallel and at any time by different readout neurons. This approach leads to computer models of generic recurrent circuits of integrate-and-fire neurons for tasks that require temporal integration of inputs and, it is argued, provides a new conceptual framework for the experimental investigation of neural microcircuits and larger neural systems.

# II.6. Dynamics and Learning in Artificial Networks

## Dynamic Systems

Statistical Mechanics of Neural Networks
Stochastic Resonance
Winner-Take-All Networks

Much interest in ANNs has been based on the use of trainable feedforward networks as universal approximators for functions $f$: $X \rightarrow Y$ from the input space $X$ to the output space $Y$. However, their provenance was more general. The founding paper of Pitts and McCulloch established the result that, by the mid-1950s, could be rephrased as saying that any finite automaton could be simulated by a network of McCulloch-Pitts neurons. A *finite automaton* is a discrete-time dynamic system; that is, on some suitable time scale, it specifies the next state $q(t + 1)$ as a function $\delta(q(t), x(t))$ of the current state and input (for articles related to automata and theory of computation, see the road map **Computability and Complexity**). But a neuron can be modeled as a continuous-time system (as in a leaky integrator neuron with the membrane potential as the state variable). A network of continuous-time neurons can then be considered as a continuous-time system with the rate of change of the state (which could, for example, be a vector whose elements are the membrane potentials of the individual neurons) defined as a function $\dot{q}(t) = f(q(t), x(t))$ of the current state and input. When the input is held constant, the network (whether discrete- or continuous-time) may be analyzed by dynamical systems theory. Computing with Attractors shows some of the benefits of such an approach. In particular, a net with internal loops may go to equilibrium (providing a state from which the answer to some problem may be read out), enter a limit cycle (undergoing repetitive oscillations which are useful in control of movement, and in other situations in which a "clock cycle" is of value), or exhibit chaotic behavior (acting in an apparently random way, even though it is deterministic). In particular, the article builds on the notion of a Hopfield network. Hopfield contributed much to the resurgence of interest in neural networks in the 1980s by associating an "energy function" with a network, showing that if only one neuron changed state at a time, a symmetrically connected net would settle to a local minimum of the energy, and that many optimization problems could be mapped to energy functions for symmetric neural nets. Energy Functionals for Neural Networks uses the notion of Lyapunov function from the dynamical study of ordinary differential equations to show how the definition of energy function and the conditions for convergence to a local minimum can be broadened considerably. (Of course, a network undergoing limit cycles or chaos will not have an energy function that is minimized in this sense.) Optimization, Neural shows that this property can be exploited to solve combinatorial optimization problems that require a more or less exhaustive search to achieve exact solutions, with a computational effort growing exponentially or worse with system size. The article shows that ANN methods can provide heuristic methods that yield reasonably good approximate solutions. Recurrent network methods based on deterministic annealing use an interpolating continuous (analog) space, allowing for shortcuts to good solutions (compare "Simulated Annealing and Boltzmann Machines"). The key to the approach offered here is the technique of mean-field approximation from statistical mechanics. While early neural optimizations were confined to problems encodable with a quadratic energy in terms of a set of binary variables, in the past decade the method has been extended to deal with more general problem types, both in terms of variable types and energy functions, and has evolved to a general-purpose heuristic for combinatorial optimization.

Dynamics and Bifurcation in Neural Nets notes that the powerful qualitative and geometric tools of dynamical systems theory are most useful when the behavior of interest is stationary in the sense that the inputs are at most time or space periodic. It then shows how to analyze what kind of behavior we can expect over the long run for a given neural network. In ANNs, the final state may represent the recognition of an input pattern, the segmentation of an image, or any number of machine computations. The stationary states of biological neural networks may correspond to cognitive decisions (e.g., binding via synchronous oscillations) or to pathological behavior such as seizures and hallucinations. Another important issue that is addressed by dynamical systems theory is how the qualitative dynamics depends on parameters. The qualitative change of a dynamical system as a parameter is changed is the subject of bifurcation theory, which studies the appearance and disappearance of branches of solutions to a given set of equations as some parameters vary. This article shows how to use these techniques to understand how the behavior of neural nets depends on both the parameters and the initial states of the network. Phase-Plane Analysis of Neural Nets complements the study of bifurcations with a technique for studying the qualitative behavior of small systems of interacting neural networks whose neurons are, essentially, leaky integrator neurons. A complete analysis of such networks is impossible but when there are at most two variables involved, a fairly complete description can be given. The article introduces this qualitative theory of differential equations in the plane, analyzing two-neuron networks that consist of two excitatory cells, two inhibitory cells, or an excitatory and inhibitory cell. While planar systems may seem to be a rather extreme simplification, it is argued that in some local cortical circuits we can view the simple planar system as representing a population of coupled excitatory and inhibitory neurons. Computational methods are a very powerful adjunct to this type of analysis. The article concludes with comments on numerical methods and software.

Canonical Neural Models starts from the observation that various models of the same neural structure could produce different results. It thus shows how to derive results that can be observed in a class or a family of models. To exemplify the utility of considering families of neural models instead of a single model, the article shows how to reduce an entire family of Hodgkin-Huxley-type models to a *canonical model*. A model is canonical for a family if there is a continuous change of variables that transforms any other model from the family into this one. As an example, a canonical phase model is presented for a family of weakly coupled oscillators. The change of variables does not have to invertible, so the canonical model is usually lower-dimensional, simple, and tractable, and yet retains many important features of the family. For example, if the canonical model has multiple attractors, then each member of the family has multiple attractors.

Chaotic phenomena, in which a deterministic law generates complicated, nonperiodic, and unpredictable behavior, exist in many real-world systems and mathematical models. Chaos has many intriguing characteristics, such as sensitive dependence on initial conditions. Chaos in Biological Systems provides a view of the appearance of this phenomenon of "deterministic randomness" in a variety of models of physical and biological systems. Features used in assessing time series for chaotic behavior include the power spectrum, dimension, Lyapunov exponent, and Poincaré map. Examples are given from ion channels through cellular activity to complex networks, and "dynamical disease" is characterized by qualitative changes in dynamics in biological control systems. However, the high dimensions of biological systems and the environmental fluctuations that lead to nonstationarity make convincing demonstration of chaos in vivo (as opposed to computer models) a difficult matter. Chaos in Neural Systems looks at chaos in the dynamics of axons, neurons, and networks. An open issue is to understand the significance, if any, of observed fluctuations that appear chaotic. Does a neuron function well despite fluctuations in the timing between spikes, or are the irregularities essential to its task? And if the irregularities are essential to the task, is there any reason to expect that deterministic (chaotic) irregularities would be better than random ones? The vexing question of whether chaos adds functionality to neural networks is still open (see also "Synaptic Noise and Chaos in Vertebrate Neurons"). Stochastic Resonance is a nonlinear phenomenon whereby the addition of a random process, or "noise," to a weak incoming signal can enhance the probability that it will be detected by a system. Information about the signal transmitted through the system is also enhanced. The information content or detectability of the signal is degraded for noise intensities that are either smaller or larger than some optimal value. Stochastic resonance has been demonstrated at several levels in biology, from ion channels in cell membranes to animal and human cognition, perception, and, ultimately, behavior.

Pattern Formation, Biological presents a general methodology, based on analysis of the largest eigenvalue, for tracing the asymptotic behavior of a dynamical system, and applies it to the problem of biological pattern formation. Turing originally considered the problem of how animal coat patterns develop. He suggested that chemical markers in the skin comprise a system of diffusion-coupled chemical reactions among substances called morphogens. Turing showed that in a two-component reaction-diffusion system, a state of uniform chemical concentration can undergo a diffusion-driven instability, leading to the formation of a spatially inhomogeneous state. In population biology, patchiness in population densities is the norm rather than the exception. In developmental biology, groups of previously identical cells follow different developmental pathways, depending on their position, to yield the rich spectrum of mammalian coat patterns and the patterns found in fishes, reptiles, mollusks, and butterflies. The article closes with a mechanical model of the process of angiogenesis (genesis of the blood supply) and network formation of endothelial cells in the extracellular matrix, as well as a new approach for predicting brain tumor growth. Pattern Formation, Neural shows that the Turing mechanism for spontaneous pattern formation plays an important role in studying two key questions on the large-scale functional and anatomical structure of cortex: How did the structure develop? What forms of spontaneous and stimulus-driven neural dynamics are generated by such a cortical structure? In the neural context, interactions are mediated not by molecular diffusion but by long-range axonal connections. This neural version of the Turing instability has been applied to many problems concerning the dynamics and development of cortex. In the former case, pattern formation occurs in neural activity; in the latter it occurs in synaptic weights. In most cases there exists some underlying symmetry in the model that plays a crucial role in the selection and stability of the resulting patterns.

Complementing this theme of pattern formation, Self-Organization and the Brain contrasts the algorithmic division of labor between programmer and computer in most current man-made computers with the view of the brain as a dynamical system in which ordered structures arise by processes of self-organization. It argues that, whereas the theory of self-organization has so far focused on the establishment of static structures, the nervous system is concerned with the generation of purposeful, nested processes evolving in time. However, if a self-organizing system is to create the appropriate patterns, quite a few control parameters in a system must all be put in the right ballpark. The article argues that, in view of the variability of the physiological state of the nervous system, evolution must have developed general mechanisms to actively and autonomously regulate its systems such as to produce interesting self-organized processes and states. The process of brain organization is seen as a cascade of steps, each one taking place within the boundary conditions established by the previous one, but the theory of such cascades is still nonexistent, posing massive challenges for future research. Cooperative Phenomena offers a related perspective, developing what has been a major theme in physics for the last century: statistical mechanics, which shows how, for example, to average out the individual variations in position and velocity of the myriad molecules in a gas to understand the relationship between pressure, volume, and temperature, or to see how variations in temperature can yield dramatic phase transitions, such as from ice to water or from water to steam. The article places these ideas in a general setting, stressing the notion of an *order parameter* (such as temperature in the previous example) that describes the macroscopic order of the system and whose variation can yield qualitative changes in system behavior. Unlike a control parameter, which is a quantity imposed on the system from the outside, an order parameter is established by the system itself via self-organization. The argument is mainly presented at a general level, but the article concludes by briefly examining cooperative phenomena in neuroscience, including pattern formation (see also Pattern Formation, Biological), EEG, MEG, movement coordination, and hallucinations (see also Pattern Formation, Neural).

Statistical Mechanics of Neural Networks introduces the reader to some of the basic methods of statistical mechanics and shows that they can be applied to systems made up of large numbers of (formal) neurons. Statistical mechanics has studied magnets as lattices with an atomic magnet (modeled as, e.g., a spin that can be up or down) at each lattice point, and this has led to the statistical analysis of neural networks as "spin glasses," where firing and nonfiring correspond to "spin up" and "spin down," respectively. It has also led to the study of "Markov Random Field Models in Image Processing," in which the initial information at each lattice site represents some local features of the raw image, while the final state allows one to read off a processed image.

Collective Behavior of Coupled Oscillators explains the use of phase models (here, the phase is the phase of an oscillation, not the type of phase whose transition is studied in statistical mechanics) to help understand how temporal coherence arises over populations of densely interconnected oscillators, even when their frequencies are randomly distributed. The phase oscillator model for neural populations exemplifies the idea that certain aspects of brain functions seem largely independent of the neurophysiological details of the individual neurons while trying to recover phase information, i.e., the kind of information encoded in the form of specific temporal structures of the sequence of neuronal spikings. The article reviews the collective behavior of coupled oscillators using the phase model and assuming all-to-all type interconnections. Despite this simplification, a great variety of collective behaviors is exhibited. Special attention is given to the onset and persistence of collective oscillation in frequency-distributed systems, splitting of the population into a few subgroups (clustering), and the more complex collective behavior called slow switching. Collections of oscillators that send signals to one another can phase lock, with many patterns of phase differences. Chains of Oscillators in Motor and Sensory Systems discusses a set of examples that illustrate how those phases emerge from the oscillator interactions. Much of the work was motivated by spatiotemporal patterns in networks of neurons that govern undulatory locomotion. The original experimental preparation to which this work was applied is the lamprey central pattern generator (CPG) for locomotion, but the mathematics is considerably more general. The article discusses several motor systems, then turns to the procerebral lobe of *Limax*, the common garden slug, to illustrate chains of oscillators in a sensory system. Since the details of the oscillators often are not known and difficult to obtain, the object of the mathematics is to find the consequences of what is known, and to generate sharper questions to motivate further experimentation.

Amplification, Attenuation, and Integration focuses on the computational role of the recurrent connections in networks of leaky integrator neurons. Setting the transfer function $f(u)$ to be simply $u$ in the network equations yields a linear network that can be completely analyzed using the tools of linear systems theory. The article describes the properties of linear networks and gives some examples of their application to neural modeling. In this framework, it is shown how recurrent synaptic connectivity can either attenuate or speed up responses; both effects can occur simultaneously in the same network. Besides amplification and attenuation, a linear network can also carry out temporal integration, in the sense of Newtonian calculus, when the strength of feedback is precisely tuned for an eigenmode, so that its gain and time constant diverge to infinity. Finally, it is noted that the linear computations of amplification, attenuation, and integration can be ascribed to a number of brain areas.

Winner-Take-All Networks presents a number of designs for neural networks that solve the following problem: given a number of networks, each of which provides as output some "confidence measure," find in a distributed manner the network whose output is strongest. Two important variants of winner-take-all are $k$-winner-take-all, where the $k$ largest inputs are identified, and softmax, which consists of assigning each input a weight so that all weights sum to 1 and the largest input receives the biggest weight. The article first describes softmax and shows how winner-take-all can be derived as a limiting case; it then describes how they can both be derived from probabilistic, or energy function, formulations; and it closes with a discussion of VLSI and biological mechanisms. "Modular and Hierarchical Learning Systems" addresses a somewhat related topic: Given a complex problem, find a set of networks, each of which provides an approximate solution in some region of the state space, together with a gating network that can combine these approximations to yield a globally satisfactory solution (i.e., blend the "good" solutions rather than extract the "best" solution).

Dynamics of Association and Recall uses dynamical studies to analyze the pattern recall process and its relation with the choice of initial state, the properties of stored patterns, noise level, and network architecture. For large networks and in global recall processes, the strategy is to derive dynamical laws at a *macroscopic* level (i.e., dependent on many neuron states). The challenge is to find the smallest set of macroscopic quantities which will obey closed deterministic equations in the limit of an infinitely large network. The article focuses on simple Hopfield-type models, but closes with a discussion of some variations and generalizations. Short-Term Memory asks: What are the different types of STM traces? How do intrinsic and synaptic mechanisms contribute to the formation of STM traces? How do STM traces translate into long-term memory representation of temporal sequences? The stress is on computational mechanisms underlying these processes with the suggestion that these mechanisms may well underlie a wide variety of seemingly different biological processes. The article examines both the short-term preservation of patterns of neural firing in a circuit and ways in which short-term maintained activity may be transferred into long-term memory traces.

The majority of articles in this road map deal with learning in artificial neural networks. Nonetheless, the road map is titled "Learning in Artificial Networks" to emphasize the inclusion of a body of research on statistical inference and learning that can be seen either as generalizing neural networks or as analyzing other forms of networks, such as Bayesian networks and graphical models.

The fundamental difference between a system that learns and one that merely memorizes is that the learning system generalizes to unseen examples. Much of our concern is with supervised learning, getting a network to behave in a way that successfully approximates some specified pattern of behavior or input-output relationship. In particular, much emphasis has been placed on feedforward networks which have no loops, so that the output of the net depends on its input alone, since there is then no internal state defined by reverberating activity. The most direct form of this is a synaptic matrix, a one-layer neural network for which input lines directly drive the output neurons and a "supervised Hebbian" rule sets synapses so that the network will exhibit specified input-output pairs in its response repertoire. This is addressed in Asso-

CIATIVE NETWORKS, which notes the problems that arise if the input patterns (the "keys" for associations) are not orthogonal vectors. Association also extends to recurrent networks, but in such systems of "dynamic memories" (e.g., Hopfield networks) there are no external inputs as such. Rather the "input" is the initial state of the network, and the "output" is the "attractor" or equilibrium state to which the network then settles. For neurons whose output is a sigmoid function of the linear combination of their inputs, the memory capacity of the associative memory is approximately $0.15n$, where $n$ is the number of neurons in the net. Unfortunately, such an "attractor network" memory model has many spurious memories, i.e., equilibria other than the memorized patterns, and there is no way to decide whether a recalled pattern was memorized or not. DYNAMICS OF ASSOCIATION AND RECALL (see the road map **Dynamic Systems** for more details) shows how to move away from microscopic equations at the level of individual neurons to derive dynamical laws at a macroscopic level that characterize association and recall in Hopfield-type networks (with some discussion of variations and generalizations).

Historically, the earliest forms of supervised learning involved changing synaptic weights to oppose the error in a neuron with a binary output (the perceptron error-correction rule), or to minimize the sum of squares of errors of output neurons in a network with real-valued outputs (the Widrow-Hoff rule). This work is charted in PERCEPTRONS, ADALINES, AND BACKPROPAGATION, which also charts the extension of these classic ideas to multilayered networks. In multilayered networks, there is the *structural credit assignment problem*: When an error is made at the output of a network, how is credit (or blame) to be assigned to neurons deep within the network? One of the most popular techniques is called backpropagation, whereby the error of output units is propagated back to yield estimates of how much a given "hidden unit" contributed to the output error. These estimates are used in the adjustment of synaptic weights to these units within the network. BACKPROPAGATION: GENERAL PRINCIPLES places this idea in a broader framework by providing an overview of contributions that enrich our understanding of the pros and cons (such as "plateaus") of this adaptive architecture. It also assesses the biological plausibility of backpropagation.

The underlying theoretical grounding is that, given any function $f: X \rightarrow Y$ for which $X$ and $Y$ are codable as input and output patterns of a neural network, then, as shown in UNIVERSAL APPROXIMATORS, $f$ can be approximated arbitrarily well by a feedforward network with one layer of hidden units. The catch, of course, is that many, many hidden units may be required for a close fit. It is thus often treated as an empirical question whether there exists a sufficiently good approximation achievable in principle by a network of a given size—an approximation that a given learning rule may or may not find (it may, for example, get stuck in a local optimum rather than a global one). Gradient descent methods have also been extended to adapt the synaptic weights of recurrent networks. The backpropagation algorithm for feedforward networks has been successfully applied to a wide range of problems, but what can be implemented by a feedforward network is just a static mapping of the input vectors. However, to model dynamical functions of brains or machines, one must use a system capable of storing internal states and implementing complex dynamics. RECURRENT NETWORKS: LEARNING ALGORITHMS presents, then, learning algorithms for recurrent neural networks that have feedback connections and time delays. In a recurrent network, the state of the system can be encoded in the activity pattern of the units, and a wide variety of dynamical behaviors can be programmed by the connection weights. A popular subclass of recurrent networks consists of those with symmetric connection weights. In this case, the network dynamics is guaranteed to converge to a minimum of some "energy" function (see "Energy Functionals for Neural Networks" and "Computing with Attractors"). However, steady-state solutions are only a limited portion of the capabilities of recurrent networks. For example, they can transform an input sequence into a distinct output sequence, and they can serve as a nonlinear filter, a nonlinear controller, or a finite-state machine. This article reviews the learning algorithms for training recurrent networks, with the main focus on supervised learning algorithms. (See "Recurrent Networks: Neurophysiological Modeling" for the use of such networks in modeling biological neural circuitry.)

One useful perspective for supervised learning views learning as hill-climbing in weight space, so that each "experience" adjusts the synaptic weights of the network to climb (or descend) a metaphorical hill for which "height" at a particular point in "weight space" corresponds to some measure of the performance of the network (or the organism or robot of which it is a part). When the aim is to minimize this measure, the learning process is then an example of what mathematicians call *gradient descent*. The term *reinforcement* comes from studies of animal learning in experimental psychology, where it refers to the occurrence of an event, in the proper relation to a response, that tends to increase the probability that the response will occur again in the same situation. REINFORCEMENT LEARNING describes a form of "semisupervised" learning where the network is not provided with an explicit form of error at each time step but rather receives only generalized reinforcement ("you're doing well"; "that was bad!"), which yields little immediate indication of how any neuron should change its behavior. Moreover, the reinforcement is intermittent, thus raising the temporal credit assignment problem (see also "Reinforcement Learning in Motor Control"): How is an action at one time to be credited for positive reinforcement at a later time? The solution is to build an "adaptive critic" that learns to evaluate actions of the network on the basis of how often they occur on a path leading to positive or negative reinforcement. Methods for this assessment of future expected reinforcement include temporal difference (TD) learning and Q-learning (see "Q-Learning for Robots"). Current reinforcement learning research includes parameterized function approximation methods; understanding how exploratory behavior is best introduced and controlled; learning under conditions in which the environment state cannot be fully observed; introducing various forms of abstraction such as temporally extended actions and hierarchy; and relating computational reinforcement learning theories to brain reward mechanisms (see "Dopamine, Roles of").

The task par excellence for supervised learning is pattern recognition—the problem of classifying objects, often represented as vectors or as strings of symbols, into categories. Historically, the field of pattern recognition started with early efforts in neural networks (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION). While neural networks played a less central role in pattern recognition for some years, recent progress has made them the method of choice for many applications. As PATTERN RECOGNITION demonstrates, properly designed multilayer networks can learn complex mappings in high-dimensional spaces without requiring complicated hand-crafted feature extractors. To rely more on learning, and less on detailed engineering of feature extractors, it is crucial to tailor the network architecture to the task, incorporating prior knowledge to be able to learn complex tasks without requiring excessively large networks and training sets. ENSEMBLE LEARNING describes algorithms that, rather than finding one best hypothesis to explain the data, construct a set (sometimes called a committee or ensemble) of hypotheses and then have those hypotheses vote to classify new patterns. Ensemble methods are often much more accurate than any single hypothesis. For example, the representational problem arises when the hypothesis space does not contain any hypotheses that are good approximations to the true decision function $f$. In some cases, a weighted sum of hypotheses expands the space of functions that can be represented. Hence, by taking a weighted vote of hypotheses, the learning algorithm may be able to form a more accurate approximation to $f$. The bulk of research into ensemble methods has focused on constructing ensembles of decision trees. The article introduces the techniques of bagging and boosting, among others, and analyzes their relative merits under different conditions.

Many specific architectures have been developed to solve particular types of learning problem. ADAPTIVE RESONANCE THEORY (ART) bases learning on internal expectations. A pattern matching process compares an external input with the internal memory of various coded patterns. ART matching leads either to a *resonant* state, which persists long enough to permit learning, or to a parallel memory search. If the search ends at an established code, the memory representation may either remain the same or incorporate new information from matched portions of the current input. When the external world fails to match an ART network's expectations or predictions, a search process selects a new category, representing a new hypothesis about what is important in the present environment.

The neocognitron (see NEOCOGNITRON: A MODEL FOR VISUAL PATTERN RECOGNITION) was developed as a neural network model for visual pattern recognition that addresses the specific question, "How can a pattern be recognized despite variations in size and position?" by using a multilayer architecture in which local features are replicated in many different scales and locations. More generally, as shown in CONVOLUTIONAL NETWORKS FOR IMAGES, SPEECH, AND TIME SERIES, shift invariance in convolutional networks is obtained by forcing the replication of weight configurations across space. Moreover, the topology of the input is taken into account, enabling such networks to force the extraction of local features by restricting the receptive fields of hidden units to be local, and enforcing a built-in invariance with respect to translations, or local distortions of the inputs. The idea of connecting units to local receptive fields on the input goes back to the perceptron in the early 1960s, and was almost simultaneous with Hubel and Wiesel's discovery of locally sensitive, orientation-selective neurons in the cat's visual system.

Just as a polynomial of too high a degree is not useful for curve fitting, a network that is too large will fail to generalize well, and will require longer training times. Smaller networks, with fewer free parameters, enforce a smoothness constraint on the function found. For best performance, it is therefore desirable to find the smallest network that will "fit" the training data. To create a neural network, a designer typically fixes a network topology and uses training data to tune its parameters such as connection weights. The designer, however, often does not have enough knowledge to specify the ideal topology. It is thus desirable to learn the topology from training data as well. LEARNING NETWORK TOPOLOGY reviews algorithms that adjust network topology, adding neurons and removing neurons during the learning process, to arrive at a network appropriate to a given task. For topology learning, a bias is added to prefer smaller models. It is often found that this bias produces a neural network that has better generalization and is more interpretable. This framework is applied to learning the topologies of both feedforward neural networks and BAYESIAN NETWORKS. In Bayesian networks, all the nodes of the network are given and set, and one searches for a topology by adding or deleting links.

Many articles in the *Handbook* emphasize situations where, e.g., learning from examples is stochastic in the sense that examples are randomly generated and the network behavior is thus to be analyzed from a statistical point of view. Statistical estimation identifies the mechanism underlying stochastic phenomena. LEARNING AND STATISTICAL INFERENCE studies learning by using such statistical notions as Fisher information, Bayesian loss, and sequential estimation, as well as the Expectation-Maximization (EM) algorithm for estimating hidden variables. Nonlinear neurodynamics, learning, and self-organization are seen as adding new concepts to statistical science. The article examines the dynamical behaviors of a learning network under a general loss criterion. The behavior of learning curves is related to neural network complexity to elucidate the discrepancy between training and generalization errors. This perspective is further developed in NEUROMANIFOLDS AND INFORMATION GEOMETRY. A neural network is specified by its architecture and a number of parameters such as synaptic weights and thresholds. Any neural network of this architecture is specified by a point in the parameter space. Learning takes place in the parameter space and a learning process is represented by a trajectory. The article presents the approach of information geometry which sees the geometrical structure of the parameter space as given by a Riemannian manifold. The article shows how dynamical behaviors of neural learning on these "neuromanifolds" are related to the underlying geometrical structures, using multilayer perceptrons and Boltzmann machines as examples.

GENERALIZATION AND REGULARIZATION IN NONLINEAR LEARNING SYSTEMS sets forth the essential relationship between multivariate function estimation in a statistical context and supervised machine learning. Given a training set consisting of (input, output) pairs $(x_i, y_i)$, the task is to construct a map that generalizes well in that, given a new value of $x$, the map will provide a reasonable prediction for the hitherto unobserved output associated with this $x$. Regularization simplifies the problem by applying constraints to the construction of the map that reduce the generalization error (see also "Probabilistic Regularization Methods for Low-Level Vision"). Ideally, these constraints embody a priori information concerning the true relationship between input and output, though various ad hoc constraints have sometimes been shown to work well in practice. Feedforward neural nets, radial basis functions, and various forms of splines all provide regularized or regularizable methods for estimating "smooth" functions of several variables from a given training set. Which method to use depends on the particular nature of the underlying but unknown "truth," the nature of any prior information that might be available about this "truth," the nature of any noise in the data, the ability of the experimenter to choose the various smoothing or regularization parameters well, and so on.

MODULAR AND HIERARCHICAL LEARNING SYSTEMS solves a complex learning problem by dividing it into a set of subproblems. In the context of supervised learning, modular architectures arise when the data can be described by a collection of functions, each of which works well over a relatively local region of the input space, allocating different modules to different regions of the space. The challenge is that, in general, the learner is not provided with prior knowledge of the partitioning of the input space. To solve this, a "gating network" can learn which module to "listen to" in different situations. The learning algorithms described here solve the credit assignment problem by computing a set of posterior probabilities that can be thought of as estimating the utility of different modules in different parts of the input space. An EM algorithm (cf. LEARNING AND STATISTICAL INFERENCE), an alternative to gradient methods, can be derived for estimating the parameters of both the modular system and its extension to hierarchical architectures. The latter arise when we assume that the data are well described by a multiresolution model in which regions are divided recursively into subregions.

BAYESIAN METHODS AND NEURAL NETWORKS shows how to apply Bayes's rule for the use of probabilities to quantify inferences about hypotheses from given data. The idea is to take the predictions $p(d|h_i)$ made by alternative models $h_i$ about data $d$, and the prior probabilities of the models $p(h_i)$, and obtain the posterior probabilities $p(h_i|d)$ of the models given the data, using Bayes's rule in the form $p(h_i|d) = p(d|h_i)p(h_i)/p(d)$. To apply this to neural networks, regard a supervised neural network as a nonlinear parameterized mapping from an input $x$ to an output $y = y(x; w)$, which depends continuously on the "weights" parameter $w$. The idea is to choose $w$ from a weight space with some given probability distribution $p(w)$ so as to maximize the likelihood of the nets yielding the given set of (input, output) observations. The Bayesian framework deals with uncertainty in a natural, consistent manner by combining prior beliefs about which models are appropriate with how likely each model would be to have generated the data. This results in an elegant, general framework for fitting models to data that, however, may be compromised by computational difficulties in carrying out the ideal procedure. There are many approximate Bayesian implementations, using methods such as sampling, perturbation techniques, and variational methods. In the case of models linear in their parameters, Bayesian neural networks are closely related to GAUSSIAN PROCESSES (q.v.), where many of the computational difficulties of dealing with more general stochastic nonlinear systems can be avoided. Traditionally, neural networks are graphical representations of functions in which the computations at each node are deterministic. By contrast, networks in which nodes represent stochastic variables are called graphical models (see BAYESIAN NETWORKS and GRAPHICAL MODELS: PROBABILISTIC INFERENCE).

RADIAL BASIS FUNCTION NETWORKS applies Bayesian methods to the case where the approximation to the given $y = y(x; w)$ is based on a network using combinations of "radial basis" functions, each of which is "centered" around a weight vector $w$, so that the response to input $x$ depends on some measure of "distance" of $x$ from $w$, rather than on the dot product $w \cdot x = \Sigma_i w_i x_i$ as in many formal neurons. The distribution of the $w$'s may be determined by some form of clustering (see DATA CLUSTERING AND LEARNING). Further learning adjusts the connection strengths to a neuron whose outputs give an estimate of, e.g., the posterior probability $p(c|x)$ that class $c$ is present given the observation (network input) $x$. However, it is easier to model other related aspects of the data, such as the unconditional distribution of the data $p(x)$ and the likelihood of the data, $p(x|c)$, and then recreate the posterior from these quantities according to Bayes's rule, $p(c_i|x) = p(c_i)p(x|c_i)/p(x)$.

GAUSSIAN PROCESSES continues the Bayesian approach to neural network learning, placing a prior probability distribution over possible functions and then letting the observed data "sculpt" this prior into a posterior using the available data. One can place a prior distribution $P(w)$ on the weights $w$ of a neural network to induce a prior over functions $P(y(x;w))$ but the computations required to make predictions are not easy, owing to nonlinearities in the system. A Gaussian process, defined by a mean function and covariance matrix, can prove useful as a way of specifying a prior directly over function space—it is often simpler to do this than to work with priors over parameters. Gaussian processes are probably the simplest kind of function space prior that one can consider, being a generalization of finite-dimensional Gaussian distributions over vectors. A Gaussian process is defined by a mean function (which we shall usually take to be identically zero), and a covariance function $C(x, x')$ which indicates how correlated the value of the function y is at $x$ and $x'$. This function encodes our assumptions about the problem (e.g., that the function is smooth and continuous) and will influence the quality of the predictions. The article shows how to use Gaussian processes for classification problems, and describes how data can be used to adapt the covariance function to the given prediction problem.

MINIMUM DESCRIPTION LENGTH ANALYSIS shows how ideas relating to minimum description length (MDL) have been applied to neural networks, emphasizing the direct relationship between MDL and Bayesian model selection methods. The classic MDL approach defined the information in a binary string to be the length of the shortest program with which a general-purpose computer could generate the string. The Bayes bridge is obtained by replacing the Bayesian goal of inferring the "most likely" model $M$ from a set of observations by minimizing the length of an encoded message which describe $M$ as well as the data $D$ expressed in term of $M$. MDL and Bayesian methods both formalize Occam's razor in that a complex network is preferred only if its predictions are sufficiently more accurate.

UNSUPERVISED LEARNING WITH GLOBAL OBJECTIVE FUNCTIONS makes the point that even unsupervised learning involves an *implicit* training signal based on the network's ability to predict its own input, or on some more general measure of the quality of its internal representation. The main problem in unsupervised learning research is then seen as the formulation of a performance measure or cost function for the learning to generate this internal supervisory signal. The cost function is also known as an objective function, since it sets the objective for the learning process. The article reviews three types of unsupervised neural network learning procedures: information-preserving algorithms, density estimation techniques, and invariance-based learning procedures. The first method is based on the preservation of mutual information $I_{x;y} = H(x) - H(x|y)$ between the input vector $x$ and output vector $y$, where $H(x)$ is the entropy of random variable $x$ and $H(x|y)$ is the entropy of the conditional distribution of $x$ given $y$. The second approach is to assume a priori a class of models that constrains the general form of the probability density function and then to search for the particular model parameters defining the density function (or mixture of density functions) most likely to have generated the observed data (cf. the earlier discussion of Bayesian methods). Finally, invariance-based learning extracts higher-order features and builds more abstract representations. Once again, the approach is to make constraining assumptions about the structure that is being sought, and to build these constraints into the network's architecture and/or objective function to develop more efficient, specialized learning procedures.

The Bayesian articles stress the "global" statistical idea of "find the weights which, according to given probability distributions maximize some expectation" as distinct from the deterministic idea of adjusting the weights at each time step to provide a local increment in performance on the current input. However, gradient descent provides an important tool for finding the weight settings which decrease some stochastic expectation of error, too. STOCHASTIC APPROXIMATION AND EFFICIENT LEARNING shows that gradient descent has a long tradition in the literature of stochastic approximation. Any stochastic process that can be interpreted as minimizing a cost function based on noisy gradient measurements in a sequential, recursive manner may be considered to be a stochastic approximation. "Sequential" means that each estimate of the location of a minimum is used to make a new observation, which in turn immediately leads to a new estimate; "recursive" means that the estimates depend on past gradient measurements only through a fixed number of scalar statistics. Such on-line algorithms are useful because they enjoy significant performance advantages for large-scale learning problems. The article describes their properties using stochastic approximation theory as a very broad framework, and provides a brief overview of newer insights obtained using information geometry (see NEUROMANIFOLDS AND INFORMATION GEOMETRY) and replica calculations (see STATISTICAL MECHANICS OF ON-LINE LEARNING AND GENERALIZATION).

In order to understand the performance of learning machines, and to gain insight that helps to design better ones, it is helpful to have theoretical bounds on the generalization ability of the machines. The determination of such bounds is the subject of LEARNING AND GENERALIZATION: THEORETICAL BOUNDS. Here it is necessary to formalize the learning problem and turn the question of how well a machine generalizes into a mathematical question. The article adopts the formalization used in statistical learning theory, which is shown to include both pattern recognition and function learning. The road map **Computability and Complexity** gives more information on this and related articles, such as "PAC Learning and Neural Networks" and "Vapnik-Chervonenkis Dimension of Neural Networks," which offer bounds on the performance of learning methods. SUPPORT VECTOR MACHINES addresses the (binary) pattern recognition problem of learning theory: given two classes of objects, to assign a new object to one of the two classes. Trying to find the best classifier involves notions of similarity in the set $X$ of inputs. Support vector machines (SVMs) build a decision function as a kernel expansion corresponding to a separating hyperplane in a feature space. SVMs rest on methods for the selection of the patterns on which the kernels are centered and in the choice of weights that are placed on the individual kernels in the decision function. SVMs and other kernel methods have a number of advantages compared to classical neural network approaches, such as the absence of spurious local minima in the optimization procedure, the need to tune only a few parameters, and modularity in the design. Kernel methods connect similarity measures, nonlinearities, and data representations in linear spaces where simple geometric algorithms are performed.

The passage of the "energy" of a Hopfield network to a local minimum can be construed as a means for solving an optimization problem. The catch is the word "local" in local minimum—the solution may be the best in the neighborhood, yet far better solutions may be located elsewhere. One resolution of this is described in SIMULATED ANNEALING AND BOLTZMANN MACHINES. At the expense of great increases in time to convergence, simulated annealing escapes local minima by adding noise, which is then gradually reduced ("lowering the temperature"). The initially high temperature (i.e., noise level) stops the system from getting trapped in "high valleys" of the energy landscape, the lowering of temperature allows optimization to occur in the "deepest valley" once it has been found. The Boltzmann machine then applies this method to design a class of neural networks. These machines use stochastic computing elements to extend discrete Hopfield networks in two ways: they replace the deterministic, asynchronous dynamics of Hopfield networks with a randomized local search dynamics, and they replace the Hebbian learning rule with a more powerful stochastic learning algorithm.

Turning from neural networks to another form of network structure, BAYESIAN NETWORKS (as distinct from BAYESIAN METHODS AND NEURAL NETWORKS) provides an explicit method for following chains of probabilistic inference such as those appropriate to expert systems, extending the Bayes's rule for updating probabilities in the light of new evidence. The nodes in a Bayesian network represent propositional variables of interest and the links represent informational or causal dependencies among the variables. The dependencies are quantified by conditional probabilities for each node, given its parents in the network. The network supports the computation of the probabilities of any subset of variables, given evidence about any other subset, and the reasoning processes can operate on Bayesian networks by propagating information in any direction. HELMHOLTZ MACHINES AND SLEEP-WAKE LEARNING starts by observing that since unsupervised learning is largely concerned with finding structure among sets of input patterns, it is important to take advantage of cases in which the input patterns are generated in a systematic way, thus forming a manifold that has many fewer dimensions than the space of all possible activation patterns. The Helmholtz machine is an analysis-by-synthesis model. The key idea is to have an imperfect generative model train a better analysis or recognition model, and an imperfect recognition model train a better generative model. The generative model for the Helmholtz machine is a structured belief network (i.e., Bayesian network) that is viewed as a model for hierarchical top-down connections in the cortex. New inputs are analyzed in an approximate fashion using a second structured belief network (called the recognition model), which is viewed as a model for the standard, bottom-up connections in cortex. The generative and recognition models are learned from data in two phases. In the *wake phase*, the recognition model is used to estimate the underlying generators for a particular input pattern, and then the generative model is altered so that those generators are more likely to have produced the input that is actually observed. In the *sleep phase*, the generative model fantasizes inputs by choosing particular generators stochastically, and then the recognition model is altered so that it is more likely to report those particular generators if the fantasized input were actually to be observed. YING-YANG LEARNING further develops this notion of simultaneously building up two pathways, a bottom-up pathway for encoding a pattern in the observation space into its representation in a representation space, and a top-down pathway for decoding or reconstructing a pattern from an inner representation back to a pattern in the observation space. The theory of Bayesian Ying-Yang harmony learning formulates the two-pathway approach in a general statistical framework, modeling the two pathways via two complementary Bayesian representations of the joint distribution on the observation space and representation space. The article shows how a number of major learning problems and methods can be seen as special cases of this unified perspective. Moreover, the ability of Ying-Yang learning for regularization and model selection is placed in an information-theoretic perspective.

GRAPHICAL MODELS: PROBABILISTIC INFERENCE introduces a generalization of Bayesian networks. The graphical models framework provides a clean mathematical formalism that has made it possible to understand the relationships among a wide variety of network-based approaches to computation, and in particular to understand many neural network algorithms and architectures as instances of a broader probabilistic methodology. Graphical models use graphs to represent and manipulate joint probability distributions. The graph underlying a graphical model may be directed, in which case the model is often referred to as a belief network or a Bayesian network, or the graph may be undirected, in which case the model is generally referred to as a Markov random field. A graphical model has both a structural component, encoded by the pattern of edges in the graph, and a parametric component, encoded by numerical "potentials" associated with sets of edges in the graph. General inference algorithms allow statistical quantities (such as likelihoods and conditional probabilities) and information-theoretic quantities (such as mutual information and conditional entropies) to be computed efficiently. The article closes by noting that many neural network architectures are special cases of the general graphical model formalism, both representationally and algorithmically. Special cases of graphical models include essentially all models of unsupervised learning, as well as Boltzmann machines, mixtures of experts, and radial basis function networks, while many other neural networks, including the classical multilayer perceptron, can be profitably analyzed from the viewpoint of graphical models. The next two articles present learning algorithms that build on these inference algorithms and allow parameters and structures to be estimated from data. GRAPHICAL MODELS: PARAMETER LEARNING discusses the learning of parameters for a fixed graphical model. As noted, each node in the graph represents a random variable, while the edges in the graph represent the qualitative dependencies between the variables; the absence of an edge between two nodes means that any statistical dependency between these two variables is mediated via some other variable or set of variables. The quantitative dependencies between variables that are connected via edges are specified via parameterized conditional distributions, or more generally nonnegative "potential functions." The pattern of edges is the structure of the graph, while the parameters of the potential functions are parameters of the graph. The present article assumes that the structure of the graph is given, and shows how to then learn the parameters of the graph from data. GRAPHICAL MODELS: STRUCTURE LEARNING turns to the simultaneous learning of parameters and structure. Real-world applications of such learning abound, the example presented being an analysis of data regarding factors that influence the intention of high school students to attend college. For simplicity, the article focuses on directed-acyclic graphical models, but the basic principles thus defined can be applied more generally. The Bayesian approach is emphasized, and then several common non-Bayesian approaches are mentioned briefly.

COMPETITIVE LEARNING is a form of unsupervised learning in which each input pattern comes, through learning, to be associated with the activity of one or at most a few neurons, leading to sparse representations of data that are easy to decode. Competitive learning algorithms employ some sort of competition between neurons in the same layer via lateral connections. This competition limits the set of neurons to be affected in a given learning trial. Hard competition allows the final activity of only one neuron, the strongest one to start with, whereas in soft competition the activity of the lateral neurons does not necessarily drive all but one to zero. One form of competitive learning algorithm can be described as an application of a successful single-neuron learning algorithm in a network with lateral connections between adjacent neurons. The lateral connections are needed so that each neuron can be inhibited from adapting to a feature of the data already captured by other neurons. A second family of algorithms uses the competition between neurons for improving, sharpening, or even forming the features extracted from the data by each single neuron. DATA CLUSTERING AND LEARNING emphasizes the related idea of data clustering, discovering, and emphasizing structure that is hidden in a data set (e.g., the pronounced similarity of groups of data vectors) in an unsupervised fashion. There is a delicate trade-off: not to superimpose too much structure, and yet not to overlook structure. The choice of data representation predetermines what kind of cluster structures can be discovered in the data. Formulating the search for clusters as an optimization problem then supports validation of clustering results by checking that the cluster structures found in a data set vary little from one data set to a second data set generated by the same data source. The two tasks of clustering, density estimation and data compression, are tightly related by the fact that the correct identification of the probability model of the source yields the best code for data compression. PRINCIPAL COMPONENT ANALYSIS shows how, in data compression applications like image or speech coding, a distribution of input vectors may be economically encoded, with small expected values of the distortions, in terms of eigenvectors of the largest eigenvalues of the correlation matrix that describes the distribution of these patterns (these eigenvectors are the "principal components"). However, it is usually not possible to find the eigenvectors on-line. The ideal solution is then replaced by a neural network learning rule embodying a constrained optimization problem that converges to the solution given by the principal components. INDEPENDENT COMPONENT ANALYSIS (ICA) is a linear transform of multivariate data designed to make components of the resulting random vector as statistically independent (factorial) as possible. In signal processing it is used to attack the problem of the blind separation of sources, for example of audio signals that have been mixed together by an unknown process (the "cocktail party effect"). In the area of neural networks and brain theory, it is an example of an information-theoretic unsupervised learning algorithm. When an ICA network is trained on an ensemble of natural images, it learns localized-oriented receptive fields qualitatively similar to those found in area V1 of mammalian visual cortex. ICA has been used to decompose multivariate brain data into components that help us understand task-related spatial and temporal brain dynamics. Thus the same neural network algorithm is being used both as an explanation of brain properties and as a method of probing the brain. Where principal component analysis (PCA) uses second-order statistics (the covariance matrix) to remove correlations between the elements of a vector, ICA uses statistics of all orders. PCA attempts to decorrelate the outputs, while ICA attempts to make the outputs statistically independent. The most widely used adaptive, on-line method for ICA is also the most "neural-network-like" and is the one described in the body of this article.

SELF-ORGANIZING FEATURE MAPS introduces the self-organizing feature map (SOFM or SOM; also known as a Kohonen map), a nonlinear method by which features can be obtained with an unsupervised learning process. It is based on a layer of adaptive "neurons" that gradually develops into an array of feature detectors. The linking of input signals to response locations in the map can be viewed as a nonlinear projection from a signal or input space to the (usually) 2D map layer. The learning method is an augmented Hebbian method in which learning by the element most responsive to an input pattern is "shared" with its neighbors. The result is that the resulting "compressed image" of the (usually higher-dimensional) input space has the property of a topographic map that reflects important metric and statistical properties of the input signal distribution: distance relationships in the input space (expressing, e.g., pattern similarities) are approximately preserved as distance relationships between corresponding excitation sites in the map, and clusters of similar input patterns tend to become mapped to areas of the neural array whose size varies in proportion to the frequency of the occurrence of their patterns. This resembles in many ways the structure of topographic feature maps found in many brain areas, for which the SOFM offers a neural model that bridges the gap between microscopic adaptation rules postulated at the single neuron or synapse level and the formation of experimentally better accessible, macroscopic patterns of feature selectivity in neural layers. From a statistical point of view, the SOFM provides a nonlinear generalization of principal component analysis and has proved valuable in many application contexts.

In order to give a quantitative answer to the question of how well the trained network will be able to classify an input that it has not seen before, it is common to assume that all inputs, both from the training set and the test set, are produced independently and at random. Clearly, the generalization error depends on the specific algorithm that was used during the training, and its calculation requires knowledge of the network weights generated by the learning process. In general, these weights will be complicated functions of the examples, and an explicit form will not be available in most cases. The methods of statistical mechanics provide an approach to this problem, which often enables an exact calculation of learning curves in the limit of a very large network. In the statistical mechanics approach one studies the ensemble of all networks that implement the same set of input/output examples to a given accuracy. In this way the typical generalization behavior of a neural network (in contrast to the worst or optimal behavior) can be described. We thus turn to two articles that apply the methods introduced in the article "Statistical Mechanics of Neural Networks": STATISTICAL MECHANICS OF ON-LINE LEARNING AND GENERALIZATION emphasizes on-line learning in which training examples are dealt with one at a time, while STATISTICAL MECHANICS OF GENERALIZATION emphasizes off-line or memory-based methods, where learning is guided by the minimization of a cost function as averaged over the whole training set. From a statistical physics point of view, the distinction is between systems that can be thought of as being in a state of thermal equilibrium (off-line ≈ on-equilibrium) and away-from-equilibrium situations where the network is not allowed to extract all possible information from a set of examples (on-line ≈ off-equilibrium). While on-line learning is an intrinsically stochastic process, the restriction to large networks, together with assumptions about the statistical properties of the inputs, permits a concise description of the dynamics in terms of coupled ordinary differential equations. These deterministic equations govern the average evolution of quantities that completely define the macroscopic state of the ANN. The average is taken with respect to the data, which is straightforward if the presented examples are statistically independent. The probability that the network will make a mistake on the new input defines its generalization error for a given training set. Its average over many realizations of the training set, as a function of the number of examples, gives the so-called learning curve. Calculation of the learning curve requires knowledge of the network weights generated by the learning process, for which an explicit form will not be available in most cases. The methods of statistical mechanics provide an approach to this problem, in many cases yielding an exact calculation of learning curves in the "thermodynamic limit" of a very large network in which the network size increases in proportion to the number of training examples, while the statistical or information-theoretic approach is applicable to the learning curve of a medium-size network (cf. LEARNING AND STATISTICAL INFERENCE).

MODEL VALIDATION shows how the data analyst tries to infer a "model" that summarizes functional dependencies that may be observed in a given set of empirical data. A good model fit should reproduce the behavior of the studied system in the parameter range to be explained by the model study. Model complexity has to be controlled to avoid both missing essential features of the system (underfitting) and adapting to irrelevant fluctuations in the data (overfitting). Model validation provides the crucial step in modeling between model synthesis and analysis, assessing how appropriate the model is to gain insight into the real-world system. Model validation can make use of bounds of the VC type (cf. "Vapnik-Chervonenkis Dimension of Neural Networks"), which usually contain a complexity term that accounts for the flexibility of the hypothesis class and a fitting term that measures the contraction of measure due to the large number of samples. It is shown how these terms can be controlled either by numerical methods like cross-validation and bootstrap or by analytical techniques from computational learning theory. The trade-off between model complexity and goodness of fit and its relation to the computational complexity of learning remains a deep challenge for research.

HIDDEN MARKOV MODELS describes the use of deterministic and stochastic finite state automata for sequence processing, with special attention to hidden Markov models as tools for the processing of complex piecewise stationary sequences. It also describes a few applications of ANNs to further improve these methods. HMMs allow complex sequential learning problems to be solved by assuming that the sequential pattern can be decomposed into piecewise stationary segments, with each stationary segment parameterized in terms of a stochastic function. The HMM is called "hidden" because there is an underlying stochastic process (i.e., the sequence of states) that is not observable but that affects the observed sequence of events.

TEMPORAL PATTERN PROCESSING notes that time is embodied in a temporal pattern in two different ways: the temporal order among the components of a sequence and the temporal duration of the elements (see also "Sequence Learning"). A sequence is defined as *complex* if it contains repetitions of the same subsequence, and otherwise is *simple*. For the generation of complex sequences, the correct successor can be determined only by knowing components prior to the current one. We refer to the prior subsequence required to determine the current component as the *context* of the component. Temporal processing requires that a neural network have a capacity of short-term memory (STM) in order to maintain a component for some time. Time warping is challenging because we would like to have invariance over limited warping, but dramatic change in relative duration must be recognized differently. Another fundamental ability of human information processing is chunking, which, in the context of temporal processing, means that frequently encountered and meaningful subsequences organize into chunks that form basic units for further chunking at a higher level. TEMPORAL SEQUENCES: LEARNING AND GLOBAL ANALYSIS studies how elementary pattern sequences may be represented in neural structures at a low architectural and computational cost, seeking to understand mechanisms to memorize spatiotemporal associations in a robust fashion within model neural networks. The article focuses on formal neural networks where the interplay between neural and synaptic dynamics and, in particular, the role of transmission delays can be analyzed using methods from nonlinear dynamics and statistical mechanics. Among the questions studied are how to train a network so that its limit cycles will resemble taught sequences. Such simplified systems are necessarily caricatures of biological structures yet suggest aspects that are important for more elaborate approaches to real neural systems.

EVOLUTION OF ARTIFICIAL NEURAL NETWORKS adds another temporal dimension to the biological process of adaptation, namely, that of evolution. Rather than adapt the weights of a single network to solve a problem in the network's "lifetime," the evolutionary approach applies the methodology of genetic algorithms to evolve a population of neural networks over several generations so that the population becomes better and better suited to some computational ecology. EVOLUTION AND LEARNING IN NEURAL NETWORKS extends this selection of networks on the basis of the result of their adaptation to the environment through lifetime learning. The article shows how studies of ANNs that are subjected both to an evolutionary and a lifetime learning process have been conducted to look at the advantages, in terms of performance, of combining two different adaptation techniques or to help understand the role of the interaction between learning and evolution in natural organisms.

## Computability and Complexity

ANALOG NEURAL NETS: COMPUTATIONAL POWER
LEARNING AND GENERALIZATION: THEORETICAL BOUNDS
NEURAL AUTOMATA AND ANALOG COMPUTATIONAL COMPLEXITY
PAC LEARNING AND NEURAL NETWORKS
UNIVERSAL APPROXIMATORS
VAPNIK-CHERVONENKIS DIMENSION OF NEURAL NETWORKS

The 1930s saw the definition of an abstract notion of computability when it was discovered that the set of functions on the natural numbers, $f\colon \mathbb{N} \rightarrow \mathbb{N}$, computable by a Turing machine (an abstraction from following a finite set of rules to calculate on a finite but extendible tape, each square of which could hold one of a fixed set of symbols), lambda functions (which later came to be better known as functions computable by programs written in LISP), and general recursive functions (a class of functions obtained from very simple numerical functions by repeated application of composition, minimization, etc.), were identical. As general-purpose electronic computers were developed and used in the 1940s and 1950s, it was firmly established that these *computable functions* were precisely the functions that could be computed by such computers with suitable programs, provided there were no limitations on computer memory or computation time. This set the stage for the development of complexity theory in the 1960s and beyond: to chart the different subsets of the computable functions that would be obtained when restrictions were placed on computing resources.

Many classification or pattern recognition tasks can be formulated as mappings between subsets of multidimensional vector spaces by using a suitable coding of inputs and outputs, and many types of feedforward networks are *universal* in the sense that, given enough adjustable synaptic weights, they can approximate any mapping between subsets of Euclidean spaces. UNIVERSAL APPROXIMATORS surveys recent developments in the mathematical theory of feedforward networks and includes proofs of the universal approximation capabilities of perceptron and radial basis function networks with general activation and radial functions, and provides estimates of rates of approximation. The article also characterizes sets of multivariable functions that can be approximated without the "curse of dimensionality," which is an exponentially fast scaling of the number of parameters with the number of variables.

Neural Automata and Analog Computational Complexity explores what happens when the discrete operations of conventional automata theory are replaced by a computing model in which operations on real numbers are treated as basic. Whereas classical automata describe digital machines, neural models frequently require a framework of analog computation defined on a continuous phase space, with a dynamics characterized by the existence of real constants that influence the macroscopic behavior of the system. Moreover, unlike the flow in digital computation, analog models do not include local discontinuities. Neural networks with real weights are more powerful than traditional models of computation in that they can compute more functions within given time bounds. However, the practicality of an approach based on infinite precision real operations remains to be seen. Nonetheless, the new attention to real numbers has renewed complexity theory and introduced many open problems in computational learning theory and neural network theory. The article thus pays special attention to analog computation in the presence of noise. Analog Neural Nets: Computational Power then analyzes the exact and approximate representational power of feedforward and recurrent neural nets with synchronous update, with a brief discussion of networks of spiking neurons and their relation to sigmoidal nets. Learning complexity increases with increasing representational power of the underlying neural model and care has to be exercised to strike a balance between representational power on the one hand and learning complexity on the other. However, the emphasis of the article is on representational power, i.e., on what can be represented with networks using a given set of activation functions, rather than on learning complexity. Splines (i.e., piecewise polynomial functions) have turned out to be powerful approximators, and they are used here as the benchmark class of activation functions. Much attention is given to studying the properties that a class of activation functions needs to reach the approximation power of splines.

PAC Learning and Neural Networks discusses the "probably approximately correct" (PAC) learning paradigm as it applies to ANNs. Roughly speaking, if a large enough sample of randomly drawn training examples is presented, then it should be likely that, after learning, the neural network will classify most other randomly drawn examples correctly. The PAC model formalizes the terms "likely" and "most." The two main issues in PAC learning theory are how many training examples should be presented, and whether learning can be achieved using a fast algorithm. These are known, respectively, as the *sample complexity* and *computational complexity* problems. PAC learning makes use of the Vapnik-Chervonenkis dimension (VC-dimension) as a combinatorial parameter that measures the "expressive power" of a family of functions. This parameter is described more fully in Vapnik-Chervonenkis Dimension of Neural Networks. Bounds for the VC-dimension of a neural net **N** provide estimates for the number of random examples that are needed to train **N** so that it has good generalization properties (i.e., so that the error of **N** on new examples from the same distribution is very small, with probability very close to 1). Typically, the VC-dimension for a class of networks grows polynomially (in many cases, between linearly and quadratically) with the number of adjustable parameters of the neural network. In particular, if the number of training examples is large compared to the VC-dimension, the network's performance on training data is a reliable indication of its future performance on subsequent data. The bounds on training set size tend to be large, since they provide generalization guarantees simultaneously for any probability distribution on the examples and for any training algorithm that minimizes disagreement on the training examples. Tighter bounds are available for some special distributions and specific training algorithms. This theme is further developed in Learning and Generalization: Theoretical Bounds in relation to three learning problems: pattern recognition, regression estimation, and density estimation. Because of the looseness of its bounds as well as the difficulty of evaluating them, VC theory was until recently largely neglected by practitioners. This has changed markedly with the development of support vector machines. Using nonlinear similarity measures, referred to as kernels, one can reduce a large class of learning algorithms to linear algorithms in an associated feature space. For the linear algorithms, a VC analysis can be carried out, identifying precisely the factors that need to be controlled to achieve high generalization ability in a variety of learning tasks. "Support Vector Machines" casts these factors into a convex optimization framework, leading to efficient and mathematically well-founded algorithms that have been shown to produce state-of-the-art results on a large variety of problems.

Visual Scene Segmentation

The topic of **Vision** has provided one of the most fertile fields of investigation both for brain theorists and for technologists constructing ANNs. Six articles in the road map **Mammalian Brain Regions**—Retina, Collicular Visuomotor Transformations for Gaze Control, "Thalamus," Visual Cortex: Anatomical Structure and Models of Function, and Visual Scene Perception—introduce various brain regions associated with vision. It is important to emphasize the role of "active vision" in gaining information relevant for animals and robots considered as real-time perception-action systems. This is a theme that is further developed in the road maps **Neuroethology and Evolution** and **Mammalian Motor Control**. Nonetheless, many articles in the present road map will analyze vision as the process of discovering from images what is present in the world: we may see active vision as more like the mode of vision employed by the "where/how" system described in Visual Scene Perception, whereas "passive" vision may be closer to the role of the "what" pathway. Dissociations Between Visual Processing Modes explores the notion that the visual system has two kinds of jobs to do. One is to support visual cognition, the other is to drive visually guided behavior. Qualitative information about location may be adequate for cognition, but the sensorimotor function needs quantitative egocentrically calibrated spatial information to guide motor acts. The article reviews evidence from neurophysiology, neurological analysis of patients, and psychophysics that the two systems should be modeled as separate maps of visual space rather than as a single visual representation with two readouts. Moreover, spatial information can flow from the cognitive to the sensorimotor representation, but not in the other direction.

However, even "passive" vision is not so passive, since attentional mechanisms are constantly moving the eyes to foveate on items of particular relevance to the current interests of the organism. Collicular Visuomotor Transformations for Gaze Control reviews the role of the superior colliculus in the control of gaze shifts (combined eye-head movements) and its possible involvement in the control of eye movements in 3D space (direction and depth). During attentive fixation, the "Vestibulo-Ocular Reflex" (VOR) and slow vergence maintain binocular foveal fixation to correct for body movements. When the task requires inspection of an eccentric stimulus, a complex synergy of coordinated movements comes into play. Such refixations typically involve a rapid combined eye-head movement (saccadic gaze shift) and often require binocular adjustment in depth (vergence). By virtue of its topographical organization, the superior colliculus has become a key area for experimental and modeling approaches to the question of how sensory signals can be transformed into goal-directed movements. Interestingly, the superior colliculus is not driven by visual input alone. Auditory and somatosensory cues are transformed to register with the visual map in the colliculus for the control of saccades. Sensor Fusion picks up this theme of ways in which sensory information can be brought together in the brains of diverse animals (snakes, cats, monkeys, and humans) and surveys biologically inspired technological implementations (such as the use of infrared to enhance vision). Pursuit Eye Movements takes us from saccadic "jumps" to those smooth eye movements involved in following a moving target. Current models of pursuit include "image motion" models, "target velocity" models, and models that address the role of prediction in pursuit. These models make no explicit reference to the neural structures that might be responsible, but the article analyzes the neural pathways for pursuit, stressing the importance of both visual areas of the cerebral cortex and oculomotor regions of the cerebellum.

The Retina, the outpost of the brain that contains both light-sensitive receptors and several layers of neurons that "preprocess" these responses, transforms visual signals in a multitude of ways to code properties of the visual world such as contrast, color, and motion. The article suggests that much of the retina's signal coding and structural detail is derived from the need to optimally amplify the signal and eliminate noise. But retinal circuitry is diverse. The exact details are probably related to the ecological niche occupied by the organism. In mammals, the retinal output branches into two pathways, the collicular pathway and the geniculostriate pathway. The destination of the former is the midbrain region known as the superior colliculus, discussed above. Visual Cortex: Anatomical Structure and Models of Function reviews features of the microcircuitry of the target of the geniculostriate pathway, the primary visual cortex (area V1), and discusses the physiological properties of cells in its different laminae. It then outlines several hypotheses as to how the anatomical structure and connections might serve the functional organization of the region. For example, a connectionist model of layer IVc of V1 demonstrated that the gradient of change in properties of the layer could indeed be replicated using dendritic overlap through the lower two-thirds of the IVc layer. However, it was insufficient to explain the continuous and sharply increasing field size and contrast sensitivity observable near the top of the layer. The article shows how this discrepancy led to new experiments and related changes in the model which resulted in a good replication of the actual physiological data and required only feedforward excitation. The article goes on to analyze the anatomical substrates for orientation specificity and for surround modulation of visual responses, and concludes by discussing the origins of patterned anatomical connections. Ocular Dominance and Orientation Columns discusses further properties of cells in layer IVc of V1. When these cells are tested to see which eye drives them more strongly, it is found that ocular dominance takes the form of a zebra-stripe-like pattern of alternating dominance. Within this high-level organization are "hypercolumns" devoted to a particular retinotopic region of visual space, each hypercolumn being further refined into columns whose cells are best responsive to edges of the same specific orientation. The article also presents models for how these structures might form through self-organization during development. The article reviews data on the orientation specificity of cells of V1 and their columnar organization, and offers models for the way in which development may yield such features of cortical structure. Gabor Wavelets and Statistical Pattern Recognition shows how the response properties of many cells in primary visual cortex may be better described by what are called "Gabor wavelets" than as simple edge detectors. Each Gabor wavelet responds best to patterns of a given spatial frequency and orientation within a given neighborhood. The article relates this notion to both biology and technology. The detection of edge information from within a visual scene is an essential component of visual processing. This processing is believed to be initiated in the primary visual cortex, where individual neurons are known to act as feature detectors of the orientation of edges within the visual scene. Individual neurons can have an *orientation preference* (which states that neuron's preferred orientation of the angle of edges) and *orientation selectivity* (which measures the neuron's sensitivity as a detector of orientation). ORIENTATION SELECTIVITY focuses on mechanisms of orientation selectivity in the visual cortex, arguing that the orientation preference of each neuron and the orderly orientation preference map in cortex are likely to be consequences of a pattern of feedforward convergence. However, the selectivity observed in steady-state and orientation dynamics experiments cannot be achieved by a purely feedforward model. Corticocortical inhibition is a crucial ingredient in the emergence of orientation selectivity in the visual cortex, while the relative importance of corticocortical excitation in enhancing orientation selectivity is still under investigation but appears to be more significant for the function of complex cells than for simple cells in V1. Moving beyond the orientation features of primary visual cortex, INFORMATION THEORY AND VISUAL PLASTICITY demonstrates some aspects of information theory that are relevant to relaying information in cortex and connects entropy-based methods, projection pursuit, and extraction of simple cells in visual cortex. FEATURE ANALYSIS offers a more general view of the characterization of visual features based on the redundancy of the visual signal and the transformation of the signal as it passes along the visual pathway. Describing a particular cell as an "*x* detector" implies that the cell responds when and only when that particular feature is present (e.g., an edge detector responds only in the presence of an edge), but the article argues that describing cells in the early visual system as "detectors" of any type of feature is misleading. Features are useful for describing natural images because the latter have massive informational redundancy. Image space itself is too vast to search directly. Feature analysis depends on the proposition that the search for particular objects can be concentrated in a subspace of image space, the feature space. Localized receptive fields in primary visual cortex provide the primitive basis set for the feature space of vision. These form the basis for the elaboration of neurons responding selectively to geometrical features in area TE of the inferotemporal cortex (IT), and these in turn from the basis for object recognition in different but overlapping areas of IT.

Given that cells in the early stages of the visual system, at least, provide a distributed (more or less retinotopic) set of "features" (in some suitably general sense, given the above caution, of patterns that yield the best response rather than patterns that yield the only response), the issue arises of how those features that correspond to a single object in the visual scene are bound together. CONTOUR AND SURFACE PERCEPTION introduces parallel interacting subsystems that follow complementary processing strategies. Boundary formation proceeds by spatially linking oriented contrast measures along smooth contour patterns, while perceptual surface attributes, such as lightness or texture, are derived from local ratio measures of image contrast of regions lying within contours. Mechanisms of both subsystems mutually interact to resolve initial ambiguities and to generate coherent representations of surface layout. Representations of intrinsic scene characteristics are constrained in terms of the consistency of the set of solutions, which often involve smoothness assumptions for correlated feature estimates. These consistency constraints are typically based on the laws of physical image generation. The article reviews fundamental approaches to computation of intrinsic scene characteristics and various neural models of boundary and surface computation. Each model involves lateral propagation of signals to interpolate and smooth sparse estimates.

ADAPTIVE RESONANCE THEORY (ART) bases learning on internal expectations. A pattern matching process (both for visual patterns and in other domains) compares an external input with the internal memory code for various patterns. ART matching leads either to a *resonant* state, which persists long enough to permit learning, or to a parallel memory search. If the search ends at an established code, the memory representation may either remain the same or incorporate new information from matched portions of the current input. When the external world fails to match an ART network's expectations or predictions, a search process selects a new category, representing a new hypothesis about what is important in the present environment. LAMINAR CORTICAL ARCHITECTURE IN VISUAL PERCEPTION uses the LAMINART model (an extension of ART) to propose functional roles for cortical layers in visual perception. Neocortex has an intricate design that exhibits a characteristic organization into six distinct cortical layers, but few models have addressed the functional utility of the laminar organization itself in the control of behavior. LAMINART integrates data about visual perception and neuroscience for such processes as preattentive grouping and attention. It is suggested that the functional roles for cortical layers proposed here—binding together distributed cortical data through a combination of bottom-up adaptive filtering and horizontal associations, and modulating it with top-down attention—generalize, with appropriate specializations, to other forms of sensory and cognitive processing.

CORTICAL POPULATION DYNAMICS AND PSYCHOPHYSICS models cortical population dynamics to explain dynamical properties of the primate visual system on different levels, reaching from single neuron properties like selectivity for the orientation of a stimulus up to higher cognitive functions related to the binding and processing of stimulus features in psychophysical discrimination experiments. On the other hand, SYNCHRONIZATION, BINDING AND EXPECTANCY argues that the "binding" of cells that correspond to a given visual object may exploit another dimension of cellular firing, namely, the phase at which a cell fires within some overall rhythm of firing. The article presents data consistent with the proposal that the synchronization of responses on a time scale of milliseconds provides an efficient mechanism for response selection and binding of population responses. Synchronization also increases the saliency of responses because it allows for effective spatial summation in the population of neurons receiving convergent input from synchronized input cells. VISUAL SCENE SEGMENTATION tackles the segmentation of a visual scene into a set of coherent patterns corresponding to objects. Objects appear in a natural scene as the grouping of similar sensory features and the segregation of dissimilar ones. Studies in visual perception, in particular *Gestalt* psychology, have uncovered a number of principles for perceptual organization, such as proximity, similarity, connectedness, and relatedness in memory. Scene segmentation requires neural networks to address the binding problem. The temporal correlation approach is to encode the binding by the correlation of temporal activities of feature-detecting cells. A special form of temporal correlation is *oscillatory correlation*, where the basic units are neural oscillators. The article first reviews nonoscillatory approaches in scene segmentation, and then turns to oscillatory approaches. The temporal correlation approach is further developed in DYNAMIC LINK ARCHITECTURE, which views the brain's data structure as a graph composed of nodes connected by links, where both units and links bear activity variables changing on the rapid time scale of fractions of a second. The nodes play the role of symbolic elements. Dynamic links constitute the glue by which higher data structures are built up from more elementary ones.

Beyond the basic issue of how the visual scene is segmented (how visual elements are grouped) into possibly meaningful wholes lies the question of determining for a region so determined its color, motion, distance, shape, etc. These issues are addressed in the next set of articles. COLOR PERCEPTION stresses that color is not a local property inferred from the wavelength of light hitting a patch of retina but is a property of regions of space that depends both on the light they reflect and on the surrounding context. Our visual system "recreates" the world in the form of boundaries that contain surfaces, and color perception involves the perception of aspects of these surfaces. Matching surfaces with the same reflectance properties in different parts of the visual scene or under different illuminants are the two problems of color constancy. In addition, wavelength signals can be used in the course of perceiving form or motion independent of their role in the subjective experience of color. Directional Selectivity first reviews models of retinal direction selectivity (which contributes to oculomotor responses rather than motion perception). Older models depend on the way in which amacrine and other cells of the retina are connected to the ganglion cells, the retinal output cells. A newer model is based on the directionality of synaptic interactions on the dendrites of amacrine cells, involving a spatial asymmetry in the inputs and outputs of a dendrodendritic synapse, and its shunting inhibition. It is argued that development of this latter mechanism might involve Hebbian processes driven by spontaneous activity and light. Cortical directional selectivity (which does contribute to motion perception as well as the control of eye movements) involves many cortical regions. Directionally sensitive cells in primary visual cortex (V1) project to middle temporal cortex (MT) where directional selectivity becomes more complex, MT cells typically having larger receptive fields. From MT, the motion pathway projects to middle superior temporal cortex. Cortical directional selectivity has been modeled in three manners: as a spatially asymmetric excitatory drive followed by multiplication or squaring, via a spatially asymmetric nonlinear inhibitory drive, and through a spatially asymmetric linear inhibitory drive followed by positive feedback. This selectivity might involve Hebbian processes driven by spontaneous activity and binocular interactions. The issues in this article have some overlap with those presented in Motion Perception: Elementary Mechanisms, which emphasizes measurement of the direction and speed of movement of features in the 2D image linking successive views to infer *optic flow*, which is the pattern of image velocities that is projected onto the retina. The article discusses the cortical correlates of these various representations. Motion Perception: Navigation shows how, when an observer moves through the world, the optic flow can inform him about his own motion through space and about the 3D structure and motion of objects in the scene. This information is essential for tasks such as the visual guidance of locomotion through the environment and the manipulation and recognition of objects. This article focuses on the recovery of observer motion from optic flow. It includes strategies for detecting moving objects and avoiding collisions, discusses how optic flow may be used to control actions, and describes the neural mechanisms underlying heading perception. Global Visual Pattern Extraction continues the study of neural mechanisms which mediate between the extraction of local edge and contour information by orientation-selective simple cells in primary visual cortex (V1) and the high levels of cortical form vision in inferior temporal cortex (IT), where many neurons are sensitive to complex global patterns, including objects and faces. The ventral form vision pathway includes at least areas V1, V2, V4, TEO, and TE (the highest level of IT), raising the question of what processes occur at these intervening stages to transform local V1 orientation information into global pattern representations. Essentially the same question may be posed in cortical motion processing along the dorsal pathway comprising V1, V2, MT, MST, and higher parietal areas. V1 neurons extract only local motion vectors perpendicular to moving edge segments, while MST neurons are sensitive to complex optic flow patterns, including expansion. This article suggests answers to these analogous questions about transitions from local to global processing in both motion and form vision by focusing on intermediate levels of these two pathways, mainly V4 and MST.

Perception of Three-Dimensional Structure reviews various computational models for inferring an object's 3D structure from different types of optical information, such as shading, texture, motion, and stereo, and examines how the performance of these models compares with the capabilities and limitations of human observers in judging different aspects of 3D structure under varying viewing conditions. In particular, stereoscopic vision exploits the fact that points in a 3D scene will in general project to different positions in the images formed in the left and right eyes. The differences in these positions are termed *disparities*. The stereo *correspondence problem* is to identify which points in a pair of stereo images correspond to a single point in 3D space. Solving this problem allows the stereo pair to be mapped into a single representation, called a disparity map, that makes explicit the disparities of various points common to both images, thus revealing the distance of various visual elements from the observer. Depth perception is then completed by determining depth values for all points in the images. Stereo Correspondence notes that various constraints have been used to help determine which features on the two eyes should be matched in inferring depth. These include compatibility of matching primitives, cohesivity, uniqueness, figural continuity, and the ordering constraint. Various neural network stereo correspondence algorithms are then reviewed, and the problems of surface discontinuities and uncorrelated points, and of transparency, are addressed. The article also reviews neurophysiological studies of disparity mechanisms.

A more abstract approach to the correspondence problem, from the perspective of computer vision rather than psychology or neurophysiology, is offered in Tensor Voting and Visual Segmentation. In 3D, as we have seen, surfaces are inferred from binocular images by obtaining depth hypotheses for points and/or edges. In image sequence analysis, the estimation of motion and shape starts with local measurements of feature correspondences, which gives noisy data for the subsequent computation of scene information. Hence, any salient structure estimator must be able to handle the presence of multiple structures and their interaction in the presence of noisy data. This article analyzes approaches to address early to midlevel vision problems, emphasizing the tensor voting methodology for the robust inference of multiple salient structures such as junctions, curves, regions, and surfaces from any combination of points, curve elements, and surface patch element inputs in 2D and 3D. The article describes two regularization formalisms, one that imposes certain physical constraints so that the search space can be constrained and algorithmically tractable, and another using a Bayesian formalism to transform an ill-posed problem into one of functional optimization.

Probabilistic Regularization Methods for Low-Level Vision offers regularization theory (cf. "Generalization and Regularization in Nonlinear Learning Systems") as a general mathematical framework to deal with the fact that the problem of inferring 3D structure from 2D images is *ill-posed*: there are many spatial configurations compatible with a given 2D image or set (motion sequence, stereo pair, etc.) of images. The issue then becomes to find which spatial configuration is most probable. We have already seen a number of constraints associated with stereo vision. Deterministic regularization theory defines a "cost function," which combines a measure of how close a spatial configuration comes to yielding the given image (set) with a measure of the extent to which the configuration violates the constraints, and then seeks that configuration which minimizes this cost. The present article emphasizes a more general probabilistic approach in which the "actual" field $f$ and the observed field $g$ are considered as realizations of random fields, with the reconstruction of $f$ understood as an estimation problem. Markov Random Field Models in Image Processing views the task of image modeling as being one of finding an adequate representation of the intensity distribution of a given image. What is adequate often depends on the task at hand. The general properties of the local spatiotemporal structure of images or image sequences are characterized by a Markov random field (MRF) in which the probability distribution for the image intensity and a further set of other attributes (edges, texture, and region labels) at a particular location are conditioned on values in a neighborhood of pixels (picture elements or image points). The observed quantities are usually noisy, blurred images. The article presents five steps of MRF image modeling within a Bayesian estimation/inference paradigm, and provides a number of examples. Particular attention is paid to maximum a posteriori (MAP) estimates. MRF image models have proved versatile enough to be applied to image and texture synthesis, image restoration, flow field segmentation, and surface reconstruction.

Kalman Filtering: Neural Implications introduces Kalman filtering, which, under linear and Gaussian conditions, produces a recursive estimate of the hidden state of a dynamic system, i.e., one that is updated with each subsequent (noisy) measurement of the observed system. The article shows how Kalman filtering provides insight into visual recognition and the role of the cerebellum in motor control. In particular, it presents a hierarchically organized neural network for visual recognition, with each intermediate level of the hierarchy receiving two kinds of information: bottom-up information from the preceding level, and top-down information from the higher level. For its implementation, the model uses a multiscale estimation algorithm that may be viewed as a hierarchical form of the extended Kalman filter that is used to simultaneously learn the feedforward, feedback, and prediction parameters of the model on the basis of visual experiences in a dynamic environment. The resulting adaptive process involves a fast dynamic state-estimation process that allows the dynamic model to anticipate incoming stimuli, as well as a slow Hebbian learning process that provides for synaptic weight adjustments in the model.

Imaging the Visual Brain addresses functional brain imaging of visual processes, with emphasis on limits in spatial and temporal resolution, constraints on subject participation, and trade-offs in experimental design. The articles focuses on retinotopy, visual motion perception and visual object representation, and voluntary modulation of attention and visual imagery, emphasizing some of the areas where modeling and brain theory might be testable using current imaging tools. Visual Attention offers data and hypotheses for cortical mechanisms to overtly and covertly shift attention (i.e., with and without eye movements). Attention guides where to look next based on both bottom-up (image-based) and top-down (task-dependent) cues—and indeed, the anatomy of the visual system includes extensive feedback connections from later stages and horizontal connections within each layer. Vision appears to rely on sophisticated interactions between coarse, massively parallel, full-field preattentive analysis systems and the more detailed, circumscribed, and sequential attentional analysis system. The articles focus on the brain area involved in visual attention and then analyzes a variety of relevant mechanisms. Yet, having stressed the way in which we normally take a number of shifts of attention to fully take in the details of a visual scene, it is intriguing to learn how much can be absorbed in a single fixation. Fast Visual Processing notes that much information can be extracted from briefly glimpsed scenes, even at presentation rates of around 10 frames/s, a technique known as rapid sequential visual presentation (RSVP). Since interspike intervals for neurons are seldom shorter than 5 ms, the underlying algorithms should involve no more than about 20 sequential, though massively parallel, steps. There is an important distinction in neural computation between feedforward processing models and those with recurrent connections that allow feedback and iterative processing. Pure feedforward models (e.g., multilayer perceptrons, MLPs) can operate very quickly in parallel hardware. The article argues that even in systems that use extensive recurrent connections, the fastest behavioral responses may essentially depend on a single feedforward processing wave. It looks at how detailed measurements of processing speed can be combined with anatomical and physiological constraints to constrain models of how the brain performs such computations.

There is a vast literature on pattern recognition in neural networks (see, for example, "Pattern Recognition" and "Concept Learning"). Here we discuss articles on face recognition and object recognition. The recognition of other individuals, and in particular the recognition of faces, is a major prerequisite for human social interaction and indeed has been shown to employ specific brain mechanisms. The ability to recognize people from their faces is part of a spectrum of related skills that include face segmentation (i.e., finding faces in a scene or image) and estimation of the pose, direction of gaze, and the person's emotional state. Face Recognition: Neurophysiology and Neural Technology starts with a review of relevant neurophysiology. Brain injury can lead to prosopagnosia, the loss of ability to recognize individual faces, while leaving intact the ability to recognize general objects. Single-unit recordings in the IT cortex of macaque monkeys have revealed neurons with a high responsiveness to the presence of a face, an individual, or the expression on the face, and neural models for face recognition are reviewed in relation to such data. The article then focuses on computational theories that are inspired by neural ideas (see Dynamic Link Architecture; Gabor Wavelets and Statistical Pattern Recognition) but that find their justification in the construction of successful computer systems for the recognition of human faces even when the gallery of possible faces is very large indeed. Face Recognition: Psychology and Connectionism provides a brief history of connectionist approaches to face recognition and surveys the broad range of tasks to which these models have been applied. The article relates the models to psychological theories for the subtasks of representing faces and retrieving them from memory, comparing human and model performance along these dimensions.

Object Recognition focuses on models of viewpoint-invariant object recognition that are constrained by psychological data on human object recognition. It present three main approaches to object recognition—invariant based, model based, and appearance based—and analyzes the strengths of each of these in a framework of decision complexity, noting the trade-off between representations that emphasize invariance and those designed for discriminability. The analysis shows that it is unlikely for a single form of representation to satisfy all kinds of object recognition tasks a human or other visual animal may encounter. The article thus argues that a key ingredient in a comprehensive brain theory for object recognition is a computational framework that allows on-demand selection or adaptation of representations based on the current task and proposes a simple "first past the post" scheme (a temporal winner-take-all scheme) for self-selecting the most appropriate level of abstraction, given a finite set of available representations along a visual processing pathway.

Object Structure, Visual Processing emphasizes structure-processing tasks that call for separate treatment of various fragments of the visual stimulus, each of which spans only a fraction of the visual extent of the object or scene under consideration. Examples of structural tasks include recognition of part-part similarities, and identifying a region in an object toward which an action can be directed. After discussing object form processing in computer vision and relevant neurophysiological data on primate vision, the article focuses on two neuromorphic models of visual structure processing. The JIM model implements a recognition-by-components scenario based on geons ("geometrical elements," which are generalized cylinders formed by moving a cross-section along a possibly curved axis). The Chorus of Fragments model exploits both the "what" and the "where" streams of visual cortex to recognize fragments no matter what their position, but then uses their approximate spatial relationships to see whether they together form cues for the recognition of an object. In particular, then, it avoids the binding problem of explicitly linking neural activity related to a specific object as a prerequisite to analysis of that object's characteristics. (By contrast, SYNCHRONIZATION, BINDING AND EXPECTANCY argues that the brain does solve the binding problem, and does so by synchronization of neural firing for those neurons related to a single object.)

OBJECT RECOGNITION, NEUROPHYSIOLOGY reviews some theoretical approaches to object recognition in the context of mainly neurophysiological evidence. It also considers briefly the analysis of visual scenes. Scene analysis is relevant to object recognition because scenes may themselves be recognized initially at a holistic, object-like level, providing a context or "gist" that influences the speed and accuracy of recognition of the constituent objects. The article proposes that object recognition is based on a distributed, view-based representation in which objects are recognized on the basis of multiple, 2D-feature-selective neurons. Specialist cells appear to play a role in associating such feature combinations into certain nontrivial image transformations, coding for a certain percentage of all stimuli in a largely view-invariant manner. The article offers evidence that a convergent hierarchy is used to build invariant representations over several stages, and that at each stage lateral competitive processes are at work between the neurons. It is argued that the association of views of objects observed over the course of time could play a key role in building up object representations. The review focuses mainly on the "what" stream of IT cortex, seen as the center of object recognition. VISUAL SCENE PERCEPTION also brings in the "where/how" stream of parietal cortex as it analyzes how mechanisms that integrate schemas for recognition of different objects into the perception of some overall scene may be linked to the distributed planning of action. It also presents recent neurophysiology suggesting how the context of a natural scene may modify the response properties of neurons responsive to visual features. The article compares three approaches—the slide-box metaphor, short-term memory in the VISIONS system, and the visuospatial scratchpad—for creating a theory of how the visual perception of objects may be integrated with the perception of spatial layout. The first two stress a schema-theoretic approach, while the latter is strongly tied to visual neurophysiology and modeling in terms of quasi-neural attractor networks. The aim is to open the way to future research that will embed the study of visual scene perception in an action-oriented integration of IT and parietal visual systems.

## Other Sensory Systems

AUDITORY CORTEX
AUDITORY PERIPHERY AND COCHLEAR NUCLEUS
AUDITORY SCENE ANALYSIS
ECHOLOCATION: COCHLEOTOPIC AND COMPUTATIONAL MAPS
ELECTROLOCATION
OLFACTORY BULB
OLFACTORY CORTEX
PAIN NETWORKS
PROSTHETICS, SENSORY SYSTEMS
SENSOR FUSION
SOMATOSENSORY SYSTEM
SOMATOTOPY: PLASTICITY OF SENSORY MAPS
SOUND LOCALIZATION AND BINAURAL PROCESSING

Here we analyze sensory systems other than vision—e.g., touch, audition, and pain. Moreover, when one sense cannot provide all the necessary information, complementary observations may be provided by another sense. For example, touch complements vision in placing a peg in a hole when the effector occludes the agent's view. Also, senses may offer competing observations, such as the competition between vision and the vestibular system in maintaining balance (and its occasional side effect of seasickness). Another type of interplay between the senses is the use of information extracted by one sense to focus the attention of another sense, coordinating the two, as in audition cueing vision. SENSOR FUSION explores a number of ways sensory information is brought together in the brains of diverse animals (snakes, cats, monkeys, humans) and surveys biologically inspired technological implementations (such as the use of infrared to enhance vision). (See also "Collicular Visuomotor Transformations for Gaze Control" for an important example of sensor fusion—the transformation of auditory and somatosensory cues into a visual map for the control of rapid eye movements.)

The road map **Mammalian Brain Regions** introduced a number of regions linked to sensory systems other than vision, but we will now meet a number of related and additional topics as well. SOMATOSENSORY SYSTEM shows how the somatosensory system changes the tactile stimulus representation from a form more or less isomorphic to the stimulus to a completely distributed form in a series of partial transformations in successive subcortical and cortical networks. It further argues that the causal factors involved in body/object interactions are explicitly represented by an internal model in the pyramidal cells of somatosensory cortex that is crucial for haptic perception of proximal surroundings and for control of object manipulation. Somatotopy, a dominant feature of subdivisions of the somatosensory system, is defined by a topographic representation, or map, in the brain of sensory receptors on the body surface. SOMATOTOPY: PLASTICITY OF SENSORY MAPS shows that these orderly representations of cutaneous receptors in the spinal cord, lower brainstem, thalamus, and neocortex represent both the peripheral distribution of receptors and dynamic aspects of brain function. The article reviews evidence for somatosensory plasticity involving cortical reorganization after peripheral injury and as a result of training. The article analyzes the features of somatotopic maps that change, the contribution of subcortical changes to cortical plasticity, the mechanisms involved, and the functional consequences of sensory map changes. An important issue is the relation between the plasticity of the sensory and motor systems.

PAIN NETWORKS adds a new dimension to bodily sensation. The pain system encodes information on the intensity, location, and dynamics of tissue-threatening stimuli but differs from other sensory systems in its "emotional-motivational" factors (see also "Motivation"). In the pain system, these factors strongly modulate the relation between stimulus and felt response. At one extreme is allodynia, a state in which the slightest touch with a cotton wisp is agonizing. People display wide individual and trial-to-trial variability in the amount of pain reported following administration of calibrated noxious stimuli; pain sensation is subject to ongoing modulation by a complex of extrinsic (stimulus-generated) and intrinsic (CNS-generated) state variables. The article spells out how these act in the CNS as well as the periphery.

AUDITORY PERIPHERY AND COCHLEAR NUCLEUS spells out how the auditory periphery parcels out acoustic stimulus across hundreds of nerve fibers, and how the cochlear nucleus continues this process by creating multiple representations of the original acoustic stimulus. The article emphasizes monaural signal processing, whereas SOUND LOCALIZATION AND BINAURAL PROCESSING shows how information from the two ears is brought together. The article focuses on the use of interaural time difference (ITD) as one way to estimate the azimuthal angle of a sound source. It describes one biological model (ITD detection in the barn owl's brainstem) and two psychological models. The underlying idea is that the brain attempts to match the sounds in the two ears by shifting one sound relative to the other, with the shift that produces the best match assumed to be the one that just balances the "real" ITD. AUDITORY CORTEX stresses the crucial role that auditory cortex plays in the perception and localization of complex sounds, examining auditory tasks vital for all mammals, such as sound localization, timbre recognition, and pitch perception. AUDITORY SCENE ANALYSIS discusses how the auditory system parses the acoustic mixture that reaches the ears of an animal to segregate a targeted sound source from the background of other sounds. The first stage, segmentation, decomposes the acoustic mixture into its constituent components. In the second stage, acoustic components that are likely to have arisen from the same environmental event are grouped, forming a perceptual representation (stream) that describes a single sound source. At the physiological level, segmentation corresponds (at least in part) to peripheral auditory processing, which performs a frequency analysis of the acoustic input, whereas the physiological substrate of auditory grouping is much less well understood. The article focuses on models that are at least physiologically plausible, while noting that other models of auditory scene analysis adopt a more abstract information processing perspective.

ECHOLOCATION: COCHLEOTOPIC AND COMPUTATIONAL MAPS provides us with a more detailed understanding of the auditory system in a very special class of mammals, the bats. Mustached bats emit echolocation (ultrasonic) pulses for navigation and for hunting flying insects. On the basis of the echo, prey must be detected and distinguished from the background clutter of vegetation, characterized as appropriate for consumption, and localized in space for orientation and prey capture. The bats emit ultrasonic pulses that consist of a long constant-frequency component followed by a short frequency-modulated component. Each pulse-echo combination provides a discrete sample of the continuously changing auditory scene. The auditory network contains two key design features: neurons that are sensitive to combinations of pulse and echo components, and computational maps that represent systematic changes in echo parameters to extract the relevant information.

Electrolocation is another sense that helps the animal locate itself in its world, but this time the animals are electric fishes rather than bats, and the signals are electrical rather than auditory. ELECTROLOCATION relates its topic to the general issue of mechanisms that facilitate the processing of relevant signals while rejecting noise, and of attentional processes that select which stimuli are to be attended to. Weakly electric fish generate an electrical field around their body and measure this field via electroreceptors embedded in the skin to "electrolocate" animate or inanimate targets in the environment. The article emphasizes a widespread but poorly understood characteristic of sensory processing circuits, namely, the presence of massive descending or feedback connections by which higher centers presumably modulate the operation of lower centers. Not only are response gain and receptive field organization controlled by these descending connections, but there are adaptive filtering mechanisms that can reject stimuli that otherwise might mask critical functions. This use of stored sensory expectations for the cancellation or perhaps the identification of specific input patterns may yield insights into diverse neural circuits, including the cochlear nuclei and the cerebellum, in other species.

Two articles introduce data and models for the olfactory system (see also the road map **Mammalian Brain Regions**). OLFACTORY BULB describes the special circuitry involved in basic preprocessing, while OLFACTORY CORTEX presents a dynamical systems analysis of further olfactory processing. The olfactory bulb receives input from the sensory neurons in the olfactory epithelium and sends its outputs to the olfactory cortex, among other brain regions. The bulb was one of the first regions of the brain for which compartmental models of neurons were constructed, which led to some of the first computational models of functional microcircuits. OLFACTORY BULB gives an overview of olfactory bulb cells and circuits, current ideas about the computational functions of the bulb, and modeling studies to investigate these functions. The olfactory cortex is defined as the region of the cerebral cortex that receives direct connections from the olfactory bulb. It is the earliest cortical region to differentiate in the evolution of the vertebrate forebrain and the only region within the forebrain to receive direct sensory input. Moreover, the olfactory cortex has the simplest organization among the main types of cerebral cortex. OLFACTORY CORTEX thus views it as a model for understanding basic principles underlying cortical organization.

Finally, a very different view of sensory systems is provided by PROSTHETICS, SENSORY SYSTEMS, which discusses how information collected by electronic sensors may be delivered directly to the nervous system by electrical stimulation. After assessing the amenability of all sensory modalities (hearing, vision, touch, proprioception, balance, smell, and taste), the article focuses on auditory and visual prostheses. The great success story has been with cochlear implants. Here the article reviews improved temporospatial representations of speech sounds, combined electrical and acoustic stimulation in patients with residual hearing, and psychophysical correlates of performance variability. Since a prosthesis does not necessarily match natural neural encoding of a stimulus, the success of the prosthesis depends in part on the plasticity of the human brain as it remaps to accommodate this new class of signals. For example, the success of cochlear implants rests in part on the ability of auditory cortex to remap itself in a similar fashion to the remapping of somatosensory cortex described in SOMATOTOPY: PLASTICITY OF SENSORY MAPS.

SENSORIMOTOR LEARNING

As noted in the "Historical Fragment" section of Part I, the interchange between biology and technology that characterizes the study of neural networks is an outgrowth of work in *cybernetics* in the 1940s. One of the keys to cybernetics was control (the other was communication of the kind studied in information theory). It is thus appropriate that control theory should have become a major application area for neural networks as well as being a key concept of brain theory. The objective of control is to influence the behavior of a dynamical system in some desired fashion. The latter includes maintaining the outputs of systems at constant values (regulation) or forcing them to follow prescribed time functions (tracking). Maintaining the altitude of an aircraft or the glucose level in the blood at constant values are examples of regulation; controlling a rocket to follow a given trajectory is an example of tracking. MOTOR CONTROL, BIOLOGICAL AND THEORETICAL sets forth the basic cybernetic concepts. A motor control system acts by sending motor commands to a controlled object, often referred to as "the plant," which in turn acts on the local environment. The plant or the environment has one or more variables which the controller attempts to regulate. If the controller bases its actions on signals which are not affected by the plant output, it is said to be a feedforward controller. If the controller bases its actions on a comparison between desired behavior and the controlled variables, it is a feedback controller. "Motor Pattern Generation" provides a related perspective (see the road map **Motor Pattern Generators**).

The major advantage of negative feedback control, in which the controller seeks constantly to cancel the feedback error, is that it is a very simple, robust strategy that operates well without exact knowledge of the controlled object, and despite internal or external disturbances. The advantage of feedforward control is that it can, in the ideal case, give perfect performance with no error between the reference and the controlled variable. The main disadvantages are the practical difficulties in developing an accurate controller, and the lack of corrections for unexpected disturbances. IDENTIFICATION AND CONTROL explores the major strategy for developing an accurate controller, namely to "identify" the plant as belonging to (or more precisely, being well approximated by) a system obtained from a general family of systems by setting a key set of parameters (e.g., the coefficients in the matrices of a linear system). By coupling a controller to an identification procedure, one obtains an adaptive controller that can handle an unknown plant even if its dynamics are (slowly) changing. In both biology and many technological applications, nonlinearities and uncertainties play a major role, and linear approximations are not satisfactory. The article presents research using neural networks to handle these nonlinearities and examines the theoretical assumptions that have to be made when such networks are used as identifiers and controllers.

REINFORCEMENT LEARNING IN MOTOR CONTROL recalls the general theory introduced in "Reinforcement Learning" and proceeds to note its utility in motor control. Many motor skills are attained in the absence of explicit feedback about muscle contractions or joint angles. In contrast to supervised learning, such learning depends on "reinforcement" (or evaluative feedback; it need not involve pleasure or pain), which tells the learner whether or not, and possibly by how much, its behavior has improved, or provides an indication of success or failure. Instead of trying to match a standard of correctness, a reinforcement learning system tries to maximize the goodness of behavior as indicated by evaluative feedback. To do this, it has to actively try alternatives, compare the resulting evaluations, and use some kind of selection mechanism to guide behavior toward the better alternatives. Q-LEARNING FOR ROBOTS applies reinforcement learning techniques to robot control. Q-learning does not require a model of the robot-world interaction, and it uses learning examples in the form of triplets (situation, action, Q-value), where the Q-value is the *utility* of executing the action in the situation. Q-learning involves three different functions, *evaluation, memorization*, and *updating*. Heuristically adapted Q-learning has proved successful in applications such as obstacle avoidance, wall following, go-to-the-nest, etc., using neural-based implementations such as multilayer perceptrons trained with backpropagation, or self-organizing maps.

SENSORIMOTOR LEARNING explains how neural nets can acquire "models" of some desired sensorimotor transformation. A *forward model* is a representation of the transformation from motor commands to movements, in other words, a model of the controlled object. An *inverse model* is a representation of the transformation from desired movements to motor commands, and so can be used as the controller for the controlled object. The managing of multiple models, each with their own range of applicability in given tasks, is given special attention. ROBOT LEARNING focuses on learning robot control, the process of acquiring a sensorimotor control strategy for a particular movement task and movement system. The article offers a formal framework within which to discuss robot learning in terms of the different methods that have been suggested for the learning of control policies, such as learning the control policy directly, learning the control policy in a modular way, indirect learning of control policies, imitation learning, and learning of motor control components. The article also reviews specific function approximation problems in robot learning, including neural network approaches. ROBOT ARM CONTROL addresses related issues concerning the availability of precise mappings from physical space or sensor space to joint space or motor space. Robot arm controllers are usually hierarchically structured from the lowest level of servomotors to the highest levels of trajectory generation and task supervision. In each case an actual motion is made to follow as closely as possible a commanded motion through the use of feedback. The difference lies in the coordinate systems used at each level. At least four coordinate spaces can be distinguished: the task space (used to specify tasks, possibly in terms of sensor readings), the workspace (6D Cartesian coordinates defining a position and orientation of the end-effector), the joint space (intrinsic coordinates determining a robot configuration), and the actuator space (in which actual motions are commanded). Correlational procedures carry out feature discovery or clustering and are often used to represent a given state space in a compact and topology-preserving manner, using procedures such as those described in "Self-Organizing Feature Maps." Error-minimization procedures require explicit data on input-output pairs; their goal is to build a mapping from inputs to outputs that generalizes adequately using, e.g., the least-mean-squares (LMS) rule and backpropagation. In between both extremes lie procedures that use reinforcement learning to build a mapping that maximizes reward. ARM AND HAND MOVEMENT CONTROL discusses some of the most prominent regularities of arm and hand control, and examines computational and neural network models designed to explain them. The analysis reveals an interesting competition between explanations sought on the neural, biomechanical, perceptual, and computational levels that has created its share of controversy. Whereas some topics, such as internal model control, have gained solid grounding, the importance of the dynamic properties of the musculoskeletal system in facilitating motor control, the role of real-time perceptual modulation of motor control, and the balance between dynamical systems models versus optimal control-based models are still seen as offering many open questions.

BIOLOGICALLY INSPIRED ROBOTICS describes how modern robotics may learn from the way organisms are constructed biologically and how this creates adaptive behaviors. (I cannot resist noting here the acronym introduced by R. I. Damper, R. L. B. French, and T. W. Scutt, 2000, ARBIB: An Autonomous Robot Based on Inspiration from Biology, *Robotics and Autonomous Systems*, 31:247–274.) Research on autonomous robots based on inspiration from biology ranges from modeling animal sensors in hardware to guiding robots in target environments to investigating the interaction between neural learning and evolution in a variety of robot tasks. After reviewing the historical roots of the subject, the article provides a general introduction to biologically inspired robotics, with special emphasis on the ideas that the robot is situated in the world and that many complex behaviors are emergent properties of the collective effects of linking a variety of simple behaviors. REACTIVE ROBOTIC SYSTEMS provides a conceptual framework for robotics that is rooted in "Schema Theory" (q.v.) rather than symbolic AI. Here, robot behavior is controlled by the activation of a collection of low-level primitive behaviors (schemas), and complex behavior emerges through the interaction of these schemas and the complexities of the environment in which the robot finds itself. This work was inspired in part by studies of animal behavior (see, e.g., "Neuroethology, Computational" and related articles discussed in the road maps on **Motor Pattern Generators** and **Neuroethology and Evolution**). However, the article not only shows the power of reactive robots in many applications, it also notes the utility of hybrid systems capable of using deliberative reasoning as well as reactive execution (which fits with an evolutionary view of the human brain in which reactive systems handle many functions but can be overruled or orchestrated by, e.g., the deliberative activities of prefrontal cortex).

Robot Navigation examines how to get a mobile robot to move to its destination efficiently (e.g., along short trajectories) and safely (i.e., without colliding). If a target location is either visible or identified by a landmark (or sequence of landmarks), a simple stimulus-response strategy can be adopted. However, if targets are not visible, the robot needs a model (or map) of the environment encoding the spatial relationships between its present and desired locations. Sensor uncertainty, together with the inaccuracy of the robot's actuators and the unpredictability of real environments, makes the design of mobile robot controllers a difficult task. It has thus proved desirable to endow robots with learning capabilities in order to acquire autonomously their control system and to adapt their behavior to never experienced situations. The article thus reviews neural approaches to localization, map building, and navigation. More specifically, Potential Fields and Neural Networks examines biological findings on the use of potential fields (which represent, e.g., the force field that drives the motor output of an animal or part of an animal, such as a limb) to characterize the control and learning of motor primitives. The notion of potential fields has also been used to model externally induced constraints as well as internally constructed sensorimotor maps for robot motion control. A robot can reach a stable configuration in its environment by following the negative gradient of its potential field. In this case, the configurations reached will be locally stable but may not be optimal with respect to some behavioral criterion. This deficit can be overcome either by incorporating a global motion planner or by using a harmonic function that does not contain any local minima. The article further indicates how potential field–based motion control can benefit from the use of ANN-based learning. There are links here to the more biological concerns of the articles "Cognitive Maps," "Hippocampus: Spatial Models," and "Motor Primitives."

Scratch Reflex
Sensorimotor Interactions and Central Pattern Generators
Spinal Cord of Lamprey: Generation of Locomotor Patterns

Motor Pattern Generation provides an overview of the basic building blocks of behavior (see "Motor Control, Biological and Theoretical" for more general background) to be expanded upon in many of the following articles. The emphasis is on rhythmic behaviors (such as flight or locomotion), but a variety of "one-off" motor patterns (as typified in a frog snapping at its prey) are also studied. The crucial notion is that a central pattern generator (CPG), an autonomous neural circuit, can yield a good "sketch" of a movement, but that the full motor pattern generator (MPG) augments the CPG with sensory input which can adjust the motor pattern to changing circumstances (e.g., the pattern of locomotion varies when going uphill rather than on level terrain, or when the animal carries a heavy load). Sensorimotor Interactions and Central Pattern Generators discusses both the impact of sensory information on CPGs and the influence of motor systems on sensory activity. It stresses that interaction between motor and sensory systems is pervasive, from the first steps of sensory detection to the highest levels of processing, emphasizing that descending motor commands are only acted upon by spinal circuits when these circuits integrate their intrinsic activity with all incoming information.

Command Neurons and Command Systems analyzes the extent to which an MPG may be activated alone or in concert with others through perceptual stimuli mediated by a single "command neuron" or by more diffuse "command systems." Command functions provide the sensorimotor interface between sensory pattern recognition and localization, on the one side, and motor pattern generation on the other. For example, if a certain interneuron is stimulated electrically in the brain of a marine slug, the animal then displays a species-specific escape swimming behavior, although no predator is present. If in a toad a certain brain area of the optic tectum is stimulated in this manner, snapping behavior is triggered, although no prey is present. In both cases, a stimulus produces a rapid ballistic response.

Motor Primitives and Scratch Reflex look at two behaviors (the former studied in frogs, the latter primarily in turtles) elicited by an irritant applied to the animal's skin. In each case, the position at which the limb is aimed varies with the position of the irritant; there is somatotopic (i.e., based on place on the body) control of the reflex. In both frog and turtle, and thus more generally, spinal cord neural networks can by themselves generate complex sensorimotor transformations even when disconnected from supraspinal structures. Moreover, each reflex has different "modes." To understand this, just think of scratching your lower back. As the scratch site moves higher, the positioning of the limb changes continuously with the position of the irritant until the irritant moves up so much that you make a discontinuous switch to the "over-the-shoulder" mode of back-scratching. The mode changes in these two articles may be compared to the Gait Transitions (q.v.), discussed below. In any case, we see here two important issues: how is an appropriate pattern of action chosen, and how is the chosen pattern parameterized on the basis of sensory input? Motor Primitives advances the idea that CPGs construct spinal motor acts by recruiting a few motor primitives from a set encoded in the spinal cord. The best evidence comes from examination of wiping movements and microstimulation of frog spinal cord, where movements are constructed as a sequencing and combination of a collection of force-field motor primitives or fundamental elements. "Visuomotor Coordination in Frog and Toad" discusses how the frog's motor acts may be assembled on the basis of visual input.

With this, we switch to articles in which the emphasis is on rhythmic behavior, with rather little concern for the spatial structure of the movement (for example, the discussion of locomotion will focus on coordinating the rhythms of the legs when the animal progresses straight ahead, rather than on how these rhythms are modified when the animal traverses uneven terrain or turns to avoid an obstacle). Crustacean Stomatogastric System analyzes specific circuits of identified neurons controlling the chewing (by teeth inside the stomach) behavior of crustaceans. Of particular interest is the finding that neuropeptides (see "Neuromodulation in Invertebrate Nervous Systems") can change the properties of cells and the strengths of connections so that, e.g., a cell can become a pacemaker or a previously ineffective connection can come to exert a strong influence, and with this a network can dramatically change its overall behavior. Thus, the change of "mode" may be under the control of an explicit chemical "switch" of underlying cellular properties. Of course, in some systems, different input patterns of excitation and inhibition may enable a given circuit to act in one of several modes; while in other cases the change of mode may involve the transfer of control from one neural circuit to another. Locomotion, Invertebrate focuses on invertebrate locomotion systems for which quantitative modeling has been done, reviewing computer models of swimming, flying, crawling, and walking, paying special attention to the interaction of neural networks with the biomechanical systems they control. The article also reviews the use of biologically inspired locomotion controllers in robotics, stressing their distributed nature, their robustness, and their computational efficiency. Conversely, robots can serve as an important new modeling methodology for testing biological hypotheses. Locust Flight: Components and Mechanisms in the Motor narrows the focus to one specific invertebrate motor system. The article emphasizes the interactions of the intrinsic properties of flight neurons, the operation of complex circuits, and phase-specific proprioceptive input, all subject to the concentrations of circulating neuromodulators. Locust flight can adapt to the demands of a constantly changing sensory environment, and the flight system is flexible and able to operate despite severe ablations and then to recover from these lesions.

Half-Center Oscillators Underlying Rhythmic Movements looks at a set of minimal circuits for generating rhythmic behavior, starting with the half-center oscillator model first proposed to account for the observation that spinal cats (i.e., cats in which connections between brain and spinal cord had been severed) could produce stepping movements even when all sensory feedback from the animal's motion was eliminated. The article shows the utility of models of this type in analyzing rhythms in invertebrates as well as vertebrates—the pelagic mollusk *Clione*, tadpoles, and lampreys—in terms of the intrinsic membrane properties of the component neurons interacting with reciprocal inhibition to initiate and sustain oscillation in these networks. Spinal Cord of Lamprey: Generation of Locomotor Patterns marks an important transition: from seeing how one network can oscillate to seeing how the oscillation of a series of networks can be coordinated. Experiments show that neural circuitry in isolated pieces of the spinal cord of lamprey (a jawless, primitive type of fish) can exhibit oscillations, and when these pieces constitute an intact spinal cord, they all oscillate with the same frequency but form a "traveling wave" with a phase relationship that in the complete fish would yield a wave of bending progressing down the fish from head to tail to yield the coordinated "wiggling" that yields swimming. The article reviews the interaction between experimentation and modeling stimulated by such findings. Respiratory Rhythm Generation presents several alternative models of breathing and evaluates them against mammalian data. These data point to the importance both of endogenous bursting neurons and of network interactions in generating the basic rhythm. In most models, rhythmogenesis is either pacemaker or network driven. The article reviews the data and these models, and then points the way to future models that clarify the integration of endogenous bursting with network interactions. Locomotion, Vertebrate shows how neural networks in the spinal cord generate the basic rhythmic patterns necessary for vertebrate locomotion, while higher control centers interact with the spinal circuits for posture control and accurate limb movements, and by sending higher-level commands such as stop and go signals, speed, and heading of motion. In mammals, evolution of the CPGs has been accompanied by important modifications of the descending pathways under the requirements of complex posture control and accurate limb movements, although the extent of the respective changes remains unknown. Computer models that combine neural models with biomechanical models are seen as having an important role to play in studying these issues. One example uses "genetic algorithms" to model the transition from a lamprey-like spinal cord that supports traveling waves to a salamander-like spinal cord that supports both traveling waves for swimming and "standing waves" for terrestrial locomotion, and shows how vision may modulate spinal activity to yield locomotion toward a goal (see also "Visuomotor Coordination in Salamander").

Chains of Oscillators in Motor and Sensory Systems abstracts from the specific circuitry to show how oscillators and their coupling can be characterized in a way that allows the proof of mathematical theorems about patterns of coordination. CPGs are discussed not only for the spinal cord of lamprey, but also for the crayfish swimmeret system and the leech network of swimming. In the context of locomotion, each oscillator is likely to be a local subnetwork of neurons that produces rhythmic patterns of membrane potentials. Since the details of the oscillators often are not known and are difficult to obtain, the object of the mathematics is to find the consequences of what is known, and to generate sharper questions to motivate further experimentation. Gait Transitions also studies its topic (e.g., the transition from walking to running) from the abstract perspective of dynamical systems.

Muscle transduces chemical energy into force and motion, thereby providing power to move the skeleton. Because of the intricacies of muscle microstructure and architecture, no comprehensive models are yet able to predict muscle performance completely. Muscle Models reviews three classes of models each fulfilling a more narrowly defined objective, ranging from attempts to understand the molecular level (cross-bridge models) through lumped parameter mechanical models to input-output models of whole muscle behavior that can be used as part of a broader study of basic musculoskeletal biomechanics or issues of neural control. A motor neuron together with the muscle fibers that it innervates constitutes a motor unit, and each muscle is a composite structure whose force-generating components, the motor units, are typically heterogeneous. Such aggregates can produce much larger forces than a single motor unit. MOTONEURON RECRUITMENT shows how the motor units can be recruited in the service of reflexes, voluntary movement, and posture. The article considers mechanisms that compensate for muscle fatigue and yielding, models the possible role of Renshaw cells in linearization or equalization of motor neuron pool responses, and considers the possible role of cerebellum in control of motor neuron gain, as well as the roles of motor cortex in motor neuron recruitment.

PROSTHETICS, MOTOR CONTROL deals with the use of electrical stimulation to alter the function of motor systems, either directly or indirectly. The article presents three clinical applications. Therapeutic electrical stimulation is electrically produced exercise in which the beneficial effect occurs primarily off-line as a result of trophic effects on muscles and perhaps the CNS. Neuromodulatory stimulation is preprogrammed stimulation that directly triggers or modulates a function without ongoing control or feedback from the patient, and functional electrical stimulation (FES) provides precisely controlled muscle contractions that produce specific movements required by the patient to perform a task. The article also describes subsystems for muscle stimulation, sensory feedback, sensorimotor regulation, control systems, and command signals, most of which are under development to improve on-line control of FES.

MOTOR CONTROL, BIOLOGICAL AND THEORETICAL sets forth the basic cybernetic concepts. A motor control system acts by sending motor commands to a controlled object, often referred to as "the plant," which in turn acts on the local environment. The plant or the environment has one or more variables that the controller attempts to regulate. If the controller bases its actions on signals that are not affected by the plant output, it is said to be a feedforward controller. The full understanding of movement must rest on a full analysis of the integration of neural networks with the biomechanics of the skeletomuscular system. Nonetheless, much has been learned about limb control from a more abstract viewpoint, as the next four articles show. Optimization theory has become an important aid to discovering organizing principles that guide the generation of goal-directed motor behavior, specifying the results of the underlying neural computations without requiring specific details of the way those computations are carried out. OPTIMIZATION PRINCIPLES IN MOTOR CONTROL concedes that not all motor behaviors are necessarily optimal but argues that attempts to identify optimization principles can yield a useful taxonomy of motor behavior. The hypothesis is that in performing a motor task, the brain produces coordinated actions that minimize some measure of performance (such as effort, smoothness, etc.). The article reviews several studies in which such ideas were examined in the context of planar upper limb movements, comparing the purely kinematic minimum jerk model with the more dynamics-based minimum torque change model. Bur how does one go from a kinematic description of the movement of the hand to the pattern of muscle control that yields it? There are still many competing hypotheses. One approach seeks to find control systems that yield optimal trajectories in the absence of disturbances. Another starts from the observation that a muscle is like a controlled-length spring: set its length, and it will naturally return to the equilibrium length that was set. The EQUILIBRIUM POINT HYPOTHESIS builds on this a systems-level description of how the nervous system controls the muscles so that a stable posture is maintained or a movement is produced. In this framework, the controller is composed of muscles and the spinal-based reflexes, and the plant is the skeletal system. The controller defines a force field that is meant to capture the mechanical behavior of the muscles and the effect of spinal reflexes. The equilibrium point hypothesis views motion as a gradual postural transition, and it is suggested that for the case of multijoint arm movements, one can predict the hand's motion if the supraspinal system smoothly shifts the equilibrium point from the start point to a target location. GEOMETRICAL PRINCIPLES IN MOTOR CONTROL considers a different transition, that from the spatial representation of a motor goal to a set of appropriate neuromuscular commands, which is in many respects similar to a coordinate transformation. (A word of caution: The matter is subtle because the brain rarely has neurons whose firing encodes a single coordinate. Consider, for example, retinotopic coding as distinct from the specific use of $(x, y)$ or $(r, \theta)$ coordinates. Thus the issue is whether the activity in certain networks is better described as encoding one representation than another, such as those related to the eye rather than those related to the shoulder.) The article describes three types of coordinate system—end-point coordinates, generalized coordinates, and actuator coordinates—each representing a particular "point of view" on motor behavior, then examines the geometrical rules that govern the transformations between these classes of coordinates. It shows how a proper representation of dynamics may greatly simplify the transformation of motor planning into action. LIMB GEOMETRY, NEURAL CONTROL offers another perspective, starting from a discussion of the role of extrinsic and intrinsic coordinates when a human makes a movement. Multijointed coordination complicates the problem of motor control. Consider the case of arm movements. The activation of an elbow flexor will always contribute a flexor torque at the elbow, but the resulting elbow movement can be flexion, extension, or no motion at all, depending on the actively produced torque at the shoulder. Although in principle a coordinated motor action could be planned muscle by muscle, a more parsimonious solution is to plan more global goals at higher levels of organization and let the lower-level controllers specify the implementation details. The article reviews issues related to the kinematic aspects of limb geometry control for arm movements and for posture and gait.

Fast, coordinated movements depend on the nervous system being able to use copies of motor control signals (the corollary discharge) to compute expectations of how the body will move, rather than always waiting for sensory feedback to signal the current state of the body. ACTION MONITORING AND FORWARD CONTROL OF MOVEMENTS spells out three functions of corollary discharge. The stability of visual perception during eye movements was one of the first physiological applications proposed for an internal comparison between a movement and its sensory outcome. Second, goal-directed behavior implies that the action should continue until the goal has been satisfied, so that motor representations must involve not only forward mechanisms for steering the action but also mechanisms for monitoring its course and checking its completion. Third, similar processes have been postulated for actions aimed at complex and relatively long-term goals, for comparing the representation of the intended action to the actual action and compensating for possible mismatch between the two. Clearly, the effective use of corollary discharge rests on the brain having learned the relation between current state, motor command, and the movement that ensues. SENSORIMOTOR LEARNING explains how neural nets can acquire forward and inverse "models" of some desired sensorimotor transformation. The managing of multiple models, each with its own range of applicability in given tasks, is given special attention. The relevance of such models to the role of cerebellum (CEREBELLUM AND MOTOR CONTROL) is briefly noted, as is the idea that these models may act by controlling lower-level "Motor

Primitives" (q.v.). Reinforcement Learning in Motor Control, which presents general learning strategies based on adaptive neural networks, is treated further in the road map **Robotics and Control Theory**.

With this background, we turn to articles primarily concerned with visually controlled behaviors for which neurophysiological data are available from the mammalian (and in many cases the monkey) brain, as well as behavioral and, in some cases, imaging data for humans. The road map takes us from basic unconscious behaviors to those involving skilled action. The vestibulo-ocular reflex (VOR) serves to stabilize the retinal image by producing eye rotations that counterbalance head rotations. Vestibular nuclei neurons are much more than a simple relay; their functions include multimodality integration, temporal signal processing, and adaptive plasticity. Vestibulo-Ocular Reflex reviews the empirical data, as well as control-theoretic and neural network models for the neural circuits that mediate the VOR. These perform diverse computations that include oculomotor command integration, temporal signal processing, temporal pattern generation, and experience-dependent plasticity.

Collicular Visuomotor Transformations for Gaze Control analyzes the role of superior colliculus in the control of the rapid movement, called a saccade, of the eyes toward a target. The article touches on afferent and efferent mapping, target selection, visuomotor transformations in motor error maps, remapping models, and coding of dynamic motor error. The theme of remapping is pursued in Dynamic Remapping, which distinguishes "one-shot" remapping (updating the internal representation in one operation to compensate for an entire movement) from a continuous remapping process based on the integration of a velocity signal or the relaxation of a recurrent network. In both cases, the problem amounts to moving a hill of activity in neuronal maps. The article uses data on arm movements as well as saccades. Models can be constrained by considering deficits that accompany localized lesions in humans. These data not only provide valuable insights into the nature of remappings but they might also help bridge the gap between behavior and single-cell responses. Pursuit Eye Movements takes us from saccadic "jumps" to those smooth eye movements involved in following a moving target. Current models of pursuit vary in their organization and in the features of pursuit that they are designed to reproduce. Three main types of model are "image motion" models, "target velocity" models, and models that address the role of prediction in pursuit. However, these models make no explicit reference to the neural structures that might be responsible. The article thus analyzes the neural pathways for pursuit, stressing the importance of both visual areas of the cerebral cortex and oculomotor regions of the cerebellum, to set goals for future modeling.

Imaging the Motor Brain shows that the behavioral form and context of a movement are important determinants of functional activity within cortical motor areas and the cerebellum, stressing that functional imaging of the human motor system requires one to study the interaction of neurological and cognitive processes with the biomechanical characteristics of the limb. Neuroimaging shows that multiple neural systems and their functional interactions are needed to successfully perform motor tasks, encode relevant information for motor learning, and update behavioral performance in real time. The article discusses how evidence from functional imaging studies provides insight into motor automaticity as well as the role of internal models in movement.

Two articles explore the way in which the rat charts the spatial structure of its environment, using both "landmark cues" and a sense of its head orientation with respect to some key aspects of its environment. Hippocampus: Spatial Models starts with the finding that single-unit recordings in freely moving rats have revealed "place cells" in fields CA3 and CA1 of the hippocampus, so called because their firing is restricted to small portions of the rat's environment (the corresponding place fields), but the firing properties of place cells change when the rat is placed in a new environment. The article focuses on data and models for the role of place cell firing in the rat's navigation (see "Cognitive Maps" for a less neurophysiological approach to the same general issues). Rodent Head Direction System focuses on head direction cells in a number of brain areas that fire maximally when the rat's head is pointed in a specific preferred direction, with a gradual falloff in firing as the heading departs from that direction. Head direction is not a simple reflection of sensory stimuli since, for example, the neural coding can be updated when the animal turns in the dark. The authors analyze such phenomena using attractor networks.

The next six articles are concerned with reaching and grasping. Motor Cortex: Coding and Decoding of Directional Operations spells out the relation between the direction of reaching and changes in neuronal activity that have been established for several brain areas, including the motor cortex. The cells involved each have a broad tuning function, the peak of which denotes the "preferred" direction of the cell. A movement in a particular direction will engage a whole population of cells. It is found that the weighted vector sum of these neuronal preferences is a "population vector" that points in (close to) the direction of the movement for discrete movements in 2D and 3D space. Further observations link this population encoding to speed of movement as well as to preparation for movement. The present article addresses the question of how movement variables are encoded in the motor cortex and how this information could be used to drive a simulated actuator that mimics the primate arm. Arm and Hand Movement Control discusses some of the most prominent regularities of arm and hand control, and examines computational and neural network models designed to explain them. The analysis reveals the controversies engendered by competition between explanations sought on different levels—neural, biomechanical, perceptual, or computational. Although some topics, such as internal model control, have gained solid grounding, the importance of the dynamic properties of the musculoskeletal system in facilitating motor control, the role of real-time perceptual modulation of motor control, and the balance between dynamical systems models versus optimal control-based models are still seen as offering many open questions. Reaching Movements: Implications for Computational Models reviews a number of issues that are emerging from neurophysiological studies of motor control and stresses their implications for development of future models. Data on movement planning, trajectory generation, temporal features of cortical activity, and overlapping polymodal gradients are used to set challenges for computational models that will meet the demands of both functional competence and biological plausibility.

Eye-Hand Coordination in Reaching Movements focuses on possible mechanisms responsible for visually guiding the hand toward a point within the prehension space. Reaching at a visual target requires transformation of visual information about target position into a frame of reference suitable for the planning of hand movement. Accurate encoding of target location requires concomitant foveal and extraretinal signals. The most popular hypothesis to explain how trajectories are planned is that the trajectory is specified as a vector in the arm's joint space, with joint angle variations controlled in a synergic way (temporal coupling). The motor command initially sent to the arm is based on an extrafoveal visual signal; at the end of the ocular saccade, the updated visual signal is used to adjust the ongoing trajectory. Because of consistent delays in sensorimotor loops, the rapid path corrections observed during reaching movements cannot be attributed to sensory information only but must rely on a "forward model" of arm dynamics. In any case, where this article focuses on how the hand is brought to a target, Grasping Movements: Visuomotor Transforma-

TIONS emphasizes the neural mechanisms that control the shaping of the hand itself to grasp an object, noting the crucial preshaping of the hand during reaching prior to grasping the object. The analysis emphasizes the cooperative computation of visual mechanisms in parietal cortex with motor mechanisms in premotor cortex to integrate sensing and corollary discharge throughout the movement.

CEREBELLUM AND MOTOR CONTROL reviews a number of models of the role of the cerebellum in building "internal models" to improve motor skills. The article asserts that motor control and learning in the brain employ a modsular approach in which multiple controllers coexist, with each controller suitable for one or a small set of contexts. The basic idea is that, to select the appropriate controller or controllers at each moment, each of the multiple inverse models is augmented with a forward model that determines the responsibility each controller should assume during movement. This view is exemplified in the MOSAIC (MOdular Selection And Identification Control) model. Recent human brain imaging studies have started to accumulate evidence supporting multiple internal models of tools in the cerebellum. (One caveat: The article stresses the idea that the cerebellum provides complete motor controllers; other authors emphasize the idea that the cerebellum provides a corrective side path that learns how best to augment controllers located elsewhere in the brain.) Finally, BASAL GANGLIA reviews the structure of this system in terms of multiple loops, with special emphasis on those involved in skeletomotor and oculomotor functions. It also reviews the role of dopamine in motor learning and the mechanisms underlying Parkinson's disease.

## Applications

BRAIN-COMPUTER INTERFACES
DECISION SUPPORT SYSTEMS AND EXPERT SYSTEMS
FILTERING, ADAPTIVE
FORECASTING
KALMAN FILTERING: NEURAL IMPLICATIONS
PROSTHETICS, MOTOR CONTROL
PROSTHETICS, NEURAL
PROSTHETICS, SENSORY SYSTEMS

The road map **Robotics and Control Theory** presents a number of applications of neural networks. Here we offer a representative (but by no means exhaustive) set of other applications, a list that can be augmented by the study of many other road maps. Examples include a variety of topics in vision and speech processing (see the road maps **Vision** and **Linguistics and Speech Processing**, respectively). As noted in the Preface, the discussion of applications of ANNs in areas from astronomy to steel making was a feature of the first edition of the *Handbook* that is not reproduced in the second edition.

Several articles review the various contributions of adaptive neural networks to signal processing. FILTERING, ADAPTIVE notes that adaptive filtering has found widespread use in noise canceling and noise reduction, channel equalization, cochannel signal separation, system identification, pattern recognition, fetal heart monitoring, and array processing. The parameters of an adaptive filter are adjusted to "learn" or track signal and system variations according to a task-specific performance criterion. The field of adaptive filtering was derived from work on neural networks and adaptive pattern recognition. An adaptive filter can be viewed as a signal combiner consisting of a set of adjustable weights (or coefficients represented by a polynomial) and an algorithm (learning rule) that updates these weights using the filter input and output, as well as other available signals. The filter may include internal signal feedback, whereby delayed versions of the output are used to generate the current output, and it may contain some nonlinear components. The single-layer perceptron is a well-known type of adaptive filter that has a binary output nonlinearity (see "Perceptrons, Adalines, and Backpropagation"). The article focuses on the most widely used adaptive filter architecture and describes in some detail two representative adaptive algorithms: the least-mean-square algorithm and the constant modulus algorithm. KALMAN FILTERING: NEURAL IMPLICATIONS then introduces Kalman filtering, a powerful idea rooted in modern control theory and adaptive signal processing. Under linear and Gaussian conditions, the Kalman filter produces a recursive estimate of the hidden state of a dynamic system, i.e., one that is updated with each subsequent (noisy) measurement of the observed system, with the estimate being optimum in the mean-square-error sense. The Kalman filter provides an indispensable tool for the design of automatic tracking and guidance systems, and an enabling technology for the design of recurrent multilayer perceptrons that can simulate any finite-state machine. In the context of neurobiology, Kalman filtering provides insights into visual recognition and motor control. Related applications are discussed in FORECASTING. Neural nets, mostly of the standard backpropagation type, have been used with great success in many forecasting applications. This article looks at the use of neural nets for forecasting with particular attention to understanding when they perform better or worse than other technologies, showing how the success of neural networks in forecasting depends significantly on the characteristics of the process being forecast.

A decision support system is an information system that helps humans make a decision on a given problem, under given circumstances and constraints. Expert systems are information systems that contain expert knowledge for a particular problem area and perform inferences when new data are entered that may be partial or inexact. They provide a solution that is expected to be similar to the solution provided by experts in the field. DECISION SUPPORT SYSTEMS AND EXPERT SYSTEMS uses the collective term *decision system* to refer to either a decision support system or an expert system. The article discusses how neural networks can be employed in a decision system. Such systems help humans in their decision process and so should be comprehensible by humans. The article reviews results of connectionist-based decision systems. In particular, trainable knowledge-based neural networks can be used to accumulate both knowledge (rules) and data, building adaptive decision systems with incremental, on-line learning. (For further developments related to the construction of expert systems, see "Bayesian Networks" and the three articles on "Graphical Models.")

BRAIN-COMPUTER INTERFACES discusses the use of on-line analysis of brainwaves to derive information about a subject's mental state as a basis for driving some external action, such as selecting a letter from a virtual keyboard or moving a robotics device, providing an alternative communication and control channel that does not depend on the brain's normal output pathway of peripheral nerves and muscles, which may be nonfunctional in some patients. The brainwave signals may be evoked potentials generated in response to external stimuli or components associated with spontaneous mental activity. Targets for current research include the extraction of local components of brain activity with fast dynamics that subjects can consciously control. The article reviews the challenge of developing classifiers that work while the subject operates a brain-actuated application, with ANNs providing robust approaches to on-line learning. These studies are complemented by a range of articles on prosthetics. Prosthetics, Neural provides an overview of the physical components that tend to be common to all neural prosthetic systems. It emphasizes the biophysical factors that constrain the sophistication of those interfaces. Electroneural interfaces for both stimulation of and recording from neural tissue are analyzed in terms of biophysics and electrochemistry. It is also shown how the design of practical neural prostheses must address the systems hardware issues of power and data management and packaging. Prosthetics, Sensory Systems focuses on sensory prostheses, in which information is collected by electronic sensors and delivered directly to the nervous system by electrical stimulation of pathways in or leading to the parts of the brain that normally process a given sensory modality. After assessing the amenability of all sensory modalities (hearing, vision, touch, proprioception, balance, smell, and taste) the article focuses on auditory and visual prostheses. The great success story has been with cochlear implants. Here the article reviews improved temporospatial representations of speech sounds, combined electrical and acoustic stimulation in patients with residual hearing, and psychophysical correlates of performance variability. Visual prostheses are still in their early days, with no general agreement on the most promising site to apply electrical stimulation to the visual pathways. The article reviews the cortical approach and the retinal approach. Finally, it is noted that since a prosthesis does not necessarily match natural neural encoding of a stimulus, the success of the prosthesis depends in part on the plasticity of the human brain as it remaps to accommodate this new class of signals. Prosthetics, Motor Control deals with the subset of neural prosthetic interfaces that employ electrical stimulation to alter the function of motor systems, either directly or indirectly. The article presents three clinical applications. Therapeutic electrical stimulation is electrically produced exercise in which the beneficial effect occurs primarily off-line as a result of trophic effects on muscles and perhaps the CNS; neuromodulatory stimulation is preprogrammed stimulation that directly triggers or modulates a function without ongoing control or feedback from the patient; and functional electrical stimulation (FES) provides precisely controlled muscle contractions that produce specific movements required by the patient to perform a task. The article describes subsystems for muscle stimulation, sensory feedback, sensorimotor regulation, control systems, and command signals, most of which are under development to improve on-line control of FES. Electrical stimulation of the nervous system is also being used to treat other disorders, including spinal cord stimulation to control pain and basal ganglia stimulation to control parkinsonian dyskinesias.

To close this road map, we note the importance of using special-purpose VLSI chips to gain the full efficiency of artificial neural network in various applications. Such chips are among the methods for implementation of neural networks discussed in the next road map, **Implementation and Analysis**.

## Implementation and Analysis

Photonic Implementations of Neurobiologically Inspired Networks
Programmable Neurocomputing Systems
Silicon Neurons
Statistical Parametric Mapping of Cortical Activity Patterns

Briefly, a neural network (whether an artificial neural network for technological application or a simulation of a biological neural network in computational neuroscience) can be implemented in three main ways: by programming a general-purpose electronic computer, by programming an electronic computer designed for neural net implementation, or by building a special-purpose device to emulate a particular network or parametric family of networks. We discuss these three approaches in turn, and then review a number of articles describing tools and methods for the analysis of brain signals and related activity.

Neurosimulation: Tools and Resources reviews neurosimulators, i.e., programs designed to reduce the time and effort required to build models of neurons and neural networks. A neurosimulator requires, at the very least, a highly developed interface, a scalable design (e.g., through parallel hardware), and extendibility with new neural network paradigms. The review includes programs for modeling networks of biological neurons as well as programs for kinetic modeling of intracellular signaling cascades and regulatory genetic networks but does not cover connectionist simulators. It provides a general picture of the capabilities of several neurosimulators, highlighting some of the best features of the various programs, and also describes ongoing efforts to increase compatibility among the various programs. Compatibility allows models built with one neurosimulator to be independently evaluated and extended by investigators using different programs, thereby reducing duplication of effort, and also allows models describing different levels of complexity (molecular, cellular, network) to be related to one another. The next three articles present some of the methods necessary for efficient simulation of detailed models of single neurons (see, e.g., the articles "Axonal Modeling" and "Dendritic Processing" in the **Biological Neurons and Synapses** road map). Biophysical Mechanisms in Neuronal Modeling is a primer on biophysically detailed compartmental models of single neurons (see the road map **Biological Neurons and Synapses** for a fuller précis), but contributes to the topic of neurosimulators by illustrating examples of model definitions using the Surf-Hippo Neuron Simulation System, providing a minimal syntax that facilitates model documentation and analysis. GENESIS Simulation System describes GENESIS (GEneral NEural SImulation System), which was developed to support "structurally realistic" simulations, computer-based implementations of models designed to capture the anatomical structure and physiological characteristics of the neural system of interest. GENESIS has been widely used for single-cell "compartmental" modeling but is also used for large network models, using libraries of ion channels and complete cell models, respectively. NEURON is a neurosimulator that was first developed for simulating empirically based models of biological neurons with extended geometry and biophysical mechanisms that are spatially nonuniform and kinetically complex. This functionality has been enhanced to include extracellular fields, linear circuits to emulate the effects of nonideal instrumentation, models of artificial (integrate-and-fire) neurons, and networks that can involve any combination of artificial and biological neuron models. NEURON Simulation Environment shows how these capabilities have been implemented so as to achieve computational efficiency while maintaining conceptual clarity, i.e., the knowledge that what has been instantiated in the computer model is an accurate representation of the user's conceptual model. Where NEURON has been primarily used for detailed modeling of single neurons, NSL Neural Simulation Language provides methods for simulating very large networks of relatively simple (artificial or biological simulation) neurons. NSL (pronounced "Nissl") models focus on modularity, a well-known software development strategy in dealing with large and complex systems. Full understanding of a system is gained both by simulating modules in isolation and by designing computer experiments that follow the dynamics of the interactions between the various modules. An NSL model can be described either by direct programming in NSLM, the NSL (compiled) Modeling language, or by using the Schematic Capture System (SCS), a visual programming interface to NSLM supporting the description of module assemblages. "Phase-Plane Analysis of Neural Nets" introduces the qualitative theory of differential equations in the plane for analyzing neural networks. Computational methods are a very powerful adjunct to this type of analysis. The article concludes with comments on numerical methods and software. Between them, the articles reviewed in this paragraph make clear the challenge of providing multilevel neurosimulation environments in which one can move effortlessly between the levels of schemas (functional decomposition of an overall behavior), large neural networks, detailed models of single neurons, and neurochemical models of synaptic plasticity. To be fully effective, such an environment will also need visualization tools, and the ability to access a database to provide experimental results for comparison with model-based predictions.

The next two articles address the *digital*, parallel implementation of neural networks. Digital VLSI for Neural Networks starts by looking at the differences between digital and analog design techniques, with a focus on analyzing cost-performance trade-offs in flexibility (Amdahl's Law), and then considers the use of standard VLSI processors in parallel configurations for ANN emulation. The Adaptive Solutions CNAPS custom digital ANN processor is then discussed to convey a sense of some of the issues involved in designing digital structures for ANN emulation. Although this chip is no longer produced, it is still being used and provides a good vehicle for understanding the trade-offs inherent in emulating neural structures digitally. Finally, the article looks at field programmable gate array (FPGA) technology as a promising vehicle for digital implementation of ANNs. Programmable Neurocomputing Systems emphasizes that the design of specialized digital neurocomputers has exploited three items common to many neural (ANN) algorithms to improve cost/performance: the limited numeric precision required; the inherently high data parallelism, where the same operation is performed across large arrays of data; and communication patterns restricted enough to allow broadcast buses or unidirectional rings to support parallel execution of many common neural network algorithms. However, in the future, the work of commercial design teams to incorporate multimedia-style kernels into the workloads they consider during the design of new microprocessors will have as a by-product the ability to dramatically improve performance for ANN algorithms. This suggests that in the future there will be greatly reduced interest in special-purpose neurocomputers but much attention to software strategies to optimize ANN performance on commercially available microprocessors.

However, the above three assumptions are not so useful in the implementation of detailed "compartmental" models of neurons. Here, attention has been paid to the design of highly special-purpose *analog* VLSI circuits. Digital VLSI assigns a different circuit to each bit of information that is to be stored and processed. Each circuit is driven to the limit so that it settles into a 0-state or a 1-state, passing through a linear voltage-current regime to get from one saturation state to the other. Thus, if a synaptic weight is to be stored with eight-bit precision in digital VLSI, it requires eight such circuits. By contrast, the linear regime of a single circuit element on a VLSI chip can store data with about three bits of precision with far less "real estate" on the chip, and with far less power loss. The price, of course, is that precision cannot be guaranteed on the same scale as for digital circuits, but in many neural net applications, analog precision is more than adequate. Analog VLSI Implementations of Neural Networks provides an overview of the implementation of circuitry in analog VLSI, and then summarizes a number of technological implementations of such analog chips for ANNs. The article introduces the difference between the constraints imposed by the biological and silicon media and emphasizes that letting the silicon medium constrain the design of a system results in more efficient methods of computation. Special emphasis is given to five properties of a silicon synapse that are essential for building large-scale adaptive analog VLSI synaptic arrays. This article focuses on building neural network integrated circuits (IC), and especially on building connectionist neural network models. Silicon Neurons takes the same implementation methodology into the realm of computational neuroscience. Biological neural networks are difficult to model because they are composed of large numbers of nonlinear elements and have a wide range of time constants. Simulation on a general-purpose digital computer slows dramatically as the number and coupling of elements increase. By contrast, silicon neurons operate in real time, and the speed of the network is independent of the number of neurons or their coupling. On the other hand, high connectivity still poses problems in 2D chip layouts, and the design of special-purpose hardware is a significant investment, particularly if it is analog hardware, since analog VLSI still lacks a general set of easy-to-use design tools. In any case, Neuromorphic VLSI Circuits and Systems charts the virtues of using analog VLSI to build "neuromorphic" chips, i.e., chips whose design is based on the structure of actual biological neural networks. Biological systems excel at sensory perception, motor control, and sensorimotor coordination by sustaining high computational throughput with minimal energy consumption. Neuromorphic VLSI systems employ distributed and parallel representations and computation akin to those found in their biological counterparts. The high levels of system integration offered in VLSI technology make it attractive for the implementation of highly complex artificial neuronal systems, even though the physics of the liquid-crystalline state of biological structures is different from the physics of the solid-state silicon technologies. The article provides a basic foundation in device physics and presents a set of specific circuits that implement certain essential functions that exemplify the breadth possible within this design paradigm. However, VLSI-based neural networks have difficulty in scaling up or interconnecting multiple neural chips to incorporate large numbers of neuron units in highly interconnected architectures without significantly increasing the computational time. This motivates the use of optical interconnections. The success of optic fibers as media for telecommunications has been complemented by the use of holograms and spatial light modulators as mechanisms for storing and processing information via patterns of light (photonics) rather than patterns of electrons (electronics). The current state of photonic approaches to neural network implementation is charted in Photonic Implementations of Neurobiologically Inspired Networks, which provides a perspective on the use of holography as a technique for building adaptive connection matrices for ANNs, as well as earlier discussions of holography as a metaphor for the working of associative memory in actual brains. In photonic implementation of neurobiologically inspired networks, optical (free-space or through-substrate) techniques enable an increase in the number of neuron units and the interconnection complexity by using the off-chip (third) dimension. This merging of optical and photonic devices with electronic circuitry provides additional features such as parallel weight implementation, adaptation, and modular scalability.

The remaining articles provide a number of perspectives on the analysis of data on the brain.

Brain Signal Analysis reviews applications of ANNs to brain signal analysis, including analysis of the EEG and MEG, the electromyogram (EMG), and computed tomographic (CT) images and magnetic resonance (MR) brain images, and to series of functional MR brain images (fMRI). Since most medical signals usually are not produced by variations in a single variable or factor, many medical problems, particularly those involving decision making, must involve a multifactorial decision process. In these cases, changing one variable at a time to find the best solution may never reach the desired objective, whereas multifactorial ANN approaches may be more successful. The review is organized according to the nature of brain signals to be analyzed and the role that ANNs play in the applications.

Statistical Parametric Mapping of Cortical Activity Patterns describes the construction of statistical maps to test hypotheses about regionally specific effects like "activations" during brain imaging studies. Statistical parametric maps (SPMs) are image processes with voxel values that are, under the null hypothesis, distributed according to a known probability density function (usually Student's $T$ or $F$ distributions), analyzing each and every voxel using any standard (univariate) statistical test. The resulting statistical parameters are assembled into an image, the SPM. SPM{T} refers to an SPM comprising $T$ statistics; similarly, SPM{F} denotes an SPM of $F$ statistics. SPMs are interpreted as spatially extended statistical processes by referring to the probabilistic behavior of stationary Gaussian fields. Unlikely excursions of the SPM are interpreted as regionally specific effects, attributable to the sensorimotor or cognitive process that has been manipulated experimentally.

Neuroinformatics presents an integrated view of neuroinformatics that combines tools for the storage and analysis of neuroscience data with the use of computational models in structuring masses of such data. In Europe, *neuroinformatics* is a term used to encompass the full range of computational approaches to brain theory and neural networks. In the United States, some people use the term neuroinformatics solely to refer to databases in neuroscience. Taking the perspective of the *Handbook*, this article sees the key challenge for neuroinformatics to be to integrate insights from synthetic data obtained from running a model with data obtained empirically from studying the animal or human brain. The problem is that the data, and thus the models, of neuroscience are so diverse. Neuroscience integrates anatomy, behavior, physiology, and chemistry, and studies levels from molecules to compartments and neurons up to biological neural networks and on to the behavior of organisms. The article thus presents an architecture for a federation of databases of empirical neuroscientific data in which results from diverse laboratories can be integrated. It further advocates a cumulative approach to modeling in neuroscience that facilitates the reusability (with appropriate changes) of modules within current neural models, with the pattern of re-use fully documented and tightly constrained by the linkage with this federation of databases. Databases for Neuroscience then focuses on the issues in constructing such databases. In order to be able to integrate such diverse sources, the various communities within the neurosciences must begin to develop standards for their community's data. Neuroscientists use many different and incompatible data formats that do not allow for the free exchange of data, and the article stresses the need for standards for the description of the actual data (i.e., a formalized description of the metadata), possibly using extensible markup language (XML) technologies. (On a related theme, Neurosimulation: Tools and Resources examines two of the enabling neurosimulation technologies that will allow modelers to compare and modify models, verify one another's simulations, and extend models with their own tools.) One possible solution to integrating data from sources with heterogeneous data and representation is to extend the conventional wrapper-mediator architecture with domain-specific knowledge. The article concludes with analysis of a specific database of brain images (the fMRI Data Center) and a comprehensive table of neuroscience databases constructed to date.

# Part III: Articles

# Action Monitoring and Forward Control of Movements

*Marc Jeannerod*

## Introduction

Monitoring its own output is thought to be a basic principle of functioning of the nervous system. This idea, inherited from the cybernetic era, and still operational now, is based on the notion of a comparison of the actual output of the system with the expected, or desired, output. In the domain of motor control, for example, it is assumed that each time the motor centers generate an outflow signal for producing a movement, a "copy" of this command (the "efference copy") is retained. The reafferent inflow signals generated by the movement (e.g., visual, proprioceptive) are compared with the copy. If a mismatch between the two types of signals is recorded, new commands are generated until the actual outcome of the movement corresponds to the desired movement. This comparison cannot be made, however, until the reafferent signals and the efference copy have been rendered compatible with one another. Proprioceptive signals, in principle, should be directly compatible with motor output (they arise from the same muscles and joints that are activated during the movement). Visual signals, by contrast, are generated in a set of coordinates quite different from those of motor output. Thus, a common set of coordinates must be computed to make the comparison useful.

The efference copy can only measure the performance error when the action comes to execution. In order to give this mechanism a predictive role in anticipating the effects of an action, one must assume the existence of a more complex "internal model" of that action. Such a model should be able to simulate the action generation process without waiting for the sensory reafference, or even without performing it. According to Wolpert, Ghahramani, and Jordan (1995), a combination of two processes is required: "The first process uses the current state estimate and motor command to predict the next state by simulating the movement dynamics with a forward model. The second process uses a model of the sensory output process to predict the sensory feedback from the current state estimate. The sensory error—the difference between actual and predicted sensory feedback—is used to correct the state estimate resulting from the forward model" (p. 1881). Several possible applications for this mechanism are reviewed in the following discussion.

## Stability of Visual Perception and Target Localization

The stability of visual perception during eye movements was one of the first physiological applications proposed for an internal comparison between a movement and its sensory outcome. When one moves one's eyes across the visual field, objects tend to appear stationary in spite of their displacement on the retina; if, however, the same displacement is produced by an external agent (e.g., by gently pressing against the eye at the external canthus), objects no longer appear stationary. To account for this phenomenon, it has been conjectured that the command signals to the eye muscles are effective in remapping the visual scene and canceling out the visual displacement. In the absence of this signal, the visual displacement becomes visible. Sperry (1950) coined the term of "corollary discharge" (CD) for the centrally arising discharge that reaches the visual centers as a corollary of any command generated by the motor centers. In this way, the visual centers can distinguish the retinal displacement related to a self-generated movement from that produced by a moving scene. Visual changes produced by a movement of the eye are normally "canceled" by a CD of a corresponding size and direction. If, however, the CD is absent or does not correspond to the visual changes (e.g., when the eye is pressed), these changes are not canceled and are read by the visual system as having their origin in the external world. The combination of the retinal signals and the extraretinal command signals (CD) thus produces a perceived stability of the visual world (Jeannerod, Kennedy, and Magnin, 1979). Signals arising from eye muscle proprioceptors also contribute to visual stability during eye movements (see Gauthier, Nommay, and Vercher, 1990). A CD type of regulation should in principle be more advantageous, however, because of its timing: a discharge propagating directly from the motor to the visual centers should be available to the visual system earlier than discharges arising from the periphery.

The same logic used for perceptual visual stability can also apply to egocentric localization of visual targets. The retinal position of a target cannot in itself be sufficient for its localization in space because, as the eyes move in the head, and the head moves on the trunk, several different retinal positions correspond to the same spatial locus. The spatial location of the target must therefore be reconstructed by combining eye/head position signals with the position of the target on the retina. The relationships between the retinal error signal (the position of the target on the retina) and the eye position signal were first formalized by Robinson (1975). In this influential model, the efference copy from eye position is derived from the output of a neural integrator that maintains the eye at a given position during fixation. It is this signal of actual eye position that is combined with retinal error to provide other motor systems (e.g., the arm) with the target location information. Eye movements are not generated on the basis of retinal error. Instead, the driving signal for the eye to reach the desired eye position relative to the head is the eye motor error signal. This signal is obtained by "subtracting" the actual change in eye position in orbit from the desired position. The movement stops when the motor error equals zero.

Guitton (1992) was able to directly demonstrate the dynamic nature of this process, by showing that output neurons from the superior colliculus—the tectoreticular (TR) neurons—code the change in eye motor error during the movement. Before the movement takes place, a TR neuron with a preferred vector corresponding to the desired eye position will be activated and will drive the eye movement generator. As the movement progresses and motor error is reduced, other TR neurons coding for smaller vectors will be activated until the error is zero. At this point, a TR neuron coding for a zero vector will be activated and fixation will be maintained. Guitton postulates that an internal representation of change in gaze position is generated and compared with the desired gaze position to yield instantaneous gaze motor error. If one assumes that this error is the parameter represented topographically on the collicular map, one can conceive how this signal will activate the proper sequence of TR neurons. Hence Guitton's hypothesis of a moving "hill" of activity shifting across the collicular map, from the caudal part where large vectors are encoded to the rostral part where fixation vectors are encoded. There are some difficulties with this model, however, notably with the timing of discharges in the superior colliculus which, in order to be suitable for coding motor error, should precede those of the eye movement generator.

## Representation of Goals of Movements

Goal-directed behavior implies that the action should continue until the goal has been satisfied. Motor representations must therefore involve not only forward mechanisms for steering and directing the action, but also mechanisms for monitoring its course and for checking its completion. This error correction mechanism implies a short-term storage of outflow information processed at each level of action generation. Because reafferent signals during execution of a movement are normally delayed with respect to the command signal, the comparison mechanism must look ahead in time and produce an estimate of the movement velocity corresponding to the command. The image of this estimated velocity is used for computing the actual position of the limb with respect to the target (Hoff and Arbib, 1992). It is only because the current state of the action is monitored on-line (rather than after the movement terminates), that corrections can be applied without delay as soon as the deviation of the current trajectory from the desired trajectory is detected. A subtle mechanism postulated by Miles and Evarts (1979) for the regulation of movements could be useful here. They pointed out that the discharge of muscle spindles in the agonist muscle during a movement (due to the co-activation of the gamma motoneurons) exactly fulfills the criterion for an efference copy that propagates "upward" and is an exact copy of the motor input sent to the alpha motoneurons. This signal could well be used for on-line comparison with incoming signals resulting from the limb movement.

It has been proposed that the information stored in the comparison process should encode, not joint rotations or kinematic parameters, but final configurations (of the body, of the moving segments, etc.) as they should arise at the end of the action. In other words, the goal of the action, rather than the action itself, would be represented in the internal model of the action. This hypothetical mechanism is supported by experimental arguments. Desmurget et al. (1995) recorded reach and grasp movements directed at a handle that had to be grasped with a power grip. When the orientation of the handle was suddenly changed at the onset of a movement, the arm smoothly shifted from the optimal configuration initially planned to reach the object to another optimal configuration corresponding to the object in its new orientation. The shift was achieved by simultaneous changes at several joints (shoulder abduction, wrist rotation), so that the final grasp was effected in the correct position. In this case the comparison between the desired and the actual arm position could be effected dynamically through a process similar to that which has been proposed to solve the problem of coordinate transformation during goal-directed movements. The position of an object in space is initially coded in extrinsic (e.g., visual) coordinates. In order to be matched by the moving limb, however, this position must be transferred into an intrinsic coordinate frame. If the position of the object in extrinsic coordinates and the position of the extremity of the limb in intrinsic coordinates coincide (that is, if these positions correspond to the same point in the two systems of coordinates), the action should logically be considered as terminated (see Carrozzo and Lacquaniti, 1994).

In addition to matching the movement trajectory to the representation of the intended movement, this mechanism has also other potential functions for the control of movements. The comparison between corollary and incoming signals might be used to produce a correspondence between the motor command and the amount of muscular contraction, even if the muscular plant is not linear. Other nonlinearities may also arise from interaction of the moving limb with external forces, especially if it is loaded (for a review, see Weiss and Jeannerod, 1998). This mapping problem, which is a critical factor for producing accurate limb movements, is less important for eye movements, where interactions with the external force field are minimal and where the load of the moving segment is constant. In this case, the pattern of command issued by the eye movement generator should unequivocally reflect the final desired position of the eye, that is, the position where the retinal error is zero.

## Action Monitoring

At a still higher level, that of actions aimed at complex and relatively long-term goals, similar processes have been postulated for comparing the representation of the intended action to the actual action and compensating for possible mismatch between the two. Several studies, using brain imaging techniques, have focused on identifying neural structures that would fulfill the requirements for a comparison mechanism or an error detecting device. Carter et al. (1998) studied the activity of the anterior cingulate gyrus, a region lying on the medial cortical surface of the frontal lobe, in a letter detection task designed to increase error rates and manipulate response competition. Activity was found to increase during erroneous responses, but also during correct responses in conditions of high levels of response competition. They concluded that the anterior cingular gyrus detects conditions under which errors are likely to occur, rather than errors themselves. This result suggests that action-monitoring mechanisms anticipate the occurrence of errors, by using internal models of the effects of the action on the world. In other words, the sensory consequences of an action are evaluated before they occur, even in conditions in which the action may not be executed. This mechanism can also become a powerful means of determining whether a sensory event is produced by our own action or by an external agent (and ultimately, if an action is self-produced or not). Blakemore, Rees, and Frith (1998) compared brain activity during the processing of externally produced tones and the processing of tones resulting from self-produced movements. They found an increase in the right inferior temporal lobe activity when the tones were externally produced, suggesting that this area would be inhibited by the volitional system in the self-produced condition. This result raises interesting questions about the possible consequences of a dysfunction of such a system. Increased activity in the primary auditory areas in the temporal lobe has been observed during auditory hallucinations in psychotic patients (Dierks et al., 1999). Hence, it is possibility that a defective self-monitoring system would produce false attribution of one's own speech to an external source.

# Activity-Dependent Regulation of Neuronal Conductances

*Larry F. Abbott and Eve Marder*

## Introduction

An enormous amount of both theoretical and experimental work has focused on the implications of activity-dependent synaptic plasticity for development, learning, and memory. Less attention has been paid to the fact that the intrinsic characteristics of individual neurons change during development (Spitzer and Ribera, 1998) and can be modified by activity (Franklin, Fickbohm, and Willard, 1992; Desai, Rutherford, and Turrigiano, 1999), yet these too play a vital role in shaping network function.

The electrical characteristics of a neuron depend on the numbers of channels of various types that are active within the cell membrane and on how these channels are distributed over the surface of the cell. The conventional approach to developing a conductance-based model is to attempt to measure all the ionic currents expressed by a neuron, describe them with Hodgkin-Huxley equations, and finally assemble the neuron model (Koch and Segev, 1998). This approach is based on the assumptions that individual neurons of a given class have the same ionic currents expressed at the same levels and that a neuron expresses the same currents whenever it is sampled under a specified set of experimental conditions. However, these assumptions appear to be contradicted by experimental evidence (see, e.g., Liu et al., 1998). In addition, it is rarely possible to make all of the measurements needed to construct a conductance-based model in this manner. Most neurons have many types of ion channels with complex spatial distributions. It is unlikely that all these currents and their spatial distributions can be measured. As a result, conventional conductance-based models depend on considerable hand-tuning of parameters. Each attempt to make neurons more biologically realistic is accompanied by a worsening of this problem. Hand-tuning a detailed, multicompartment, conductance-based model can be extremely time consuming and frustrating.

Neurons accomplish the feat of expressing appropriate numbers of ion channels in the relevant locations without running months of computer simulations. This suggests that a set of parameter adjustment mechanisms may allow neurons to self-tune their conductance densities to produce specific electrophysiological properties. A number of attempts have been made at incorporating such mechanisms into conductance-based neuron models (Bell, 1992; LeMasson, Marder, and Abbott, 1993; Siegel, Marder, and Abbott, 1994; Liu et al., 1998; Golowasch et al., 1999; Stemmler and Koch, 1999). Self-tuning activity-dependent models provide an alternative approach to modeling neurons and networks. This class of models does not assume that neurons necessarily have the same conductance densities over time, nor that individual neurons of a well-defined class are identical. Rather, they depend on simple negative feedback mechanisms to develop and maintain sets of conductances that produce particular firing patterns and response characteristics. In these models, a second-messenger system, which may involve $Ca^{2+}$ influx and a variety of $Ca^{2+}$ sensors, guides the expression of the membrane conductances in a self-regulating manner.

## Results

### A Model Neuron with Self-Regulating Conductances

Self-regulating models are constructed by specifying a set of activity sensors and the rules by which they modify conductance densities. Experimental work indicates that the intracellular $Ca^{2+}$ concentration is a good indicator of neuronal activity. Intracellular $Ca^{2+}$ concentrations become elevated in response to activity and fall during inactive periods (Ross, 1989). Many $Ca^{2+}$-dependent cellular processes, controlled by a variety of $Ca^{2+}$ sensors that monitor $Ca^{2+}$ entry through different ion channels, can affect channel densities (Bito, Deisseroth, and Tsien, 1997; Barish, 1998; Finkbeiner and Greenberg, 1998). The intracellular $Ca^{2+}$ concentration itself, or sensors of inward $Ca^{2+}$ currents, can thus be used as feedback elements that monitor activity and change conductances. In general, when the neuron's activity is high, the activity-dependent rules decrease excitability, and when activity is low, they increase excitability by modifying appropriate conductances.

A model neuron constructed on these principles can start with almost any initial conductance densities and self-assemble a set of maximal conductances that produce particular intrinsic characteristics and patterns of activity. An example of a model spontaneously developing a set of maximal conductances that produces bursting behavior, starting from an initially silent state, is shown in Figure 1 (Liu et al., 1998). This illustrates but one example of the many ways that the model can generate bursting activity. Virtually any initial state leads ultimately to bursting, but, interestingly, the sets of conductances constructed by the model differ from trial to trial, although the final pattern of bursting is always similar to that shown in Figure 1. Thus, there is a non-unique map between maximal conductances and activity. The final set of conductances depends on initial conditions and is variable, even though the pattern of activity produced by the model is not.

### A Model Network with Self-Regulating Conductances

Circuits of self-regulating neurons can self-assemble into functional circuits. This can be illustrated using a simplified model of the pyloric circuit of the crab stomatogastric ganglion (STG). The pyloric rhythm of the STG consists of alternating bursts of activity in several neurons, including the lateral pyloric (LP) and pyloric

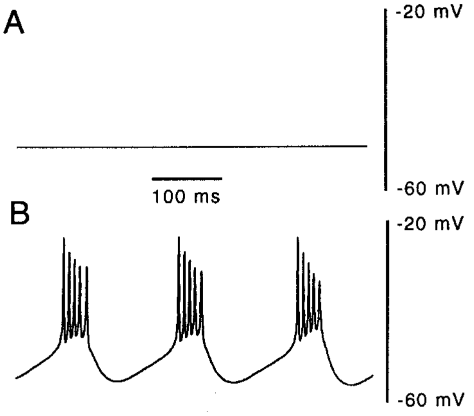

**Figure 1.** Self-assembly of a bursting model neuron (*B*) starting from different initial conditions (*A*). *A* and *B* represent the voltage traces at the beginning and end of the self-tuning process. (Adapted from Liu et al., 1998).

(PY) neurons, and the anterior burst (AB)/pyloric dilator (PD) pacemaker unit. The model shown in Figure 2 is a three-neuron circuit with individual neurons and synaptic connections similar to those of the LP and PY neurons and the AB/PD unit of the STG. Each model neuron consists of two compartments and has maximal conductances that are regulated by activity as described in the previous section.

When isolated from each other, the individual AB/PD, LP, and PY neurons of the model, like the neuron model shown in Figure 1, self-assemble their conductances. A novel feature of the circuit model is apparent when a realistic pattern of fixed synaptic connections is established between the model cells. In this case, the entire network self-assembles to generate a pattern of activity similar to the triphasic rhythm recorded in the intact STG, and it can do so from any initial configuration of the maximal conductances of the three neurons (Golowasch et al., 1999). Interestingly, the intrinsic maximal conductances and responses properties of the individual model neurons are different if they self-assemble as a coupled circuit rather than in isolation. When assembled in a circuit, each of the model neurons ends up similar to its biological counterpart when acutely isolated, and the entire network generates realistic rhythmic activity. Thus, a cell-autonomous, activity-dependent regulatory rule is sufficient to self-assemble an entire circuit, at least in this example. It is not necessary to use any sensor that monitors the output of the whole circuit. Rather, each neuron takes care of its own activity, and the resultant circuit is tuned as a consequence of each cell's independent self-adjustment.

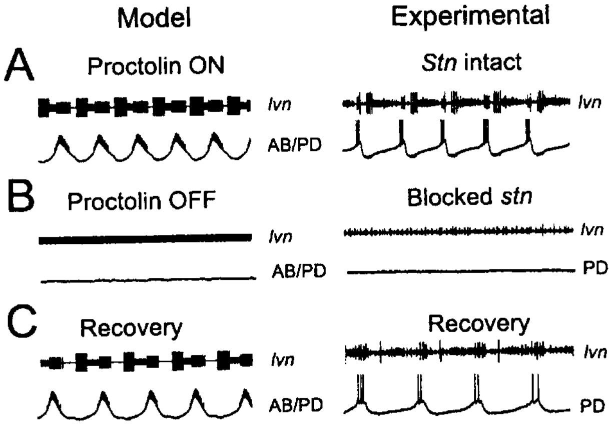

**Figure 2.** Comparison of a network model and experimental data. *A*, Control conditions in the model (left) and experiment (right). There is a triphasic motor pattern, revealed in the extracellular lvn recording. Intracellular PD recordings are also shown. In the model, the AB/PD and LP neurons contain a proctolin current. In the experiment, the modulatory inputs in the *stn* were left intact. *B*, Immediately after the modulatory inputs are removed, rhythmic activity is lost. Modulatory inputs are removed in the model by setting the proctolin current to zero. In the experiment, impulse activity in the *stn* was blocked to prevent the release of the neuromodulators. *C*, Activity eventually resumes. In the model, the activity-dependent sensors in each cell respond to the change in activity seen in *B*, and slowly modify the conductances of each of the model neurons, resulting in the recovery of rhythmic network activity, as occurred in the experimental case. (Adapted from Golowasch et al., 1999.)

### *Comparison with Data from STG Organ Culture*

Generation of the pyloric rhythm normally requires the presence of neuromodulatory substances released from axon terminals of the stomatogastric nerve (*stn*). If the *stn* is cut or blocked, rhythmic activity slows considerably or ceases. However, if the preparation is maintained over a period of days without *stn* modulatory input, rhythmic activity eventually resumes (Golowasch et al., 1999). Thus, it appears that prolonged removal of modulatory input alters the configuration of the pyloric circuit, allowing it to operate independently of the modulators that it normally requires.

The right side of Figure 2 shows the basic experimental result. Before blockade of the *stn*, the preparation shown on the right side of Figure 2*A* displayed a robust pyloric rhythm. Immediately following blockade of action potential conduction along the *stn*, the rhythm completely terminated (Figure 2*B*, right). However, when the block was maintained for approximately 24 hours, rhythmic pyloric activity resumed (Figure 2*C*, right). This recovery may be due, at least in part, to changes in the intrinsic properties of the neurons of the STG induced by the shift in activity following *stn* blockade, which allows the pyloric network to operate in the absence of neuromodulatory input.

This hypothesis can be studied, using the model discussed in the previous section, by including a proctolin conductance to simulate the effects of neuromodulators released by *stn* axons. The peptide proctolin is only one of many substances released from axon terminals of the *stn*, but it is a particularly potent modulator of the pyloric network. Figure 2 compares the behavior of the model with experimental results. Initially, the activity of the model network with the proctolin current included (Figure 2*A*, left) was similar to the pyloric activity of the experimental preparation with the *stn* intact (Figure 2*A*, right). To simulate the effects of blocking the *stn*, the proctolin conductance in the LP and AB/PD neurons was set to zero (Figure 2*B*, left). This immediately terminated the rhythmic activity of the model network, duplicating the effect of blocking the *stn* in the real preparation (Figure 2*B*, right). The suppression of the rhythm following the elimination of the proctolin conductance caused the activity-dependent conductance regulation mechanisms to modify the maximal conductances of the model neurons. This resulted in restoration of the pyloric rhythm in the model network after elimination of the proctolin conductance (Figure 2*C*, left), matching the natural resumption of the rhythm (Figure 2*C*, right).

It is important to stress that although the pyloric rhythms in Figures 2*A* and 2*C* look similar, they are produced by quite different cellular mechanisms. In Figure 2*A*, the existence of the rhythm depends on the presence of the modulatory proctolin current, while in Figure 2*C* the rhythms are produced in the absence of the modulator.

## Discussion

The homeostatic regulation of neuronal circuits is an essential element in their development and maintenance as functioning systems. This is often ignored in the construction of neural networks, because fixed parameters are adjusted and used to control network function. Biological systems do not have the luxury of using fixed constants, because of the continual recycling of the proteins from which they are built. As a consequence, biological networks are typically more robust than artificial networks, and they are self-assembling. The work described here is an attempt to incorporate these features into neural network models.

The model studies described have revealed several interesting consequences of activity-dependent regulation of conductances: (1) Conductance regulation stabilizes a model neuron against activity shifts caused by extracellular perturbations. (2) Intrinsic properties of model neurons are modified by sustained shifts in activity. (3) The regulation scheme described here, applied as a local regulator of channel density in a multicompartment model, can produce a realistic spatial distribution of conductances. (4) Regulation of the activity of individual neurons in a network may, in some case, be sufficient for the development and maintenance of a network pattern requiring coordination across neurons.

One of the most significant messages provided by models of conductance regulation is that the same mechanisms that develop and maintain membrane conductances are likely to modify these conductances in response to long-lasting changes in the activity of the neuron. Furthermore, different neurons, or the same neuron at different times, may exhibit similar characteristics and activity while expressing membrane conductances at quite different levels. These observations make it apparent that neuron models must be much more flexible and dynamic than has conventionally been the case.

# Adaptive Resonance Theory

*Gail A. Carpenter and Stephen Grossberg*

## Introduction

Principles derived from an analysis of experimental literatures in vision, speech, cortical development, and reinforcement learning, including attentional blocking and cognitive-emotional interactions, led to the introduction of adaptive resonance as a theory of human cognitive information processing (Grossberg, 1976a, 1976b). The theory has evolved as a series of real-time neural network models that perform unsupervised and supervised learning, pattern recognition, and prediction (Levine, 2000; Duda, Hart, and Stork, 2001). Models of unsupervised learning include ART 1 (Carpenter and Grossberg, 1987) for binary input patterns and fuzzy ART (Carpenter, Grossberg, and Rosen, 1991) for analog input patterns. ARTMAP models (Carpenter et al., 1992) combine two unsupervised modules to carry out supervised learning. Many variations of the basic supervised and unsupervised networks have since been adapted for technological applications and biological analyses.

## Match-Based Learning, Error-Based Learning, and Stable Fast Learning

A central feature of all ART systems is a pattern matching process that compares an external input with the internal memory of an active code. ART matching leads either to a *resonant* state, which persists long enough to permit learning, or to a parallel memory search. If the search ends at an established code, the memory representation may either remain the same or incorporate new information from matched portions of the current input. If the search ends at a new code, the memory representation learns the current input. This *match-based learning* process is the foundation of ART code stability. Match-based learning allows memories to change only when input from the external world is close enough to internal expectations, or when something completely new occurs. This feature makes ART systems well suited to problems that require on-line learning of large and evolving databases.

Match-based learning is complementary to *error-based learning*, which responds to a mismatch by changing memories so as to reduce the difference between a target output and an actual output, rather than by searching for a better match. Error-based learning is naturally suited to problems such as adaptive control and the learning of sensorimotor maps, which require ongoing adaptation to present statistics. Neural networks that employ error-based learning include backpropagation and other multilayer perceptrons (MLPs) (Duda et al., 2001; see BACKPROPAGATION: GENERAL PRINCIPLES).

Many ART applications use *fast learning*, whereby adaptive weights converge to equilibrium in response to each input pattern. Fast learning enables a system to adapt quickly to inputs that occur rarely but that may require immediate accurate recall. Remembering details of an exciting movie is a typical example of learning on one trial. Fast learning creates memories that depend on the order of input presentation. Many ART applications exploit this feature to improve accuracy by voting across several trained networks, with voters providing a measure of *confidence* in each prediction.

## Coding, Matching, and Expectation

Figure 1 illustrates a typical ART search cycle. To begin, an input pattern **I** registers itself as a short-term memory activity pattern **x** across a field of nodes $F_1$ (Figure 1*A*). Converging and diverging pathways from $F_1$ to a coding field $F_2$, each weighted by an adaptive long-term memory trace, transform **x** into a net signal vector **T**. Internal competitive dynamics at $F_2$ further transform **T**, generating a compressed code **y**, or *content-addressable memory*. With strong competition, activation is concentrated at the $F_2$ node that receives the maximal $F_1 \rightarrow F_2$ signal; in this *winner-take-all* mode, only one code component remains positive (see WINNER-TAKE-ALL NETWORKS).

Before learning can change memories, ART treats the chosen code as a *hypothesis*, which it tests by matching the *top-down expectation* of **y** against the input that selected it (Figure 1*B*). Parallel specific and nonspecific feedback from $F_2$ implements matching as a real-time locally defined network computation. Nodes at $F_1$ receive both learned excitatory signals and unlearned inhibitory signals from $F_2$. These complementary signals act to suppress those portions of the pattern **I** of bottom-up inputs that are not matched by the pattern **V** of top-down expectations. The residual activity **x*** represents a pattern of *critical features* in the current input with respect to the chosen code **y**. If **y** has never been active before, **x*** = **x** = **I**, and $F_1$ registers a perfect match.

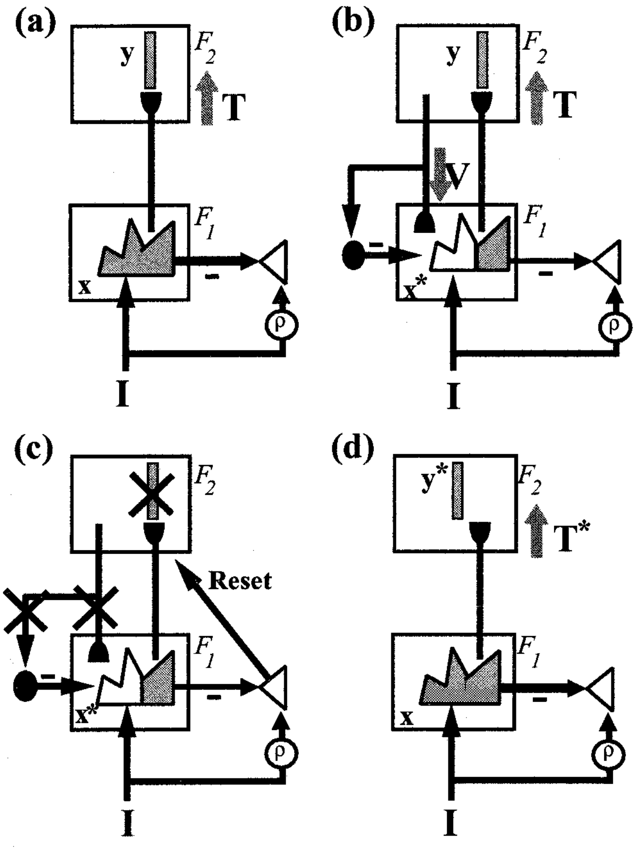

**Figure 1.** An ART search cycle imposes a matching criterion, defined by a dimensionless vigilance parameter $\rho$, on the degree of match between a bottom-up input **I** and the top-down expectation **V** previously learned by the $F_2$ code **y** chosen by **I**. See text for discussion of *A* through *D* sequence.

## Attention, Search, Resonance, and Learning

If the matched pattern **x*** is close enough to the input **I**, then the memory trace of the active $F_2$ code converges toward **x***. The property of encoding an *attentional focus* of critical features is key to code stability. This learning strategy differentiates ART networks from MLPs, which typically encode the current input rather than a matched pattern, and hence employ slow learning across many input trials to avoid catastrophic forgetting.

ART memory search begins when the network determines that the bottom-up input **I** is too novel or unexpected with respect to the active code to satisfy a matching criterion. The search process resets the $F_2$ code **y** before an erroneous association to **x*** can form (Figure 1*C*). After reset, medium-term memory within the $F_1 \rightarrow F_2$ pathways (Carpenter and Grossberg, 1990) biases the network against the previously chosen node, so that a new code $y^*$ may be chosen and tested (Figure 1*D*).

The ART matching criterion is determined by a parameter $\rho$ called *vigilance*, which specifies the minimum fraction of the input that must remain in the matched pattern in order for resonance to occur. Low vigilance allows broad generalization, coarse categories, and abstract memories. High vigilance leads to narrow generalization, fine categories, and detailed memories. At maximal vigilance, category learning reduces to exemplar learning. While vigilance is a free parameter in unsupervised ART networks, in supervised networks vigilance becomes an internally controlled variable that triggers a search after rising in response to a predictive error. Because vigilance then varies across learning trials, the memories of a single ARTMAP system typically exhibit a range of degrees of refinement. By varying vigilance, a single system can recognize both abstract categories, such as faces and dogs, and individual examples of these categories.

## Supervised Learning and Prediction

An ARTMAP system includes a pair of ART modules, ART$_a$ and ART$_b$ (Figure 2). During supervised learning, ART$_a$ receives a stream of patterns $\{\mathbf{a}^{(n)}\}$ and ART$_b$ receives a stream of patterns $\{\mathbf{b}^{(n)}\}$, where $\mathbf{b}^{(n)}$ is the correct prediction given $\mathbf{a}^{(n)}$. An associative learning network and a vigilance controller link these modules to make the ARTMAP system operate in real time, creating the minimal number of ART$_a$ recognition categories, or *hidden units*, needed to meet accuracy criteria. A minimax learning rule enables ARTMAP to learn quickly, efficiently, and accurately as it conjointly minimizes predictive error and maximizes code compression in an on-line setting. A *baseline vigilance* parameter $\bar{\rho}_a$ sets the minimum matching criterion, with smaller $\bar{\rho}_a$ allowing broader categories to form. At the start of a training trial, $\rho_a = \bar{\rho}_a$. A predictive failure at ART$_b$ increases $\rho_a$ just enough to trigger a search, through a feedback control mechanism called *match tracking*. A

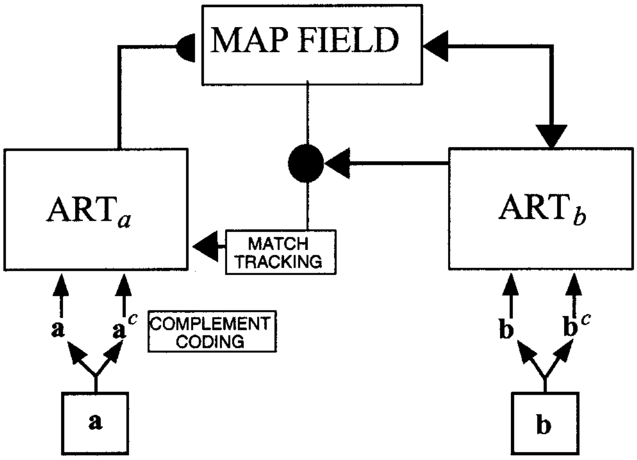

**Figure 2.** The general ARTMAP network for supervised learning includes two ART modules. For classification tasks, the ART$_b$ module may be simplified.

newly active code focuses attention on a different cluster of input features, and checks whether these features are better able to predict the correct outcome. Match tracking allows ARTMAP to learn a prediction for a rare event embedded in a cloud of similar frequent events that make a different prediction.

ARTMAP employs a preprocessing step, called *complement coding*, which, by normalizing input patterns, solves a potential category proliferation problem (Carpenter et al., 1991). Complement coding doubles the number of input components, presenting to the network both the original feature vector and its complement. In neurobiological terms, complement coding uses both on-cells and off-cells to represent an input pattern. The corresponding on-cell portion of a weight vector encodes features that are consistently present in category exemplars, while the off-cell portion encodes features that are consistently absent. Small weights in complementary portions of a category representation encode as uninformative those features that are sometimes present and sometimes absent.

## Distributed Coding

Winner-take-all activation in ART networks supports stable coding but causes category proliferation when noisy inputs are trained with fast learning. In contrast, distributed McCulloch-Pitts activation in MLPs promotes noise tolerance but causes catastrophic forgetting with fast learning (see Localized Versus Distributed Representations). *Distributed ART* (dART) models are designed to bridge these two worlds: distributed activation enhances noise tolerance, while new system dynamics retain the stable learning capabilities of winner-take-all ART systems (Carpenter, 1997). These networks automatically apportion learned changes according to the degree of activation of each coding node, which permits fast as well as slow distributed learning without catastrophic forgetting.

New learning laws and rules of synaptic transmission in the reconfigured dART network (Figure 3) sidestep computational problems that occur when distributed coding is imposed on the architecture of a traditional ART network (Figure 1). The critical design element that allows dART to solve the catastrophic forgetting problem of fast distributed learning is the *dynamic weight.* This quantity equals the rectified difference between coding node activation and an *adaptive threshold*, thereby combining short-term and long-term memory in the network's fundamental computational unit.

Thresholds $\tau_{ij}$ in paths projecting directly from an input field $F_0$ to a coding field $F_2$ obey a *distributed instar* (dInstar) learning law, which reduces to an instar law when coding is winner-take-all. Rather than adaptive gain, learning in the $F_0 \rightarrow F_2$ paths resembles the *redistribution of synaptic efficacy* (RSE) observed by Markram and Tsodyks (1996) at neocortical synapses. In these experiments, pairing enhances the strength, or efficacy, of synaptic transmission for low-frequency test inputs, but fails to enhance, and can even depress, synaptic efficacy for high-frequency test inputs. In the dART learning system, RSE is precisely the computational dynamic needed to support real-time stable distributed coding.

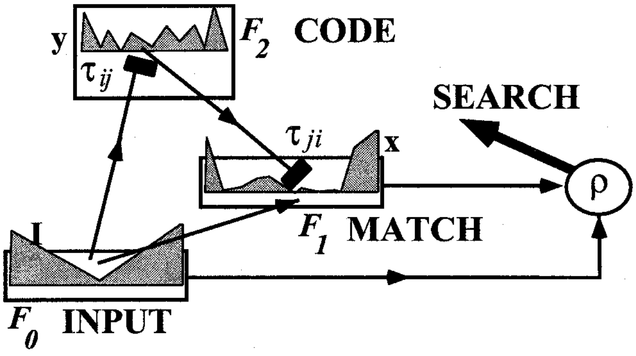

**Figure 3.** A distributed ART (dART) architecture retains the stability of WTA ART networks but allows the $F_2$ code to be distributed across arbitrarily many nodes.

Thresholds $\tau_{ji}$ in paths projecting from the coding field $F_2$ to a matching field $F_1$ obey a distributed outstar (dOutstar) law, which realizes a principle of atrophy due to disuse to learn the network's expectations with respect to the distributed coding field activation pattern. As in winner-take-all ART systems, dART compares top-down expectation with the bottom-up input at the matching field, and quickly searches for a new code if the match fails to meet the vigilance criterion.

## Discussion: Applications, Rules, and Biological Substrates

ART and dART systems are part of a growing family of self-organizing network models that feature attentional feedback and stable code learning. Areas of technological application include industrial design and manufacturing, the control of mobile robots, face recognition, remote sensing land cover classification, target recognition, medical diagnosis, electrocardiogram analysis, signature verification, tool failure monitoring, chemical analysis, circuit design, protein/DNA analysis, three-dimensional visual object recognition, musical analysis, and seismic, sonar, and radar recognition (e.g., Caudell et al., 1994; Griffith and Todd, 1999; Fay et al., 2001). A book by Serrano-Gotarredona, Linares-Barranco, and Andreou (1998) discusses the implementation of ART systems as VLSI microchips. Applications exploit the ability of ART systems to learn to classify large databases in a stable fashion, to calibrate confidence in a classification, and to focus attention on those featural groupings that the system deems to be important based on experience. ART memories also translate to a transparent set of IF-THEN rules that characterize the decision-making process and may be used for feature selection.

ART principles have further helped explain parametric behavioral and brain data in the areas of visual perception, object recognition, auditory source identification, variable-rate speech and word recognition, and adaptive sensorimotor control (e.g., Levine, 2000; Page, 2000). One area of recent progress concerns how the neocortex is organized into layers, clarifying how ART design principles are found in neocortical circuits (see LAMINAR CORTICAL ARCHITECTURE IN VISUAL PERCEPTION).

Pollen (1999) resolves various past and current views of cortical function by placing them in a framework he calls *adaptive resonance theories.* This unifying perspective postulates resonant feedback loops as the substrate of phenomenal experience. Adaptive resonance offers a core module for the representation of hypothesized processes underlying learning, attention, search, recognition, and prediction. At the model's field of coding neurons, the continuous stream of information pauses for a moment, holding a fixed activation pattern long enough for memories to change. Intrafield competitive loops fixing the moment are broken by active reset, which flexibly segments the flow of experience according to the demands of perception and environmental feedback. As Pollen (1999, pp. 15–16) suggests, "[I]t may be the consensus of neuronal activity across ascending and descending pathways linking multiple cortical areas that in anatomical sequence subserves phenomenal visual experience and object recognition and that may underlie the normal unity of conscious experience."

## Introduction

The meaning of any signal that we receive from our environment is modulated by the context within which it appears. Our interpretation of color, a spoken phoneme, or a patch of luminance depends critically on its context. Although "context" may be a rather abstract notion, it is often reasonable to understand the term as meaning the statistical ensemble in which the signal is embedded. Interpreting a message requires both registering the signal itself and knowing something about this statistical ensemble. The relevant temporal or spatial ensemble depends on the task. The context may be highly local; we interpret appropriately gradations of light and dark in a scene where local brightness typically varies over orders of magnitude (see FEATURE ANALYSIS). For tasks such as decision making, the relevant statistics may reflect complex descriptions of the world accumulated over long periods.

Neural representations at every level of information processing should be similarly modulated by context. Information theoretically, this has measurable advantages: representations that appropriately take into account the statistical properties of the incoming signal are more efficient. Since the 1950s it has been suggested that efficiency is a design principle of the nervous system, allowing neurons to transmit more useful information with their limited dynamic range (see OPTIMAL SENSORY ENCODING). Thus, one expects that learning the context and implementing this knowledge through coding strategy is inherent in the formation of representations.

Such adjustments occur over a wide range of time scales. Through the genetic code, species adapt to environmental changes over many generations. In a single individual, learning, implemented through neural plasticity, continues throughout life in response to experience of the world; perceptual learning is stored even at low levels of neural information processing (see SOMATOTOPY: PLASTICITY OF SENSORY MAPS). In the article, we discuss even more rapid changes: neural adaptation, which we take to mean reversible change in the response properties of neurons on short time scales.

Since Adrian's first observations of adaptation in spiking neurons, it has been suggested that adaptation serves a useful function for information processing, preventing a neuron from continuing to transmit redundant information and increasing its responsiveness to new stimuli. Within the simplified picture of a neuron as a combination of linear filtering followed by a threshold, or a decision rule for spiking, either or both of the two components—the filter and the threshold function—may be adaptive functions of the input, and both may implement the goal of increasing information transmission. We will discuss both of these possibilities.

Neurons in every sensory modality have been shown to have adaptive properties, and the mechanisms governing various types of adaptation have been at least partially explored (Torre et al., 1995). Here we will discuss adaptation as the simplest form of learning and memory. We describe recent experiments that explicitly aim to link the phenomenology of adaptive spike coding to its functional relevance, in particular to improved information transmission. A common feature of adaptation is the existence of multiple time scales. In examining mechanisms, we concentrate on recent work suggesting that the long time scales retaining short-term memory can be generated through single-cell properties.

## Adaptive Coding

Adaptation of neural firing rate to stationary stimuli has been seen in all modalities of the primary sensory system. In the visual system, photoreceptors adapt to light level, and retinal ganglion cells show rapid contrast gain control. The trade-offs and information processing gains due to adaptation in insect eyes, relevant also for the vertebrate retina, are discussed in Laughlin (1989). Mechanoreceptors in the somatosensory system have been classified into four main types of cells, three of which are distinguished by the time scales of their adaptation (rapidly and slowly adapting), and these time scales in part determine the cells' function: slowly adapting cells are implicated in the perception of spatial form and texture, while the experience of flutter and of motion is mediated by rapidly adapting cells (Johnson, 2001). Thus, the dynamics of adaptation can determine a neuron's functional role.

Adaptation is not limited to primary receptors. In visual cortex, V1 neurons show contrast adaptation, which is thought to occur entirely at the level of cortex. The motion aftereffect, a familiar phenomenon whereby following exposure to motion in one direction, the visual field appears to move in the opposite direction, is thought to be due to adaptation of direction-sensitive neurons in visual cortex.

### *Adaptation to a Distribution*

Understanding the significance of adaptation for information processing requires going beyond fixed stimuli. Recently, studies have focused on adaptation to the stimulus *distribution*. This approach is necessary to characterize coding information theoretically: the evaluation of a coding strategy requires considering the entire ensemble of inputs and outputs. In Smirnakis et al. (1997), retinal ganglion cells were stimulated with dynamic movies of flickering light intensity where the mean light level was fixed but the variance was switched periodically from one value to another. The spike rate of the neurons showed typical adaptive behavior (Figure 1): following an increase in variance, the firing rate increased initially, but gradually returned to a considerably lower level; a decrease in variance led to a sudden dip in firing rate, with eventual recovery.

The experiments of Smirnakis et al. (1997) consider only firing rate. However, the timing of single spikes can convey a great deal of information about the stimulus. In the visual system of the fly, in particular the motion-sensitive identified neuron H1 in the fly's lobula plate, much is understood about single-spike coding, providing an excellent opportunity to study the effects of adaptation in detail.

H1 responds to a simple stimulus, wide-field horizontal motion. The neuron is characterized by its input/output relation $P(\text{spike}|s)$, or the probability of a spike given the projection $s$ of the dynamic stimulus onto a relevant feature, determined by reverse correlation.

When the system has reached steady state through exposure to a zero-mean, white noise velocity stimulus with a given variance $\sigma^2$, its input/output relation is measured. The resulting curves, measured for a range of values of the variance, are shown in Figure 2. Clearly, the input/output relation is not a fixed property of the system but adapts to the distribution of inputs. Indeed, it does so in such a way that the stimulus appears to be measured in units of its standard deviation; when the curves are replotted with the stimulus normalized by its RMS value, they superimpose. Thus, a scale factor $\lambda$ multiplying the stimulus, and thereby matching the dynamic range of the response to the distribution of the inputs, is a degree of freedom for the system. The value of $\lambda$ chosen by the system achieves a maximum of information transmission (Brenner, Bialek, and de Ruyter van Steveninck, 2000).

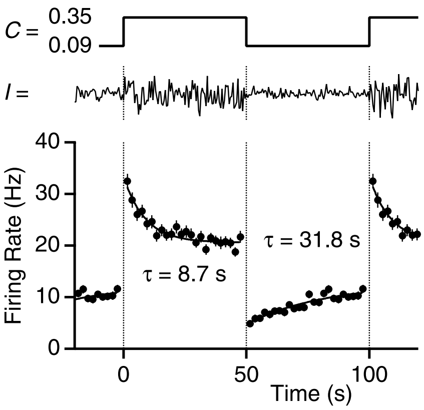

**Figure 1.** Firing rate of rabbit retinal ganglion cells in response to a flicker stimulus where the variance of the light intensity *I* switches periodically in time. (From Smirnakis S. M., et al., 1997, Adaptation of retinal processing to image contrast and spatial scale, *Nature*, 386: 69–73. Copyright 1997, Macmillan Publishers Ltd.; reprinted with permission.)

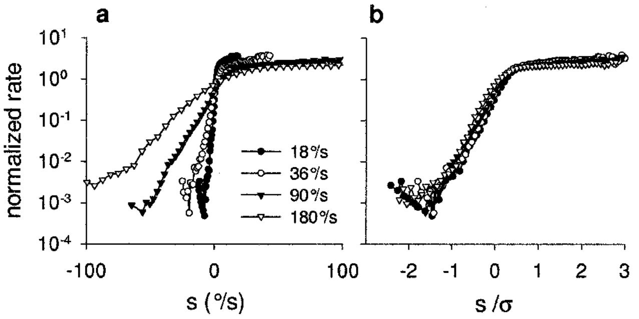

**Figure 2.** (a) A set of input/output relations relating the probability of spiking to the velocity stimulus, measured for stationary white noise stimuli with different variances. (b) The curves differ only by a scale factor as is shown by normalizing the stimulus by its standard deviation. In this case the curves coincide. (From Brenner, N., Bialek, W., and de Ruyter van Steveninck, R. R., 2001, Adaptive rescaling maximizes information transmission, *Neuron*, 26:695–702. Copyright 2000, Elsevier Science, reprinted with permission.)

This is a simple form of learning: the system gauges the standard deviation of the signal and modifies its response properties to adjust its dynamic range to the range of inputs. The adjustment must take some time, as the new distribution must be sampled from examples. This sets fundamental physical and statistical limits for the system's estimate of the current variance. We can examine the time scale for learning (Fairhall et al., 2001) by, as in the retina experiments described earlier, switching periodically between two distributions. The firing rate shows the same pattern of adaptation as was seen in the experiments of Smirnakis et al. (1997), but this pattern need not correspond to the time scale for adjustment of the input/output relation. Indeed, it was found that the scale factor of the input/output relations, measured dynamically, adjusts much more rapidly than the relaxation time of the rate—on the order of 100 ms, compared with several seconds. This short time scale is consistent with the limits imposed by estimates of noise from the photoreceptors. One can verify that the dynamic adaptation of the input/output relation maintains information transmission through the system by computing how much information one can extract from the spikes about the stimulus (see Sensory Coding and Information Transmission and Fairhall et al., 2001). The information rate recovers on comparably short time scales.

For the decoder, a potential drawback of adaptive coding is *ambiguity*: it is necessary to know the context in order to interpret the signal correctly. Thus, information about the context must be conveyed independently. Although this information might be carried by other neurons in the network, here the information about the ensemble is carried simultaneously by the same spike train: it can be read off, either through the rate (taking into account the delays due to the slow relaxation) or, more accurately, through the variance dependence of the statistics of *spike time differences* (Fairhall et al., 2001). Thus, for the code of H1, spikes carry multiple meanings: in absolute timing, as precise markers of single stimulus events, and in relative timing, as indicators of the stimulus ensemble.

### Multiple Time Scales

The slow relaxation of the rate appears to be related to a commonly observed property of adapting primary sensory neurons: a power law decay of the firing rate $r$, $r \sim t^{-\alpha}$. More generally, in the case just presented, the rate is close to the *fractional derivative* of the logarithm of the stimulus variance. For each frequency $\omega$, fractional differentiation shifts the frequency component by a constant phase, and scales each component by $\omega^{\alpha}$, where $\alpha$ is a power less than 1. Some of the properties of a fractional differentiator are illustrated in Figure 3. Several examples of a power law decay of the rate following a step change in stimulus amplitude were collected by Thorson and Biederman-Thorson (1974; Figure 4) and more have since been observed; examples include various invertebrate mechanoreceptors and photoreceptors, mammalian carotid sinus baroreceptors, and cat retinal ganglion cells.

We have noted a separation of time scales in the adaptation of the input/output relation compared with the rate. This type of adaptation on its own signals the existence of many time scales. Power-law scaling implies the lack of a typical time scale or the presence of multiple time scales. Fractional differentiation is nonlocal; the response at time $t_0$ is affected by times $t \ll t_0$. This is a linear "memory" mechanism.

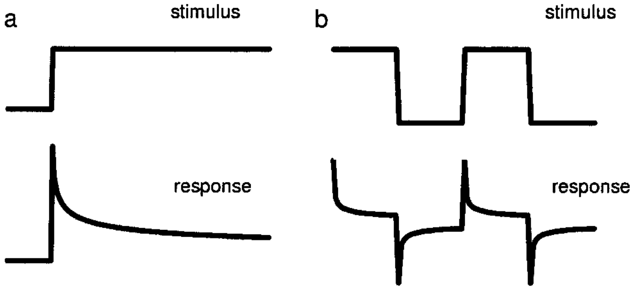

**Figure 3.** Illustration of some properties of a fractional differentiator with exponent $\alpha = 0.3$. (a) A step function stimulus leads to a power law decaying rate. In a log-log plot the curve would appear as a straight line with slope $-\alpha$. (b) A square wave leads to a similar adaptation curve as shown in Figure 1.

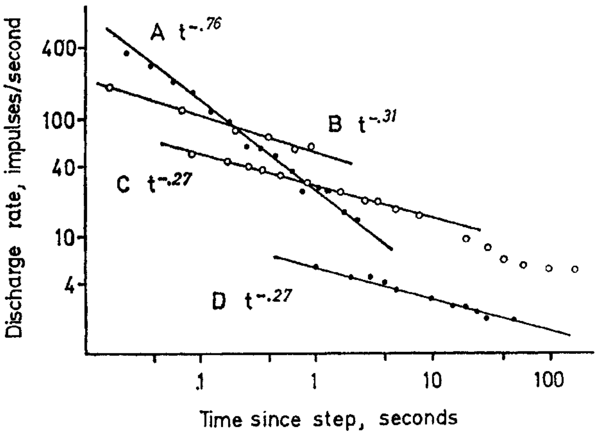

**Figure 4.** Four curves showing power law adaptation in response to a step increase in stimulus in four different receptors: cockroach leg mechanoreceptor, in response to distortion of the tactile spine on the femur (curve A); slit sensillum on the leg of the hunting spider in response to 1,200 Hz sound (curve B); slowly adapting stretch receptor of the crayfish (curve C); and increase of response over light-adapted level of *Limulus* lateral-eye eccentric cell to an increase in light intensity (curve D). (Examples from Thorson, J., and Biedermann-Thorson, M., 1974, Distributed relaxation processes in a sensory adaptation, *Science*, 183:161–172. Copyright 1974, American Association for the Advancement of Science; reprinted with permission.)

Such adaptation is particularly interesting both because it is so prevalent and because it may have an important role in optimizing information transmission. Fractional-differentiation-like behavior is observed in fly photoreceptors, and in that case, the exponent of the fractional differentiator appears to be matched to the spectrum of natural stimuli (van Hateren and Snippe, 2001). Thus the effect of the transformation is to whiten the spectrum of natural signals. Because many natural stimuli have power-law characteristics, it is intriguing to speculate that fractional differentiation at the sensory periphery may be a general neural mechanism for whitening input statistics.

## Mechanisms

Adaptation requires retaining memory of activity over extended time scales. These long time scales can arise from a number of sources. Intracellular calcium concentration has been identified as playing an important role in information processing, acting as a slowly changing "integrator" of activity. Other forms of adaptation, particularly the power-law-like behavior discussed in the previous section, are also likely to be a property of single cells rather than of the network. Recent biophysical studies show that membrane dynamics can have long time scales that retain memory of the history of stimulation/activity over hundreds of seconds (Marom, 1998). This could be brought about either by the modification of intrinsic properties or by intrinsic properties that have built-in long time scales through *state-dependent inactivation* (Turrigiano, Marder, and Abbott, 1996; Marom, 1998).

### Calcium as an Integrator of Activity

Each spike introduces a roughly constant amount of calcium into the cell through voltage-dependent $Ca^{2+}$ channels. The $Ca^{2+}$ concentration then decays slowly. Thus, $[Ca^{2+}]$ can be modeled as a leaky integrator of activity, with a decay time scale of ca. 100 ms. This calcium signal can allow activity-dependent regulation of subsequent neural activity through the modification of conductances (see ACTIVITY-DEPENDENT REGULATION OF NEURONAL CONDUCTANCES).

Recent evidence indicates that single-cell properties may contribute to contrast adaptation in cortex (Sanchez-Vives, Nowak, and McCormick, 2000). Previous work has shown that contrast adaptation is associated with hyperpolarization of the membrane potential in cat area 17 neurons. By stimulating the neurons directly with injected current, effects similar to contrast adaptation are seen (though less dramatically than to real visual input). This suggests that these effects can be induced through the modulation of intrinsic cell properties; the activation of $Ca^{2+}$- and $Na^{+}$-dependent potassium conductances is indicated.

### *State-Dependent Channel Dynamics*

In some cases the relevant dynamics may be due to the complex behavior of the channels themselves. Recently it has become clear that the dynamics of inactivation provide the membrane with the possibility for extended history dependence (Marom, 1998).

A simplified picture of the gating of voltage-gated ion channels is a three-state scheme:

$$\mathrm{C} \Leftrightarrow \mathrm{O} \Leftrightarrow \mathrm{I} \tag{1}$$

where channels can be either closed (C), open (O), or inactivated (I). Generally, the transition between closed and open is voltage-dependent and rapid, on the order of the duration of an action potential. The transition between open and inactivated, on the other hand, is voltage-independent and can have very long time scale dynamics. Intriguingly, studies in vitro show that some sodium channel types have inactivation rates that scale with the duration of the input (Marom, 1998), providing time scales of up to several minutes. The precise mechanism underlying this large variety of time scales is not yet well understood; it is hypothesized that the system cascades through a multiplicity of inactivation states. Earlier theoretical work has shown that the coupling of many states leads to a scaling relation between the duration of activity and the rate of recovery from inactivation.

In a step closer to a realistic preparation, the dynamic clamp was applied to cultured stomatogastric ganglion neurons to add an effective slowly inactivating potassium current (Turrigiano et al., 1996). As had been observed previously, this produced long delays to firing during depolarization, and an increase in excitability with a time scale much longer than the duration of the input. Further, the slow channel dynamics produced a long-lasting effect on the firing properties of the neuron.

In vivo, the contribution of slowly inactivating sodium channels to power-law-like adaptation has been suggested. Mechanosensory neurons in the cockroach femoral tactile spine have been shown to display power-law adaptation. From intracellular measurements, Basarsky and French (1991) found that the spike rate adaptation is due to cumulative slowing of the recovery of the membrane potential between spikes. Previous work had demonstrated that calcium channel blockers or blockers of $Ca^{2+}$-activated $K^{+}$ channels did not reduce adaptation, while modifying sodium channel inactivation did.

These mechanisms might be seen as primitives for short-term "learning and memory."

## Modeling

Historically, attempts to model adaptation have considered the process to involve a dynamic threshold. More recently, modeling approaches have taken a functional perspective on the outcome of adaptation and have proposed algorithms whereby the conductances may adjust to provide the cell with desirable properties, such as approximately constant activity (see ACTIVITY-DEPENDENT REGULATION OF NEURONAL CONDUCTANCES). Closer to our earlier discussion, Stemmler and Koch (1999) derive a learning rule for conductances that maximizes the mutual information between input and output, where the output is taken to be the neuron's firing rate. The learning rule adjusts conductances at every new presentation of the stimulus, subject to biologically plausible constraints. Under this learning rule, a realistic conductance-based model neuron was indeed able to learn a changing distribution and adjust its firing statistics accordingly. The time scales treated were orders of magnitude longer than those observed experimentally in Fairhall et al. (2001) and predicted theoretically from statistical considerations. Experimental evidence is still required to determine whether such a model is realistic.

As noted, many adaptation processes in sensory receptors follow a power-law relaxation. Assuming that most elementary processes involve a single time scale, with exponential dynamics, Thorson and Biederman-Thorson (1974) proposed that power laws may arise from a superposition of many elementary processes with a wide range of time scales. From the definition of the gamma function,

$$t^{-\alpha} = \frac{1}{\Gamma(\alpha)} \int_0^\infty dr\, r^{\alpha-1} e^{-rt} \tag{2}$$

a power law may be generated by a weighted sum of exponentials with a range of time scales. This distribution was considered to be generated through geometric factors, such as the inhomogeneous distribution of elements within the receptor.

This model has met with some skepticism because of the requirements both for a continuous distribution of time scales and for these to be present in the appropriate proportions. It has been noted that power-law-like behavior results from much less stringent conditions: the superposition of only a few exponentials can produce a power law over the decade or two normally available to experiment. However, recent experimental advances, outlined in the previous section, may provide a better underpinning for the derivation of power-law adaptation from membrane mechanisms.

## Adaptation of Receptive Fields

As noted in the Introduction, a neuron can be modeled as a combination of feature extraction (linear filtering) and a nonlinear decision function (or threshold). Although we have discussed the effects of adaptation on the nonlinear decision function, adaptation can also affect the feature that causes the neuron to spike: the receptive field can depend on the ensemble of inputs. Although this result had been frequently observed in work on invertebrate vision, recent experiments demonstrate analogous results for cortical receptive fields. Sceniak et al. (1999) show that the extent of spatial summation implemented by neurons in V1 depends adaptively on contrast; this has parallels in the adaptation of filters in retina (Laughlin, 1989). Theunissen, Sen, and Doupe (2000) found that the spatiotemporal receptive fields of neurons in auditory cortex showed a strong dependence on the stimulus ensemble. This is a natural consequence of neural nonlinearity, but such a dependence is also necessary for optimal information processing.

## Discussion

The ubiquity of adaptation throughout the nervous system should be proof of its fundamental importance. Although the phenomenology of adaptation, particularly to constant stimuli, has been extensively explored, recent experimental and theoretical approaches have made contact with the principles of information theory in order to evaluate adaptive coding. For fly motion-sensitive neurons, it was found that the coding strategy of the system adapts rapidly and continuously to track dynamic changes in the statistics of the stimulus.

We have discussed a variety of mechanisms that may implement adaptive coding at the level of single cells. Although it is likely that systems will implement such important behavior at many levels, it is appealing that the simplest elements of neural computation have the power to carry out dynamic aspects of information processing.

## Introduction

Differential equations such as

$$\tau \dot{x}_i + x_i = f\left(\sum_j W_{ij} x_j + b_i\right) \qquad (1)$$

have long been used to model networks of interacting neurons (Ermentrout, 1998; PHASE-PLANE ANALYSIS OF NEURAL NETS). The activity of neuron $i$ is represented by a single dynamical variable $x_i$, and its input-output characteristics by a single transfer function $f$. There are more biophysically realistic descriptions of neural networks that include many dynamical variables per neuron, in order to explicitly model dendritic integration, action potential generation, and synaptic transmission. Nevertheless, simplified models like that in Equation 1 have been useful for understanding how the computational properties of neural networks are related to their synaptic organization.

The parameter $W_{ij}$ in Equation 1 represents the strength of the synapse from neuron $j$ to $i$. These synapses are termed *recurrent*, as they connect to other neurons in the same network. Feedforward synaptic input from outside the network is implicit in the bias $b_i$. The feedforward synapses could be made explicit by writing $b_i = b_i^0 + \Sigma_a V_{ia} z_a$, where $z_a$ are input neuron activities, $V_{ia}$ the strengths of the feedforward synapses, and $b_i^0$ any intrinsic tendency of neuron $i$ to be active. But the feedforward connections will be left implicit in the following, so as to focus on the computational role of the recurrent connections.

Accordingly, the biases $b_i$ in Equation 1 will be regarded as the inputs to the network, while the activities $x_i$ are the outputs. If there were no recurrent synapses ($W_{ij} = 0$ for all $i$ and $j$), then each neuron $i$ would respond by low-pass filtering the signal $f(b_i)$ with time constant $\tau$. When there are recurrent synapses, a general characterization of the response properties of a network is difficult, but the situation is greatly simplified when nonlinearity is neglected. Putting the transfer function $f(u) = u$ in Equation 1 yields the linear network

$$\tau \dot{x}_i + x_i = \sum_j W_{ij} x_j + b_i \qquad (2)$$

which can be completely analyzed using the tools of linear systems theory. The modest goal of this article is to describe some properties of linear networks and give examples of their application to neural modeling.

In particular, the focus is on the role of recurrent synaptic connectivity. Provided that they do not lead to instability, the recurrent connections alter both the gain and speed of response to feedforward input. Either they amplify and slow down responses to feedforward input, or they attenuate and speed up responses. Both effects can occur simultaneously in the same network, as can be seen by mathematically transforming the network of interacting neurons into a set of noninteracting eigenmodes. The effect of the recurrent synapses generally varies from mode to mode.

Besides amplification and attenuation, a linear network can also carry out the operation of temporal integration, in the sense of Newtonian calculus. This happens when the strength of feedback is precisely tuned for an eigenmode, so that its gain and time constant diverge to infinity.

Admittedly, the neglect of nonlinearity is a step away from biological realism. Nevertheless, linear models are important because they give insight into the local behavior of nonlinear networks, which can often be linearly approximated in the vicinity of fixed points. And the linear computations of amplification, attenuation, and integration have been ascribed to a number of brain areas.

## Autapse

The simplest example of a recurrent synapse is a single neuron with a synapse onto itself, or *autapse*, in the terminology of neurophysiology. For this case, the dynamics (Equation 2) takes the form

$$\tau\dot{x} + x = Wx + b \qquad (3)$$

The autapse has strength $W$ and is said to be excitatory if $W > 0$ and inhibitory if $W < 0$. The example is not meant to be a realistic model of a biological autapse; it is only a simple illustration of some of the effects of recurrent synaptic connections. The parameter $W$ will also be called the strength of *feedback*, in the terminology of engineering. Without feedback ($W = 0$), the neuron acts as a low-pass filter of input $b$ with time constant $\tau$. When the effect of feedback is considered, the first distinction that has to be made is between the unstable $W > 1$ and the stable $W < 1$ cases. (Discussion of the borderline $W = 1$ case is postponed until later.)

If $W > 1$, the autapse is unstable, as can be seen by solving Equation 3 for input $b$ that is constant in time. The solution diverges exponentially to infinity, because the feedback is so strong that it leads to runaway instability. Note that in a more realistic model, the growth of this runaway instability would eventually be limited by nonlinearity, but in the idealized linear model (Equation 3), divergence to infinity is possible.

If $W < 1$, the autapse is stable, and the dynamics (Equation 3) can be rewritten in the form

$$\frac{\tau}{1 - W}\dot{x} + x = \frac{b}{1 - W} \qquad (4)$$

From this formula can be read two numbers that characterize the autapse: the steady-state gain, and the time constant of response. The gain is operationally defined by holding the input constant and allowing the output to relax to the steady-state value $x_\infty = b/(1 - W)$. Then the steady-state gain, defined as the ratio of output $x_\infty$ to input $b$, is $1/(1 - W)$. By this definition, the gain is exactly unity in the case of no feedback ($W = 0$). Positive ($W > 0$) and negative ($W < 0$) feedback have different effects. Positive feedback amplifies, boosting the gain to a value greater than 1. Negative feedback attenuates, making the gain less than 1.

Positive and negative feedback also have opposite effects on the speed of response. The time constant of the exponential relaxation to the steady state is $\tau/(1 - W)$. In the case of no feedback, this is equal to the fundamental time constant $\tau$. But positive feedback lengthens the time constant, while negative feedback shortens it. This means that there is a trade-off between amplification and speed, sometimes known as the gain-bandwidth trade-off. Intuitively speaking, the trade-off arises because feedback amplification requires that the signal circulate in the feedback loop, so that more amplification requires more time.

In summary, a feedback loop containing a perfectly linear element behaves in a simple way. Positive feedback ($W > 0$) amplifies and slows down response, assuming that it doesn't lead to instability. Negative feedback ($W < 0$) attenuates and speeds up response.

The idea of amplification by positive feedback has been prominent in a number of models of primary visual cortex (Douglas et al., 1995). Neurons in layer 4 receive both feedforward drive from the thalamus and recurrent input from other cortical neurons. It has been proposed that the recurrent interactions amplify the responses to feedforward input. To test this idea, Ferster and colleagues recorded from layer 4 neurons. They inactivated corticocortical inputs both by cooling (Ferster, Chung, and Wheat, 1996) and electrical stimulation (Chung and Ferster, 1998). In both cases, they measured a two- or threefold reduction in the amplitude of cortical responses to visual stimulation, which was interpreted as a loss of amplification by positive feedback.

The above discussion omitted the special case of $W = 1$, which is the borderline between stability and instability. For $W \neq 1$, there was exactly one steady state, which was either stable or unstable, depending on whether $W$ was less than or greater than 1. In contrast, if $W = 1$, there is not a unique steady state. The number of steady states depends on $b$. There are infinitely many if $b = 0$, and none at all if $b \neq 0$. To understand the case of non-zero $b$, it is helpful to return to Equation 3, which reduces to $\tau\dot{x} = b$. In other words, the response $x$ is the time integral of $b$. Therefore, a linear autapse can act as an integrator, if the strength of feedback is precisely tuned (Seung et al., 2000). Variants of this idea have been used to model neural integrators, brain areas that integrate their inputs in the sense of Newtonian calculus (Robinson, 1989).

## Mutually Inhibitory Pair

While the autapse illustrates the gain-bandwidth trade-off in feedback amplification, it involves only a single neuron, and cannot capture genuine population behaviors. A more interesting example consists of two linear neurons with mutual inhibition:

$$\tau\dot{x}_1 + x_1 = -\beta x_2 + b_1 \qquad (5)$$

$$\tau\dot{x}_2 + x_2 = -\beta x_1 + b_2 \qquad (6)$$

The parameter $\beta$ is assumed to be positive, so that the interaction is inhibitory. This dynamics is more complex than Equation 3 because it involves two differential equations that are coupled to each other. Luckily, it turns out that the equations can be decoupled by adding and subtracting them.

Adding the two equations yields an equation for the common mode $x_c = x_1 + x_2$,

$$\tau\frac{d}{dt}(x_1 + x_2) + (x_1 + x_2) = -\beta(x_1 + x_2) + (b_1 + b_2) \qquad (7)$$

Comparison with Equation 3 reveals that the common mode behaves like an autapse with negative feedback. Therefore the common mode attenuates its input $b_1 + b_2$ with steady-state gain $1/(1 + \beta)$ and time constant $\tau/(1 + \beta)$.

Similarly, subtracting the two equations yields an equation for the differential mode $x_d = x_1 - x_2$,

$$\tau\frac{d}{dt}(x_1 - x_2) + (x_1 - x_2) = \beta(x_1 - x_2) + (b_1 - b_2) \qquad (8)$$

The differential mode behaves like an autapse with positive feedback. If $\beta > 1$, the differential mode is unstable. If $\beta < 1$, then the differential mode amplifies its input $b_1 - b_2$ with steady-state gain $1/(1 - \beta)$ and time constant $\tau/(1 - \beta)$.

To recapitulate, transforming from $(x_1, x_2)$ to $(x_c, x_d)$ formally decoupled the mutually inhibitory pair of neurons into two "virtual" autapses. Note that the transformation is reversible, as $x_1$ and $x_2$ can be reconstructed from the common and differential modes, e.g., $x_1 = (x_c + x_d)/2$.

A striking aspect of this example is that mutual inhibition has completely opposite effects on the common and differential modes. For the common mode, inhibition mediates negative feedback, which leads to attenuation. But inhibition mediates positive feedback for the differential mode, which leads to amplification.

The general lesson to be drawn is that no direct correspondence exists between the sign of synaptic connections and the sign of feedback. This is because a synapse is local, belonging to just two neurons. In contrast, feedback strength is global, belonging to a distributed mode of the network. As will be described below, the feedback strength is given in general by the eigenvalues of the synaptic weight matrix $W$. The autapse is a special exception for which the sign of the synaptic connection directly corresponds to the sign of feedback, but this does not hold true in general.

The idea that inhibition between neurons can amplify differences has been used to explain the fact that visual systems are more sensitive to relative luminance, or contrast, than to absolute luminance. For example, the *Limulus* retina consists of visual receptors that are topographically organized in a two-dimensional network and interact via lateral inhibition. Measurements of retinal output reveal enhancement of luminance differences, a fact that has been successfully explained using network models that are generalizations of the mutually inhibitory pair considered here (Hartline and Ratliff, 1972).

The special case $\beta = 1$ is also of interest. It is the borderline of stability for the differential mode. If $b_1 - b_2$ is zero, then the differential mode $x_1 - x_2$ is constant in time, according to Equation 8, while the common mode $x_1 + x_2$ converges exponentially to the value $(b_1 + b_2)/2$. This is a simple example of a *line attractor*, a line of fixed points to which all trajectories are attracted (Seung, 1996). More complex nonlinear network models with approximate line attractors have been used to model the phenomenon of persistent neural activity (Seung, 1996; Zhang, 1996).

Note that having a continuous set of fixed points is an unusual situation, requiring the precise tuning of the inhibitory strength $\beta$ and the differential input $b_1 - b_2$. When $b_1 - b_2$ is non-zero, then it is integrated by the differential mode. In this case, inhibitory interactions yield an integrator, in contrast to the autapse, which requires excitatory feedback to integrate. Robinson et al. proposed that lateral inhibition is the mechanism of the oculomotor neural integrator, which converts vestibular and other velocity-coded inputs into eye position outputs (Cannon, Robinson, and Shamma, 1983).

## General Network

For a general network of $N$ neurons, the effects of feedback can be understood via eigensystem analysis. It is convenient to rewrite the dynamics in Equation 2 in matrix-vector form as

$$\tau \frac{d}{dt} x + x = Wx + b \tag{9}$$

where $x$ and $b$ are vectors and $W$ is the synaptic weight matrix.

Suppose that the weight matrix can be factorized as $W = S\Lambda S^{-1}$, where $\Lambda$ is a real diagonal matrix and $S$ is a real invertible matrix. A sufficient condition for a real diagonalization is that the weight matrix $W$ be symmetric, but this is not a necessary condition. The diagonal entries of $\Lambda$ are the eigenvalues of $W$. The columns of $S$ are the right eigenvectors of $W$, and the rows of $S^{-1}$ are the left eigenvectors.

Recall that transforming to the common and differential modes simplified the dynamics of the mutually inhibitory pair. The analogue here is to change from $x$ and $b$ to

$$\tilde{x} = S^{-1}x, \qquad \tilde{b} = S^{-1}b$$

These vectors can be used to express $x$ and $b$ as linear combinations of the right eigenvectors, $x = S\tilde{x}$ and $b = S\tilde{b}$.

The transformation of Equation 9 is effected by multiplying with $S^{-1}$,

$$\tau \frac{d}{dt} \tilde{x} + \tilde{x} = S^{-1}Wx + \tilde{b} \tag{10}$$

$$= S^{-1}WS\tilde{x} + \tilde{b} \tag{11}$$

$$= \Lambda\tilde{x} + \tilde{b} \tag{12}$$

Writing out the last expression component by component yields

$$\tau \frac{d}{dt} \tilde{x}_a + \tilde{x}_a = \lambda_a \tilde{x}_a + \tilde{b}_a$$

where $\lambda_a$ is the $a$th diagonal element of $\Lambda$, or equivalently the $a$th eigenvalue of $W$. This is a great simplification: the network (Equation 9) of $N$ interacting neurons has been transformed into $N$ noninteracting “virtual” autapses. Each autapse has feedback with strength given by the eigenvalues $\lambda_a$. Assuming that the eigenvalues are less than or equal to 1, each autapse can perform the operations of amplification, attenuation, or integration.

## Discussion

In this article, some effects of recurrent synaptic connectivity on linear networks were characterized. The autapse example demonstrated that there is a gain-bandwidth trade-off in amplification and attenuation by feedback, and the possibility of integration when feedback is precisely tuned. The mutually inhibitory pair illustrated the decoupling of an interacting network into “virtual” autapses, and also illustrated that the sign of feedback is not directly related to the sign of synaptic connections. Such a decoupling is generally possible for any synaptic weight matrix $W$ that is diagonalizable with all real eigenvalues.

More generally, the eigenvalues (and eigenvectors) are complex numbers. When an eigenvalue of $W$ has a non-zero imaginary part, the corresponding eigenmode exhibits oscillatory behavior. Accordingly, linear analyses have been used to explain the existence of oscillations in some neural network models (Li and Hopfield, 1989).

It is natural to ask whether the concepts introduced above have any relevance for *nonlinear* neural networks. A simple way of modeling nonlinearity is to introduce a threshold for activation by choosing $f(x) = \max\{x, 0\}$ for the transfer function in Equation 1. Because the resulting dynamics are piecewise linear, eigenvalues and eigenvectors are still essential for mathematical analysis (Hadeler and Kuhn, 1987; Hahnloser et al., 2000), but the threshold nonlinearity leads to a richer variety of dynamical behaviors. A full discussion of threshold linear networks is beyond the scope of this article, but let us briefly reconsider the example of a mutually inhibitory pair of neurons presented with inputs that are constant in time. For linear neurons, the mutual inhibition caused differences in input to be amplified in the steady-state response. If the neurons are instead threshold linear, *winner-take-all* behavior can result for some choices of model parameters. Then only a single neuron is active at steady state, no matter how small the difference in inputs may be (Amari and Arbib, 1977). As in the purely linear case, the difference in steady-state outputs is greater than the difference in inputs. However, this behavior cannot be explained in terms of a simple linear amplification. For a more detailed explanation, see Winner-Take-All Networks.

## Introduction

The last two decades have seen a surge in theoretical techniques to design and analyze the performance of neural nets as well as novel applications of neural nets to various applied areas. Theoretical studies on the computational capabilities of neural nets have provided valuable insights into the mechanisms of these models.

In subsequent discussion, we distinguish between feedforward neural nets and recurrent neural nets. The architecture of a feedforward net $\mathcal{N}$ is described by an interconnection graph and the activation functions of $\mathcal{N}$. A node (processor or neuron) $v$ of $\mathcal{N}$ computes a function

$$\gamma_v\left(\sum_{i=1}^{k} a_{v_i,v}u_{v_i} + b_v\right) \tag{1}$$

of its inputs $u_{v_1}, \ldots, u_{v_k}$. These inputs are either external (i.e., representing the input data) or internal (i.e., representing the outputs of the immediate predecessors of $v$). The coefficients $a_{v_i,v}$ (respectively $b_v$) in Equation 1 are the *weights* (respectively *threshold*) of node $v$, and the function $\gamma_v$ is the *activation function* of $v$. No cycles are allowed in the interconnection graph, and the output of designated nodes provides the output of the network. A recurrent neural net, on the other hand, allows cycles, thereby providing potentially higher computational capabilities. The *state* $u_v$ of node $v$ in a recurrent net is updated over time according to

$$u_v(t + 1) = \gamma_v\left(\sum_{i=1}^{k} a_{v_i,v}u_{v_i}(t) + b_v\right) \tag{2}$$

In this article, we emphasize the exact and approximate representational power of feedforward and recurrent neural nets. This line of research can be traced back to Kolmogorov (1957), who essentially proved the first existential result on the (exact) representation capabilities of neural nets (cf. UNIVERSAL APPROXIMATORS). The need to work with "well-behaved" activation functions, however, enforces approximative representations of target functions, and the question of the approximation power (with limited resources) becomes fundamental.

The representation power of neural nets has immediate consequences for learning, since we cannot learn (approximately) what we cannot represent (approximately). On the other hand, the complexity of learning increases with increasing representational power of the underlying neural model, and care must be exercised to strike a balance between representational power, on the one hand, and learning complexity, on the other. The emphasis of this article is on representational power, i.e., what can be represented with networks using a given set of activation functions, rather than on learning complexity.

In this article, we discuss only a small subset of the literature on this topic. After introducing the basic notation, we discuss the representational power of feedforward and recurrent neural nets. There follows a brief discussion of networks of spiking neurons and their relation to sigmoidal nets, with a summary statement.

## Models and Basic Definitions

In this section we present the notation and basic definitions used in subsequent sections. For real-valued functions we measure the approximation quality of function $f$ by function $g$ (over a domain $D \subseteq \mathbb{R}^n$) by the Chebychev norm,

$$\|f - g\|_D = \sup\{|f(x) - g(x)| : x \in D\}$$

(the subscript $D$ will be omitted when clear from the context). To emphasize the selection of activation functions, we introduce the concept of $\Gamma$-nets for a class $\Gamma$ of real-valued activation functions. A $\Gamma$-net $\mathcal{N}$ assigns only functions in $\Gamma$ to nodes. We assume that each function in $\Gamma$ is defined on some subset of $\mathbb{R}$, and require that $\Gamma$ contain the identity function by default (thus allowing weighted additions as node outputs). Finally, we restrict our attention to $\Gamma$-nets with a single output node.

The *depth* of a feedforward net $\mathcal{N}$ is the length of the longest path of the (acyclic) interconnection graph of $\mathcal{N}$, and the *size* of $\mathcal{N}$ is the number of nodes. The *hidden nodes* are all nodes excluding all input nodes and the output node.

The class of important activation functions is rather large and includes, among others, the binary threshold function

$$\mathcal{H}(x) = \begin{cases} 0 & \text{if } x \leq 0, \\ 1 & \text{if } x > 0, \end{cases}$$

the cosine squasher, the Gaussian, the standard sigmoid $\sigma(x) = 1/(1 + e^{-x})$, the hyperbolic tangent, (generalized) radial basis functions, polynomials and trigonometric polynomials, splines, and rational functions.

Care must be exercised when using a neural net with continuous activation functions to compute a Boolean-valued function, since in general, the output node computes a real number. A standard output convention in this case is as follows (see Maass, 1994):

*Definition 1.* A $\Gamma$-net $\mathcal{N}$ computes a Boolean function $F$: $\mathbb{R}^n \to \{0, 1\}$ with separation $\varepsilon > 0$ if there is some $t \in \mathbb{R}$ such that for any input $x \in \mathbb{R}^n$, the output node of $\mathcal{N}$ computes a value that is at least $t + \varepsilon$ if $F(x) = 1$, and at most $t - \varepsilon$ otherwise.

Recurrent neural nets, unlike their feedforward counterparts, allow loops in their interconnection graph. Certainly *asynchronous* recurrent nets are an important neural model, but we assume in Equation 2 that all nodes update *synchronously* at each time step. Typically, besides internal and external data lines, some of the inputs and outputs are validation lines, indicating if there is any input or output present at the time.

## Computational Power of Feedforward Nets

The simple perceptron as a feedforward neural net with one layer has only limited computational abilities. For instance, if we restrict ourselves to one-node simple perceptrons and assume monotone, but otherwise arbitrary, activation functions, then the XOR function $\mathrm{XOR}(x_1, x_2) = x_1 \oplus x_2$ cannot be computed.

On the other hand, if we choose the binary threshold function $\mathcal{H}$ as activation function, then the learning problem for simple perceptrons is efficiently solvable by linear programming. This positive result is also extendable to a large class of activation functions, including the standard sigmoid. But simple perceptrons should not be underestimated, since the problem of approximately minimizing the missclassification ratio (when the target function is not representable as a simple perceptron) has been shown to be (probably) intractable (Arora et al., 1997).

However, the power of feedforward nets increases significantly when networks of more layers are considered. In fact, a result of Kolmogorov (refuting Hilbert's 13th problem for continuous functions), when translated into neural net terminology, shows that any continuous function can be computed *exactly* by a feedforward net of depth 3.

*Theorem 1 (Kolmogorov, 1957).* Let $n$ be a natural number. Then there are continuous functions $h_1, \ldots, h_{2n+1} : [0, 1] \to \mathbb{R}$ such that any continuous function $f$: $[0, 1]^n \to \mathbb{R}$ can be represented as

$$f(x) = \sum_{j=1}^{2n+1} g\left(\sum_{i=1}^{n} \alpha_i h_j(x_i)\right)$$

where the function $g$ as well as the weights $\alpha_1, \ldots, \alpha_n$ depend on $f$.

But, unfortunately, the function $g$ depends on the function to be represented. Moreover, the functions $h_j$ are nondifferentiable and hence cannot be used by current learning algorithms. For further discussion, we refer the reader to Poggio and Girosi (1989).

However, if we only allow everywhere differentiable activation functions (such as the standard sigmoid), then we can only represent everywhere differentiable target functions. Thus, one has to relax the requirement of exact representation, and demand only that the approximation error (in an appropriate norm) is small. Applying the Stone-Weierstrass theorem one obtains, for instance, (trigonometric) polynomials as universal approximators, and hence we get neural nets with one hidden layer as universal approximators.

Cybenko (1989) considers activation functions from the class of continuous *discriminatory* functions. This class contains, for instance, *sigmoidal* functions, i.e., continuous functions $\sigma$ satisfying

$$\sigma(t) \to \begin{cases} 1 & \text{as } t \to +\infty \\ 0 & \text{as } t \to -\infty \end{cases}$$

*Theorem 2.* Let $\sigma$ be a continuous discriminatory function and let $f : [0, 1]^n \to \mathbb{R}$ be a continuous target function. Then, for every $\varepsilon > 0$ and for sufficiently large $N$ (where $N$ depends on the target function $f$ and $\varepsilon$), there exist weights $\alpha_{ij}$, $w_j$ and thresholds $\beta_j$, such that $\|f - g\| < \varepsilon$, where $g = \Sigma_{j=1}^{N} w_j \cdot \sigma(\Sigma_{i=1}^{n} \alpha_{ij} \cdot x_i + \beta_j)$.

In particular, one hidden layer suffices to approximate any continuous function by sigmoidal nets within arbitrarily small error. Further results along this line are shown by Hornik; Stinchcombe and White; Funahashi, Moore, and Poggio; and Poggio and Girosi, to mention just a few. Whereas most arguments in the above-mentioned results are nonconstructive, Carroll and Dickinson describe a method using Radon transforms to approximate a given $L_2$ function to within a given mean square error.

Barron (1993) discusses the approximation quality achievable by sigmoidal nets of small size. In particular, let $B_r^n(0)$ denote the $n$-dimensional ball with radius $r$ around 0 and let $f : B_r^n(0) \to \mathbb{R}$ be the target function. Assume that $F$ is the magnitude distribution of the Fourier transform of $f$.

*Theorem 3 (Barron, 1993).* Let $\sigma$ be any sigmoidal function. Then for every probability measure $\mu$ and for every $N$ there exist weights $\alpha_{ij}$, $w_j$ and thresholds $\beta_j$, such that

$$\int_{B_r^n(0)} \left(f(x) - \sum_{j=1}^{N} w_j \cdot \sigma\left(\sum_{i=1}^{n} \alpha_{ij} \cdot x_i + \beta_j\right)\right)^2 \mu(dx) \le \frac{(2\int r \cdot |w| \cdot F(dw))^2}{N}$$

Set $C_f = \int r \cdot |w| \cdot F(dw)$, and the approximation error achievable by sigmoidal nets of size $N$ is bounded by $(2 \cdot C_f)^2/N$. However, $C_f$ may depend superpolynomially on $n$, and the curse of dimensionality may strike. As an aside, the best achievable squared error for linear combinations of $N$ *basis functions* will be at least $\Omega(C_f/n \cdot N^{1/n})$ for certain functions $f$ (Barron, 1993), and hence neural networks are superior to conventional approximation methods from this point of view.

The results just enumerated show that depth-2 feedforward nets are universal approximators. This dramatically increased computing power, however, has a rather negative consequence. Kharitonov (1993) showed that under certain cryptographic assumptions, no efficient learning algorithm will be able to predict the input-output behavior of binary threshold nets with a fixed number of layers. This result holds even when experimentation is allowed, that is, when the learning algorithm is allowed to submit inputs for classification.

In the next section, we compare important activation functions in terms of their approximation power, when resources such as depth and size are limited. The following section discusses networks of spiking neurons. Lower size bounds for sigmoidal nets are mentioned when we compare networks of spiking neurons and sigmoidal nets.

### *Efficient Approximation by Feedforward Nets*

Our discussion will be informal, and we refer the reader to DasGupta and Schnitger (1993) for details. Our goal is to compare activation functions in terms of the size and depth required to obtain tight approximations. Another resource of interest is the *Lipschitz bound* of the net, which is a measure of the numerical stability of the circuit. Informally speaking, for a net $\mathcal{N}$ to have Lipschitz-bound $L$, we first demand that all weights and thresholds of $\mathcal{N}$ be bounded in absolute value by $L$. Moreover, we require that each activation function of $\mathcal{N}$ have (the conventional) Lipschitz-bound L on the inputs it receives. Finally, the actually received inputs have to be bounded away from regions with higher Lipschitz bounds.

We formalize the notion of having *essentially the same approximation power.*

*Definition 2.* Let $\Gamma_1$ and $\Gamma_2$ be classes of activation functions.

(a) We say that $\Gamma_2$ simulates $\Gamma_1$ (denoted by $\Gamma_1 \le \Gamma_2$) if and only if there is a constant $k \ge 1$ such that for all $\Gamma_1$-nets $C_2$ of size at most $s$, depth at most $d$, and Lipschitz bound $2^s$, there is a $\Gamma_2$-circuit $C_1$ of size at most $(s + 1)^k$, depth at most $k \cdot (d + 1)$, and Lipschitz bound $2^{(s+1)^k}$, such that

$$\|C_1 - C_2\|_{[-1,1]^n} \le 2^{-s}$$

(b) We say that $\Gamma_1$ and $\Gamma_2$ are equivalent if and only if $\Gamma_1 \le \Gamma_2$ and $\Gamma_2 \le \Gamma_1$.

In other words, when simulating classes of gate functions, we allow depth to increase by a constant factor size and the logarithm of the Lipschitz bound to increase polynomially. The relatively large Lipschitz bounds should not come as a surprise, since the negative exponential error $2^{-s}$ requires correspondingly large weights in the simulating circuit.

Splines (i.e., piecewise polynomial functions) have turned out to be powerful approximators, and they are our benchmark class of activation functions; in particular, we assume that a spline net of size $s$ has as its activation functions splines of degree at most $s$ with at most one knot. Which properties does a class $\Gamma$ of activation functions need to reach the approximation power of splines? The activation functions should be able to approximate polynomials as well as the binary threshold $\mathcal{H}$ with few layers and relatively few nodes.

Tightly approximating polynomials is not difficult as long as there is at least one "sufficiently smooth" nontrivial function $\gamma \in \Gamma$. The crucial problem is to obtain a tight approximation of $\mathcal{H}$. It turns out that $\gamma$-nets achieve tight approximations of $\mathcal{H}$ whenever

$$|\gamma(x) - \gamma(x + \varepsilon)| = O(\varepsilon/x^2)$$
$$\text{for } x \ge 1, \qquad \varepsilon \ge 0 \qquad \text{and} \qquad \left|\int_1^\infty \gamma(u^2)du\right| \ne 0$$

Let us call a function with these two properties *strongly sigmoidal.* (We are actually demanding too much, since it suffices to tightly approximate a strongly sigmoidal function $\gamma$ by small $\Gamma$-nets with few layers.) Let us call a class $\Gamma$ *powerful* if there is at least one "sufficiently smooth" nontrivial function in $\Gamma$ and if a strongly sigmoidal function can be approximated as demanded above.

Examples of powerful singleton classes include, for instance, $1/x$ as a prime example, and more generally any rational function that is not a polynomial, $\exp(x)$ (since $\exp(-x)$ is strongly sigmoidal) and $\ln(x)$ (since $\ln(x + 1) - \ln(x)$ is strongly sigmoidal), any power $x^\alpha$ provided $\alpha$ is not a natural number, and the standard sigmoid as well as the Gaussian $\exp(-x^2)$.

*Theorem 4.*

(a) Assume that $\Gamma$ is powerful. Then splines $\le \Gamma$.

(b) The following classes of activation function have equivalent approximation power: splines (of degree $s$ for nets of size $s$), any rational function that is not a polynomial, any power $x^\alpha$ (provided $\alpha$ is not a natural number), the logarithm (for any base), $\exp(x)$, and the Gaussian $\exp(-x^2)$.

Notably missing from the list of equivalent activation functions are polynomials, trigonometric polynomials, and the binary threshold function $\mathcal{H}$ (or, more generally, low-degree splines). Low-degree splines turn out to be properly weaker. The same applies to polynomials, even if we allow any polynomial of degree $s$ an activation function for nets of size $s$. Finally, sine nets cannot be simulated (as defined in Definition 2), for instance by nets of standard sigmoids, and we conjecture that the reverse is also true, namely, that nets of standard sigmoids cannot be simulated efficiently by sine nets.

What happens if we relax the required approximation quality from $2^{-s}$ to $s^{-d}$, when simulating nets of depth $d$ and size $s$? Linear splines and the standard sigmoid are still not equivalent, but the situation changes completely if we *count* the number of inputs when determining size and if we restrict the Lipschitz bound of the target function to be at most $s^{-d}$. With this modification an even larger class of important functions, including linear splines, polynomials, and the sine function, turn out to be equivalent with the standard sigmoid.

The situation for Boolean input and output is somewhat comparable. Maass, Schnitger, and Sontag, and subsequently DasGupta and Schnitger constructed Boolean functions that are computed by sigmoidal nets of constant size (i.e., independent of the number of input bits), whereas $\mathcal{H}$-nets of constant size do not suffice. (See Maass, 1994, for a more detailed discussion.) However, Maass (1993) showed that spline nets of constant degree, constant depth, and polynomial size (in the number of input bits) can be simulated by $\mathcal{H}$-nets of constant depth and polynomial size. This simulation holds without any restriction on the weights used by the spline net.

Thus, analog computation does help for discrete problems, but apparently by not too much. For a thorough discussion of discrete neural computation, see Siu, Roychowdhury, and Kailath (1994).

## *Sigmoidal Nets and Nets of Spiking Neurons*

A formal model of networks of spiking neurons is defined in Maass (1997); see SPIKING NEURONS, COMPUTATION WITH. The architecture is described by a directed graph $G = (V, E)$, with $V$ as the set of nodes and $E$ as the set of edges. We interpret nodes as neurons and edges as synapses, and assign to each neuron $v$ a threshold function $\Theta_v : \mathbb{R}^+ \to \mathbb{R}^+$. ($\mathbb{R}^+$ denotes the set of nonnegative reals.) The value of $\Theta_v(t - t')$ measures the "reluctance" (or the threshold to be exceeded) of neuron $v$ to fire at time $t$ ($t > t'$), assuming that $v$ has fired at time $t'$. This reluctance can be overcome only if the potential $P_v(t)$ of neuron $v$ at time $t$ is at least correspondingly as large.

The potential of $v$ at time $t$ depends on the recent firing history of the presynaptic neurons (or the immediate predecessors) $u$ of $v$. In particular, if the synapse between neurons $u$ and $v$ has the efficacy (or weight) $w_{uv}$, if $\varepsilon_{uv}(t - s)$ is the response to the firing of neuron $u$ at time $s$ ($s < t$) and if the presynaptic neuron $u$ has fired previously for the times in the set $\mathrm{Fire}_u^t$, then the potential at time $t$ is defined as

$$P_v(t) = \sum_{(u,v)\in E} \sum_{s\in \mathrm{Fire}_u^t} w_{uv} \cdot \varepsilon_{uv}(t - s) \tag{3}$$

Two models, namely deterministic (respectively noisy) nets of spiking neurons, are distinguished. The deterministic version assumes that neuron $v$ fires whenever its potentials $P_v(t)$ reach $\Theta_v(t - t')$ (with most recent firing $t'$), whereas the more realistic noisy version assumes that the firing probability increases with increasing difference $P_v(t) - \Theta_v(t - t)$.

Thus we can complete the definition of the formal model, assuming that a response function $\varepsilon_{uv} : \mathbb{R}^+ \to \mathbb{R}$ as well as the weight $w_{uv}$ is assigned to the synapse between $u$ and $v$. The model computes by transforming a spike train of inputs into a spike train of outputs. For instance assuming temporal coding with constants $T$ and $c$, the output of a designated neuron with firing times $T + c \cdot t_1, \ldots, T + c \cdot \Sigma_{i=1}^k t_i, \ldots$ is defined as $t_1, \ldots, \Sigma_{i=1}^k t_i, \ldots$

The power of spiking neurons shows for the example of the element distinctness function $ED_n$ with real inputs $x_1, \ldots, x_n$, where

$$ED_n(x) = \begin{cases} 1 & \text{if } x_i = x_j \text{ for some } i \neq j, \\ 0 & \text{if } |x_i - x_j| \geq 1 \text{ for all } i \neq j, \\ \text{arbitrary} & \text{otherwise.} \end{cases}$$

We assume that the inputs $x_1, \ldots, x_n$ are represented by $n$ input trains of single spikes. Now it is easy to choose a simple threshold function as well as simple (and indeed identical) response functions such that even a single spiking neuron with unit weights is capable of computing $ED_n$. On the other hand, any sigmoidal net computing $ED_n$ requires at least $(n - 4)/2 - 1$ hidden units (Maass, 1997). This result is also the strongest lower size bound for sigmoidal nets computing a specific function; the argument builds on techniques from Sontag (1997).

Certainly this one-neuron computation requires time, because of the temporal input coding, but the same applies to sigmoidal networks, since, from the point of neurobiology, the $x_i$'s will be obtained after sampling the firing rate of their input neurons.

Nets of spiking neurons are capable of simulating $\mathcal{H}$-nets with at most the same size, and hence are properly stronger than $\mathcal{H}$-nets and at least in some cases stronger than sigmoidal nets. Thus, careful timing is an advantage that synchronized models cannot overcome.

## Computational Power of Recurrent Nets

The computational power of recurrent nets is investigated in Siegelmann and Sontag (1994, 1995). (See also Siegelmann, 1998, for a thorough discussion of recurrent nets and analog computation in general.) Recurrent nets include feedforward nets, and thus the results for feedforward nets apply to recurrent nets as well. But recurrent nets gain considerably more computational power with increasing computation time. In the following discussion, for the sake of concreteness, we assume that the piecewise linear function

$$\pi(x) = \begin{cases} 0 & \text{if } x \leq 0 \\ x & \text{if } 0 \leq x \leq 1 \\ 1 & \text{if } x \geq 1 \end{cases}$$

is chosen as the activation function. We concentrate on binary input and assume that the input is provided one bit at a time.

First of all, if weights and thresholds are integers, then each node computes a bit. Recurrent nets with integer weights thus turn out to be equivalent to finite automata, and they recognize exactly the class of regular language over the binary alphabet $\{0, 1\}$.

The computational power increases considerably for rational weights and thresholds. For instance, a "rational" recurrent net is, up to a polynomial time computation, equivalent to a Turing machine. In particular, a network that simulates a universal Turing machine does exist, and one could refer to such a network as "universal" in the Turing sense. It is important to note that the number of nodes in the simulating recurrent net is fixed (i.e., *does not grow* with increasing input length).

Irrational weights provide a further boost in computation power. If the net is allowed exponential computation time, then arbitrary Boolean functions (including noncomputable functions) are recognizable. However, if only polynomial computation time is allowed, then nets have less power and recognize exactly the languages computable by polynomial-size Boolean circuits.

## Discussion

We have discussed the computing power of neural nets, including universal approximation results for feedforward and recurrent neural networks as well as efficient approximation by feedforward nets with various activation functions. We emphasize that this survey is far from complete. For instance, we omitted important topics such as the Vapnik-Chervonenkis Dimension of Neural Networks (q.v.) and the complexity of discrete neural computation.

Important open questions relate to proving better upper and lower bounds for sigmoidal nets computing (or approximating) specific functions, and achieving a better understanding of size and depth trade-offs for important function classes. Other neural models, such as networks of spiking neurons, significantly change the computing power, and the questions we have identified apply to these models as well.

# Analog VLSI Implementations of Neural Networks

*Paul Hasler and Jeff Dugger*

## Introduction

The primary goal of analog implementations of neural networks is to incorporate some level of realistic biological modeling of adaptive systems into engineering systems built in silicon. We cannot simply duplicate biological models in silicon media because the constraints imposed by the biological media and the silicon media are not identical. Approaches that have been successful begin with the constraints that the silicon medium imposes on the learning system. Therefore, letting the silicon medium constrain the design of a system results in more efficient methods of computation.

We will focus our attention on issues concerning building neural network integrated circuits (ICs), and in particular on building connectionist neural network models. Connectionist neural networks, loosely based on biological computation and learning, can be useful for biological modeling if the limitations are understood. These neural systems are typically built as mappings of mathematical models into analog silicon hardware either by using standard building blocks (i.e., Gilbert multipliers: Mead, 1989) or by taking advantage of device physics (Hasler et al., 1995). This approach, related to investigations of adaptation and learning in neurobiological systems, provides the minimum necessary model of synaptic interaction between neurons, even for biological models. Neuromorphic (Mead, 1989, see also NEUROMORPHIC VLSI CIRCUITS AND SYSTEMS) and connectionist approaches develop adaptive systems from different levels of neural inspiration, and therefore lead to different levels of model complexity. Adding dendritic interactions and precise models of biological learning (e.g., LTP) to the connectionist model yields more biological realism. Implementations of fuzzy systems typically follow a similar approach to implementations of neural networks. The related field of cellular neural networks (CNNs), started by Chua, is particularly concerned with the circuit techniques used to build locally connected two-dimensional (2D) meshes of neuron processors (Chua, 1998), but the architecture design is fundamentally different and imposes different constraints on implementation.

## Neural Network Basics Focused on Implementation Issues

Figure 1 shows the basic feedforward structure typically used in neural network implementations. Most approaches focus on feedforward structures, since feedback systems and networks with time dynamics (e.g., time delays) are straightforward extensions for silicon implementation, although the algorithm design is considerably more difficult. In this model, we encode a neuron's activity as an analog quantity based on the mean spiking rate in a given time window. One can build linear or nonlinear filters at the input to the sigmoid function. Typically, a low-pass filter is built or modeled, since that will naturally occur for a given implementation or will set a desired convergence to an attractor (i.e., recurrent networks). This model is excellent for describing neurobiology if only mean-firing-rate behavior with minimal dendritic interactions is considered.

A basic model synapse (either digital or analog) must be able to store a weight, multiply its input with the stored weight, and adapt that weight based on a function of the input and a fed-back error signal. We model feedforward computation mathematically as

$$y_i = w_{ij}x_j \rightarrow \mathbf{y} = \mathbf{W}\mathbf{x} \tag{1}$$

where $x_j$ is the $j$th input ($\mathbf{x}$ is a vector of inputs), $y_i$ is the $i$th output ($\mathbf{y}$ is a vector of outputs), and $w_{ij}$ is the stored weight at position $(i,j)$ ($\mathbf{W}$ is a matrix of weights). The result of this output is passed through a nonlinear function

$$z_i = \tanh(a(y_i - \theta_i)) \tag{2}$$

where we designate $z_i$ as the result of the computation, $a$ is a gain factor, and $\theta_j$ is a variable threshold value. Other nonlinear functions, like radial basis functions (see RADIAL BASIS FUNCTION NETWORKS), are also often used, which would typically modify the

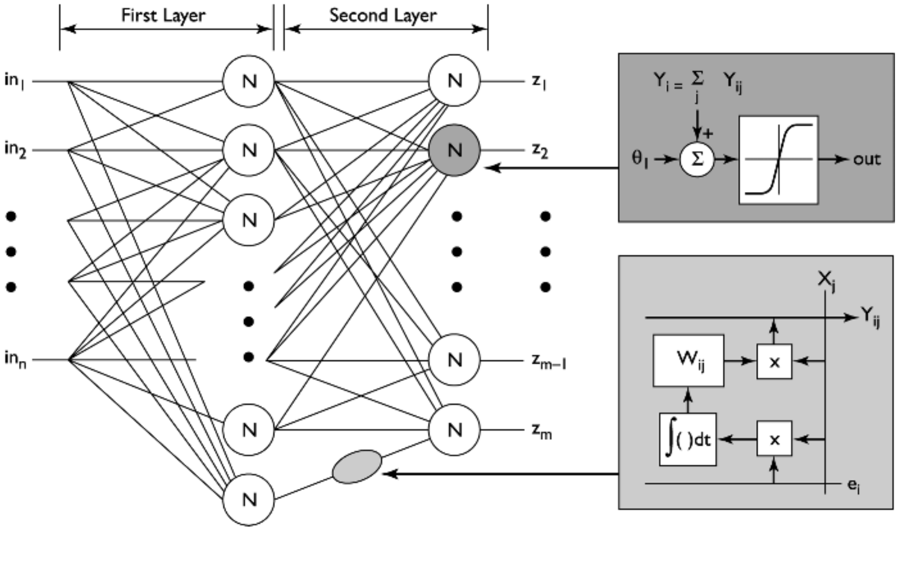

**Figure 1.** Classic picture of a two-layer neural network from the perspective of implementating these networks in hardware. The neural networks are layers of simple processors, called neurons, that are interconnected through weighting elements, called synapses. The neurons aggregate the incoming inputs (including a threshold or offset) and are applied through a tanh(·) nonlinearity. The synapse elements, which in general are far more numerous than the neuron elements, must multiply the incoming signal by an internally stored value, called the weight, and must adapt this weight according to a particular learning rule. Learning rules implemented in silicon are typically functions of correlations of signals passing through each synapse processor.

**Wx** computation. We model the weight adaptation mathematically as

$$\tau \frac{d\mathbf{W}}{dt} = f(\mathbf{W}, \mathbf{x}\mathbf{e}^T) \qquad (3)$$

where **e** is a vector of error signals that is fed back along various rows. We call this an outer-product learning rule, or a *local* learning rule, because of the $\mathbf{x}\mathbf{e}^T$ computation. The outer-product learning rule is dependent on the choice of $f(\mathbf{W}, \mathbf{x}\mathbf{e}^T)$ and the choice of the error signal.

Several learning algorithms have been proposed that conform to this functional form; representative examples can be found elsewhere in the *Handbook*. Learning algorithms usually divide into two categories, supervised and unsupervised. *Supervised algorithms* adapt the weights based on the input signals and a supervisory signal to train the network to produce an appropriate response. In many supervised algorithms (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION) this weight change is a time average of the product of the input and some fed-back error signal ($\mathbf{e} = \mathbf{y} - \hat{\mathbf{y}}$, where $\hat{\mathbf{y}}$ is the target signal). *Unsupervised algorithms* adapt the weights based only on the input and output signals, and in general the weights are a function of the input statistics. Although these learning algorithms result in very different results, both weight-update rules are similar from an implementation viewpoint. Most unsupervised algorithms are based on Hebbian learning algorithms, which correspond to neurobiological evidence of learning (see HEBBIAN SYNAPTIC PLASTICITY). For a Hebbian synapse, the weight change is a time average of the product of the input and output activity ($\mathbf{e} = \mathbf{y}$).

## Neural Network Implementations: Architecture Issues

Before considering circuit implementations of neurons and synapses, we first frame the overall architecture issues involved in implementing neural networks. In most implementations, a single layer of synapses is built as mesh architectures connected to a column of neuron processors (Figure 2). Because silicon ICs are 2D, mesh architectures work optimally with 2D routing constraints.

### *Feedforward Computation*

Figure 2*A* shows the typical mesh implementation of feedforward computation for a single-layer architecture. A mesh of processors is an optimal communication architecture for interconnect limited systems, which is the case for small synapse elements. Currents are preferred for outputs, because the summation typically required for most connectionist models is easily performed on a single wire, and voltages are preferred for inputs because they are easy to broadcast. Local processing is defined as interaction between *physically close* elements, voltage broadcast along global lines (inputs), or current/charge summation along a wire (outputs). As a result, each synapse has only to compute the local computation: $\mathbf{W}_{ij}\mathbf{x}_j$. Because the synapses store a weight value, the picture in Figure 2*A* resembles an analog memory that allows a full matrix-vector multiplication in the equivalent of one memory column access. This approach, called analog computing arrays, is defined and its implication for signal processing is described elsewhere (Kucic et al., 2001). Figure 2*B* shows how to modify a mesh architecture when considering *m*-nearest-neighbor connections. Other sparse

**Figure 2.** Typical architectures for neural network implementations. Although the routing looks complicated in Figure 1, it can easily be implemented in a mesh architecture. *A*, Diagram of the classic mesh architecture, typically used for fully connected architectures. *B*, Diagram of a mesh processor architecture optimized for nearest-neighbor computations.

encodings require digital communication and processing to handle the addressing schemes (i.e., address translation tables) and additional complexity (i.e., multiplexing scheme to access the inputs of each synapse).

To implement a neuron, we need a function that can compute a tanh(·) function. Fortunately, this function occurs in many IC circuits using either BJT or MOSFET (subthreshold or above-threshold) devices, such as the differential transistor pair (Mead, 1989). Since we only need a column of neuron circuits, they do not have the same area constraints that are imposed on synapse elements. Dynamics (e.g., low-pass filtering) are usually achieved by adding additional capacitance. Often one needs a current to perform voltage conversion between the summed synapse outputs and tanh(·) output, as well as at the output of a differential transistor pair. This conversion often can be nonlinear, or it may have to be nonlinear to interface with later processing stages.

## *Adaptive Neural Network Architectures*

Synapses require both feedforward and adaptation computations; therefore, architectural constraints imposed by the learning algorithm are an essential consideration for any neural network. Only learning algorithms that scale to large numbers of inputs and outputs are practical. A single-layer architecture with a local supervised or unsupervised rule of the form of Equation 3 only requires communicating the *error* signal along each row (Figure 3). The complexity of the synapse computation will depend on the particular learning rule. Many complicated algorithms, such as the generalized Hebbian algorithm (GHA) (Hasler and Akers, 1992) and Independent Component Analysis (ICA) (q.v.), require additional matrix-vector multiplications, but can be developed into a mesh architecture. Algorithms requiring matrix-matrix multiplications are difficult in standard IC technologies.

For multilayer algorithms, the architecture gets more complicated, particularly for supervised algorithms such as multilayer backpropagation. To extend the basic silicon synapse to a backpropagating synapse, we need an additional function: we need an output current that is the product of the fed-back error signal (drain voltage) and stored weight. We show this architecture in Figure 4*A*. This additional function results in two issues, one concerning the signal-to-noise ratio of the resulting error signal and the other concerning the overall synapse size. The effect of these small error signals, even without the resolution issues, is a slow learning rate.

The neural network literature is replete with possible alternative approaches, but we will base our proposed research on the Helmholtz machine concept (see Helmholtz Machines and Sleep-Wake Learning). Our primary reason for using this approach rests on our desire to use single-layer networks as primitives for building larger networks, as well as the fact that this reciprocal adaptive single-layer network architecture is seen in various models of sensory neurosystems, such as the pathways from retina to LGN to V1 or some of the pathways between the cochlea and auditory cortex (A1). Figure 4*B* considers a two-layer network implementation of a backpropagation-like learning rule using this Helmholtz block. In this case, we double the number of layers, and therefore double the effective synapse size; for a backpropagation algorithm, we require the same number of floating-gate multipliers, but with significant additional implementation costs that greatly increase the synapse complexity. This approach seems more IC-friendly for the development of adaptive multilayer algorithms than backpropagation approaches, although its digital implementation is nominally equivalent to backpropagation approaches. This approach directly expands to multiple layers and could be used in limited reconfigurable networks because we are building networks with single adaptive layers. Starting with the single-layer network as the basic building block simplifies the abstraction toward system development.

## *Resulting Synapse Design Criteria*

Because the synapse is the critical element of any neural network implementation, we state five properties of a silicon synapse that are essential for building large-scale adaptive analog VLSI synaptic arrays (Hasler et al., 1995):

1. The synapse must store a weight permanently in the absence of learning.
2. The synapse must compute an output current as the product of its input signal and its synaptic weight.
3. The synapse must modify its weight at least using outer-product learning rules.
4. The synapse must consume minimal silicon area, thereby maximizing the number of synapses in a given area.
5. The synapse must dissipate a minimal amount of power; therefore, the synaptic array is not power constrained.

Achieving all five requirements requires a detailed discussion of the circuits used to implement a synapse, which is the subject of the next section.

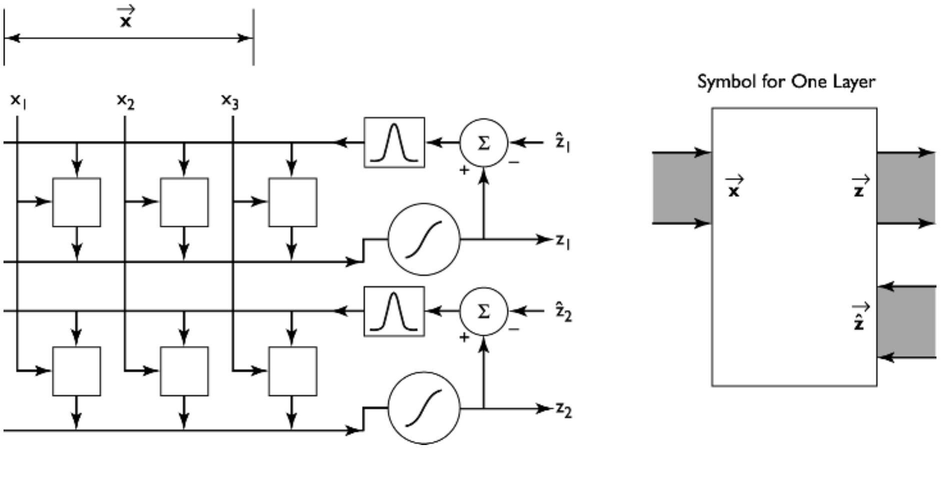

**Figure 3.** Learning in a single layer. We can build either supervised algorithms (LMS is explicitly shown) or unsupervised one-layer networks in this architecture. For a one-layer supervised case, $\hat{\mathbf{z}}$ is the desired or target output signal vector, where $e_j = z_j - \hat{z}_j$. Further, one might apply a nonlinear function to the resulting error signal; in LMS, one applies a nonlinear function to counteract the effect of the sigmoid in the feedforward path. Many unsupervised rules, like Hebbian or Oja rules, can be formulated as $\hat{\mathbf{z}} = \mathbf{f}(\mathbf{z})$. One can schematically represent this network from its terminals, **x**, **z**, and $\hat{\mathbf{z}}$, as shown from its block diagram. Finally, the nonlinear (sigmoid) elements typically convert current to voltage.

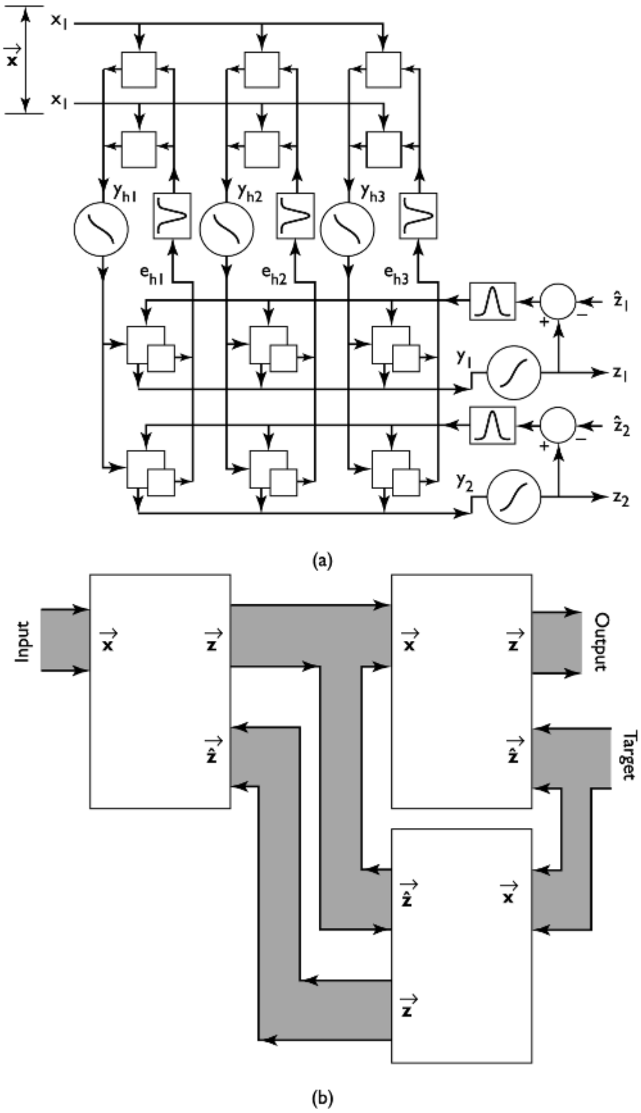

**Figure 4.** Possible architectures for adaptive multilayer neural networks. *A*, Implementation for backpropagation networks. There are many forms and modifications, but from an implementation viewpoint, these approaches can be modified toward this architecture. This approach significantly increases synapse size, because one typically requires the complexity of two synapses for weight feedback. Further, this approach limits some circuit approaches to building dense synapses. The output from the hidden layer, or layer 1, is $\mathbf{y}_h$ and the error signal given to the hidden layer is $\mathbf{e}_h$. The synapses in the second layer must also output a current proportional to the product of error * stored weight; the sum of these currents along a column is the error for the next layer. As a result, the synapses on the second layer must be more complex. *B*, Implementation using Helmholtz machine concepts. This approach requires twice as many synapses for all but the first layer, which yields the same complexity as the backpropagation approaches. This approach will converge to the same steady states and requires only a modular tiling of single-layer networks; its reciprocal feedback has a similar feel to communication between layers of cortical neurons.

## Neural Network Implementation: Synapse Circuits

### *Early Research in Synapse Design*

Several neural networks have been built in analog silicon hardware. Several good recent implementation techniques can be found in Cauwenberghs and Bayoumi (1999); here we present an overview. From the architecture discussions, we require a synapse block where an input voltage should modulate an output current, which is summed along a line; therefore, most implementations employ a variable resistance or transconductance element. As a result, a primary issue in synapse circuit designs is developing dense multiplier circuits, because multiplication of an input by a weight is fundamental to every synapse. Earlier approaches for implementating the feedforward synapse computation included fixed resistances (which were among the earliest implementations), switched-capacitor implementations (Tsividis and Satyanarayana, 1987), Gilbert multiplier cells (Mead, 1989), and linearized conductance elements (Dupuie and Ismail, 1990; Cauwenberghs, Neugebaur, and Yariv, 1991; Hasler and Akers, 1992). Intel's ETANN chip was the first commercially available neural network IC that used floating gates for weight storage (Holler et al., 1989). One of the most successful implementations of a large-scale adaptive neural system was the Heuralt-Juetten algorithm, but it required a great deal of circuit complexity (Cohen and Andreou, 1992). Other researchers have implemented unsupervised learning and backpropagation algorithms, with mixed success (Furman, White, and Abidi, 1988; Hasler and Akers, 1992). Successful analog implementations of connectionist networks have included algorithmic modifications that facilitate implementation in silicon. The history of this field has shown that the success of an implementation is strongly correlated with the degree to which the algorithm is adapted to the silicon medium.

Synapses in previous silicon implementations have required large circuit complexity because they have typically been constructed using traditional circuit building blocks to realize memory, computation, and adaptation functions separately, rather than taking advantage of device physics to combine these functions in a compact circuit element. Not only does large circuit complexity consume tremendous circuit area and power, but the chance of a network operating correctly decreases exponentially with cell size.

The most difficult problem to overcome when building efficient adaptive circuits is the effect of p-n junction leakage currents (Hasler et al., 1995; Hasler and Minch, 2002). First, since many implementations dynamically store their weight parameters on a capacitor, these junction leakage currents typically limit the hold time, on the order of seconds; therefore, weight storage often becomes a critical concern in many of these applications. Several on-chip refreshing schemes have been proposed and built (Hasler and Akers, 1992) and are currently finding applications in various ICs (Cauwenberghs and Bayoumi, 1999). Second, since real-time learning often requires time constants from 10 ms to days, junction leakage currents limit the use of capacitor storage techniques, unless prohibitively large capacitor areas are used. Weight update schemes based on weight perturbation methods, i.e., where the error signal is based on random known changes in the weights, can often work in these constraints if some form of dynamic refreshing scheme is used (Cauwenberghs and Bayoumi, 1999). Often, junction leakage is too large for many adaptive system problems.

### *Single-Transistor Learning Synapses*

Current research into analog neural network ICs pursues two directions. The first direction is based on refreshable DRAM elements with adaptation using weight perturbation techniques (Cauwenberghs and Bayoumi, 1999). The second direction is based on a wide range of techniques using floating-gate synapses. Floating gates have seen use in neural networks as storage elements (Holler et al., 1989), which eliminates the long-term weight storage issues but still results in fairly complex synapse circuits. Here, we briefly describe the potential of using floating-gate synapses.

The single-transistor learning synapse (STLS), or transistor synapse, makes use of device physics and constraints inherent to the

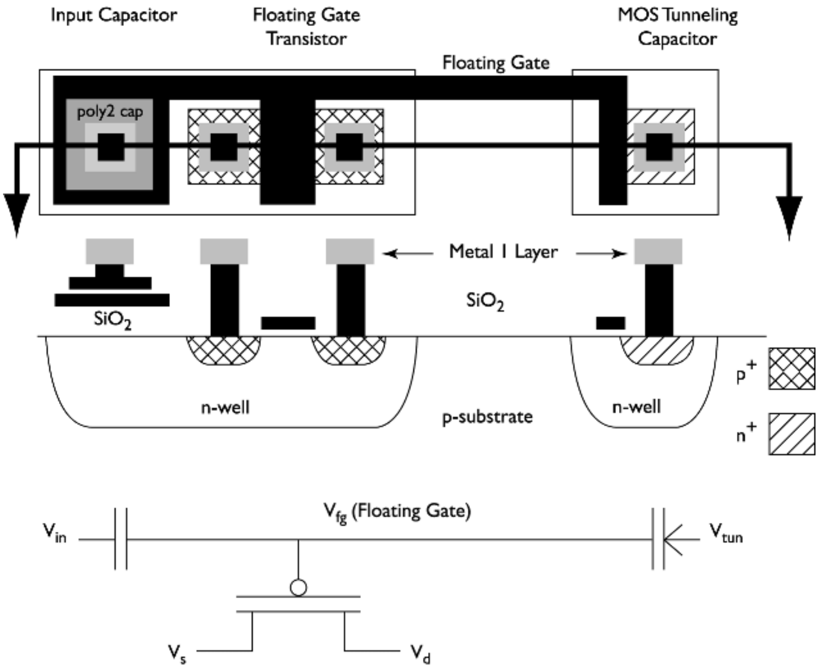

**Figure 5.** Layout, cross-section, and circuit diagram of the floating-gate pFET in a standard double-poly *n*-well MOSIS process. The cross-section corresponds to the horizonatal line slicing through the layout view. The pFET transistor is the standard pFET transistor in the *n*-well process. The gate input capacitively couples to the floating gate by either a poly-poly capacitor, a diffused linear capacitor, or a MOS capacitor, as seen in the circuit diagram (not explicitly shown in the other figures). We add floating-gate charge by electron tunneling, and we remove floating-gate charge by hot-electron injection. The tunneling junctions used by the single-transistor synapses is a region of gate oxide between the polysilicon floating gate and *n*-well (a MOS capacitor). Between $V_{tun}$ and the floating gate is our symbol for a tunneling junction, a capacitor with an added arrow designating the charge flow.

silicon medium to realize learning and adaptation functions, rather than direct implementation of learning rules using traditional circuit building blocks (Hasler et al., 1995). This technology is rooted in floating-gate circuits (Hasler and Lande, 2001; Hasler and Minch, 2002) in which multiple features of a floating-gate transistor are used, not just the nonvolatile storage (Figure 5). These elements utilize physical characteristics of the silicon medium, such as electron tunneling and hot-electron injection, which traditionally have posed problems for engineers. The starting point for this technology is a floating-gate transistor (Hasler et al., 1995; Kucic et al., 2001) operating with subthreshold currents and configured to simultaneously store permanently the weight charge, compute an output current that is the product of the input signal and the synaptic weight, and modify its weight charge based on many outer-product learning rules. This approach meets all five requirements for a silicon synapse. These weights can be automatically programmed, which enables setting fixed weights, setting initial bias conditions, and employing weight perturbation learning rules (Kucic et al., 2001). Further, by setting the appropriate boundary circuits for the synapse array, we can get a wide range of learning rules by continuously enabling our *programming mechanisms* during computation (Kucic et al., 2001). One form of the learning rules looks like

$$\tau \frac{dw_{i,j}}{dt} = \eta E[x_i e_j] - w_{i,j} \tag{4}$$

where $\tau$ is the adaptation time constant and $\eta$ is the strength of the correlating term.

# Analogy-Based Reasoning and Metaphor

*Dedre Gentner and Arthur B. Markman*

## Introduction

Analogy and metaphor have been characterized as comparison processes that permit one domain to be seen in terms of another. They are important to connectionism for two reasons. First, there is an affinity at the descriptive level: many of the advantages suggested for connectionist models—representation completion, similarity-based generalization, graceful degradation, and learning—also apply to analogy (Barnden, 1994). Second, analogical processing poses significant challenges for connectionist models. Analogy involves the comparison of *systems of relations* between items in a domain. To model analogy requires representations that include internal relations. Many connectionist models have concentrated instead on statistical learning of correlational patterns over featural or dimensional representations.

## Tenets of Analogy and Metaphor

Analogy derives from the perception of relational commonalities between domains that are dissimilar on the surface. These correspondences often suggest new inferences about the target domain. Analogy has been widely studied in humans. In the past decade, psychological research on analogy has converged on a set of benchmark phenomena against which models of analogy can be measured. These eight benchmarks, shown in Table 1, can be organized according to four processing principles. Analogy and metaphor involve (1) structured pattern matching; (2) structured pattern completion, (3) a focus on common relational structure rather than on common object descriptions, and (4) flexibility in that (a) the same domain may yield different interpretations in different comparisons, and (b) a single comparison may yield multiple distinct interpretations. Any model of analogy must account for these phenomena.

We begin by reviewing the principles and benchmarks, and then discuss current connectionist models of analogy and metaphor. Our discussion takes place at Marr's *computational and algorithmic levels*, at which cognition is explained in terms of representations and associated processes. We will not evaluate the models in terms of brain function, partly because the neural basis is not yet understood, but also because we believe a computational model must first justify itself as a cognitive account. We will focus mainly on analogy, which has been well studied at the processing level. Much of what we know about analogy can be applied to metaphor as well. Later, we will explore ways in which analogy and metaphor may differ.

**Table 1.** Eight Benchmark Phenomena of Analogy

| | |
|---|---|
| 1. Relational Similarity | Analogies involve relational commonalities; object commonalities are optional. |
| 2. Structured Pattern Matching | Analogical mapping involves one-to-one correspondence and parallel connectivity. |
| 3. Systematicity | In interpreting analogy, connected systems of relations are preferred over sets of isolated relations. |
| 4. Candidate Inferences | Analogical inferences are generated via structural completion. |
| 5. Alignable Differences | Differences that are connected to the commonalities of a pair are rendered more salient by a comparison. |
| 6. Flexibility (1): Interactive Interpretation | Analogy interpretation depends on both terms. The same term yields different interpretations in different comparisons. |
| 7. Flexibility (2): Multiple Interpretation | Analogy allows multiple interpretations of a single comparison. |
| 8. Cross-mapping | People typically perceive both interpretations of a cross-mapping and prefer the relational interpretation. |

## Structured Pattern Matching

The defining characteristic of analogy and many metaphors is the alignment of relational structure. Alignment involves finding *structurally consistent matches* (those observing parallel connectivity and one-to-one correspondence). *Parallel connectivity* requires that matching relations have matching arguments; *one-to-one correspondence* limits any element in one representation to at most one matching element in the other representation (Gentner and Markman, 1997; Holyoak and Thagard, 1995). For example, in the analogy "The atom is like the solar system," the nucleus in the atom (the *target*) corresponds to the sun in the solar system (the *base*) and the electrons to the planets, because they play similar roles in a common relational structure: e.g., **revolve** (sun, planets) and **revolve** (nucleus, electron). The sun is not matched to both the nucleus and the electron, as that violates one-to-one correspondence. Another characteristic of analogy is *relational focus*: objects correspond by virtue of playing like roles and need not be similar (e.g., the nucleus need not be hot).

There is considerable evidence that people can align two situations, preserving connected systems of commonalities and making the appropriate lower-order substitutions. For example, Clement and Gentner (1991) showed people analogous stories and asked them to state which of two assertions shared by base and target was most important to the match. Subjects chose the assertion connected to matching causal antecedents. More generally, people's correspondences are based both on the goodness of the local match and on its connection to a larger matching system (Markman and Gentner, 1993). This finding demonstrates the systematicity principle: Analogies seek *connected systems of matching relations* rather than isolated relational matches.

When making comparisons, it often occurs that nonidentical items are matched by virtue of playing a common role in the matching system. These corresponding but nonidentical elements give rise to *alignable differences*, and have been shown to be salient outputs of the comparison process (Gentner and Markman, 1997). In contrast, aspects of one situation that have no correspondence in the other, called *nonalignable differences*, are not salient outputs of comparison. For example, when comparing the atom to the solar system, the fact that atoms have electrons and solar systems have planets is an alignable difference. The fact that solar systems have asteroids, while atoms have nothing that corresponds to asteroids, is a nonalignable difference.

## Structured Pattern Completion

Analogical reasoning also involves the mapping of inferences from one domain to another. Thus, a partial representation of the target is completed based on its structural similarity to the base. For example, Clement and Gentner (1991) extended the findings described earlier by deleting some key matching facts from the target story and asking subjects to make a new prediction about the target based on the analogy with the base story. Consistent with the previous result, subjects mapped just those predicates that were causally connected to other matching predicates.

## Flexibility: Interactive Interpretation

Analogy and metaphor are flexible in important ways. Indeed, Barnden (1994) suggests that analogy and metaphor may reconcile connectionism's flexibility with symbolic AI's structure-sensitivity. One way that analogy and metaphor are flexible is that the interpretations are interactions between the two terms. The same item can take part in many comparisons, with different aspects of the representation participating in each comparison.

For example, Spellman and Holyoak (1992) compared politicians' analogies for the Gulf War. Some likened it to World War II, implying that the United States was acting to stop a tyrant, whereas others likened it to Vietnam, implying that the United States had embroiled itself in a potentially endless conflict between two other opponents. Comparisons with different bases highlighted different features of the target. Flexibility is also evident when the same base term is combined with different targets. For example, the metaphor "A lake is a mirror" highlights that a lake has a flat reflective surface, whereas "Meditation is a mirror" highlights the self-examination aspect of meditation.

## Flexibility: Multiple Interpretations of the Same Comparison

A more striking kind of flexibility is that a single base-target comparison can give rise to multiple distinct interpretations. For a comparison like "Cameras are like tape recorders," people can readily provide an object-level interpretation ("Both are small mechanical devices") or a relational interpretation ("Both record events for later display"). Interestingly, children tend to prefer the former and adults the latter.

Despite this flexibility, people generally maintain structural consistency within an interpretation. In one study, Spellman and Holyoak (1992) asked subjects to map the Gulf War onto World War II (WWII). They asked "If Saddam Hussein corresponds to Hitler, who does George Bush correspond to?" Some subjects chose Franklin Delano Roosevelt, whereas others chose Winston Churchill. The key finding was that, when asked to make a further mapping for the United States in 1991, subjects chose structurally consistent correspondences. Those who mapped Bush to Roosevelt usually mapped the US-1991 to the US-during-WWII, and those who mapped Bush to Churchill mapped the US-1991 to Britain-during-WWII.

An extreme case of conflicting interpretations is *cross-mapping*, in which the object similarities suggest different correspondences than do the relational similarities. For example, in the comparison between "Spot bit Fido" and "Fido bit Rover," Fido is cross-mapped. When presented with cross-mapped comparisons, people can compute both alignments. Research suggests that adding higher-order relational commonalities increases people's preference for the relational alignment, whereas increasing the richness of the local object match increases people's preference for the object match. For example, people are more likely to select the relational correspondence in Figure 1*B* than in Figure 1*A*. This example also illustrates that the analogical processes we describe can apply to perceptual as well as conceptual materials. The ability to compute relational interpretations (even for the cross-mappings) is central to human analogizing across a wide range of domains.

This flexibility and the ability to process cross-mappings have significant implications for the comparison process, because they

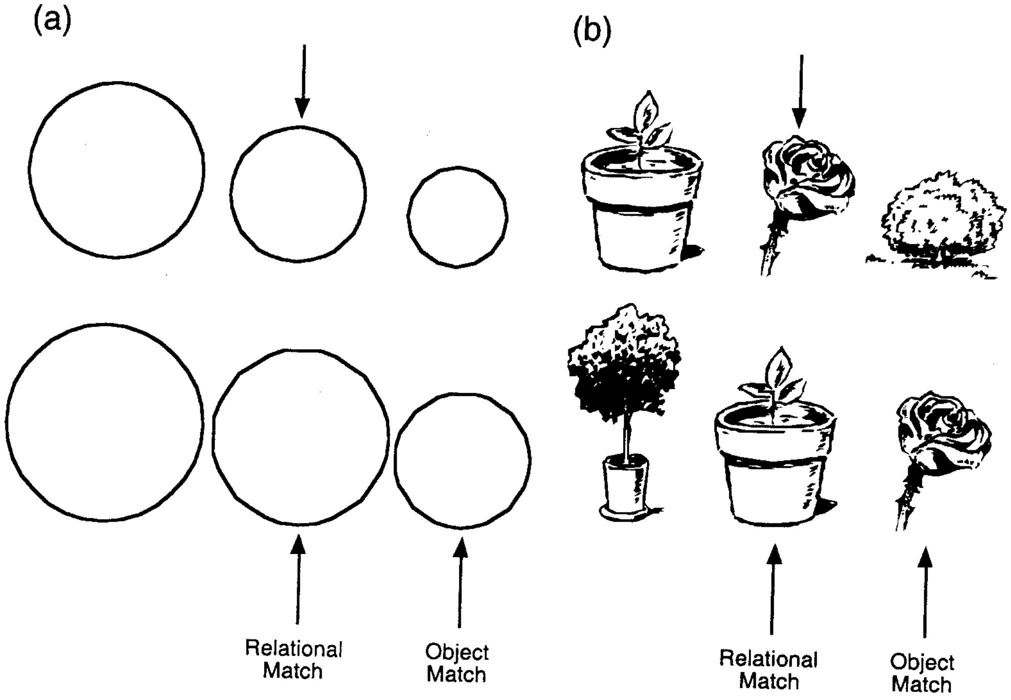

**Figure 1.** Sets of object triads containing a cross-mapping. A cross-mapping occurs when two similar objects play different roles in a matching relational system. In this case, the similar objects have different relative sizes. *(A)* shows a sparse pair of objects that are likely to have few distinguishing attributes, whereas *(B)* shows a rich pair of objects that are likely to have many distinguishing attributes.

mean that simulations cannot simply be trained to generate a particular kind of interpretation. Rather, the comparison process must be able to determine both object matches and structural matches and to attend selectively to one or the other.

## Connectionism and Analogical Mapping

As the preceding review makes clear, a central aspect of analogical reasoning and metaphor is alignment and mapping between structured representations. Symbolic models—e.g., Falkenhainer, Forbus, and Gentner's (1989) structure-mapping engine (SME)—have been able to pass the eight benchmarks in Table 1. Advances in connectionist models of analogy and metaphor have come with the development of techniques for representing structure (e.g., Hinton, 1991; Structured Connectionist Models). The best-developed models to date have been models of analogy rather than models of metaphor, and so we will focus on the analogy models here. We will discuss differences between analogy and metaphor in the following section.

An early connectionist model of analogy was ACME (Holyoak and Thagard, 1989). This model was a localist constraint-satisfaction network in which the nodes represented possible correspondences between elements in the base and target. Nodes were created using the constraint of semantic matching via a table that determined which predicates were seen as semantically similar. Nodes were connected in accordance with structural consistency, with nodes for consistent matches getting excitatory links and nodes for inconsistent matches getting inhibitory links. Finally, a pragmatic constraint was added by activating nodes related to goals and correspondences known in advance. After this activation was set up, the network was allowed to settle, and the most active nodes (above some threshold) determined the correspondences between base and target found by the system. The interpretation found by ACME need not maintain structural consistency, which can lead to problems in making inferences. Hummel, Burns, and Holyoak (1994) point out that the implementation of the pragmatic constraint often causes the important node(s) to map to everything in the other analog. Finally, because ACME settles on a single interpretation of an analogy, its solution to cross-mappings merges the object and relational interpretations.

A model of analogy has also been developed using *tensor product representations* (Smolensky, 1990). In a tensor product, two vectors **X** and **Y** are bound by taking the outer product of these vectors, $\mathbf{YX}^{\mathrm{T}}$. The outer product normally forms a matrix, but a vector can be constructed from this matrix by concatenating its columns. Given **X** and $\mathbf{YX}^{\mathrm{T}}$, the vector **Y** can be obtained as $\mathbf{YX}^{\mathrm{T}}\mathbf{X}$ if **X** is a unit vector. Variable bindings can thus be captured by using one vector to represent a predicate and the other to represent its argument.

Tensor products have been used in a distributed connectionist model—STAR—that performs a:b::c:d analogies (Halford et al., 1994). STAR represents binary relations (**R**(a, b)) using tensor products of rank 3 (which are like the binary tensor products just described except that three vectors are bound together). In this model, long-term memory consists of a matrix of tensor products corresponding to various relations the system knows about. To process an analogy, the model takes the a and b terms and probes long-term memory to find a relation between them. It then takes this relation and the c term of the analogy and finds a fourth term that shares that relation with the c term. This model uses a distributed connectionist representation to perform a one-relation analogical reasoning task. Thus, STAR performs analogy through retrieval of known relations. STAR cannot generate multiple distinct interpretations of a comparison. If the system knows many different items that could be the answer to the analogy, the output vector is a combination of them all. Finally, this model does not make use of higher-order relational structure to constrain its matches.

Perhaps the most complete connectionist model of analogy is Hummel and Holyoak's (1997) LISA, which operates over structured representations by using temporal synchrony in unit firing to encode relations. The connections between relations and their arguments are maintained by having individual units, which represent concepts, fire in phase with units that represent particular relational bindings (Structured Connectionist Models). For example, to represent **kiss** (John, Mary) nodes for kiss, John and *agent* fire in phase. Nodes for kiss, Mary and *patient* also fire in phase (but out of phase with those for John and *agent*). Furthermore, each node representing a concept is connected to a distributed representation designed to capture the meaning of that concept. The semantic similarity of any two concepts is just the dot product of the vectors in the distributed representations of those concepts. Finally, higher-order relations are represented in LISA by chunking relations that are arguments to higher-order relations into a single node.

Mapping takes place in LISA by selecting one domain (either the base or the target) as a driver. A role-argument binding is activated in the driver, and activation flows from the active nodes to the distributed semantic representation, and from the semantic nodes to localist concept nodes in the other domain. LISA has a limited-capacity working memory of 4–6 nodes. This working memory holds onto the correspondences from a small number of previous firings, thus allowing some influence of higher-order relational structure. If the role bindings for a higher-order relation are fired followed by the role bindings for the relational arguments of that higher order relation, then the correspondences suggested by the higher order relation can influence the mapping given to its argument. Trainable connections between nodes in the base and target are updated only after a certain number of firing cycles (depending on the size of working memory). LISA has been tested on a number of analogy problems. It tends to make relational mappings for analogies, and generally finds structurally consistent correspondences. The model selects either the relational mapping or the object mapping for a cross-mapping. On any given run, LISA arrives at only one interpretation; however if the order in which nodes in the driver are activated is varied, the system can find different interpretations on different runs. Finally, because the model can use complex representations, it can use different aspects of the representation of a domain in different comparisons involving that domain.

LISA is the only extant model of analogical mapping to include an explicit working memory constraint. At present, two major questions remain. First, the order in which statements are activated in the driver—a crucial determinant of the outcome of a match—is currently decided by the modeler. Second, the model has not been tested on large representations of the base and target. Thus, it is not clear how it will perform on these representations.

## How Metaphor Differs from Analogy

The previous section focused on connectionist models of analogy. There has been little work on connectionist models of metaphor. To some degree, models of analogy could be extended to metaphor. In this section, we discuss some differences between analogy and metaphor that are relevant for developing a connectionist model of metaphor.

Metaphors are nonliteral assertions of likeness. They may be phrased as comparisons, in *simile* form ("A cloud is like a sponge") or as class inclusions, in *metaphor* form ("A cloud is a sponge"). When a novel metaphor is being processed, the two domains in the metaphor are compared using the same process that is applied to analogy. Unlike analogy, however, metaphors need not focus exclusively on relations. For example, the example above could be interpreted as a cloud that is fluffy, which would focus on an attribute of sponges that clouds also possess. This metaphor can also be given a relational interpretation. For example, it might be interpreted to mean that both clouds and sponges soak up water and give it back later. Typically, adults (but not children) prefer relational interpretations of metaphors to attribute interpretations.

There are three key ways in which metaphors differ from analogies. First, whereas analogies tend to have explanatory-predictive functions, metaphors may have expressive purposes and may affect the mood of the piece in which they are embedded. Thus, the primary impact of a metaphor might come in the emotions that it brings out rather than on the information in the comparison that is promoted. Second, not all metaphors are necessarily processed as comparisons. Glucksberg and his colleagues (e.g., Glucksberg and Keysar, 1990) suggest that metaphors might be processed as class inclusion statements rather than as comparisons. While there is debate as to exactly when metaphors are processed as comparisons or as class inclusion statements, some evidence suggests that novel metaphors and similes (e.g., “Some cults are termites”) are processed by alignment and mapping, whereas conventional metaphors (e.g., “Some people are sheep”) may be processed by accessing a stored metaphorical word sense. Finally, there are often systems of related metaphors in a language (Lakoff and Johnson, 1980). For example, English has a system of metaphors in which anger is described as heated fluid in a container (e.g., “Mary was boiling mad. The pressure built up in her until she finally exploded with rage.”). These metaphorical systems might reflect a large-scale mapping between a base and target domain.

One model of system metaphors has been developed by Narayanan (1999). This model uses a localist connectionist system to handle extended metaphors such as the anger as heated fluid example above. In this system, the connection between a base and target domain is assumed to be established by convention, so there is no mapping mechanism for constructing new correspondences. Instead, the model focuses on how understanding a physical base domain can aid the comprehension of an abstract target. The model has a detailed localist network representation of the base domain in which actions can be simulated as transitions through the network. After simulating a possible outcome in the physical domain, the established mapping to the target domain is used by passing activation from the base to corresponding nodes in a belief network representing the target. In this way, metaphorical inferences can be drawn from base to target. These inferences are confined to existing correspondences between the domains; there is no mechanism for establishing new correspondences. A variety of constraints on metaphor interpretation such as the intent of the speaker can be incorporated into the model by treating them as additional sources of activation.

It may be possible to extend connectionist models of analogy to metaphor. Connectionist models may be well suited to capturing emotional aspects of metaphor. Associations between emotions and words (and word sounds) are unlikely to be mediated by strictly symbolic and rule-based processes. Thus, the kinds of soft constraints that are easily implemented in connectionist models might be particularly well suited to understanding this aspect of metaphor comprehension.

## Discussion

Analogical and metaphor processing rely heavily on structurally governed correspondences between the two domains. This leads to the eight benchmarks summarized in Table 1 that pose a challenge for any model of analogy. Connectionist models that address these phenomena have focused on techniques for representing and processing structured representations. LISA, which uses structured representations and structure-sensitive processing, accounts for many of the phenomena in Table 1, although some additional specification and testing of the model is still required.

Some challenges for future research include (1) building analogical models that can preserve structural relations over incrementally extended analogies such as are used in reasoning, (2) developing models that can be used as components of a broader cognitive system such as one that would perform problem solving, and (3) developing models that can handle novel and conventional metaphors.

# Arm and Hand Movement Control

*Stefan Schaal*

## Introduction

The control of arm and hand movements in human and nonhuman primates has fascinated researchers in psychology, neuroscience, robotics, and numerous related areas. To the uninitiated observer, movement appears effortless. It is only when trying to duplicate such skills with artificial systems or when examining the underlying neural substrate that one discovers a surprising complexity that, so far, has prevented us from understanding the biological implementation, how to repair neural damage, and how to create human-like robots with a human level of movement skills.

Research directed toward understanding motor control can be approached on different levels of abstraction. For example, such research may entail examining the biochemical mechanisms of neuronal firing, the representational power of single neurons and populations of neurons, neuroanatomical pathways, the biomechanics of the musculoskeletal system, the computational principles of biological feedback control and learning, or the interaction of perception and action. No matter which level of inquiry is chosen, however, ultimately we need to solve the "reverse engineering" problem of how the properties of each level correlate with the characteristics of skillful behavior. Motor control of the arm and hand is an excellent example of the difficulties that arise in the reverse engineering problem. Behavioral research has discovered a variety of regularities in this movement domain, but it is hard to determine on which level they arise. Moreover, most of these regularities were examined in isolated arm or hand movement studies, whereas coordination of the arm and hand is a coupled process in which hand and arm movement influence each other. In this article, we discuss some of the most prominent regularities of arm and hand control and consider where these regularities come from, with a particular focus on computational and neural network models. It will become apparent that an interesting competition exists among explanations sought on the neural, biomechanical, perceptual, or computational level. These competing explanations have created a large amount of controversy in the research community over the years.

## Behavioral Phenomena of Arm and Hand Control

Most movement skills can be achieved in an infinite number of ways. For instance, during reaching for an object, an arbitrary hand path can be taken between starting point and end point, and the path can be traversed at arbitrary speed profiles. Moreover, because of the excess of the number of degrees of freedom in primate movement systems, there is an infinite number of ways for realizing a chosen hand path through postural configurations (see Robot Arm Control). On the biomechanical level there is even more redundancy, because there are many more muscles than degrees of freedom in the human body, and the redundancy increases on the neuronal level. Thus, it is extremely unlikely that two different individuals would use similar movement strategies to accomplish the same movement goal. Surprisingly, however, behavioral research did find a large number of regularities, not just across individuals of a given species but also across different species (see, e.g., Flash and Sejnowski, 2001). These regularities or invariants have become central to understanding perceptuomotor control, as they seem to indicate some fundamental organizational principles in the central nervous system (CNS).

### *Bell-Shaped Velocity Profiles and Curvature in Reaching Movements*

About 20 years ago, Morasso (see Optimization Principles in Motor Control) discovered that in point-to-point reaching movements in humans, the hand path in Cartesian (external) space was approximately straight and the tangential velocity trajectory along the path could be characterized by a symmetric bell shape, a result that was duplicated in monkeys. In contrast, velocity profiles in joint space and muscle space were much more complex. These findings gave rise to the hypothesis that point-to-point reaching movements are planned in external coordinates and not in internal ones. Later, more detailed examinations of reaching movements revealed that, although *approximately* straight, reaching movement showed a characteristic amount of curvature as a function of where in the workspace the starting point and end point of the movement were chosen. Also, the symmetry of the velocity profile varies systematically as a function of movement speed (e.g., Bullock and Grossberg, 1988). These behavioral phenomena gave rise to a variety of models to explain them.

Initial computational models of reaching focused on accounting for the bell-shaped velocity profile of hand movement, employing principles of optimal control based on a kinematic optimization criterion for movement planning that favors smooth acceleration profiles of the hand (see Optimization Principles in Motor Control). As this theory would produce perfectly straight-line movements in Cartesian space and perfectly symmetric bell-shaped velocity profiles, the observed violation of these features in behavioral expression was explained by assuming that these movement plans were executed imperfectly by an equilibrium point controller (see Equilibrium Point Hypothesis). Thus, the behavioral features of point-to-point movements were attributed to perfect motor planning and imperfect motor execution.

An alternative viewpoint was suggested by Kawato and coworkers (see Optimization Principles in Motor Control and Equilibrium Point Hypothesis). Their line of research emphasizes that the CNS takes the dynamical properties of the musculoskeletal system into account and plans trajectories that minimize "wear and tear" in the actuators, expressed as a minimum torque-change or minimum motor-command-change optimization criterion. According to this overall view, the behavioral features of arm and hand control are an intentional outcome of an underlying computational principle that employs models of the entire movement system and its environment.

Recently, Harris and Wolpert (see Optimization Principles in Motor Control) suggested that the features of arm and hand movement could also be due to the noise characteristics of neural firing, i.e., the decreasing signal-to-noise ratio of motor neurons with increasing firing frequency. Thus, the neuronal level together with the behavioral goal of accurate reaching was held responsible for behavioral characteristics.

Several other suggestions were made to account for features of arm and hand control. Perceptual distortion could potentially contribute to the curvature features in reaching, and dynamical properties of feedback loops in motor planning could generate asymmetries of bell-shaped velocity profiles (Bullock and Grossberg, 1988). Moreover, imperfection of motor learning (see Sensorimotor Learning) and delays in the control system could equally play into explaining behavior.

### *Movement Segmentation*

For efficient motor learning, it seems mandatory that movement systems plan on a higher level of abstraction than individual motor commands, as otherwise the search space for exploration during learning would become too large to find appropriate actions for a new movement task (see Robot Learning). Movement primitives (see Motor Primitives), also called units of action, basis behaviors, or gestures (see Speech Production), could offer such an abstraction. Pattern generators in invertebrates and vertebrates (see Motor Pattern Generation) and the few different behavioral modes of oculomotor control (e.g., VOR, OKR, smooth pursuit, saccades, vergence) can be seen as examples of such movement primitives. For arm and hand control, however, whether some form of units of actions exist is a topic of ongoing research (Sternad and Schaal, 1999). Finding behavioral evidence for movement segmentation could thus provide some insight into the existence of movement primitives.

Since the 1980s, kinematic features of hand trajectories have been used as one major indicator to investigate movement segmentation. From the number of modes of the tangential velocity profile of the hand in linear and curvilinear drawing movements, it was concluded that arm movements may generally be created based on discrete strokes between start points, via points, and end points, and that these strokes are piecewise planar in three-dimensional movement (for a review, see Sternad and Schaal, 1999). From these and subsequent studies, stroke-based movement generation and piecewise planarity of the hand movement in Cartesian space became one of the main hypotheses for movement segmentation (Flash and Sejnowski, 2001).

Recent work (Sternad and Schaal, 1999), however, reinterpreted these indicators of movement segmentation partially as an artifact, in particular for rhythmic movement, that, surprisingly, was also assumed to be segmented into planar stokes. Human and robot experiments demonstrated that features of apparent movement segmentation could also arise from principles of trajectory formation that use oscillatory movement primitives in joint space. When such oscillations are transformed by the nonlinear direct kinematics of an arm (see Robot Arm Control) into hand movement, complex kinematic features of hand trajectories can arise that are not due to movement segmentation. Sternad and Schaal (1999) therefore suggested that movement primitives may be better sought in terms of dynamic systems theory, looking for dynamical regimes like point and limit cycle attractors and using perturbation experiments to find principles of segmenting movements into these basic regimes.

## *The 2/3 Power Law*

Another related behavioral feature of primate hand movements trajectories, the 2/3 power law, was discovered by Lacquaniti et al. (in Flash and Sejnowski, 2001). In rhythmic drawing movements, the authors noted a power law relationship with proportionality constant $k$ between the angular velocity $a(t)$ of the hand and the curvature of the trajectory path $c(t)$:

$$a(t) = kc(t)^{2/3} \tag{1}$$

There is no physical necessity for movement systems to satisfy this relation between kinematic (i.e., velocity) and geometric (i.e., curvature) properties of hand movements. Since the power law has been reproduced in numerous behavioral experiments (Viviani and Flash, 1995, in Flash and Sejnowski, 2001) and even in population code activity in motor cortices (Schwartz and Moran, 1999, in Flash and Sejnowski, 2001), it may reflect an important principle of movement generation in the CNS.

The origins of the power law, however, remain controversial. Schaal and Sternad (2001) reported strong violations of the power law in large-scale drawing patterns and, in accordance with other studies, interpreted it as an epiphenomenon of smooth movement generation (Flash and Sejnowski, 2001). Nevertheless, the power law remains an interesting descriptive feature of regularities of human motor control and has proved to be useful even in modeling the perception of movement (see Motor Theories of Perception).

## *The Speed-Accuracy Trade-off*

In rapid reaching for a target, the movement time $MT$ of reaching the target was empirically found to depend on the distance $A$ of the start point of movement from the target and the target width $W$—equivalent to the required accuracy of reaching—in a logarithmic relationship: $MT = a + b \log2(2A/W)$, where $a$ and $b$ are proportionality constants in this so-called Fitts' law or speed-accuracy trade-off. Since Fitts' law is a robust phenomenon of human arm and hand movement, many computational models used it as a way to verify their validity. Unfortunately, Fitts' law has been modeled in many different ways, including models from dynamic system theory, noise properties of neuronal firing, and computational constraints in movement planning (for a review, see Mottet and Bootsma, 2001; Bullock and Grossberg, 1988). Thus, it seems that the constraints provided by Fitts' law are too nonspecific to give clear hints as to the organization of the nervous system. Nevertheless, the empirical phenomenon of Fitts' law remains a behavioral landmark.

## *Resolution of Redundancy*

As mentioned earlier, during reaching for a target in external space, the excess number of degrees of freedom in the human body's kinematic structure usually allows an infinite number of postures for each hand position attained during the reaching trajectory. An active area of research in motor control is thus concerned with how redundancy is resolved, whether there is within- or across-subject consistency of the resolution of redundancy, and whether it is possible to deduce constraints on motor planning and execution from the resolution of redundancy.

Early studies by Cruse et al. (in Bullock, Grossberg, and Guenther, 1993) demonstrated that redundancy resolution was well described by a multiterm optimization criterion that primarily tries to keep joint angular position as far as possible away from the extreme positions of each joint and also minimizes some physiological cost. According to this explanation, when a reaching movement is initiated in a rather unnatural posture, the movement slowly converges to the optimal posture on the way to the goal, rather than achieving optimality immediately. This strategy resembles the method of resolved motion rate control in control theory, suggested as a neural network model of human motor planning by Bullock et al. (1993). Grea, Desmurget, and Prablanc (2000) observed similar behavior in reaching and grasping movements. Noting that the final posture at a grasp target was highly repeatable even if the target changed its position and orientation during the course of the reaching movement, the authors concluded that the CNS plans the final *joint space* position for reaching and grasping, not just the final hand position. However, the optimization methods proposed by Bullock et al. (1993) could result in similar behavior, without the CNS explicitly planning the final joint space posture. An elegant alternative view to optimization methods is suggested in Geometrical Principles in Motor Control (q.v.), where motor control and planning based on force fields is emphasized. It is evident more work will be needed before a final conclusion can be reached on the issue of redundancy resolution.

## *Reaching and Grasping*

The coordination of reaching and grasping offers at least three important windows onto motor control. First, reaching and grasping require a resolution of redundancy, as outlined in the previous section. However, small changes in target orientation can lead to the need for drastic changes in arm and hand posture at the target, such that movement planning requires carefully chosen strategies for successful control. Second, reaching and grasping are two separate motor behaviors that may or not be executed independently of each other. This issue allows researchers to examine the superposition and sequencing of movement primitives. Third, grasping has a more interesting perceptual component than reaching, since appropriate grasp points, grasping strategies, and grasping forces need to be selected as a function of target shape, size, and weight. The principles of perceptuomotor coordination can thus be examined in well-controlled experiments, including the grasping of objects that induce visual illusions.

Among the key features of reaching and grasping are the following: (1) a fast initial arm movement to bring the hand close to the target, (2) a slow approach movement when the hand is near the target, and (3) a preshaping phase of the hand with initial progressive opening of the grip, followed by closure of the grip until the object size is matched and the object is finally grasped (Jeannerod et al., 1995; Arbib and Hoff, 1993, in Jeannerod et al., 1995). Although early models of reaching and grasping assumed independence of these different phases and simply executed them in a programmatic way, behavioral perturbation studies that changed the target size, orientation, or distance revealed a coupling between the phases (for a review, see Jeannerod et al., 1995), such that, e.g., the preshaping partially reversed when the target distance was suddenly increased. Using optimization principles, Hoff and Arbib (in Jeannerod et al., 1995) developed a model of these interactions by structuring the reach-and-grasp system in appropriate perceptual and motor schemas (see SCHEMA THEORY), including abstraction of the multifingered hand in terms of two or more virtual fingers to simultaneously model different grip types (e.g., precision grip, power grip) and their opposition spaces for contact selection. This model can also be mapped onto the known functional cortical anatomy in primates. Grip force selection and the anticipation of object properties has been studied by a number of authors (e.g., Flanagan and Beltzner, 2000), who generally agree that the CNS seems to use internal models to adjust grip force. From studies of the resolution of redundancy, it was concluded that the entire arm posture at the target seems to be planned in advance (Grea et al., 2000), but this result may need differentiation as outlined in the previous section. In general, there seems to be a consensus that behavioral features of reaching and grasping are carefully planned by the CNS and are not accidental.

## *Motor Learning*

Because of continuous change in body size and biomechanical properties throughout development, the ability to learn motor control is of fundamental importance in biological movement systems. Moreover, when it comes to arm and hand control, primates show an unusual flexibility in devising new motor skills to solve novel tasks. Learning must therefore play a pivotal role in computational models of motor control.

One of the most visible research impacts of motor learning was the controversy between equilibrium point control (see EQUILIBRIUM POINT HYPOTHESIS) and internal model control (see SENSORIMOTOR LEARNING and CEREBELLUM AND MOTOR CONTROL). Proponents of equilibrium point control believed that the learning of internal models is too complicated to be plausible for biological information processing, while proponents of internal model control accumulated evidence that various, in particular fast, movement behaviors cannot be accounted for by equilibrium point control. At present, there seems to be an increasing consensus that internal model control is a viable concept for biological motor learning, and that the equilibrium point control strategy in its original and appealing simplicity is not tenable. Behavioral learning experiments that were created in the wake of the equilibrium point control discussion sparked a new branch of research on motor learning (see SENSORIMOTOR LEARNING and GEOMETRICAL PRINCIPLES IN MOTOR CONTROL). Adaptation to virtual force fields, to altered perceptual environments, or to virtual objects are among the main behavioral paradigms to investigate motor learning, with the goal of better understanding the time course, representations, control circuits, retention, and functional anatomy of motor learning (see SENSORIMOTOR LEARNING).

## *Interlimb Coordination*

In robotics, the control of two limbs can be accomplished as if the two systems were completely independent, thus reducing the control problem to that of controlling two robots instead of one. In biological motor control, such independence does not exist, and a rich area of behavioral investigation examines the computational principles and constraints that arise from the coordination of multiple limbs. In arm and hand control, the approach of dynamic pattern formation (e.g., Kelso, 1995) has been a prominent methodology to account for interlimb coordination. In this approach, motor control in general and interlimb coordination in particular are viewed as an assembly of the required degrees of freedom of the motor system into a task-oriented attractor landscape (Saltzman and Kelso, 1987, in Kelso, 1995). Interlimb coordination is thus conceived of as the result of coupling terms in nonlinear differential equations. An important question thus arises as to what kind of equations model the control of movement, and what kind of variables cause the coupling. A variety of models of movement generation with nonlinear dynamics approaches were suggested, based on differential equations, that either generate movement plans (Kelso, 1995; Sternad, Dean, and Schaal, 2000) or directly generate forces. The origin of coupling between limbs, however, remains an issue of controversy. Possible sources could be perceptual, proprioceptive, purely planning-based, interaction force–based, a preference for homologous muscle activation, or neural crosstalk. By demonstrating that the orientation of limbs in external space can explain a certain class of interlimb coordination, recent behavioral results (Mechsner et al., 2001) emphasized that perceptual coupling may be much more dominant than previously suspected. In general, however, there seems to be a strong need for detailed computational modeling to elucidate the computational and neuronal principles of interlimb coordination.

## *Intralimb Coordination*

Investigations of intralimb coordination seek to uncover the specific principles by which individual segments of a limb move relative to one other. Models of arm and hand control that are based on optimal control (see OPTIMIZATION PRINCIPLES IN MOTOR CONTROL) or optimal resolution of redundancy automatically solve the intralimb coordination problem by means of their optimization framework; any kind of special behavioral features would be considered accidental. However, some research has considered whether some special rules of information processing by the CNS can be deduced from the regularities of intralimb coordination. For reaching movements, the simple mechanism of joint interpolation can account for a large set of behavioral features when the onset times of the movements in individual degrees of freedom are staggered, an older observation that has been confirmed in more recent work (Desmurget et al., 1995). For rhythmic movement, it is of interest to know how the oscillations in individual degrees of freedom remain phase-locked to each other, and whether there are preferred phase-locked modes (Schaal et al., 2000). As in interlimb coordination, models of nonlinear differential equations seem the most suitable for capturing the effects of rhythmic intralimb dynamics.

### *Perception-Action Coupling*

Most of the behavioral studies outlined in the previous sections were primarily concerned with specific aspects of *motor control* and less with issues of *perceptuomotor control*. However, the interaction of perception and action reveals many constraints on the nervous system. In the behavioral literature, there is a large body of research that examines particular perceptuomotor skills, such as the rhythmic coordination of arm movement during the juggling of objects or the interaction of external forces and limb dynamics to generate movement (e.g., Sternad, Duarte, et al., 2000). This interesting topic cannot be discussed in detail here.

## Discussion

Behavioral phenomena of arm and hand movement have sparked a rich variety of computational models on various levels of abstraction. Although some topics, such as internal model control, have gained solid ground in recent years (Flash and Sejnowski, 2001), many other issues remain controversial and deserve more detailed and computational investigations. Perhaps the most interesting topics for future research are the importance of the dynamic properties of the musculoskeletal system in facilitating motor control, the role of real-time perceptual modulation of motor control, and dynamic systems models versus optimal control-based models.

# Artificial Intelligence and Neural Networks

*John A. Barnden and Marcin Chady*

## Introduction

This article surveys the distinctions between symbolic artificial intelligence (AI) systems and neural networks (NNs), their relative advantages, and ways of attempting to bridge the gap between the two.

For this review we can take AI to consist of the development, analysis, and simulation of computationally detailed, efficient systems for performing complex tasks, where the tasks are broadly defined, involve considerable flexibility and variety, and are typically similar to aspects of human cognition or perception. These broad tasks include natural language understanding and generation; expert problem solving; common-sense reasoning; visual scene analysis; action planning; and learning.

There is nothing in this description of AI that prevents the computational systems from being neural networks. Nevertheless, it is fair to say that the bulk of AI can be called “traditional” or “symbolic” AI, relying on computation over symbolic structures (e.g., logic formulae). The rest of the review will therefore discuss relationships between symbolic AI and NNs.

## Relative Advantages

### *Advantages of Neural Networks*

One of the main benefits claimed for NNs is graceful degradation, especially when they are of the distributed variety (LOCALIZED VERSUS DISTRIBUTED REPRESENTATIONS). A computational system is said to exhibit graceful degradation when it can tolerate significant corruption of its input or internal workings. The toleration consists of the system’s continuing to perform usefully, though not necessarily perfectly. In NNs, input imperfection is typically a matter of corruption of individual input activation vectors. Internal corruption usually takes the form of deletions of nodes or links or corruptions of the link weights.

Symbolic AI systems, on the other hand, tend not to degrade gracefully. Consider a simple rule-based system. A small corruption of an input data structure is likely to make it fail to match the precise form expected by the rules that would otherwise have applied, so that they totally fail to be enabled. Equally, other rules might erroneously be enabled. Similarly, even minor damage to a rule can have very large effects on how the system operates.

As a special case of graceful degradation, NNs sometimes exhibit *error correction*, whereby an erroneous or corrupted pattern on an input bank of units leads to a corrected version of the pattern appearing in the network, enabling the network to proceed as if the correct version had been provided. Related to this type of error correction is *pattern completion*, whereby an incomplete pattern is filled out to become a more complete pattern somewhere in the network.

Also related to graceful degradation is *automatic similarity-based generalization*, in which previously unseen inputs that are sufficiently similar to training inputs lead naturally to behavior that is usefully similar to (or captures central tendencies in) the behavior elicited by the training inputs. There is a sense in which similarity of representations induces similarity of processing more readily than it does in symbolic AI: there is, by and large, a higher degree of naturally achievable continuity in the mapping from inputs to outputs. In addition, previously unseen blends of different representations will naturally tend to lead to processing that is a blend of the processing that would have arisen from the different representations that have been blended together. Such behavior is possible in symbolic AI but specific system-design effort is needed to achieve it.

Importantly, NNs can *learn* generalizations or category prototypes by exposure to instances, through fairly straightforward, uniform weight modification procedures. These generalizations or prototypes come to be implicit in the adjusted weights. Although learning is intensively studied in symbolic AI, and some learning paradigms in symbolic AI involve adjustment of numerical parameters akin to NN weights, symbolic processing does not provide any specific support to these paradigms. The paradigms could therefore be said to arise less easily and naturally out of symbolic processing than out of NN activity.

The preceding properties of NNs have found their application in *content-based access* (or *associative access*) to long-term memory (see Associative Networks). This can take two different forms. First, let us assume, as usual, that a neural net's long-term memory is its set of weights. The manipulation of an input vector by the network can be thought of as the bringing to bear of particular content-relevant long-term memories on that vector. Second, in any NN that learns a map from particular inputs to particular outputs, an output can be thought of as a particular long-term memory recalled directly on the basis of the content of the input. Content-based access is not as easily provided in symbolic systems implemented in conventional computers, although it can be obtained to some useful degree by sophisticated indexing schemes (see Bonissone et al. in Barnden and Holyoak, 1994), associative computer memories, or hashing (see Touretzky in Hinton, 1991, for discussion).

NNs can have *emergent rule-like behavior*. Such behavior can be described, approximately at least, as the result of following symbolic rules, even though the system does not contain representations of explicit rules (see Elman, 1991). Emergent rule-like behavior is a central issue in the application of neural networks to high-level cognitive tasks.

More generally, NNs tend to be more sensitive to *subtle contextual effects* than symbolic AI systems are, because multiple sources of information can more easily be brought to bear in a gracefully interacting and parallel way. This property of NNs facilitates *soft constraint satisfaction*. That is, it is possible to arrange for some hypotheses to compete and cooperate with each other, gradually influencing each other's levels of confidence until a stable set of hypotheses is found. Each hypothesis is represented by a node or group of nodes in the neural network, and the constraints are encoded by links joining those nodes or groups. The constraint-satisfaction is soft because no individual constraint needs to be satisfied absolutely. By contrast, although many symbolic AI systems are designed to do constraint satisfaction, the symbolic framework provides no special support for it, particularly when the constraints are soft.

Finally, NNs are an inherently parallel model of computation whose parallelism is straightforwardly realizable in a physical substrate.

### *Advantages of Symbolic AI Systems*

The symbolic framework is better than NNs at encoding and manipulating the *complex, dynamic structures* of information that appear to be needed in cognition. These structures can, for instance, be interpretations of natural language utterances, descriptions of complex scenes, complex plans of action, or conclusions drawn from other information. The encodings of such structures, whether these encodings are symbolic or otherwise, need to have the following important properties. (See also Shastri in Barnden and Pollack, 1991.)

1. The encodings must often be highly temporary—for instance, encodings of interpretations of natural language sentences and encodings of intermediate conclusions during reasoning need to be rapidly created, modified, and discarded. Although activation patterns in NNs are temporary, temporariness is challenging for NNs when it is combined with properties 2–6.
2. The encoding technique must allow the encoded structures to combine information items (e.g., word senses) that have never been combined before, or never been combined in quite the same way, in the experience of the system.
3. The encodings must allow the encoded information to have widely varying structural complexity. Natural language sentence interpretations provide illustrations of this point.
4. In particular, the encoded structures can be multiply nested. In the sentence "John believes that Peter's angry behavior toward Mary caused her to write him a strongly worded letter," the anger description is nested within a causation description that is nested within a belief report.
5. A given type of information can appear at different levels of nesting. A system might have to represent a sitting *room* that has a wall that bears a picture that itself depicts a dining *room*. As another illustration, a *belief* might be about a hope that is about a *belief*.
6. A given type of information may also have to be multiply instantiated in other ways, as when, for instance, there are three love relationships that need to be simultaneously represented.

Turning to manipulations, cognitive systems must exhibit strong properties of *systematicity* of processing—each information structure $J$ that one cares to mention has an extremely large class of variants that must be able to be subjected to the same sort of processing as $J$ is; and the class of variants is far too large to imagine that each variant is processed by a separate piece of neural network or a separate symbolic module. So, we must have symbolic AI systems and NNs capable of very flexible and general processing. (See also Systematicity of Generalizations in Connectionist Networks.)

The *variable-binding* problem for neural networks is one manifestation of the need for systematicity of processing. Suppose one wishes a neural network to make inferences that obey the following rule: $X$ is jealous of $Z$ whenever $X$ loves $Y$, $Y$ loves $Z$, and $X$, $Y$, and $Z$ are distinct people. In this statement of the rule, the variables $X$, $Y$, and $Z$ can be replaced by any suitable people-descriptions, such as "Joe Bloggs' father's boss." The systematicity issue in this example is that of avoiding having replication of machinery for all the different possible combinations of values for these variables. (Each such combination is a $J$ in the terms of the previous paragraph.) This issue can also be thought of as the variable binding problem for the example, even if a neural network dealing with it does not have any explicit representation of the rule or the variables in it. In the special case in which a neural network implements the rule as a subnetwork and has particular units, subnetworks, or activation patterns that play the role of the three variables, the variable binding problem, in a narrower sense now, is the problem of how the network is to be able to "bind" such a unit, subnetwork, or activation pattern to a particular value at any given moment, and how the binding is to be used in processing.

Cognitive systems must also exhibit a high degree of *structure-sensitivity* in their processing. Pieces of information that have complex structure must be processed in ways that are heavily dependent on their structure as such, not (just) on the nature of constituents taken individually. For example, consider the operation of inferring from "not both *A* and *B*" that "not *A* or not *B*." The operation is independent of what *A* and *B* are—it is only the "not both . . . and . . ." structure that is important.

These features of information structure encodings and manipulations combine to distinguish the types of information that neural networks for reasoning, natural language understanding, etc. must deal with from the types of information that typical neural networks cater for. Traditional NN techniques were originally developed largely for specific "low level" applications, such as restricted forms of pattern recognition, or for limited forms of pattern association. Because of the resulting continuing limitations in most applications of NNs, it has been sufficient for NNs to adhere, by and large, to the following restrictions (although almost every restriction is violated by some NN subparadigm). These restrictions cause difficulty in trying to apply NNs to natural language understanding, common-sense reasoning, and the like.

1. There is typically no dynamic, rapid creation and destruction of nodes and links. Therefore, temporary information cannot be encoded in temporary network topology changes. (Some of this effect can, however, be obtained by techniques such as dynamic links described in Dynamic Link Architecture (q.v.), or by higher-order units, whose activation is sensitive to weighted sums of products of input values, rather than just to weighted sums of input values.)
2. Links in NNs are not differentiated by labeling, unlike the links in symbolic structures such as Semantic Networks (q.v.). Therefore, in an NN, information that could otherwise be put into link labels has to be encoded somehow in activation values, weights, extra links, or other features of network topology, adding significantly to the cumbersomeness of the net and its processing. (See Barnden and Srinivas, 1991, for more discussion.)
3. The resolution of NN activation values is generally not fine enough to allow them individually to encode complex symbolic structures. Most typically, activation values merely encode confidence levels of some sort.
4. Pointers are usually not allowed. That is, activation values or patterns are not allowed to act as names or addresses of parts of the network itself.
5. Stored programs are not allowed. That is, activation values or patterns cannot act as instructions (names of internal computational actions).

## Further Comparative Remarks

The advantages claimed here for NNs are not clearcut. For instance, there are types of AI systems that readily exhibit forms of graceful degradation, pattern completion, and similarity-based generalization. In particular, as Barnden in Barnden and Holyoak (1994) argues in detail and other researchers have noted, these benefits are natural properties of suitably designed symbolic analogy-based reasoning systems (see Analogy-Based Reasoning and Metaphor and also Memory-Based Reasoning).

Just as NNs support some types of learning more readily than symbolic AI systems do, the converse holds as well. Symbolic AI systems, by virtue of their ability to handle complex temporary information structures, are in a better position to perform various types of rapid learning, proceeding in large steps rather than lengthy, gradual weight modification. For instance, a symbolic AI system is in a good position to reason about why some plan of action failed, and thus quickly and greatly amend relevant parts of its knowledge base or planning strategies. Also, the ability of neural networks to learn generalizations is often hindered by elaborate, extensive training regimes. It is true that in some learning regimes, such as some forms of Hebbian learning, final weights are calculated in a direct way from single presentations of training items. But more typically, the number of training-item presentations one needs to make to the network runs to tens or hundreds of thousands before useful results can be obtained.

NNs are good at allowing hypotheses to be held with varying degrees of confidence, the degrees being realized as activation levels. However, it is commonplace also in symbolic AI to have numerical degrees of confidence. These appear in Decision Support Systems and Expert Systems (q.v.) and elsewhere. However, the normal properties of activation spread and activation combination in NNs support confidence levels in a natural way. In symbolic AI systems the computations have to be specially and explicitly designed.

The contrasts between neural networks and symbolic AI that were presented earlier are clouded by the fact that NNs can be *implementational*. Implementational NNs are exact implementations of symbol processing schemes of the sort used in traditional symbolic AI systems. That is, network-unit activations (and/or link weights, possibly) can be regarded as exactly encoding symbolic representations as used in traditional AI systems—such as logic formulas, frames, schemas, or pieces of semantic network—and changes in network state can be regarded as exactly encoding traditional symbolic manipulation steps—such as traversal, concatenation, and rearrangement of structures—that are used in traditional AI for directly effecting reasoning, planning, natural language understanding, etc. See, for example, Barnden's and Shastri's chapters in Barnden and Pollack (1991) and Lange and Wharton's chapter in Barnden and Holyoak (1994).

The *non*implementational style includes NNs that can be usefully viewed as *approximately* manipulating traditional symbolic objects in traditional ways. However, the nearer an NN is to being implementational, the more it runs the danger of inheriting the disadvantages of symbolic AI, such as the tendency to lack graceful degradation.

## Bridging the Gap

The discrepancy in the relative advantages of (nonimplementational) NNs and symbolic AI systems has been the focus of much attention during the last decade or so (see, e.g., Barnden and Pollack, 1991; Browne and Sun, 2001; Hinton, 1991; Jagota et al., 1999; McGarry, Wermter, and McIntyre, 1999). We shall review here some representative attempts to tackle the problem.

A common approach to extending conventional types of NN processing to handle complex dynamic structures is to use *reduced representations*, also known as *compressed encodings*. See, e.g., Hinton, Pollack, and St. John's chapter and McClelland's chapter in Hinton (1991), as well as Elman (1991). A reduced representation is a single activation vector that is created from the several activation vectors that encode the constituents of the structure in such a way that the resulting vector is of roughly the same size as each of the constituents' vectors. For example, the constituents could be words, and a sequence of word encodings could represent a sentence. The reduced representation is then a roughly word-sized vector for the whole sentence.

One architecture used to produce reduced representations of sequences of items is a Simple Recurrent Network (SRN). An SRN is typically a three-layer network in which the input to the middle layer consists of an item in the sequence together with the previous activation pattern in the middle layer itself. As a result of backpropagation training, the encodings produced in the middle layer are compressed vectors representing the current input *in the context of* the history of items presented to the network so far. SRNs have been successfully used, for instance, for predicting the category of the next word in a sentence being inputed (Elman, 1991).

A more general-purpose architecture for producing recurrent compressed encodings is Pollack's Recursive Auto-Associative Memory (RAAM) (see Pollack in Hinton, 1991). The input and output layers are divided up into segments that hold constituent encodings. The net is trained to map sequences of constituent encodings to themselves. The activation pattern that appears on the hidden layer of the trained network in response to a particular sequence of constituent encodings on the input layer is the compressed encoding for the sequence. (And a compressed encoding can be decoded by placing it in the hidden layer: a close approximation, hopefully, to the sequence of constituent encodings appears on the output layer.) Also, during training, a hidden layer pattern can be copied into any of the segments in the input and output layer, leading to the ability of the network to handle recursive structures some of whose constituents are themselves sequences of constituents. An example of such a structure is the sentence "John knows that Sally is clever," thought of as having the sentence "Sally is clever" as a constituent.

There are some indications that compressed encodings can support *holistic* structure-sensitive processing by means of conventional NN techniques such as feedforward association networks (see, e.g., Chalmers, 1990; Pollack in Hinton, 1991). The processing is holistic in that the encodings are not uncompressed into the individual activation vectors that encode their notional constituents. For example, Chalmers successfully trained a three-layer backpropagation network to transform compressed encodings of active English sentences into compressed encodings of their passive counterparts. The hidden layer had the same size as the input and output layers (the size of a compressed encoding) and the net operated in one pass of activation, so that it cannot have been working by first decoding the input compressed encodings into the corresponding sequence of constituent encodings.

However, in-depth analysis of RAAM-like systems (Kolen, 1994) reveals that the computation depends on very fine tuning of synaptic weights and highly precise activation levels. The implication is that holistic computation based on RAAM-generated encodings is sensitive to noise, which is a significant drawback given that graceful degradation is a major argument for using neural networks. An additional complication associated with all of the aforementioned techniques of generating reduced representations is the lengthy process of weight training.

These problems are avoided in a related approach of which a central example is the Holographic Reduced Representation (HRR) technique of Plate (1995). See also Rachkovskij and Kussul (2001). HRRs use predefined combination operations (circular convolutions) to produce compressed encodings. No training is required and both encoding as well as decoding are performed in a single step. What is more important, though, is that these transformations offer a more comprehensive account of systematicity. Given a sufficiently large size of code vectors, not only can HRRs recursively bind any number of elements, but also, using simple vector addition, multiple bindings can be combined further to form collections of predicates. Such collections retain superficial and structural similarity of structures, so that decoding is not necessary to estimate an item's relevance for certain types of computation. If necessary, any one predicate can be readily extracted using inverse operations, although not without some loss of information due to the nature of circular convolution and vector addition. The operations introduce some degree of noise, which is further amplified by the decoding transformation. However, it can be rectified using an auto-associative memory to recover the original elements. Using this approach, Plate (1995) shows how HRRs can be used to represent sequences and more complex structures, and how to achieve chunking and variable binding.

In a different approach to bridging the gap, Barnden in Barnden and Holyoak (1994) capitalizes on the comment made previously that symbolic analogy-based reasoning possesses many of the main advantages of nonimplementational NNs. The claim is that an implementational NN that implements a symbolic analogy-based reasoning system inherits those advantages, as well as the symbolic AI advantage with respect to complex dynamic information structures.

The preceding approaches assume that it is worthwhile to develop gap-bridging systems that are neural networks in their entirety, rather than developing systems that are some combination of NN machinery with symbolic AI machinery (where the latter is given no NN realization). The latter, hybrid, strategy is a popular approach to bridging the gap (McGarry et al., 1999). The simpler types of hybridization occur in systems that have largely separate neural and symbolic modules (see, e.g., Hendler in Barnden and Pollack, 1991). But more intimate hybridizations have been developed, for instance, in networks where an individual node or link can act partially like those in neural networks and partially like those in symbolic networks.

Although the more implementational an NN is the more it risks inheriting disadvantages of symbolic AI, it may still be that some of the implementational NN techniques could be adapted for use in gap-bridging systems that escape those disadvantages. Therefore, we will now look at some of the techniques.

A crucial aspect of implementational NNs is the way in which they allow representational items to be rapidly and temporarily combined so as to form encodings of temporary complex information structures. One form of this *dynamic combination* (or *temporary association*) issue is the variable binding problem, and a closely related form is the role binding problem. The variable binding problem was described previously. The role binding problem is concerned with giving specific values to the roles (slots) in predicates, frames, schemas, and the like.

An immediately obvious, and somewhat natural, approach to dynamic combination is to combine network nodes or assemblies by adding new links or giving non-zero weights to existing zero-weight links. However, this method is highly cumbersome because network structure is not data that is directly manipulable by the network itself. Another rather similar approach is to facilitate existing (non-zero-weight) connection paths, between nodes/assemblies that are to be combined, by activating intermediate nodes on the paths. These nodes are called binding nodes. Since the dynamic combination structure is now encoded in the activation levels of binding nodes, the net can more easily analyze that structure. However, the processing is still cumbersome (Barnden and Srinivas, 1991).

A distinctly different approach is to deem nodes/assemblies to be bound together when they fire in synchrony (see Structured Connectionist Models, Compositionality in Neural Systems, and Dynamic Link Architecture). See in particular Shastri in Barnden and Pollack (1991), and Henderson and Lane (1998). The method is an important special case of the more general notion of binding nodes together by giving them similar spatiotemporal activation patterns. This is the pattern-similarity association technique: see Barnden and Srinivas (1991) and Barnden in Barnden and Pollack (1991).

Distinctly different again is the use of positional encodings of dynamic combinations. In the more developed forms of this idea (see Barnden in Barnden and Pollack, 1991), activation patterns are dynamically combined by being put into suitable relative positions with respect to each other, much as bit-strings in computer memory can be put into contiguous memory locations to form records.

A somewhat pointer-like technique has been implemented: see Lange and Wharton in Barnden and Holyoak (1994). Different parts of the network are capable of emitting activation patterns that are thought of as their "signatures." Other parts can then temporarily hold signatures and thereby point, in a sense, to the parts that possess the signatures.

One noteworthy way of achieving temporary association is the use of auto-associative memories with rapid Hebbian learning, as in van der Velde (1995). Van der Velde demonstrates how multiple elements can be stored in a single network while preserving their ordering. Each element in the sequence refers to the next and previous ones by unique pointers that constitute part of the memory trace in an auto-associative module. Using this approach, van der Velde builds a conventional stack-based generator of center-embedded sentences. Despite its implementational architecture, this model manages to retain the graceful-degradation property of nonimplementational NNs. Hebbian association was also used by Hadley et al. (2001) to achieve a strong from of systematicity.

Finally, Smolensky in Hinton (1991) proposed an abstract but influential binding and structure-representation approach based on tensors. Some realizations of this approach involve binding nodes, but the approach can be seen to subsume other concrete techniques as well.

## Discussion

One theme of this review has been that the relative advantages of symbolic AI and NNs are less clear-cut than is usually implied. In particular, although NNs have been successful for some purposes and can have advantages such as graceful degradation, most NN research has not addressed the complex information processing issues routinely tackled in symbolic AI research. The latter field has contributed much more, for instance, to the study of how natural language discourse can be understood and common-sense reasoning performed. Nevertheless, pursuing nonsymbolic approaches to the problems is beneficial for as long as the symbolic approaches fail to provide all the answers.

Some of the open questions in the area of this review are: Is it actually necessary to go beyond symbolic AI in order to account for complex cognition? If it is, should symbolic AI be dispensed with entirely, or is some amount of complex symbol-processing unavoidable? How can reasoning, natural language understanding, etc. be effected by neural networks without just implementing conventional symbol processing? How can different styles of system, e.g., implementational and nonimplementational neural networks, or neural networks and non-neural systems, be gracefully combined into hybrid systems?

# Associative Networks

*James A. Anderson*

## Introduction

The operation of *association* involves the linkage of information with other information. Although the basic idea is simple, association gives rise to a particular form of computation, powerful and idiosyncratic. The mechanisms and implications of association have a long history in psychology and philosophy. Association is also the most natural form of neural network computation. This article will discuss association as realized in neural networks as well as association in the more traditional senses.

Neural networks are often justified as abstractions of the architecture of the nervous system. They are composed of a number of computing units, roughly modeled on neurons, joined together by connections that are roughly modeled on the synapses connecting real neurons together. The basic computational entity in a neural network is related to the pattern of activity shown by the units in a group of many units.

Because of the use of activity patterns—mathematized as state vectors—as computational primitives, the most common neural network architectures are pattern transformers which take an input pattern and transform it into an output pattern by way of system dynamics and a set of connections with appropriate weights. In a very general sense, therefore, neural networks are frequently designed as *pattern associators*, which link an input pattern with the "correct" output pattern. Learning rules are designed to construct accurate linkages. The most common feedforward neural network architectures realize this linkage by way of connections between layers of units (Figure 1). There may be a single set of modifiable connections between input and output (Figure 1*B*), or multiple layers of connections (Figure 1*C*). Another common architecture is realized by a single layer of units where the units in the layer are recurrently interconnected (Figure 1*A*).

One common design goal of a feedforward associator (Figures 1*B* and 1*C*) is to realize what Kohonen (1977) has labeled *heteroassociation*, that is, to link input and output patterns that need have no relation to each other. Another possibility is to realize what Kohonen has called *autoassociation*, where the input and output patterns are identical. Recurrent networks (Figure 1*A*) are well suited to autoassociation.

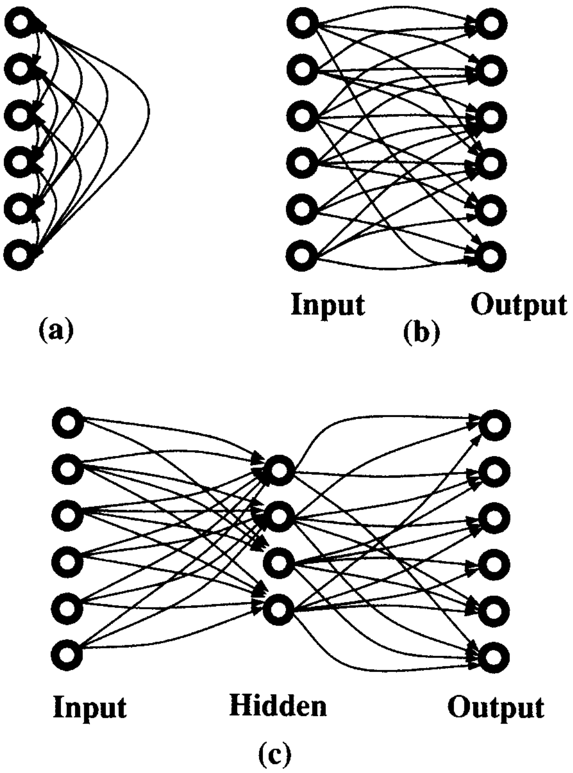

**Figure 1.** Three common basic neural network architectures. *A*, A set of units connects recurrently to itself by way of modifiable connections. (The connections are drawn as reciprocal.) *B*, A feedforward network in which an input pattern is transformed to an output pattern by way of a layer of modifiable connections. *C*, A more general feedforward network. An input layer projects to an intermediate layer of units. The intermediate layer is often called a *hidden layer* because it may not be accessible from outside the network. The hidden layer then projects to the output units.

Because the input and output patterns must correspond to information about the real world, the *data representation* is of critical importance at all levels of network operation. For example, simple pattern recognizers are often realized by neural networks as a special form of pattern associator by assuming a particular output representation, one where a single active output unit corresponds to the category of the input. Different categories correspond to different active output units. This highly localized representation is sometimes called a *grandmother cell* representation, because it implies that only when one particular unit is active is "grandmother" being represented. The alternative representation is called a *distributed representation*, where representation of a concept like "grandmother" may contain many active units. Choice of representation makes a major difference in how networks are used and how well they work, and is usually more important than the exact choice of network architecture and learning rule. A common situation in engineering applications of neural networks is to have a distributed representation at the input of the network and a grandmother cell representation at the output. In the vertebrate nervous system there is little evidence for this output representation; essentially all normal motor acts involve the coordinated discharge of large groups of neurons. Distributed activity patterns are associated with distributed patterns from one end of most biological networks to the other in vertebrates (but see LOCALIZED VERSUS DISTRIBUTED REPRESENTATIONS), though there are some examples of extreme selectivity in invertebrates. The degree of distribution is a matter for experimental investigation.

## Neural Network Associators

Let us give an example of how easily neural network learning rules and architectures give rise to associative behavior. Consider the two-layer network diagrammed in Figure 1*B*. Consider a situation where a pattern of activity, a state vector $f$, is present at the input set of units and another pattern, state vector $g$, is shown by the output set of units.

We want to link two patterns so that when $f$ is presented to the input of the network, $g$ will be generated at the output. In this two-layer network (two layers of units, one layer of connections), we will assume that the connections initially are zero and we want to change them to make the association between patterns $f$ and $g$. We will also assume that all connection strengths are potentially changeable and the set of connection strengths forms a *connection matrix* (or *synaptic matrix*) which we will call $W$, for "weights."

We have to propose a learning rule, but we also have to make some additional assumptions about the entire system. For example, virtually all artificial neural network learning assumes that the network is learning discrete pairs of patterns, that is, learning takes place only occasionally, when the time is ripe. One could speculate that learning in animals is a dangerous operation—after all, the nervous system is being rewired—and is kept under tight control. Primates are unusual in the degree of learned flexibility their nervous system allows. There is physiological evidence that amount of learning is controlled by diffuse biochemical processes. Dangerous and striking events, causing a biochemical upheaval, give rise to what have been called "flashbulb memories" where everything, including totally irrelevant detail, is learned. ("Where were you when John F. Kennedy was assassinated?" is practically guaranteed to involve a flashbulb memory in those old enough to remember it. September 11, 2001, provides a modern example.) Presumably this corresponds to an undiscriminating "learn" command. In terms of modeling, these observations mean that the decision to learn is decoupled from the act of learning.

Let us assume that we have an input pattern and an output pattern and we wish to associate them for good and sufficient reasons. We assume that we can impress pattern $f$ on the input set of units and pattern $g$ on the output set of units. By far the most common network learning rule used is one or another variant of what is called the "Hebb synapse," described in Hebb (1949). Perhaps the most quoted sentence in the neural network literature is from Hebb: "When an axon of cell *A* is near enough to excite a cell *B* and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells, such that *A*'s efficiency as one of the cells firing *B*, is increased." (Hebb, 1949:62). The essence of the Hebb synapse is that there has to be a *conjunction* of activity on the two sides of the connection.

There is good physiological evidence for the existence of some form of Hebb synapse in parts of the mammalian central nervous system (see HEBBIAN SYNAPTIC PLASTICITY). However, there are a number of "technical" problems involved in mathematically describing the resulting system. The original formulation by Hebb was concerned with coincident excitation. Nothing was said about coincident inhibition or about coincident excitation and inhibition. Also, the exact function determining strength of modification was not given, and, in fact, is not known. A common assumption in *artificial* network theory is to assume some version of what is called the *generalized Hebb rule* or the *outer product rule*. This states that the change in strength of a connection during learning is given by the *product* of activities on the two sides of the connection, that is, if $W_{ij}$ is the strength of the connection, then the change in strength $\Delta W_{ij}$ is proportional to the product, $f_j g_i$, where $f_j$ is the activity of the *j*th input unit and $g_i$ is the activity of the *i*th output unit. This convenient expression may have only a weak relationship to physiological reality.

Given the generalized Hebb rule, if we have only a single pair of vectors to associate, the results can be written compactly as

$$W = \eta g f^{\mathrm{T}}$$

where $\eta$ is a learning constant and *W* is the connection (or weight) matrix.

By making an additional assumption about the properties of the individual neural elements, this rule leads almost immediately to a simple pattern associator called the *linear associator*. Suppose the elementary computing units are linear, so that the output is given by the inner product between input activity and connection strengths. Then the output pattern is given by the matrix product of an input pattern *f* and the connection matrix *W*; that is, the output of the network is *Wf*. Because we know what *W* is—it was constructed by the generalized Hebb rule—we can compute the output pattern,

$$\text{(output pattern)} = Wf = \eta g f^{\mathrm{T}} f = \text{(constant)}g$$

since $f^{\mathrm{T}}f$ is a constant, the squared length of *f*. The output pattern is a constant multiple of *g* and, except for length, we have reconstructed the learned associate of *f*, that is, *g*.

Suppose we have a whole set of associations $\{f^i \rightarrow g^i\}$ that we want to teach the network. (Superscripts stand for individual pattern vectors.) If we assume that the overall strength of a connection is the algebraic sum of its past history (an unsupported assumption), then we have the weight matrix *W* given by

$$W = \sum_i \eta g^i f^{i\mathrm{T}}$$

Notice that in the special case where the input patterns $\{f^i\}$ are orthogonal, that is, $f^i f^j = 0$ if $i \neq j$,

$$Wf^i = \text{(constant)}g^i$$

because the contributions to the output pattern from the other terms forming *W* are identically zero since they involve the inner product $[f_i, f_j] = f_i^{\mathrm{T}} f_j$. This model, and in fact most simple network models, make the prediction that outer product associators will work best and most reliably with representations where different input associations are as orthogonal as possible. For this reason, some cortical models in the neuroscience literature have explicitly discussed aspects of cortical processing in terms of orthogonalization. The most complete reference for the linear associator and related models is Kohonen (1977, 1984).

It is possible to change almost any assumption and still have an associator. *Hebb learning rules of virtually any kind give rise to associative systems.* As only one example, the nonlinear Hebbian associator proposed by Willshaw, Buneman, and Longuet-Higgins (1969) used binary connections—with strengths either one or zero—and the resulting system still worked nicely as a pattern associator.

## Supervised Networks

The outer product associator is less accurate with nonorthogonal patterns. However, observed distortions and human performance are sometimes remarkably similar. (See Anderson, 1995, chap. 11, for a model of "concept formation" that emerges when correlated inputs are stored in the linear associator.)

Most designers of artificial networks prefer networks to produce accurate reproductions of learned associations rather than interesting distortions. (This seemingly natural assumption is not necessarily a good one.) *Supervised* network algorithms can perform more accurate association. Examples of such algorithms would include the Widrow-Hoff (LMS) algorithm, the perceptron, backpropagation, and many others. The basic mechanism employed is *error correction*. Suppose we have an initial training set of patterns to be learned. This means we know what the output patterns are for a number of input patterns. We take an input from the training set and let the network generate an output pattern. We then compare the desired output pattern and the actual output pattern in some way. This process generates an *error signal*. The network is then modified using a learning rule so as to *reduce* the error signal.

The most commonly used error signal is based on the distance between the actual and desired output; however, other error signals can be more desirable. For example, one could incorporate a term penalizing large numbers of connections or large values of connection strength. The network learning problem reduces to a minimization problem where the space formed by the connection strengths (*weight space*) is searched to find the point where error is reduced to as low a value as possible. This process requires the use of control structures that can be complex; for example, there is assumed to be an omniscient *supervisor* who compares desired and actual network output and computes the error term as well as implements the mechanisms to change connection strengths appropriately. The structure of these algorithm is designed to produce good pattern association whether or not this is the aim of the network architects. (See PERCEPTRONS, ADALINES, AND BACKPROPAGATION.)

## Autoassociative Models

We have described association as pattern linkage. However, there are alternative descriptions in the neural network literature. For example, in the first sentence of the second chapter of their textbook, *Introduction to the Theory of Neural Computation*, Hertz, Krogh, and Palmer (1991) write, "Associative memory is the 'fruit fly' or 'Bohr atom' problem of the field" (p. 11). Their definition of association is: "Store a set of patterns $\zeta$ . . . in such a way that when presented with a new pattern $\zeta_i$, the network responds by producing whichever one of the stored patterns most closely resembles $\zeta_i$" (p. 11). This is not, however, a description of association but of a *content addressable memory* where input of partial or noisy information is used to retrieve the correct stored information. The source of this limited view of association lies in the ability of autoassociative systems to reconstruct missing or noisy parts of learned patterns.

Consider the autoassociative version of the linear associator. Suppose we learn one pattern, $f$, of length 1, with learning constant $\eta = 1$. Then

$$W = ff^{\mathrm{T}} \quad \text{and} \quad Wf = f$$

Suppose we take vector $f$, with $n$ elements, and set to zero some of the elements, forming a new vector, $f'$. Let us make a second vector, $f''$, from only the elements that were set to zero in $f'$. Then $f' + f'' = f$ and $f' f''^{\mathrm{T}} = 0$. If $f'$ is input to the autoassociator,

$$Wf' = (f' + f'')(f' + f'')f'^{\mathrm{T}} = (\text{constant})f$$

where the constant is related to the length of $f'$. In operation, by putting a part of $f$, $f'$, into the network, we retrieve all of $f$, bar a constant. This behavior is often referred to as the *reconstructive* or *holographic* property of neural networks. Of course, more subtle problems arise when $W$ stores multiple vectors. Anyway, this type of memory is associative because if, for example, the state vector was meaningfully partitioned, then $f'$ is associatively linked to $f''$ and vice versa in the sense that input of one pattern will produce the other. This kind of associator produces intrinsically bidirectional links (i.e., $f' \rightarrow f''$ and $f'' \rightarrow f'$), unlike feedforward heteroassociators ($f \rightarrow g$).

Some nonlinear "attractor" neural networks with dynamics that minimize energy functions develop their associative abilities largely from their autoassociative architecture. The best-known examples of this kind of associator are Hopfield networks and parallel feedback networks such as the BSB (Brain State in a Box) model (Anderson, 1995, chap. 15). For a general review of attractor networks, see Amit (1989) and Computing with Attractors. Multilayer autoassociators are also possible. The multilayer *encoder networks*, which require the output pattern to be as accurate a reconstruction as possible of the input pattern, also have this form. Many autoassociative networks have close ties to known statistical techniques such as Principal Component Analysis.

A related associative attractor model, called a *bidirectional associative memory*, or BAM (Kosko, 1988), is a nonlinear dynamical system with a reciprocal feedback structure. It assumes two layers of units, as well as pairs of associations to be learned, as in a heteroassociator. There are connections from both input to output and output to input. Given $f$ and $g$ patterns to be learned, assumed to be binary vectors, we can form both a forward and a backward connection matrix. If $f$ is input, then $g$ will be given as the output; $g$ at the output will give rise to $f$ at the input because of the backward connections. Suppose the input is not exactly what was learned. After a few passes back and forth through the system, it can be shown that the network will stabilize, in the noise-free case, to the learned $f$ and $g$.

## Psychological Association

We have shown how neural networks easily form associators of many different kinds. We will now discuss a little of the history of association in psychology to show how associators form a style of computation with considerable power as well as severe limitations.

The major outlines of one way to use an associative computer can be found clearly expressed in Aristotle in the fourth century B.C. Aristotle made two important claims about memory structure: First, the elementary unit of memory is a *sense image*, that is, a sensory-based set of information. Second, links between these elementary memories serve as the basis for higher-level cognition. An English translation by Richard Sorabji (1969) used the term *memory* for the elementary memory unit and *recollection* for reasoning by associations between elementary units. Aristotle discussed at length how one "computes" with memorized sense images. The word *recollection* was used in the translation to denote this process: "Acts of recollection happen because one change is of a nature to occur after another." That is, Aristotle proposed a linkage mechanism between memories. He suggested several ways that linkage could occur: by temporal succession or by "something similar, or opposite, or neighboring." This list of the mechanisms for the formation of associations is approximately what would be given today by psychologists.

Recollection in Aristotle's sense was computation. It was a dynamic and flexible process: "[R]ecollecting is, as it were, a sort of reasoning." Aristotle argued that properly directed recollection is capable of discovering new truths, using memorized sense images as the raw material and learning to traverse new paths through memory (Figure 2).

A practical problem with such an associative net is branching, that is, what to do if there is more than one link leaving an elementary memory. Aristotle was aware of this problem: "[I]t is possible to move to more than one point from the same starting point." A general solution to the branching problem requires a nonlinear mechanism to select one or the other branch.

The most influential psychologists in the twentieth century were the behaviorists, in particular B. F. Skinner, the Harvard psychologist whose ideas about reinforcement learning unfortunately dominated much of the theoretical discussion in psychology for several decades. This school held that learning formed an associative link between a stimulus and a specific response. The link could be strengthened by positive reinforcement (to a first approximation, something useful or pleasant, or the cessation of something unpleasant) or weakened by negative reinforcement (either absence of something pleasant or something actively unpleasant) when the response followed the stimulus. A number of careful experiments showed that there were accurate quantitative "laws of learning" that were followed by animals in some simple situations.

It was debatable whether this view of association is useful in more complex situations. From the beginning, human behavior has seemed to humans to be far richer than stimulus-response ($S \rightarrow R$) association. In the 1950s Skinner wrote a book attempting to explain language behavior using associative rules. In a famous book review, Chomsky (1957) pointed out that simple $S \rightarrow R$ association cannot do some kinds of linguistic computation. The argument used

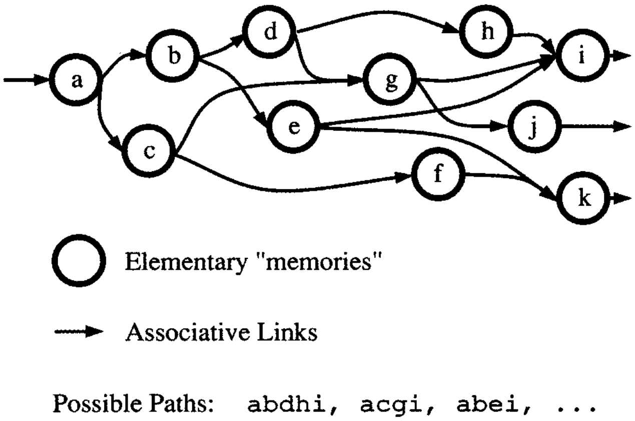

**Figure 2.** A simple model of associative computation. Elementary memories ("sense images," according to Aristotle) are associatively linked (arrows) to other sense images. Branches are possible, and they present some difficulties. There are many possible paths through the network. Forming and traversing links between elementary memories is the basis of mental computation.

was that Skinner was proposing a well-defined computing machine with his associative model and that this computing machine was not powerful enough to do the computations we know language users perform. The simple $S \rightarrow R$ models of Skinner had about as much computing power as the simplest heteroassociative neural networks, which no one claimed were general-purpose computers. However, supervised network learning algorithms applied without insight may produce systems with only this degree of overall computational power.

## "Connectionist" Models

Much modern work using association assumes that the entities linked, and the links themselves, can have complex internal structure. Flexible systems capable of complex reasoning can be produced by using labeled links: for example, a robin IS-A bird, an IS-A link, or "Fred is the father of Herb," meaning that there is an associative link between Fred and Herb and that the link carries the relationship "Father-of." Complex and sophisticated computational models, *semantic neworks*, can be built from these pieces.

In the 1980s, many of those interested in semantic network models started working with neural networks. The term *connectionism* was often used to indicate the application of neural networks to high-level cognition. Recently there have been many attempts to apply networks to reasoning, to complex concept structures, and, in particular, to language understanding. A heated but illuminating debate arose from an early connectionist paper by Rumelhart and McClelland (1986) that used a neural network to simulate the way young children learn past tenses of verbs. Past tense learning had always been considered to be a good example of the application and misapplication of a specific rule, suggesting symbolic processing. Rumelhart and McClelland's neural network acted as if it were using rules, but the rule-like behavior was the result of generalizing from examples and learning specific cases (see PAST TENSE LEARNING). Perhaps because this model was such a direct attack on the existence of rules in language, a vigorous counterattack developed. As one example, a long paper by Pinker and Prince (1988) finished its abstract with the sentence, "We conclude that connectionists' claims about the dispensability of rules in explanations in the psychology of language must be rejected, and that, on the contrary, the linguistic and developmental facts provide good evidence for such rules" (p. 74). The vigor of the attack is perhaps due in part to the authors' feeling that the connectionists had violated the "central dogma of modern cognitive science, namely that intelligence is the result of processing symbolic expressions" (Pinker and Prince, p. 74). Many other cognitive scientists feel that the "central dogma" is actually more like a central, and open, question.

Less well known outside psychology are several associative neural network models that were constructed to explain the fine structure of experimental data in more traditional areas of psychology such as verbal learning. An interesting example of such a model is the TODAM model of Murdock (see CLASSICAL LEARNING THEORY AND NEURAL NETWORKS in the first edition). TODAM and variants blur the distinction between the network and the representation. In the associative networks we have discussed, there are two formally distinct entities, state vectors and connection matrices. In the TODAM class of models, the association is stored with the items themselves and is therefore the same type of entity. TODAM makes a number of testable qualitative predictions about a wide range of data from the classical verbal learning literature. Recently, models assuming networks composed of large numbers of local networks (a "network of networks") suggest that networks like TODAM might be realizable with neural networks.

## Discussion and Open Questions

An often proclaimed virtue of neural networks is their ability to generalize effectively and to do computation based on similarity. Having learned example associations from a training set, the network can then generate correct answers to new examples. Many have pointed out the formal similarity of neural networks to approximation and interpolation as studied in numerical analysis. A properly designed neural network can act as a useful adaptive interpolator with good, even optimal, generalization around the region of the learned examples. However, it is not easy for neural networks to make good generalizations other than by approximation and interpolation. On this basis, Fodor and Pylyshyn (1988) made some telling arguments against the promiscuous application of connectionism to cognition (see SYSTEMATICITY OF GENERALIZATIONS IN CONNECTIONIST NETWORKS). The essential criticism they made is one that an engineer would be happy to make: Associative neural networks are such an inefficient way to compute that it would be foolish to build a cognitive system like that. Neural networks do not generalize well outside of a restricted definition based on mathematical interpolation, they cannot reason effectively, and they cannot extrapolate in any meaningful sense. These criticisms are part of a battle involving the limitations of association that has been going on for centuries. Fodor and Pylyshyn commented, "It's an instructive paradox that the current attempt to be thoroughly modern and 'take the brain seriously' should lead to a psychology not readily distinguishable from the worst of Hume and Berkeley" (p. 64).

Fodor and Pylyshyn contrasted neural network associators with what they call the classical view of mental operation. In essence, this view postulates "a language of thought"; that is, "mental representations have *a combinatorial syntax and semantics*" (p. 12). The classical view is dominant in virtually all branches of traditional artificial intelligence and linguistics. The power of the digital computer arises in part from the fact that it is designed to be an extreme example of this organization: a programming language operating on data is the prototype of the classical view.

Suppose we have a sentence of the form *A and B* that we hold is true. An example Fodor and Pylyshyn used is *John went to the store and Mary went to the store*. The truth of this sentence logically entails the truth of *Mary went to the store*. This conclusion arises from the rules of logic and of grammar. It is not easy for an associative neural network to handle this problem. Such a network could easily learn that *John went to the store and Mary went to the store* is associated with *Mary went to the store*. But the power of the classical approach arises from the fact that every sentence of this form gives rise to the same result. Given the huge number of possible sentences, *it makes practical sense* to assume that some kind of logical syntax exists. It would be hard to figure out how language could function without some global rule-like operations, however implemented.

The ability to understand and answer sentences or phrases that are new to the listener is hard to explain purely with association. To give one example (see MENTAL ARITHMETIC USING NEURAL NETWORKS in the first edition), consider number comparisons such as "Is 7 bigger than 5?" There are nearly 100 such single-digit comparisons, nearly 10,000 two-digit comparisons, and so on. Children cannot possibly learn them as individual cases.

If there is a qualitative difference between human and animal cognition, it lies right here. There have been attempts to build neural networks that realize parts of the classical account, with indifferent success (see Hinton, 1991). Is it possible to build a neural network based largely on natural associators that can reproduce the kind of rule-governed behavior—even in limited domains—that does in fact seem to be part of human cognition? A neural network with this ability would allow for much more powerful and useful generalization than current networks provide. It may not be easy to find this solution. There are many animals with complex nervous systems capable of associative learning, but only our own species, one out of millions of species, is really effective at using these powerful extensions to association.

# Auditory Cortex

*Shihab A. Shamma*

## Introduction

The auditory cortex plays a critical role in the perception and localization of complex sounds. It is the last station in a long chain of processing centers that begins with the cochlea of the inner ear and passes through the cochlear nuclei (CN), the superior olivary complex (SOC), the lateral lemniscus, the inferior colliculus (IC), and the medial geniculate body (MGB) (Figure 1). Recent studies have expanded our knowledge of the neuroanatomical structure, the subdivisions, and the connectivities of all central auditory stages (Winer, 1992). However, apart from the midbrain cochlear and binaural SOC nuclei, relatively little is known about the functional organization of the central auditory system, especially compared to the visual and motor systems. Consequently, modeling cortical auditory networks is complicated by uncertainty about exactly what the cortical machinery is trying to accomplish.

One exception to this state of affairs is the highly specialized echolocating bat, in which these uncertainties are much relieved by the existence of a stereotypical behavioral repertoire that is closely linked to the animal's acoustic environment (see Echolocation: Cochleotopic and Computational Maps). This has made it possible to construct a functional map of the auditory cortex, which

**Figure 1.** Schematic representation of the multiple stages of processing in the mammalian auditory pathway. Sound is analyzed in the cochlea, and an estimate of the acoustic spectrum (an auditory spectrum) is known to be extracted at the cochlear nucleus (Blackburn and Sachs, 1990). The tonotopic organization of the cochlea is preserved all the way up to the cortex, where it has a two-dimensional layout. The isofrequency plane encodes perhaps other features of the stimulus.

revealed the specific acoustic features extracted and represented in the cortex. In turn, these cortical maps have acted as a guide to discovering the organization and nature of the transformations occurring in lower auditory centers such as the MGB, IC, and SOC. Thus, it has become meaningful in these species to investigate and model cortical and other central auditory neural networks.

In other mammals, it is more difficult to isolate an auditory behavior and its associated stimulus features with comparable specificity. Nevertheless, a few tasks have been broadly accepted as vital for all species, such as sound localization, timbre recognition, and pitch perception. For each, evidence of various functional and stimulus feature maps has been found or postulated, a significant number of them in the last few years. In this review, we elaborate on a few examples of such maps and relate them to the more intuitive and better understood case of the echolocating bats. In each example, our goal is to determine how and whether models of the underlying neural networks can further our understanding of the auditory cortex.

## Parcellization and Neuroanatomy of the Auditory Cortex

The layout and neural structure of the auditory cortex is in many respects similar to that of other sensory cortices (Winer, 1992). For instance, based on cytoarchitectonic criteria and patterns of connectivity, it is subdivided into a primary auditory field (AI) and several other surrounding fields, e.g., the anterior auditory field (A) and the secondary auditory cortex (AII). The number and specific arrangement of surrounding fields vary among different species, reflecting presumably the complexity of the animal's acoustic environment. The AI, and possibly other fields, is further subdivided into smaller regions, serving perhaps different functional roles, such as echo delay and amplitude measurements in the bat (see ECHOLOCATION: COCHLEOTOPIC AND COMPUTATIONAL MAPS).

The anatomical parcellization of the auditory cortex into different fields is mirrored by physiologically based divisions. Most important is the systematic frequency organization in different fields, or so-called tonotopic maps. For example, AI cells are spatially ordered based on the tone frequency to which they best respond, i.e., their best frequency (BF). They also respond vigorously to the onset of a tone and exhibit little evidence of adaptation to its repeated presentations. In other fields, cells may be less frequency selective, may respond more adaptively, or may be totally unresponsive to single tones, preferring more spectrally or temporally complex stimuli. A sudden change in these response patterns or in the gradual spatial order of the tonotopic map is usually taken to signify a border between different fields. In the cat, which has the most extensively mapped auditory cortex, four well-ordered tonotopic fields have been described, together with many other less precise secondary areas (Clarey, Barone, and Imig, 1992).

## Timbre: Models for the Encoding of Spectral Profiles

Recognizing and classifying environmental sounds is critical for the survival and propagation of many animals. Although a multitude of cues are responsible, the single most important one is the shape of the so-called spectral envelope (or the spectral profile) of the sound. It is largely this cue that allows us to distinguish between speech vowels or between different instruments playing the same note. The spectral profile emerges early in the auditory system as the sound is analyzed into different frequency bands, in effect distributing its energy across the tonotopic axis (the auditory sensory epithelium) (Figure 1). As far as the central auditory system is concerned, the spectral profile is a one-dimensional (1D) pattern of activation analogous to the two-dimensional (2D) distribution of light intensity on the retina.

An important organizational feature of the central auditory system is the expansion of the 1D tonotopic axis of the cochlea into a 2D sheet, with each frequency represented by an entire sheet of cells (Figure 1). An immediate question thus arises as to the functional purpose of this expansion and the nature of the acoustic features that might be mapped along these isofrequency planes. For example, one might conjecture that the amplitude or the local shape of the spectrum is explicitly represented along this new dimension.

In general, there are two ways in which the spectral profile can be encoded in the central auditory system. The first is *absolute*, that is, the spectral profile is encoded in terms of the absolute intensity of sound at each frequency. Such an encoding would in effect combine both the shape information and the overall level. The second way is *relative*, in which the spectral profile shape is encoded separately from the overall loudness of the stimulus. Examples of each of these two hypotheses are discussed next.

### *The Best-Intensity Model*

The first hypothesis is motivated primarily by the strongly nonmonotonic responses as a function of stimulus intensity observed in many cortical and other central auditory cells (Clarey et al., 1992). In a sense, one can view such a cell's response as being selective to (or encoding) a particular intensity. Consequently, a population of such cells, tuned to different frequencies and intensities, can provide an explicit representation of the spectral profile by their spatial pattern of activity (Figure 2). This scheme is not a true transformation of the spectral features represented, but rather is strictly a change in the means of the representation. The most compelling example of such a representation is that in the DSCF area of AI in the mustache bat. However, an extension of this hypothesis to multicomponent stimuli (as depicted in Figure 2) has not been demonstrated in any species.

### *The Multiresolution Analysis Model*

The second hypothesis, in which the relative shape of the spectrum is encoded, is supported by physiological experiments in cat and

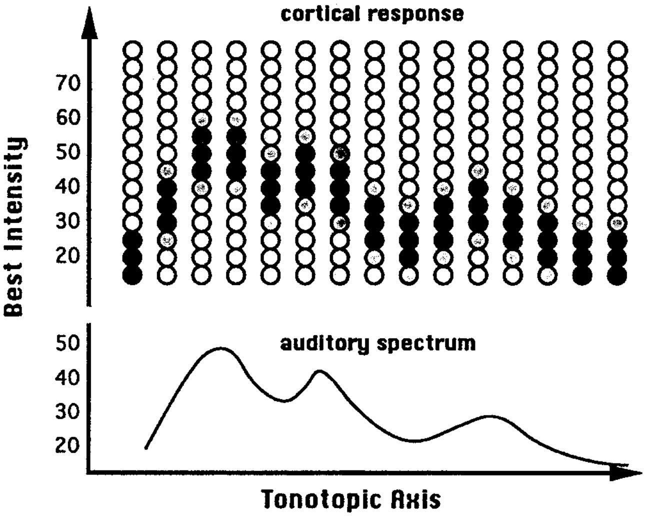

**Figure 2.** Schematic diagram of the way in which the spectral profile (lower plot) can be encoded by arrays of nonmonotonic cells (circles) tuned to different BFs (along the tonotopic axis) and best intensifies (BIs). The black circles signify strongly activated cells, whereas the white circles indicate weakly activated cells. Thus, a peak in the input pattern located at a given BF and at an intensity of 40 dB would best activate cells with the same BF and BI

ferret AI, coupled with psychoacoustical studies in human subjects. The data reveal a substantial transformation of the way the spectral profile is represented centrally. Specifically, besides the tontopic axis, two features of the response areas of AI neurons (the analogue of the receptive fields in the visual system) are found to be topographically mapped across the isofrequency planes. They are the bandwidth and symmetry of the response areas, depicted schematically in Figure 3*A* as the *scale* and *symmetry* axes, respectively. In addition, auditory cortical units exhibit systematic response patterns to dynamic spectra that give rise to complex and varied spectrotemporal response areas, as depicted in Figure 3*B*. These response properties are discussed in greater detail below.

*Changes in response area bandwidths.* Cell response areas, i.e., the excitatory and inhibitory responses they exhibit to a tone of various frequencies and intensities, change their bandwidth in orderly fashion along the isofrequency planes (Mendelson and Schneiner, 1990). Near the center of AI, cells are narrowly tuned. Toward the edges, they become more broadly tuned. This orderly progression occurs at least twice, and it correlates with several other response parameters such as increasing response thresholds toward the edges.

An intuitively appealing implication of this finding is that response areas of different bandwidths are selective to spectral profiles of different widths. Thus, broad spectral profiles (e.g., broad peaks or gross trends, such as spectral tilts due to preemphasis) would best drive cells with wide response areas. Similarly, narrower spectral profiles (e.g., sharp peaks or edges, or fine details of the spectral profile) would best be represented in the responses of cells with more compact response areas. In effect, having a range of response areas at different widths allows us to encode the spectral profile at different scales or levels of detail (resolution). From a mathematical perspective, this is basically equivalent to analyzing the spectral profile into different scales or "bands," much like performing a Fourier transform of the profile, hence representing it as a weighted sum of elementary sinusoidal spectra (usually known as *ripples*; Shamma, Versnel, and Kowalski, 1995). Coarser scales then correspond to the "low-frequency" ripples, while finer scales correspond to the "high-frequency" ripples.

*Changes in response area asymmetry.* Response areas exhibit systematic changes in the symmetry of their inhibitory response areas. For instance, cells in the center of AI have sharply tuned excitatory responses around a BF, flanked by symmetric inhibitory response areas. Toward the edges, the inhibitory response areas become significantly more asymmetric, with inhibition dominated by either higher or lower than BF frequencies. This trend is repeated at least twice across the length of the isofrequency plane.

It is intuitively clear that response areas with different symmetries would respond best to input profiles that match their symmetry. For instance, an odd-symmetric response area would respond best if the input profile had the same local odd-symmetry and worst if it had the opposite odd-symmetry. As such, one can state that a range of response areas of different symmetries (symmetry axis in Figure 3*A*) is capable of encoding the shape of a local region in the profile. From an opposite perspective, it can be shown mathematically that the local symmetry of a pattern can be changed by manipulating only the phase of its Fourier transform (Wang and Shamma, 1995). Therefore, the axis of response area asymmetries in effect is able to encode the phase of the profile transform, thus providing a complementary description to that of the magnitude along the scale axis described above.

*Dynamics of cortical responses to spectral profile changes.* Auditory cortical units also exhibit systematic and selective responses to dynamic spectra. Specifically, when stimulated by com-

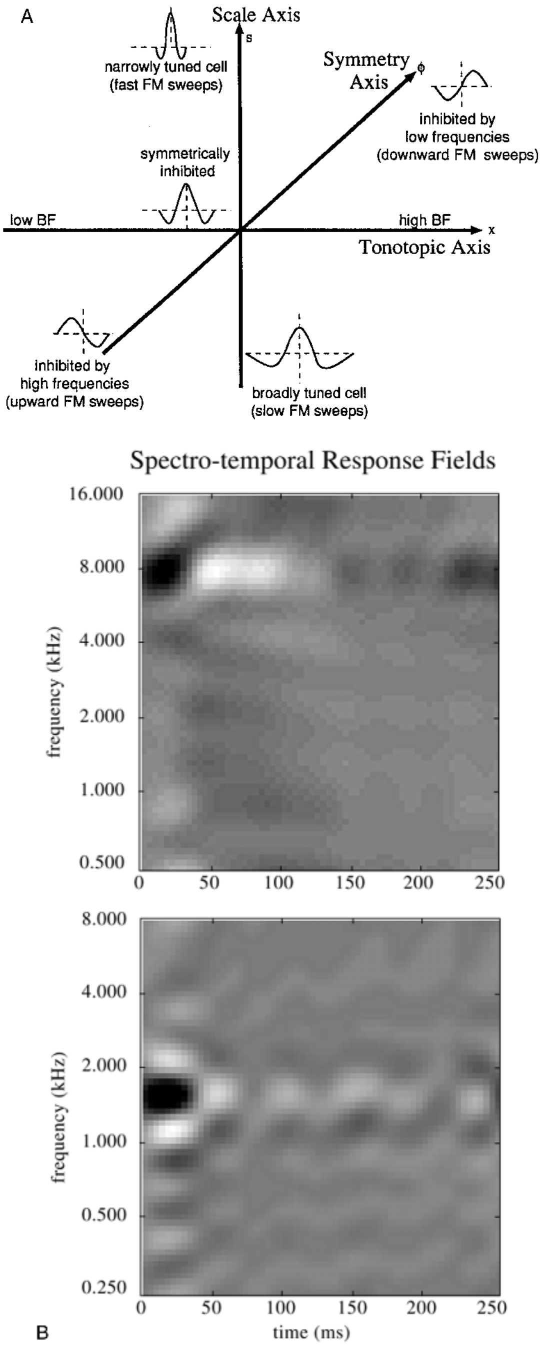

**Figure 3.** *A*, Schematic diagram of the three representational axes thought to exist in AI: the tonotopic (BF) axis, the scale (or bandwidth) axis, and the symmetry axis. *B*, Examples of spectrotemporal response fields measured from two auditory cortical units of the ferret. In each panel, the strength of the response is represented by the darkness of the display, with black indicating excitatory areas and white indicating regions of suppressed activity. Note that the excitatory central region defines the BF of the unit. Such STRFs exhibit a variety of bandwidths, asymmetry of inhibition relative to the BF, directional selectivity, and temporal dynamics. For instance, the unit in the top panel has significantly slower dynamics and much more asymmetric inhibition about the BF than the unit in the bottom panel. (From Simon, J. Z., Depireux, D. A., and Shamma, S. A., 1998, Representation of complex spectrain auditory cortex, in *Psychophysical and Physiological Advances in Hearing: Proceedings of the 11th International Symposium on Hearing* (A. R. Palmer, A. Ress, A. Q. Summerfield, and R. Meddis Eds.), London: Whurr, 1998, pp. 513–520. Reprinted with permission.)

plex sounds with rippled spectra like those described above, cortical units display preference not only to ripple density and phase, but also to the velocity at which the ripple is drifted past the BF of the cell. Unit selectivities span a wide range of best ripple velocities, from about 20 cycles/s (Hz), down to as low as 1–2 Hz (Kowalski, Depireux, and Shamma, 1996). In addition, auditory cortical units usually exhibit a range of directional sensitivities to upward- and downward-moving ripples.

This directional selectivity is probably directly linked to responses to frequency-modulated (FM) tones, a subject that has been the focus of extensive neural network modeling. These stimuli are important because they mimic the dynamic aspects of many natural vocalizations, as in speech consonant-vowel combinations or the trills of many birds and other animal sounds. The effects of manipulating two specific parameters of the FM sweep, its direction and rate, have been well studied. In several species and at almost all central auditory stages, cells can be found that are selectively sensitive to the FM direction and rate. Most studies have confirmed a qualitative theory in which directional selectivity arises from an asymmetric pattern of inhibition in the response area of the cell (Wang and Shamma, 1995), whereas rate sensitivity is correlated to the bandwidth of the response area (Heil, Langner, and Scheich, 1992).

*The full spectrotemporal response fields.* All of above mentioned response area features are integrated into a unified spectrotemporal response area (or field) as illustrated in Figure 3*B* (deCharms, Blake, and Merzenich, 1998). The full spectrotemporal response field (STRF) summarizes all the response selectivities of a unit by the relative locations, widths, duration, and orientation of its excitatory and inhibitory fields. The overall picture that emerges from these findings is that AI decomposes the auditory spectrum into a multidimensional representation with multiple resolutions along both spectral and temporal dimensions, as illustrated in Figure 4. This spectrotemporal decomposition essentially segregates diverse perceptual features into different streams, e.g., fast, spectrally broad sounds (consonants) from the relatively slow, voiced vowels and the finely resolved harmonics (pitch cues) (Wang and Shamma, 1995). This kind of multiscale analysis is closely analogous to the well-studied organization of receptive fields in the primary visual

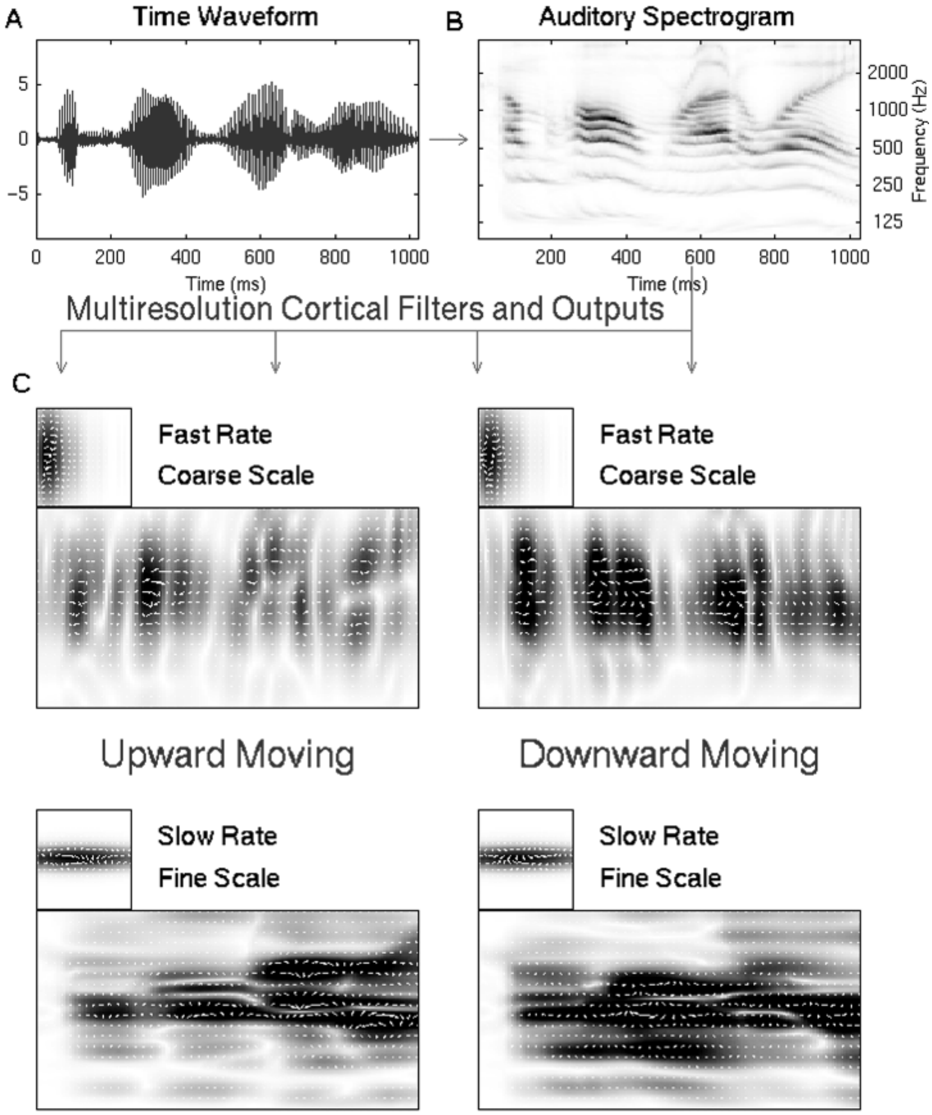

**Figure 4.** Schematic of the cortical representation of complex dynamic sound spectra. *A*, The time waveform of the acoustic signal /Come home right away/. *B*, The time-frequency representation of the signal (or the auditory spectogram) generated in the early stages of the auditory system. The *y*-axis represents the logarithmic frequency axis of the cochlea (or the tonotopic axis, as depicted in Figure 1). *C*, Cortical multiscale analysis of the auditory spectrogram along the spectral and temporal dimensions. Each panel represents the activity of a population of cortical cells with the (idealized model) STRF shown in the inset above it. Arrow direction represent the phase of the response; the strength of the response is indicated by the darkness of the display, as in Figure 3B. The two top panels are for broadly tuned but relatively fast STRFs that are selective to motion in opposite directions. The bottom panels are for narrowly tuned and relatively slow units. Different features of the spectrogram are emphasized in different panels. For instance, harmonics (pitch cues) are seen in the lower (fine-scale) panels, whereas onsets due to different consonents are seen only in the upper (fast-rate) panels.

cortex (De-Valois and De-Volois, 1990), and may reflect a general principle of analysis of sensory patterns in all other sensoricortical areas.

## Models of Pitch Representation in the Central Auditory System

A sound complex consisting of several harmonics is heard with a strong pitch at the fundamental frequency of the harmonic series, even if there is no energy at all at that frequency. This percept has been variously called the missing fundamental, virtual pitch, or residue pitch. A large number of psychoacoustical experiments have been carried out to elucidate the nature of this percept and its relationship to the physical parameters of the stimulus. Basically, all models fall into one of two camps. In the first camp, the pitch is extracted explicitly from the harmonic spectral pattern. This can be accomplished in a variety of ways, such as by finding the best match between the input pattern and various harmonic templates assumed to be stored in the brain (Goldstein, 1973). In the second camp, the pitch is extracted from the periodicities in the time-waveform of responses in the auditory pathway, which can be estimated, for example, by computing their autocorrelation functions. In this kind of model, some form of organized delay lines are assumed to exist so that the computations can be done, much like those that seem to exist in the FM-FM area of the mustached bat.

In all pitch models, however, the extracted pitch is assumed to be finally represented as a *spatial* map in higher auditory centers. This is because many studies have confirmed that neural synchrony to the repetitive features of a stimulus, be it the waveform of a tone or its AM modulations, becomes progressively worse toward the cortex (Langner, 1992). It is a remarkable aspect of pitch that, despite its fundamental and ubiquitous role in auditory perception, only a few reports exist of physiological evidence of spatial pitch maps, and none has been independently confirmed. One source is NMR scans of the primary auditory cortex in human subjects. The other source of evidence is multiunit mappings in various central auditory structures (Schreiner and Langner, 1988).

Of course, the difficulty of finding spatial pitch maps in the auditory cortex may be due to the fact that it does not exist. This possibility is counterintuitive, given the results of ablation studies showing that bilateral cortical lesions in the auditory cortex severely impair the perception of pitch of complex sounds but do not affect the fine discrimination of frequency and intensity of simple tones. Another possibility is that the maps sought are not at all as straightforward as we imagine. For example, harmonic complexes may evoke stereotypical patterns that are distributed over large areas in the auditory cortex, and not localized, as the simple notion of a pitch map implies (Wang and Shamma, 1995). Finally, it is also possible that AI simply functions as one stage that projects sufficient temporal or spectral cues for later cortical stages to extract the pitch explicitly.

## Models of Sound Localization

It has been recognized for many years that the auditory cortex (and especially the AI) is involved in sound localization. Detailed physiological studies further confirmed that AI cells are rather sensitive to all kinds of manipulations of the binaural stimulus (Clarey et al., 1992). For instance, changing either of the two most important binaural cues, the interaural level difference (ILD) or interaural time difference (ITD), causes substantial changes in their firing rate patterns. This sensitivity to interaural cues has its origins early in the auditory pathway, at the SOC, where the first convergence of binaural inputs occurs. However, despite this diversity, two elements typical of a functional organization of AI have been lacking. The first missing element is a significant transformation of the single-unit responses. For example, if ILD-sensitive cells are to encode the location of a sound source based on this cue, they ought to become uniformly more stable with overall sound intensity. This, however, does not seem to be the case (Semple and Kitzes, 1993). The second element lacking is a topographical distribution of the responses with respect to these cues or to a more complex combination of features (e.g., a map of acoustic space derived from ILD and ITD cues, as in the barn owl) (Sullivan and Konishi, 1986).

A map of auditory space has indeed been found in the superior colliculus of several mammals. No such map, however, has yet been detected in AI or other cortical fields despite intensive efforts (Clarey et al., 1992). What has been found, however, is a topographic order of certain binaural responses along the isofrequency planes of AI. Specifically, cells excited equally well by sounds from both ears (called EE cells) and others inhibited by ipsilateral sounds (called EI cells) are found clustered in alternating bands that parallel the tonotopic axis. One possible functional model that utilizes such maps assumes that EI cells are tuned to particular ILDs, and hence encode the location of a sound source based on this cue. EE cells, in contrast, would encode the absolute level of the sound. However, there is little evidence to support this hypothesis in the sense that neither EE nor EI cells are particularly stable encoders of specific ILD or absolute sound levels. An alternative hypothesis recently proposed is that these cells encode the absolute levels of the stimulus at each ear, rather than the difference and average binaural levels, as previously postulated (Semple and Kitzes, 1993). Finally, it has also been proposed that AI units encode the spatial location of a stimulus through unique patterns of temporal firing, ones that can be discerned using more elaborate pattern recognition neural networks (Middlebrooks et al., 1994).

## Discussion

The study of central auditory function has reached a sufficiently advanced stage to allow meaningful quantitative and neuronal network models to be formulated. In most mammals, these models are still systemic in nature, with a primary focus on understanding the overall functional organization of the cortex and other central auditory structures. In the bat and other specialized animals, the models are somewhat more detailed, addressing specific neuronal mechanisms, such as the coincidences and the delay lines of the FM-FM areas. The auditory system, with its multitude of diverse functions and its combination of temporal and spatial processes, should thus prove to be a valuable window into the brain and an effective vehicle for understanding the brain's underlying mechanisms.

# Auditory Periphery and Cochlear Nucleus

*David C. Mountain*

## Introduction

The auditory periphery transforms a very high information rate acoustic signal into a group of lower information rate neural signals. This process of parallelization is essential because the potential information rate in the acoustic stimulus is on the order of 0.5 megabits per second, and yet typical auditory nerve (AN) fibers have maximum sustained firing rates of 200 per second. The cochlear nucleus (CN) continues the process of parallelization by creating multiple representations of the original acoustic stimulus, with each representation emphasizing different acoustic features.

The major ascending auditory pathways are summarized in Figure 1. Sound is collected by the external ear (pinna) and passes through the ear canal to the eardrum (tympanic membrane), where it excites the middle ear. The middle ear couples the acoustic energy to the fluids of the cochlea, where transduction takes place. The sensory cells of the cochlea (hair cells) convert the mechanical signal to an electrical signal, which is then encoded by the fibers of the auditory nerve and transmitted to the CN in the brainstem. Within the CN, parallel information streams are created that feed other brainstem structures such as the superior olivary complex (SOC), the nuclei of the lateral lemniscus (NLL), and the inferior colliculus (IC). These parallel pathways are believed to be specialized for the processing of different auditory features that are used for sound source classification and localization. From the IC, auditory information is passed on to the medial geniculate body (MGB) in the thalamus, and from there to the auditory cortex.

## External Ear

The head and pinna modify the magnitude and phase of the acoustic signal reaching the tympanic membrane in such a way as to provide important cues for sound source localization (Shaw in Gilkey and Anderson, 1997). The transfer function relating tympanic membrane pressure to pressure in the free field is called the head-related transfer function (HRTF) and changes with sound source elevation and azimuth.

Three major mechanisms contribute to the creation of the HRTF. The distance between the ears in most mammals is sufficient to create significant interaural time delays (ITDs) for sound sources off to the side of the head, and the head is large enough to create interaural level differences (ILDs) for frequencies where the wavelength is comparable or smaller than the head. For higher frequencies (above 5 kHz in humans), multiple resonant modes in the pinna add further complexity. These modes are preferentially excited by sound waves from some directions but not others, resulting in an HRTF with peaks and valleys that change with sound source direction.

## Middle Ear and Cochlear Mechanics

The middle ear consists of the tympanic membrane, the three middle-ear bones (ossicles), and the Eustachian tube. The primary function of the middle ear is to match the low acoustic impedance of air to the high acoustic input impedance of the cochlea. The middle-ear transfer function (ratio of intracochlear pressure to ear canal pressure) is high-pass in nature (Rosowski in Hawkins et al.,

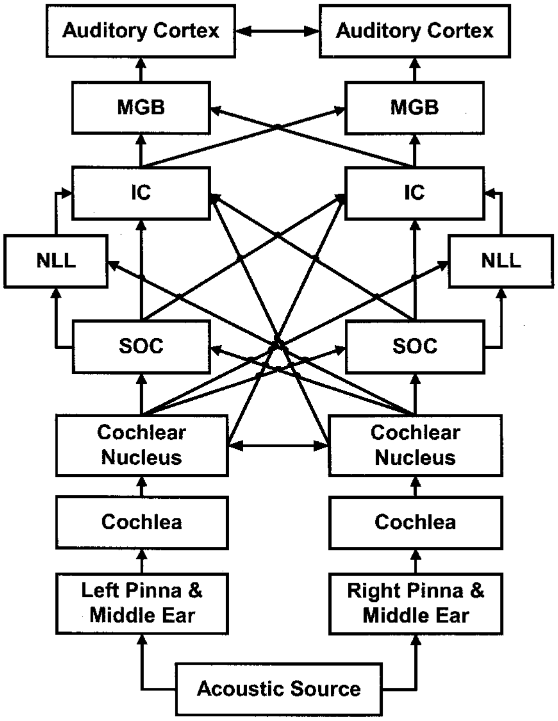

**Figure 1.** The major ascending auditory pathways. See text for explanation of abbreviations.

1996) and plays a major role in determining the audiogram for a given species.

The cochlea consists of a spiral-shaped, fluid-filled tube embedded in the temporal bone (Slepecky in Dallos, Popper, and Fay, 1996). It is separated into three longitudinal compartments by two membranes: the basilar membrane (BM) and Reissner's membrane. From a hydromechanical and physiological point of view, the BM is the more important of the two. It supports the organ of Corti, which contains the sensory hair cells. Pressure changes in the cochlear fluids produced by the middle ear excite a mechanical traveling wave that propagates along the BM. The traveling wave magnitude peaks at a location that depends on stimulus frequency: high frequencies peak near the base and low frequencies peak near the apex.

Direct measurements of BM motion demonstrate that, at low sound levels, the response can be highly tuned, with each cochlear location only responding to a narrow range of frequencies (Hubbard and Mountain in Hawkins et al., 1996). BM tuning decreases at high sound levels and appears to involve the presence of a group of sensory cells, the outer hair cells (OHCs). All hair cells respond to mechanical stimuli with voltage changes, but in the case of the OHCs, voltage changes result in cell length changes (Holley in Dallos et al., 1996). These voltage-dependent length changes appear to be mediated by voltage-sensitive transmembrane proteins. This novel form of electromotility is piezoelectric in nature, allowing the length changes to achieve very high velocities.

Many hydromechanical models have been proposed to explain these findings (Hubbard and Mountain in Hawkins et al., 1996; de Boer in Dallos et al., 1996), but these hydromechanical models are computationally intense. As a result, it is common practice to represent cochlear mechanics with a bank of digital bandpass filters that capture the salient features of the mechanical frequency response (Hubbard and Mountain in Hawkins et al., 1996). Filters of this type reproduce the magnitude of the cochlear frequency response reasonably well, but they cannot reproduce the changes in cochlear tuning that occur with changes in stimulus level. In order to replicate the nonlinear features of cochlear mechanics in filterbank models, some authors have used filters with parameters that change with stimulus level (cf. Zhang et al., 2001).

## Inner Hair Cells

The inner hair cells (IHCs) are the receptor cells that provide most of the input to the auditory nerve. Although much progress has been made in measuring basilar membrane motion, little direct data exist to explain how this motion gets coupled to the IHC hair bundle. Comparisons of IHC receptor potentials to inferred BM motion have led to the hypothesis that hair-bundle motion is a high-pass filtered version (cutoff frequency ~400 Hz) of BM motion. Alternatively, Mountain and Cody (1999) have proposed a model in which the OHCs, through their electromotility, displace the IHC hair bundles more directly, perhaps via movements of the tectorial membrane, rather than via enhanced BM motion.

The mechanical-to-electrical transduction process in hair cells is extremely sensitive, resulting in receptor potentials on the order of 1 mV for hair-bundle displacements of 1 nm. This transduction process is believed to be the result of tension-gated channels located in the hair bundle (Mountain and Hubbard in Hawkins et al., 1996). The relationship between stereocilia displacement $x$ and the mechanically induced conductance change $G(x)$ is most commonly modeled using a first-order Boltzmann model (Mountain and Hubbard in Hawkins et al., 1996).

Although IHCs also contain voltage-dependent conductances (Kros in Dallos et al., 1996), most models include only the mechanically sensitive conductance coupled to a linear leakage resistance and a linear membrane capacitance. The RC nature of the membrane acts as a low-pass filter with a cutoff frequency of around 1 kHz. The effect of this filter is to produce an IHC response that follows the fine structure of the stimulus waveform at low frequencies, while at high frequencies it follows the signal envelope (Mountain and Hubbard in Hawkins et al., 1996).

If a linear filter bank is used to represent cochlear mechanics, then it is often desirable to use a rectification function that includes considerable compression to accommodate the large dynamic range of many acoustic signals. Since the D.C. receptor potentials of IHCs measured using best-frequency tones appear to grow as a logarithmic function of sound pressure, a combination of a half-wave rectifier followed by a logarithmic compressor provides a reasonable model (Mountain and Hubbard in Hawkins et al., 1996).

## Auditory Nerve

AN fibers, the cell bodies of which are located in the SG, are divided into two classes, depending on their morphology. Each IHC synapses with 10 to 30 type I AN (AN-I) fibers (Ryugo in Webster, Popper, and Fay, 1992). In most mammals, AN-I fibers synapse only with a single IHC. In contrast, type II fibers (AN-II), which innervate the OHCs, synapse with multiple hair cells. AN-I fibers exhibit spontaneous activity in the absence of sound, and they are often segregated into low (LSR), medium (MSR), and high (HSR) spontaneous rate categories. The pattern of this spontaneous activity is random and is usually modeled as a Poisson or dead-time modified Poisson process. Spontaneous rate tends to correlate with threshold, with HSR fibers being the most sensitive to sound stimuli.

The average firing rate of AN fibers in response to sustained tones is tuned, mimicking the responses at the BM. The peristimulus time histogram (PSTH) exhibits an initial rapid increase, followed by adaptation (Figure 2) to a lower steady-state rate (Ruggero in Popper and Fay, 1992). The steady-state response has only

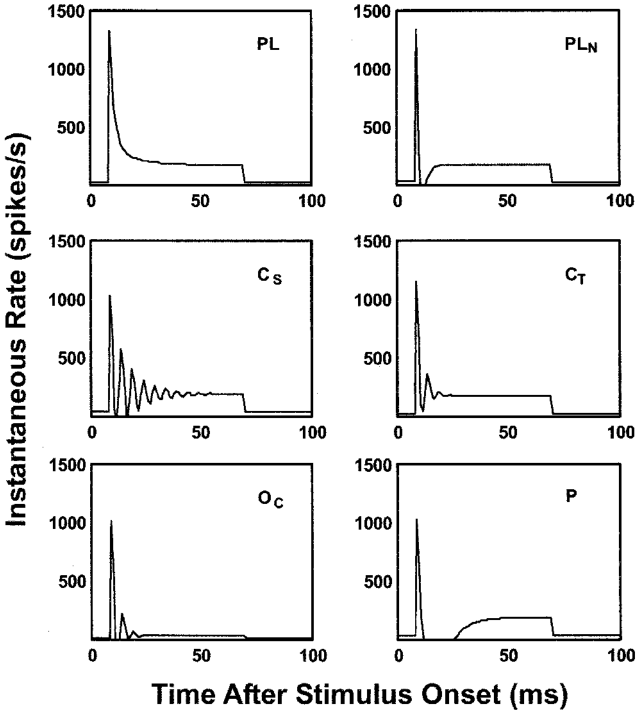

**Figure 2.** Typical auditory nerve and cochlear nucleus peristimulus time histograms. See text for explanation of abbreviations.

a limited dynamic range, typically saturating at sound levels of approximately 20 dB above the fiber's threshold. There are three components to the adaptation. The fastest component, rapid adaptation, has a time constant of a few milliseconds and creates an onset response with a large dynamic range. The second component, short-term adaptation, has a time constant of a few tens of milliseconds. It creates a slower component immediately after the onset response that has a smaller dynamic range, similar to that of the steady-state response. The third component of adaptation operates on a time scale of seconds and is not included in most auditory models.

On a finer time scale, the instantaneous firing rate (IFR) of AN fibers can be modulated on a cycle-by-cycle basis by the acoustic stimulus (phase locking) up to about 4 kHz (Ruggero in Popper and Fay, 1992). The fast dynamics of the AN IFR, coupled with only modest frequency resolution, suggests that we should think of the AN representation as that of a spectrogram that has been optimized more for temporal resolution than for spectral resolution. This excellent temporal resolution plays an important role in sound-source localization, which relies heavily on cues from interaural time delays.

Scant biophysical data are available for the IHC synapse, but since adaptation is not observed in the IHC receptor potentials, adaptation must be taking place in the IHC-AN synapse. The adaptation processes are most commonly assumed to be the result of synaptic vesicle depletion. Synaptic vesicles are typically divided into two or more pools. One of these pools represents vesicles that are docked at the active zones and is often referred to as the releasable pool or the immediate pool. Additional vesicles, which are located near the release sites but appear to be tethered to the cytoskeleton, are not available for immediate release (Mountain and Hubbard in Hawkins et al., 1996).

## Cochlear Nucleus Anatomy

The two CN are the first and only brainstem structures to receive input from the AN. The CN can be anatomically subdivided into several subdivisions, each of which appears to perform a different physiological function. The major subdivisions are the ventral cochlear nucleus (VCN), which is further divided into anteroventral (AVCN) and posteroventral (PVCN) subdivisions, and the DC nucleus (DCN). Fibers of the AN travel through the core of the cochlear spiral and enter the AVCN, where they branch. The ascending branch innervates the AVCN and the descending branch travels through the PVCN and enters the DCN. The ventral regions are surrounded by the marginal shell, which is made up of the small-cell cap (SCC) and the granule-cell layer (GCL). Within a subdivision, the low-frequency fibers project to more ventral regions and the high-frequency fibers project to more dorsal regions. This orderly arrangement of characteristic frequencies is referred to as a *tonotopic projection*.

## Cochlear Nucleus Response Types

The most commonly used physiological classification scheme in the CN is based on the PSTH. These histograms are derived by averaging the responses to short tone bursts presented at the cell's characteristic frequency (Rhode and Greenberg in Popper and Fay, 1992). Figure 2 illustrates six of the most common PSTH types found in the CN. The primary-like (PL) PSTHs are similar to the PSTHs recorded from AN fibers. The primary-like with notch ($PL_N$) response type is similar to the PL type but with better synchrony to the stimulus onset, followed by a transient dip in response due to refractory effects. The chopper-cell PSTHs exhibit periodically modulated activity at the beginning of the histogram, which is the result of the regular firing pattern of these cells becoming synchronized to the stimulus onset. This chopping effect can either be sustained ($C_S$) or transient ($C_T$). The onset cell PSTHs all have large responses to the stimulus onset, followed by reduced or nonexistent activity during the remainder of the stimulus. The onset chopper ($O_C$) PSTH exhibits a transient chopping response after the onset, whereas the $O_L$ type (not shown) shows little or no response after the onset response. Other PSTH types include the pauser (P) and build-up (B) types. The P-type PSTH is characterized by an onset response followed by a period of no activity, which is then followed by a slow build-up of activity. The B-type (not shown) is similar to the P-type but lacks the initial onset response. The different PSTH types are believed to be the result, in part, of differences in intrinsic membrane properties and different degrees of AN fiber convergence and synaptic effectiveness.

## Cochlear Nucleus Neural Circuits

### *Octopus Cells*

Octopus cells are located in the PVCN and are characterized by long, thick primary dendrites that usually arise from one side of the cell body and give the cell the appearance of an octopus. The dendrites of octopus cells are oriented perpendicular to the path of incoming AN fibers (Oertel et al., 2000) which means that they receive input from a range of characteristic frequencies. The lower CF fibers synapse on the soma and the higher CF fibers synapse on the dendrites. Octopus cells generally exhibit onset ($O_L$) responses (Rhode and Greenberg in Popper and Fay, 1992) and appear to be more sensitive to broadband stimuli than AN fibers (Oertel et al., 2000). Functionally, octopus cells appear to act as coincidence detectors that detect synchronous events across AN fibers and may form part of networks involving other subthalamic nuclei devoted to processing temporal features such as duration, periodicity, and echo delay. The octopus cells project to contralateral VNLL terminating in calyx endings (Schwartz in Webster et al., 1992). The secure nature of these terminals reinforces the notion that octopus cells play a role in temporal processing. VNLL is primarily a monaural nucleus (Irvine in Popper and Fay, 1992) that provides inhibitory input to the IC (Schwartz in Webster et al, 1992). The octopus cells also provide diffuse innervation to periolivary areas of the SOC (Schwartz in Webster et al., 1992).

### *Stellate Cells*

The stellate cells (SCs) of the VCN are hypothesized to be part of a system that uses a rate code to represent the acoustic spectrum (Rhode and Greenberg in Popper and Fay, 1992). Stellate cells have dendrites that extend away from the soma in all directions and often divide to form secondary and tertiary dendrites. The SCs can be divided into two classes, based on the path taken by their axons. The T-stellate cells project out of the CN by way of the trapezoid body (hence the name T), and the D-stellate cells are interneurons with axons that follow a descending path (hence the name D) on their way to the DCN and contralateral CN. The dendrites of T-stellate cells (also called planar cells) end in tufts and are generally aligned with the isofrequency plane created by the path of AN fibers, whereas those of D-stellate cells (also called radiate cells) extend radially across the isofrequency planes and branch sparingly. Both T- and D-stellate cells have terminal collaterals in the multipolar cell region of the PVCN and in the DCN (Oertel et al., 1990; Doucet and Ryugo, 1997).

D-stellate cells exhibit $O_C$ responses (Figure 2), have a large dynamic range (80 dB or more), and, as would be expected from their dendritic morphology, are more broadly tuned than AN fibers. In contrast, T-stellate cells exhibit $C_T$ responses (Figure 2) and have frequency tuning characteristics similar to those of AN fibers. Stellate cells have a more regular firing pattern than AN fibers and do not preserve timing information as well as the AN fibers do (Rhode and Greenberg in Popper and Fay, 1992).

The basic stellate-cell circuit is illustrated in Figure 3*A*. The D-stellate cells receive excitatory input from AN-I fibers with a range of CFs and inhibitory input that is believed to come from Golgi cells, which in turn appear to receive their input from AN-II fibers (Ferragamo, Golding, and Oertel, 1998). Golgi cells are small inhibitory interneurons located in the marginal shell with dendrites that branch extensively near the cell body (Cant in Webster et al., 1992). The Golgi cell axons branch even more extensively, forming a plexus with thousands of endings in nearby regions. In contrast to the D-stellate cells, the T-stellate cells receive excitatory input from AN-I fibers with a narrow range of CFs, and they receive inhibitory input from D-stellate cells as well as from vertical cells located in the deep DCN (Ferragamo et al., 1998). The DCN vertical cells receive excitatory input from AN-I fibers with a narrow range of CFs and are strongly inhibited by the more broadly tuned D-stellate cells. The T-stellate cells are the output neurons of this circuit; their axons project to the IC.

### *Bushy Cells*

The major cell types of the AVCN are the spherical bushy cells (SBCs) and the globular bushy cells (GBCs). The term *bushy cell* refers to their appearance, with short primary dendrites that originate from one hemisphere of the cell body and give rise to a profusion of thin, shrub-like appendages. SBCs are believed to play an important role in sound localization and are specialized to preserve timing information. The basic SBC circuit is shown in Figure 3*B*. SBCs receive their excitatory input from AN-I fibers tuned to a narrow range of frequencies, and in most respects SBCs have response properties, such as their primary-like PSTHs (Figure 2), that are very similar to those of AN fibers. The AN fibers that synapse on the SBC cell body give rise to very large synaptic endings known as the endbulbs of Held (Cant in Webster et al., 1992). These very secure synapses, in combination with a low-threshold potassium conductance in the SBCs, enhance phase locking to the acoustic stimulus (presumably through a coincidence mechanism) to be even more precise than that found in the AN. SBCs receive inhibitory input from vertical cells in the DCN. This inhibitory input is delayed with respect to the excitatory input from the AN and not as effective as the excitatory input, but it may play a role in echo suppression (Rhode and Greenberg in Popper and Fay, 1992).

SBCs project to the ipsilateral and contralateral medial superior olive (MSO), where timing differences (ITD) between the two ears are processed, and the ipsilateral lateral superior olive (LSO), where amplitude differences (ILD) are processed (Oliver in Webster et al., 1992). SBCs project as well to more central nuclei such as the contralateral ventral nucleus of the lateral lemniscus (VNLL) (Oertel and Wickesberg in Oertel, Fay, and Popper, 2002).

The innervation pattern of the GBC is similar to that of the SBC (Figure 3*B*) and forms a second part of the ILD pathway. They tend to have dendritic fields that are somewhat larger than SBCs and are preferentially contacted by HSR fibers. GBCs, like SBCs, receive extensive input from AN-I fibers on their cell bodies, but these synapses are smaller than the endbulb type found on SBCs. GBCs have response properties similar to those of AN fibers with $\mathrm{PL_N}$ PSTHs (Figure 2*B*), but with a higher degree of synchronization to the acoustic input (Yin in Oertel et al., 2002).

SBCs project primarily to the contralateral SOC, specifically the medial nucleus of the trapezoid body (MNTB), which provides inhibitory input to the LSO (Oliver and Huerta in Webster et al., 1992). The SBC axonal endings terminate in a calyx surrounding the cell bodies of the principal cells of the MNTB. This synaptic specialization suggests that timing is important in the ILD pathway as well as in the ITD pathway. Other projections of the GBCs include the ipsilateral lateral nucleus of the trapezoid body (LNTB), the contralateral VNLL, and periolivary nuclei on both sides (Yin in Oertel et al., 2002).

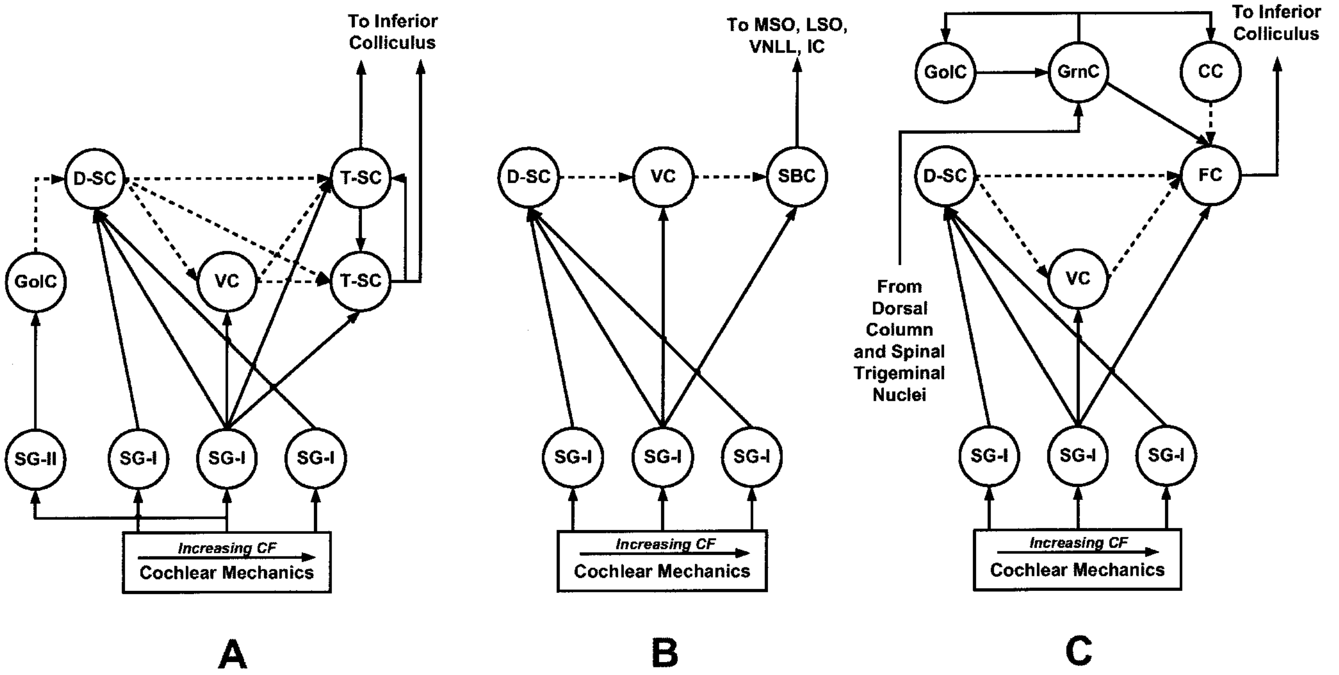

**Figure 3.** Examples of neural circuits in the cochlear nucleus. Excitatory connections are indicted by solid lines and inhibitory connections are indicated by broken lines. *A*, The stellate cell circuit. *B*, The sperical bushy cell circuit. *C*, The fusiform circuit. See text for explanation of abbreviations.

### Fusiform and Giant Cells

The DCN is believed to be involved in processing spectral cues that are important for sound source location, especially source elevation. Cats with lesions to the DCN output pathways exhibit significant deficits in their ability to orient to sources at different locations (Young and Davis in Oertel et al., 2002). The DCN is usually subdivided into three layers, a superficial or molecular layer, an intermediate layer called the granular or fusiform cell layer, and a polymorphic or deep layer. The principal cells of the DCN are the fusiform cells (from which the fusiform cell layer gets its name) and the giant cells located in the deep layer. The apical dendrites of fusiform cells (also called pyramidal cells) are highly branched and extend up into the molecular layer, while the less highly branched basal dendrites extend down into the deep layer. The dendritic morphology of the giant cells is more diverse, ranging from elongate to radiate (Cant in Webster et al., 1992). Beneath the fusiform cells are a group of cells called vertical cells. These cells have their dendritic and axonal arbors confined to an isofrequency lamina. There are two groups of vertical cells. The more superficial group gives rise to only a local axon, the deeper group gives rise to axons that project to the VCN (Rhode, 1999).

The fusiform cell circuit is shown in Figure 3*C*. The basal dendrites of fusiform cells receive excitatory input from AN-I fibers with a limited range of CFs, a narrow-band inhibitory input from the vertical cells of the DCN, and a wide-band inhibitory input from the D-stellate cells of the VCN. The inhibitory input from the vertical cells is quite strong, and as a result, fusiform cells respond poorly or not at all to pure tones. They respond well to broadband stimuli except when there is a spectral notch at the characteristic frequency, in which case these cells are strongly inhibited (Rhode and Greenberg in Popper and Fay, 1992). As a result of these properties, fusiform cell models create a spectral representation that accentuates spectral notches (Hancock and Voigt, 1999), which are important features of the HRTF for determining sound source elevation. The fusiform cells also receive excitatory input on their apical dendrites from the granule cells, which in turn receive input from the dorsal column and spinal trigeminal nuclei of the somatosensory system. This somatosensory input appears to modify DCN response properties based on head and pinna position (Kanold and Young, 2001).

The giant cell circuit (not shown) is similar to the fusiform cell circuit except that the giant cells do not receive direct input from granule cells and AN input to the giant cells spans a large range of characteristic frequencies. Fusiform and giant cells project to the contralateral ICC and also project to the contralateral DNLL, which provides inhibitory input to both ICs (Oliver and Huerta in Webster et al., 1992).

## Discussion

Significant progress has been made in understanding the anatomy and physiology of the subthalamic auditory pathways, but many questions remain. For example, the experimental data suggest that OHCs contribute to the tuned response of the BM and IHCs, but how OHCs perform their function is not well understood. Much of the basic circuitry of the CN has been worked out, but it is not clear how many subpopulations exist for each of the basic cell types described in this article. And perhaps the greatest question of all is, how is information in the parallel pathways leaving the CN reintegrated into a unified percept by higher centers? To answer these questions, future research will need to take an integrated approach, with computational models being used to aid the design and interpretation of anatomical and physiological experiments. These models will need to incorporate the major features of individual cell types as well as the interactions between cell types at different levels of the auditory system. Efforts to create suitable large-scale models have begun (cf. Hawkins et al., 1996), but much remains to be done.

# Auditory Scene Analysis

*Guy J. Brown*

## Introduction

We usually listen in environments that contain many simultaneously active sound sources. The auditory system must therefore parse the acoustic mixture that reaches our ears to segregate a target sound source from the background of other sounds. Bregman (1990) describes this process as *auditory scene analysis* (ASA) and suggests that it takes place in two conceptual stages. The first stage, *segmentation*, decomposes the acoustic mixture into its constituent components. In the second stage, acoustic components that are likely to have arisen from the same environmental event are *grouped*, forming a perceptual representation (*stream*) that describes a single sound source. Streams are subjected to higher-level processing, such as language understanding.

Bregman's account makes a distinction between *schema-driven* and *primitive* mechanisms of grouping. Schema-driven grouping applies learned knowledge of sound sources such as speech in a top-down manner (in this regard, the term "schema" refers to a recurring pattern in the acoustic environment). Primitive mechanisms operate on the acoustic signal in a bottom-up fashion and are well described by Gestalt heuristics such as proximity and common fate (see Contour and Surface Perception). Primitive organization is both *simultaneous* and *sequential.* Simultaneous grouping operates on concurrent sounds, using principles such as similarity of fundamental frequency. Sequential grouping combines acoustic events over time, according to heuristics such as temporal proximity and frequency proximity.

At the physiological level, segmentation corresponds (at least in part) to peripheral auditory processing, which performs a frequency analysis of the acoustic input. To a first approximation, this frequency analysis can be modeled by a bank of band-pass filters with overlapping passbands, in which each channel simulates the filtering characteristics of one location on the basilar membrane (see Auditory Periphery and Cochlear Nucleus). From the output of each filter, a simulation of the auditory nerve response can be obtained by rectification and compression or from a detailed model of inner hair cell function. In contrast, the physiological substrate of auditory grouping is much less well understood (Feng and Ratnam, 2000). As a result, models of ASA tend to be functional in approach. In the current review, we focus on models that are at least physiologically plausible; however, it should be noted that there is also a substantial literature that has addressed computational modeling of ASA from a more abstract information-processing perspective (e.g., Rosenthal and Okuno, 1998).

## Models of Sequential Grouping

Sequential grouping can be demonstrated by playing listeners a repeating sequence of two alternating tones with different frequencies (ABAB . . .). When the sequence is played rapidly or when the frequency separation between the tones is large, the sequence is heard to split into separate streams (A-A- . . . and B-B- . . .). This phenomenon is known as *auditory streaming* (Bregman, 1990). Listeners are able to direct their attention to only one of the streams, which appears to be subjectively louder than the other. Auditory streaming may therefore be regarded as an example of figure-ground separation.

Auditory streaming may be viewed as a consequence of sequential grouping heuristics that allocate tones to streams depending on their proximity in time and frequency. Several modeling studies have demonstrated that such principles can be implemented by relatively low-level physiological mechanisms. For example, Beauvois and Meddis (1996) describe a model of auditory streaming that has its basis in mechanisms of peripheral auditory function. The model utilizes two pathways: one in which auditory nerve activity is smoothed by temporal integration and an "excitation-level" path that adds a cumulative random element to the output of the temporal integration path. Firing activity is considered in three auditory filter channels: one at the frequency of each tone and one in between them. The channel with the highest activity in the excitation-level pathway is selected as the dominant "foreground" percept; the remaining channels are attenuated and become the "background." This simple model quantitatively matches auditory streaming phenomena, such as the effect of rate of presentation and frequency separation. Furthermore, the inclusion of a random element in the model (which is assumed to originate from the stochastic nature of auditory nerve firing patterns) explains how spontaneous shifts of attention can occur.

McCabe and Denham (1997) have extended the Beauvois and Meddis model by applying similar principles within a two-layer neural architecture. In their model, "foreground" and "background" neural arrays are connected by reciprocal inhibitory connections, which ensure that activity appearing in one array does not appear in the other (Figure 1). Their network is sensitive to frequency proximity because the strength of inhibitory feedback is related to the frequency difference between acoustic components. Additionally, each layer receives a recurrent inhibitory feedback related to the reciprocal of its own activity. As a result, previous activity in the network tends to suppress differences in subsequent stimuli. This mechanism may be viewed as a neural implementation of Bregman's (1990) "old plus new heuristic," which states that the auditory system prefers to interpret a current sound as a continuation of a previous sound unless there is strong evidence to the contrary. The inclusion of this heuristic within McCabe and Denham's model allows it to explain the effect of background organization on the perceptual foreground.

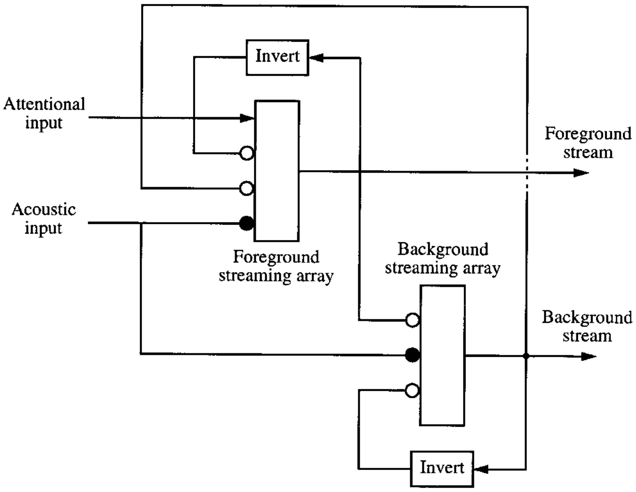

**Figure 1.** McCabe and Denham's model of auditory stream segregation. Foreground and background streams are encoded by separate neural arrays, which have reciprocal inhibitory connections. Each layer also receives recurrent inhibition. Solid circles indicate excitatory connections; open circles indicate inhibitory connections. (Modified from McCabe and Denham (1997).)

A more central explanation for auditory streaming is given by Todd (1996), who suggests that mechanisms of rhythm perception and stream segregation are underlain by cortical maps of periodicity-sensitive cells. In his model, periodicity detection leads to a spatial representation of the temporal pattern of the stimulus in terms of its amplitude modulation (AM) spectrum. Acoustic events whose AM spectra are highly correlated (as judged by a neural cross-correlation mechanism) are perceptually grouped, whereas events with uncorrelated AM spectra are segregated. Todd's model is able to qualitatively replicate the dependence of auditory streaming on tone frequency and temporal proximity.

The models of Todd (1996) and McCabe and Denham (1997) suggest that the auditory responses associated with different streams are encoded spatially in neural arrays. An alternative is that auditory streams are encoded temporally. For example, Wang (1996) suggests a principle of *oscillatory correlation*, which is a development of von der Malsburg's temporal correlation theory (von der Malsburg and Schneider, 1986). In Wang's scheme, neural oscillators alternate rapidly between relatively stable states of activity (the active phase) and inactivity (the silent phase). Oscillators that encode features of the same stream are synchronized (phase locked with zero phase lag) and are desynchronized from oscillators that represent different streams.

Wang has implemented the oscillatory correlation principle in a model of auditory streaming, in which oscillators are arranged within a two-dimensional time-frequency network. The time axis of the network is assumed to be constructed by a systematic arrangement of neural delay lines. Each oscillator is connected to others in its neighborhood with excitatory connections whose strength diminishes with increasing distance in time and frequency. In addition, every oscillator sends excitation to a global inhibitor, which feeds back inhibition to each oscillator in the network. Oscillators that are close in time and frequency tend to synchronize because the excitatory connections between them are strong. However, groups of oscillators that do not receive mutually supportive excitation tend to desynchronize because of the action of the global inhibitor. As the network dynamics evolve, the combined effects of local excitation and global inhibition cause streams of synchronized oscillators to form. The model qualitatively reproduces a number of auditory streaming phenomena. However, the oscillatory dynamics proceed rapidly, so Wang's network is not able to account for the gradual buildup of the auditory streaming effect over time.

## Models of Simultaneous Grouping

Simultaneous grouping mechanisms exploit differences in the characteristics of concurrent sounds in order to perceptually segregate them. For example, the ability of listeners to identify two simultaneously presented vowels ("double vowels") can be improved by introducing a difference in fundamental frequency (F0) between the vowels (Bregman, 1990). Apparently, simultaneous grouping mechanisms are able to segregate the acoustic components related to each F0 and hence retrieve the spectra of the two vowels.

Meddis and Hewitt (1992) describe a model of double-vowel identification based on the *correlogram*, a model of auditory pitch analysis. A correlogram is formed by computing a running autocorrelation at the output of each auditory filter channel, giving a two-dimensional representation in which frequency and time lag are represented on orthogonal axes. Meddis and Hewitt suggest that the correlogram could be computed neurally by using a system of delay lines and coincidence detectors. The F0 of one of the vowels is identified from the correlogram, and channels whose response is dominated by that F0 are removed, thus allowing a clearer view of the second vowel. This mechanism fails to separate the vowels when they both have the same F0 and successfully predicts that vowel identification performance improves when a difference in F0 is introduced.

The Meddis and Hewitt model is based on a strategy of "exclusive allocation" (Bregman, 1990); all of the energy in a single auditory filter channel is allocated to one vowel or the other. However, this need not be the case. De Cheveigné (1997) describes an approach that uses a "neural cancellation filter" to partition the energy in each channel between vowel percepts. In his scheme, a correlogram is computed, and the fundamental period of one of the vowels is identified. This period is canceled in each channel by a neural comb filter, which is implemented by a neuron with a delayed inhibitory input. This mechanism removes firing activity with a periodicity equal to the inhibitory delay. An advantage of de Cheveigné's approach is that it predicts an increase in listeners' performance with increasing difference in F0 for vowels that are weak in comparison to a harmonic background. The Meddis and Hewitt model is unable to reproduce this result because its exclusive allocation scheme tends to remove the evidence for a weak vowel when the stronger vowel is canceled.

Brown and Wang (1997) have described a neural oscillator model of vowel segregation, which is essentially an implementation of Meddis and Hewitt's (1992) scheme within an oscillatory correlation framework. In their model, each channel of the correlogram is associated with a neural oscillator. Oscillators corresponding to channels that are dominated by the same F0 become synchronized and are desynchronized from channels that are dominated by a different F0. When there is no difference in F0 between the two vowels, a single group of synchronized oscillators forms. However, when a difference in F0 is introduced, the two vowels are segregated according to their F0s, and the channels making up each vowel are encoded as separate groups of synchronized oscillators.

Von der Malsburg and Schneider (1986) describe a related model of simultaneous grouping based on temporal correlation of neural responses. Their scheme employs a neural architecture in which each member of a fully connected network of excitatory cells (E-cells) receives an input from one auditory filter channel. In addition, E-cells receive inhibition from a common inhibitory cell (H-cell). E-cells that receive simultaneous inputs tend to become synchronized by the excitatory links between them and tend to become desynchronized from other cells owing to the influence of inhibition from the H-cell. The network therefore displays a sensitivity to the common onset of acoustic components and may be regarded as implementing a Gestalt principle of common fate (Bregman, 1990).

## The Role of Temporal Continuity

With the exception of that of Wang (1996), relatively few modeling studies have demonstrated the integration of simultaneous and sequential grouping principles within the same computational framework. However, several studies have shown how a complex time-frequency mixture can be organized using simultaneous grouping principles and temporal continuity constraints.

Grossberg (1999) describes a multistage model of ASA that implements grouping by common F0 and good continuation. The first stage of his model builds redundant spectral representations of the acoustic input in a "spectral stream" layer. Each stream is represented by a separate neural array. These representations are filtered by neural "harmonic sieves," which connect a node in a "pitch stream" layer with spectral regions near to the harmonics of the corresponding pitch value. Pitch representations compete across streams to select a winner, and the winning pitch node sends top-down signals via harmonic connections to the spectral stream layer. According to an adaptive resonance theory (ART) matching rule, frequency components in the spectral stream that are consistent with the top-down signal are selected, and others are suppressed (see Adaptive Resonance Theory). Selected components reactivate their pitch node, and further top-down signals are produced. In this way, a resonance develops that binds together the frequency components constituting a sound source and its corresponding pitch.

Grossberg's model is able to account for simple simultaneous grouping phenomena, such as the perceptual fusion of components with the same F0. His model also reproduces the auditory continuity illusion (Bregman, 1990), in which a pure tone is heard to continue through a brief interrupting noise, even though the tone is not physically present during the noise burst. It is able to do so because a resonance develops for the tone that is maintained during the noise burst. The ART matching rule then selects the tone from the noise, and competitive interactions cause the tone and residual noise to be allocated to different streams.

Wang and Brown (1999) describe a neural oscillator model whose two-layer architecture echoes the two conceptual stages of ASA. The first (segmentation) layer consists of a two-dimensional time-frequency grid of oscillators with a global inhibitor (Figure 2). In this layer, excitatory connections are formed between auditory filter channels that have a similar temporal response. As a result, segments form in the time-frequency plane and thus correspond to harmonics and formants. The global inhibitor ensures that each segment desynchronizes from the others; the first layer therefore embodies the segmentation stage of ASA, in which the acoustic signal is split into its constituent elements. The second layer receives an input from the first layer. Also, segments in the second layer are connected by excitatory links if they represent time-frequency regions that are dominated by the same F0. As a result, synchronized groups of segments emerge in the second layer, each of which corresponds to a stream with harmonically related components.

## Models of Schema-Driven Grouping

Liu, Yamaguchi, and Shimizu (1994) describe a neural oscillator model of vowel recognition that may be regarded as an implementation of schema-driven grouping. The model consists of an input layer and three layers of oscillators labeled A, B, and C, which are likened to regions of the auditory cortex. The A ("feature extraction") layer identifies local peaks in the acoustic spectrum and encodes them as separate groups of oscillations, which are assumed to correspond to vowel formants. The B ("feature linking") layer acts as a simple associative memory, in which hardwired connections encode the relationship between formant frequencies for different vowels. Associative interactions between the B layer, together with top-down and bottom-up interactions between the A and B layers, lead to the activation of a vowel in terms of a global pattern of synchronized oscillations. The C ("evaluation") layer assesses the synchronization in each formant region and outputs a vowel category. Top-down reinforcement from the B center confers robustness in noise; it is demonstrated that the model is able to recognize vowels robustly in the presence of multispeaker babble.

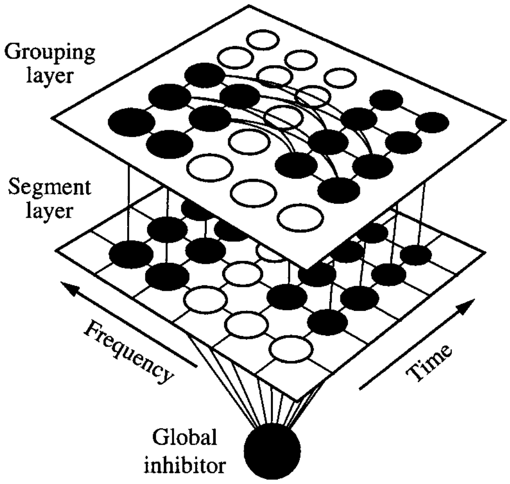

**Figure 2.** The two-layer neural oscillator model of Wang and Brown (1999). In the first layer, segments are formed that correspond to harmonics and formants. The second layer groups segments according to their fundamental frequency (F0); those with the same F0 form a stream in which all oscillators are synchronized and are desynchronized from other streams. (Modified from Wang and Brown (1999).)

## Discussion

The modeling studies reviewed here propose a neurobiological basis for the principles of auditory organization expounded in Bregman's account of ASA. Clearly, the models differ in their level of explanation, ranging from peripheral (Beauvois and Meddis, 1996) to cortical (Todd, 1996). Without exception, their approach is functional; currently, there is insufficient knowledge about the physiological mechanisms of ASA to attempt a detailed physiological model. It is likely that future research in this field will see a closer synergy between computational modeling studies and neurophysiological investigation.

Various strategies have been proposed for the neural encoding of auditory streams. Beauvois and Meddis (1996) stress that the perceptual separation of sounds need not imply a physical separation of their corresponding representations; in their model, auditory filter channels belonging to a nonattended stream are simply attenuated. This contrasts with the approaches described by Grossberg (1999) and McCabe and Denham (1997), in which different auditory streams are encoded by separate neural arrays. A further approach is to encode streams temporally in the responses of synchronized neural firing patterns (von der Malsburg and Schneider, 1986; Wang, 1996). Although all of these approaches are plausible, none are currently supported by strong neurophysiological evidence.

Many models of ASA require systematic time delays longer than those currently known to exist in the auditory system. Models of double-vowel separation based on the correlogram require delays of the order of 20 ms (Meddis and Hewitt, 1992; de Cheveigné, 1997). Similarly, it is questionable whether the system of delay lines employed in Wang's (1996) neural oscillator model is physiologically realizable. The temporal correlation architecture of von der Malsburg and Schneider (1986) does not suffer from this difficulty, since their network does not have an explicit time axis. However, the explanatory power of their model is weak in comparison to Wang's model, because temporal and frequency relationships between acoustic inputs are not preserved.

Generally speaking, the role of auditory attention has been neglected in computer models of ASA. In auditory streaming, a listener's attention can shift randomly between organizations or may be consciously directed to the high or low tones. The model of Beauvois and Meddis (1996) accounts for the former but not the latter. Similarly, McCabe and Denham's model includes an attentional input (Figure 1), but it is not utilized in their simulations. Wang (1996) suggests that in a neural oscillator framework, attention is paid to a stream when its constituent oscillators reach their active phases; attention therefore alternates quickly among the streams in turn. However, such a scheme does not explain how listeners are able to direct their attention to a particular stream over a sustained period of time.

Also, few models have attempted to model the interaction between top-down and bottom-up grouping mechanisms. In principle, the mechanism of recurrent neural connections described by Liu et al. (1994) could form the basis for such a model. Similarly, Grossberg's (1999) ART scheme could form the basis for a grouping mechanism in which bottom-up features interact with top-down information about the characteristics of sound sources.

The motivation for most of the studies reviewed here is to gain insight into the mechanisms of ASA through computational modeling. However, computer sound separation devices have many real-world applications, such as in hearing prostheses and as preprocessors for robust automatic speech recognition in noise. For example, Wang and Brown (1999) have applied their model to the separation of voiced speech from interfering sounds, with some success. Because they are founded on neurobiological principles, such approaches to sound separation may offer performance advantages over other techniques, such as blind statistical methods.

# Axonal Modeling

*Christof Koch and Öjvind Bernander*

## Introduction

Axons are highly specialized "wires" that conduct the neuron's output signal to target cells—in the case of cortical pyramidal cells up to 10,000 other cortical neurons. As such they are highly specialized, with a relatively stereotypical behavior. Most authors agree that their role in signaling is largely limited to making sure that whatever pulse train is put into one end of the axon is rapidly and faithfully propagated to the other end. This is in contrast to the complexity of electrical events occurring at the cell body and in the dendritic tree, where the information from thousands of synapses is integrated.

Despite the uniformity of electrical behavior, there is great morphological variability that largely reflects a trade-off between propagation speed and packing density. Axonal size varies over four orders of magnitude: diameters range from 0.2-$\mu$m fibers in the mammalian central nervous system to 1 mm in squid; lengths range from a few hundred microns to over a meter for motor neurons (Kandel, Schwartz, and Jessell, 2000). Some axons are bound only by the thin cellular membrane, while others are wrapped in multiple sheaths of myelin. An example of an axonal arbor is shown in Figure 1.

The majority of nerve cells encode their output as a series of brief voltage pulses. These pulses, also referred to as *action potentials* or *spikes*, originate at or close to the cell body of nerve cells and propagate down the axon at constant amplitude. Their shape is relatively constant across species and types of neurons. Common to all is the rapid upstroke (depolarization) of the membrane above 0 mV and the subsequent, somewhat slower, downstroke (repolarization) toward the resting potential and slightly beyond to more hyperpolarized potentials. At normal temperatures, the entire sequence occurs within less than 1 ms. A minority of cell types are axonless and appear to use graded voltage as output, such as cells in the early part of the retina or interneurons in invertebrates (Roberts and Bush, 1981). Action potentials are such a dominant feature of the nervous system that for a considerable period of time it was widely held—and still is in parts of the neural network community—that all neuronal computations involve only these all-or-none events. This belief provided much of the impetus behind the neural network models originating in the late 1930s and early 1940s (see SINGLE-CELL MODELS).

The ionic mechanisms underlying the initiation and propagation of action potentials were elucidated in the squid giant axon by a number of workers, most notably Hodgkin and Huxley (1952). Today, with the widespread availability of cheap and almost unlimited computational power, it is very difficult to imagine the difficulty that Hodgkin and Huxley faced 50 years ago. Not only did they have to derive a proper mathematical formalism based on incomplete data, they also had to solve a nonlinear partial differential equation, the cable equation, using a very primitive hand calculator.

For this work they shared, together with Eccles, the 1963 Nobel prize in physiology and medicine (for a historical overview, see Hodgkin, 1976). Their model has played a paradigmatic role in biophysics; indeed, the vast majority of contemporary biophysical models use essentially the same mathematical formalism Hodgkin and Huxley introduced 50 years ago. This is all the more surprising because the kinetic description of the continuous, deterministic, and macroscopic membrane permeability changes within the framework of the Hodgkin-Huxley model was achieved without any knowledge of the underlying all-or-none, stochastic, and microscopic ionic channels.

Given its importance, we will describe the Hodgkin-Huxley model and its assumptions in some detail in the following section. We then introduce the two classes of axons found in most animals, myelinated and nonmyelinated, and describe their differences. Ax-

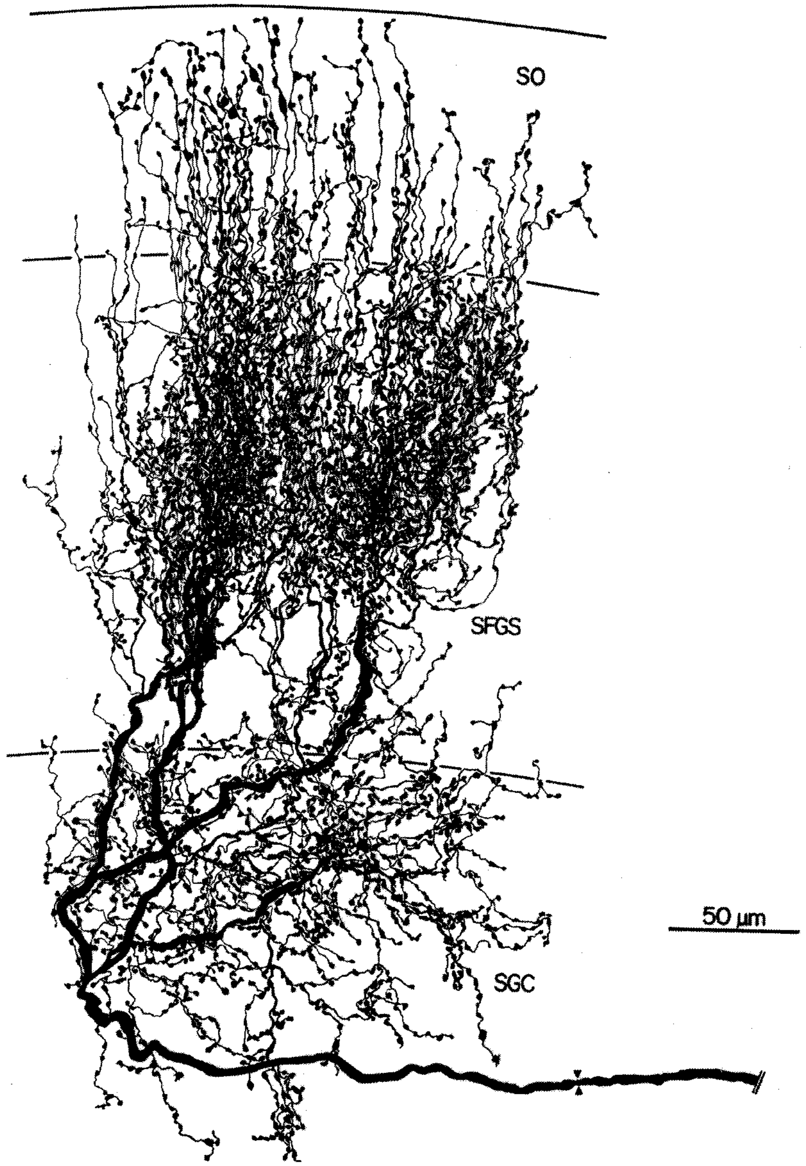

**Figure 1.** Axonal terminations. An axon from nucleus isthmi terminating in turtle tectum was labeled with horseradish peroxidase and reconstructed from a series of parallel sections. The thick parent trunk (3 $\mu$m) is wrapped in myelin and shows a node of Ranvier (triangles). The thin ($<1$ $\mu$m) branches are nonmyelinated and are home to approximately 3,600 synaptic boutons (bulbous thickenings), where contact is made onto other cells. The boutons vary greatly in size but average about 1.5 $\mu$m in diameter. (From Sereno, M. I., and Ulinski, P. S., 1987, Caudal topographic nucleus isthmi and the rostral nontopographic nucleus isthmi in the turtle, *Pseudemys scripta, J. Comp. Neurol.*, 261:319–346. Copyright © 1987 by Wiley-Liss. ## The Hodgkin-Huxley Model of Action Potential Generation

Electrical current in nerve cells is carried by the flow of ions through membrane proteins called *channels*. The concentration of sodium ions is high in the extracellular fluid and low in the intracellular axoplasm. This *concentration gradient* gives rise to a tendency for sodium ions to flow into the cell. At some membrane potential, termed the *reversal potential*, the effect of the concentration gradient will be canceled by the *electrical gradient*, and so the net flow of sodium ions will be zero at that point. The channel transitions into its closed state by virtue of a conformational state in the underlying molecular structure. In the model, this is described by a change in the $m$ variable. A similar situation holds for potassium ions flowing through separate potassium-selective channels, except that the concentration gradient is reversed.

In the squid giant axon, the membrane potential is determined by three conductances: a voltage-independent (passive) leak conductance, $g_l$, a voltage-dependent (active) sodium conductance, $g_{\mathrm{Na}}$, and an active potassium conductance, $g_{\mathrm{K}}$. The equivalent circuit used to model the membrane is shown in Figure 2. The conductances are in series with batteries, the values of which correspond to the respective reversal potentials of the ionic currents, $E_l$, $E_{\mathrm{Na}}$, and $E_{\mathrm{K}}$. The outside is connected to ground under the assumption that the resistivity of the external medium is negligible.

The time course of an action potential is illustrated in Figure 3. In this simulation of a membrane patch, a brief current pulse initiates an action potential. Before stimulation, the membrane voltage is at rest, $V_m = -65$ mV. At this potential, $g_{\mathrm{Na}}$ and $g_{\mathrm{K}}$ are almost fully inactivated. $g_{\mathrm{K}}$ is still much larger than $g_{\mathrm{Na}}$, and the membrane

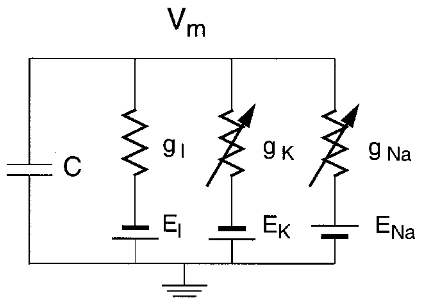

**Figure 2.** Schematic of ionic channel and neuronal membrane: Equivalent circuit of axonal membrane. The Hodgkin-Huxley model of squid axon incorporates a capacitance and three conductances. Two of the conductances are voltage dependent (active), $g_{\mathrm{Na}}$ and $g_{\mathrm{K}}$, while the third is a passive "leak" conductance, $g_l$. The maximal conductances are 120, 36, and 0.3 ms/cm$^2$, respectively. Each conductance is in series with a battery that defines the *reversal potential* for each conductance type. The values are $E_{\mathrm{Na}} = 50$, $E_{\mathrm{K}} = -77$, and $\mathrm{E}_l = -54.3$ mV. See text for the voltage dependences of $g_{\mathrm{Na}}$ and $g_{\mathrm{K}}$. The top rail corresponds to the axoplasm (inside) of the axon, while the bottom rail, grounded, is the external medium. When a *membrane action potential* or *space clamp* is modeled, only one compartment is used, as shown, and the spatial structure of the membrane is ignored. When *propagating action potentials* are modeled, the specific resistivity of the axoplasm, $R_a = 34.5$ Ωcm, cannot be ignored. $R_a$ is then modeled as a series of resistors connecting identical compartments that correspond to different spatial locations along the axon. The membrane capacitance is 1 $\mu$m F/cm$^2$.

is dominated by the leak current and the residual potassium current. The applied current slowly depolarizes the membrane by charging up the capacitance. As $V_m$ approaches threshold ($V_t \sim -50$ mV), sodium channels begin to open up, allowing for the influx of Na$^+$ ions, which further depolarizes the membrane. About 1 ms later, two events occur to bring the voltage back toward and somewhat beyond the resting value: the sodium conductance inactivates, that is, the sodium channels slowly close again, and potassium channels open up, causing an outward current to flow. This outward current forces the membrane potential below the resting value of $-65$ mV (hyperpolarization), but the K$^+$ conductance too eventually deactivates, allowing $g_l$ to pull $V_m$ back to rest.

### Mathematical Formulation

The equation describing the circuit in Figure 2 is:

$$C\frac{dV_m}{dt} = g_l(E_l - V_m) + g_{\mathrm{Na}}(E_{\mathrm{Na}} - V_m) + g_{\mathrm{K}}(E_{\mathrm{K}} - V_m) \qquad (1)$$

While $g_l$ is constant, $g_{\mathrm{Na}}$ and $g_{\mathrm{K}}$ are time and voltage dependent:

$$\begin{aligned} g_{\mathrm{Na}} &= \bar{G}_{\mathrm{Na}} \cdot m(t)^3 h(t) \\ g_{\mathrm{K}} &= \bar{G}_{\mathrm{K}} \cdot n(t)^4 \end{aligned}$$

where the constants $\bar{G}_{\mathrm{Na}}$ and $\bar{G}_{\mathrm{K}}$ are the maximal conductances and the time and voltage dependence reside in the so-called *gating variables*, described by the state variables $m$, $h$, and $n$. These fictitious variables follow first-order kinetics, relaxing exponentially toward a steady-state value $x_\infty$ with a time constant $\tau_x$:

$$\begin{aligned} \frac{dm}{dt} &= \frac{m_\infty(V_m) - m}{\tau_m(V_m)} \\ \frac{dh}{dt} &= \frac{h_\infty(V_m) - h}{\tau_h(V_m)} \\ \frac{dn}{dt} &= \frac{n_\infty(V_m) - n}{\tau_n(V_m)} \end{aligned}$$

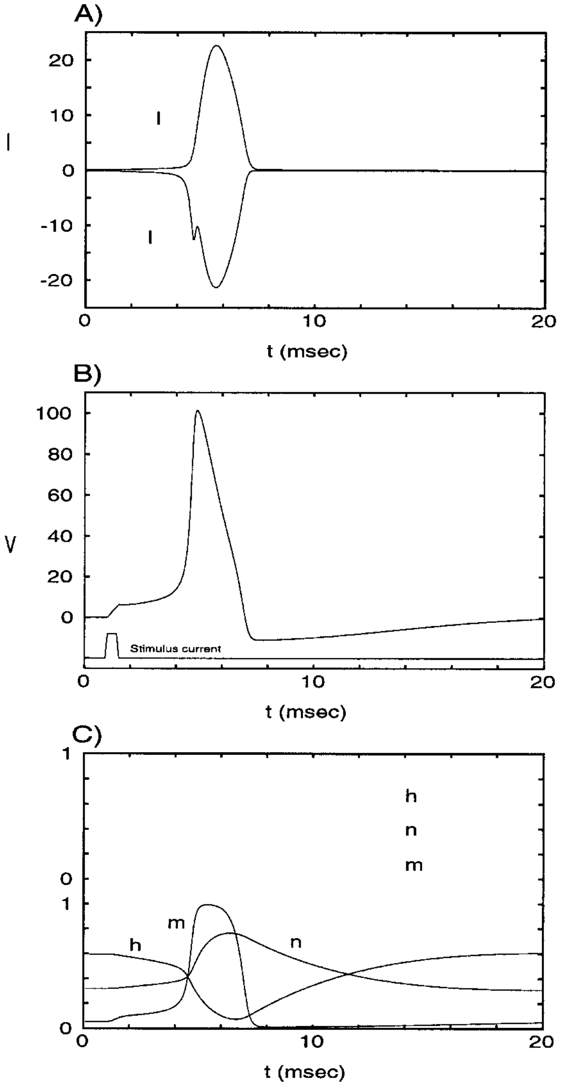

**Figure 3.** Action potential. Computed action potential in response to a 0.5-ms current pulse of 0.4-nA amplitude (solid lines) compared to a subthreshold response following a 0.35-nA current pulse (dashed lines). *A*, Time course of the two ionic currents. Note their large sizes compared to the stimulating current. *B*, Membrane potential in response to sub- and suprathreshold stimuli. The injected current charges up the membrane capacity (with an effective membrane time constant $\tau = 0.85$ ms), enabling sufficient $I_{\mathrm{Na}}$ to be recruited to outweigh the increase in $I_K$ (due to the increase in driving potential). The smaller current pulse fails to trigger an action potential, but causes a depolarization followed by a small hyperpolarization due to activation of $I_K$. *C*, Dynamics of the gating variables. Sodium activation $m$ changes much more rapidly than either $h$ or $n$. The long time course of potassium activation $n$ explains why the membrane potential takes 12 ms after the potential has first dipped below the resting potential to return to baseline level. (From Koch, C., 1999, *Biophysics of Computation*, Cambridge, MA: MIT Press, p. 150.)

The steady-state activations ($m_\infty$, $h_\infty$, and $n_\infty$) have a sigmoidal dependence on voltage. The *activation* variables $m$ and $n$ have the asymptotes $\lim_{V_m \to -\infty} m_\infty, n_\infty = 0$, $\lim_{V_m \to \infty} m_\infty, n_\infty = 1$, while the reverse holds for the *inactivation* variable $h$. That is, for very negative voltages, the $m$ and $n$ variables shut off current flow through both channel types, while at very positive potentials, the $h$ particle shuts off the sodium current. The time "constants" ($\tau_m$, $\tau_h$, and $\tau_n$)

are not constant with respect to voltage but rather have a roughly bell-shaped dependence, with peaks in the −80 to −40 mV range. The $x_\infty$ and $\tau_x$ values were the ones actually measured by Hodgkin and Huxley using a series of voltage clamp steps. Instead of fitting these curves directly with mathematical functions, which would be sufficient for simulation purposes, they chose to express $x_\infty$ and $\tau_x$ in terms of the variables $\alpha_x$ and $\beta_x$:

$$x_\infty = \frac{\alpha_x}{\alpha_x + \beta_x}$$
$$\tau_x = \frac{1}{\alpha_x + \beta_x}$$

where $\alpha_x$ and $\beta_x$ depend on $V_m$ as follows:

$$\alpha_m = \frac{0.1(V_m - 40)}{e^{(V_m - 40)/10} - 1} \qquad \beta_m = 4e^{(V_m - 65)/18}$$
$$\alpha_h = 0.07e^{(V_m - 65)/20} \qquad \beta_h = \frac{1}{e^{(V_m - 35)/10} + 1}$$
$$\alpha_n = \frac{0.01(V_m - 55)}{e^{(V_m - 55)/10} - 1} \qquad \beta_n = 0.125e^{(V_m - 65)/80}$$

Note that the dimensions of $\tau_x$, $\alpha_x$, and $\beta_x$ are all in units of 1/s, while $n_x$ is a pure number.

These rate constants assume a temperature of 6.3°C. At higher temperatures, they should be multiplied by a factor of around 3 per 10°C. The functional forms were chosen by Hodgkin and Huxley for two reasons. First, they were among the simplest that fit the data, and second, they resemble the equations that govern the movement of a charged particle in a constant field.

There is no direct way to map this set of equations in a simple manner onto the known molecular correlates of ionic channels, except that many voltage-dependent ionic channels possess four identical subunits, close or identical to the exponent of the activation variable that determines the momentary conductance. How the molecular structure and physical chemistry of these membrane pores explain the high throughput (up to $10^8$ ions per second) and selectivity (the potassium channel is at least 10,000 times more permeant to $K^+$ than to $Na^+$ ions) has been revealed in stunning detail for potassium channels by atomic-resolution pictures of them (Doyle et al., 1998).

Conceptually, $x_\infty(V_m)$ can be thought of as the probability that an $x$ particle will be in the open state at potential $V_m$. Each particle follows a two-state Markov model, where $\alpha_x$ is the rate constant from the closed to the open state and $\beta_x$ is the rate constant from the open to the closed state. The time courses of the three variables are graphed in Figure 3.

This mathematical formalism was laid down in 1952. Since then, most models of voltage-dependent conductances—not only in axons, but also in cell bodies, and dendrites—have used the same formalism, with only minor modifications (Koch and Segev, 1998).

The macroscopic Hodgkin-Huxley equations are both continuous and deterministic, yet the underlying microscopic ionic channels are binary and stochastic. That is, a correct biophysical formulation of the dynamics of the membrane potential needs to take into account the well-known probabilistic behavior of these ionic channels. However, given the large number of channels involved in axonal spike initiation and propagation, it is usually appropriate to approximate the system using the deterministic Hodgkin-Huxley equations. This is not to say, however, that for thin fibers with very high input impedances, a small number of channels, and close to the threshold, stochastic variation in channel behavior might not have large-scale effects on the timing of action potentials (Schneidman, Freedman, and Segev, 1998; Koch, 1999).

### *Action Potential Propagation*

Equation 1 describes a patch of membrane with no spatial extent. This corresponds to the original experiments, in which the axon was "space-clamped": a long electrode was inserted into the axon along its axis, removing any spatial dependence. In response to stimulation, the whole membrane would fire simultaneously as a single isopotential unit. More commonly, one end of the axon is stimulated and an action potential propagates to the other end. The equation that governs extended structures is the cable equation:

$$C\frac{\partial V_m}{\partial t} = \frac{d}{R_a}\frac{\partial^2 V_m}{\partial x^2} + g_l(E_l - V_m) + g_{\text{Na}}(E_{\text{Na}} - V_m) + g_{\text{K}}(E_{\text{K}} - V_m) \qquad (2)$$

where $d$ is the axon diameter, $C$ is the membrane capacity, and $R_a$ is the intracellular resistivity. The equation rests on the assumption of radial symmetry, i.e., radial current flow can be neglected, leaving only one spatial dimension, the distance $x$ along the cable, in addition to $t$. If the last two (active) terms are dropped from the right-hand side, we are left with the classical cable equation for passive cables (see DENDRITIC PROCESSING). Associated with that equation is the *space constant* $\lambda = 1/\sqrt{g_l R_a}$, which is the distance across which the membrane potential decays a factor $e$ in an infinite cable under steady-state conditions.

Figure 4 shows the result of a simulation of a 100-cm-long axon of diameter $d = 1$ mm. One end was stimulated with a brief current pulse and the voltage was graphed for five positions along the axon. The form of the action potential is very similar to that in Figure 3; furthermore, the action potential is self-similar as it propagates, showing no signs of dispersion.

The total delay from one end to the other is about 5 ms, giving an average velocity of about 20 m/s. By assuming a constant conduction velocity—that is, by postulating the existence of a wave, $V_m(x, t) = V_m(x - vt)$—Equation 2 shows that the velocity is proportional to the square root of axon diameter: $v \propto \sqrt{d}$ (Rushton, 1951). Indeed, in a truly remarkable test of their model, Hodgkin and Huxley estimated the velocity to be 18.8 m/s, a value within 10% of the experimental value of 21.2 m/s. This is surprisingly

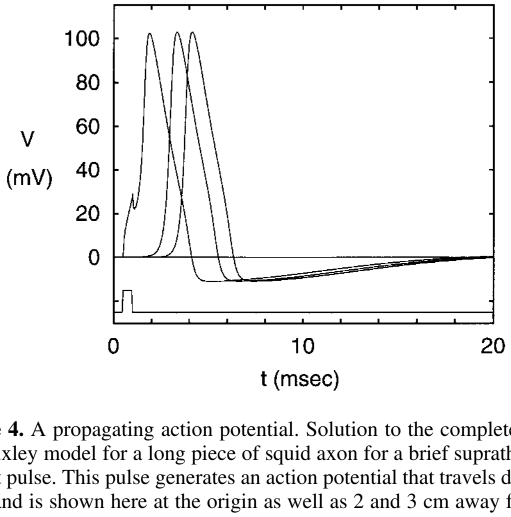

**Figure 4.** A propagating action potential. Solution to the complete Hodgkin-Huxley model for a long piece of squid axon for a brief suprathreshold current pulse. This pulse generates an action potential that travels down the cable and is shown here at the origin as well as 2 and 3 cm away from the stimulating electrode (solid lines). Note that the shape of the action potential remains invariant due to the nonlinear membrane. If the amplitude of the current pulse is halved, only a local depolarization is generated (dashed curve), which depolarizes the membrane 2 cm away by a mere 0.5 mV (not shown). This illustrates the dramatic difference between active and passive voltage propagation. (From Koch, C., 1999, *Biophysics of Computation*, Cambridge, MA: MIT Press, p. 162.)

accurate, considering that the model was derived from a space-clamped axon. This represents one of the rare instances in which a neurobiological model has made a successful quantitative prediction. The square root relationship had been discovered experimentally in the squid in the late 1930s.

## Myelinated and Nonmyelinated Fibers

The principle of action potential generation and propagation appears to be very similar across neuronal types and species. One important evolutionary invention is that of myelination in the vertebrate phylum. Myelin sheaths are white fatty extensions of Schwann cells or neuroglial cells that are wrapped in many layers around axons. Myelin is a major component of the *white matter* of the brain, as opposed to the gray matter of neocortex, which has a high concentration of cell bodies and dendrites. The myelin sheaths extend for up to 1–2 mm along the axon (the *internodes*) and are separated by the *nodes of Ranvier*, which are only a few micrometers long. The internodal distance appears to be approximately linear in fiber diameter.

Myelin insulates the axon from the surrounding medium, increasing the membrane resistance and decreasing the capacitance. This reduces the electrotonic length of the axon for both DC and AC signals, making the cable electrically shorter, thereby significantly increasing the propagation speed. While a 1-mm nonmyelinated axon in the squid has an associated propagation speed of only about 20 m/s (Hodgkin and Huxley, 1952), a myelinated 20-$\mu$m vertebrate axon can reach over 100 m/s. For a nonmyelinated axon to reach that velocity, it would have to be an inch thick! This reduction in axon diameter allows for a much higher packing density while conserving speed.

It has been shown both experimentally and theoretically that the velocity of propagation is linear or slightly sublinear in the fiber diameter for myelinated axons. Figure 5 compares the spike propagation velocity for myelinated and nonmyelinated axons for small diameters. The myelinated axons overtake nonmyelinated ones already in the submicrometer range.

As opposed to their uniform distribution in nonmyelinated nerve, the voltage-gated channels in myelinated nerve are highly segregated between node and internode (Hille, 1992). The nodal membrane has a high concentration of fast sodium channels (between 700 and 2,000 per $\mu$m$^2$) and voltage-independent leak channels. The internodal membrane has a low concentration of potassium and leak channels and is virtually devoid of sodium channels. Here, the repolarization of the membrane following the initial phase of the spike is via the leak channels and sodium inactivation. This low density of channels in the internodal membrane, which makes up the more than 99% of the axonal membrane, reduces the average current density across the membrane, resulting in great savings in metabolic energy. Most of the activity occurs at the nodes of Ranvier, while the propagation along the internodes is chiefly passive.

In summary, myelin provides three advantages: propagation speed and packing density are both dramatically increased, while power consumption is decreased.

## The Axonal Tree

Some axons branch profusely in the vicinity of the cell body. Others send off one or a few branches that course through the body for up to a meter before branching. Others extend for a few millimeters, giving rise to axonal arbors at regular intervals. The axon often arises at the "axon hillock," a somatic bulge opposite from the trunk of the dendritic tree, though other arrangements are possible, such as the axon's emanating from the dendrite rather than the soma.

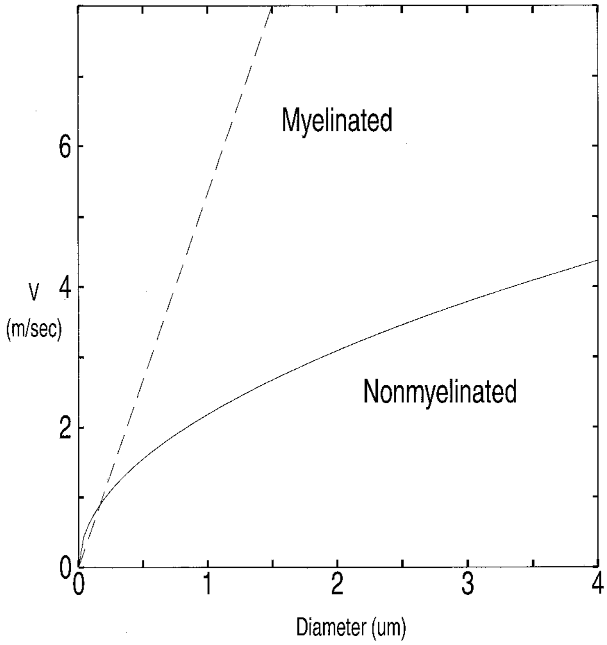

**Figure 5.** Spike propagation velocity and axonal diameter. The propagation velocity has a square root dependence on diameter for nonmyelinated axons. For myelinated axons, the dependence is linear or slightly sublinear. Myelination increases velocity for axons as thin as 0.2 $\mu$m, which are among the smallest found in the brain. (Adapted from Waxman and Bennett, 1972.)

Figure 1 shows an example of a terminal arbor in turtle tectum from a cell originating in nucleus isthmi. This particular axon has a 3-$\mu$m myelinated parent trunk and initial daughter branches. These give rise to hundreds of thin, highly varicosed daughter branches that lack myelin. The varicosities are usually the location of synaptic boutons, a local thickening where action potentials trigger the release of neurotransmitter, which in turn induces a conductance change in the postsynaptic target neuron. Boutons of some neurons may receive synaptic input that can inhibit this signal transmission, a process known as presynaptic inhibition. The 3,600 boutons on this arbor average 1.5 $\mu$m in diameter, though the size is highly variable, with a few boutons being as large as 7 $\mu$m.

The propagation speed along an unbranched axon depends on the diameter, as discussed earlier. In addition, a delay might be introduced at branch points, at varicosities at presynaptic terminals, and at locations where the diameter changes abruptly (Manor, Koch, and Segev, 1991). The delay may be negative (a speed-up), depending on the geometrical aspects, in particular the diameter of the parent branch in relation to that of the daughter branches. In a simulation of a 3.5-mm-long branched terminal axonal tree, Manor et al. found that the total axonal delay from the cell body to the synaptic terminals ranged from about 3 ms to 6 ms. Most of this delay (67%–78%) arose from the properties of unbranched, uniform cables; 16%–26% resulted from branch point delays, and 6%–7% from the presence of varicosities. In theory, the delay at a single branch point may be as large as 2 ms or more, if the temperature is low and the impedance mismatch is large. If the mismatch is too large, however, *branch point failure* may occur, a condition in which the action potential fails to propagate beyond the branch point. The concept of branch point filtering has been put forth by Chung, Raymond, and Lettvin (1970): the branch point may constitute a point of control where selective transmission occurs, allowing the axonal tree to distribute action potentials only to a subset of nerve terminals. Experimentally, little is known concerning the amplitude of temporal dispersion of action potentials due to axonal branching.

While the axonal propagation delay may seem an unavoidable fact of life that slows down neural communication, it may also have important computational advantages. For instance, sound localization (see Sound Localization and Binaural Processing) in the barn owl depends on interaural time differences as small as a tenth of a millisecond and is apparently obtained by using the axon as a delay line (Konishi, 1992), and several models of brain function depend critically on the exact timing of inputs from different sources. Although delays may be imposed by the dendritic trees at the input end of the neuron, the axons are also important candidates for this function.

Debanne and colleagues (1997) discovered that action potentials can be selectively filtered at or beyond axonal branch points via a fast-inactivating A-type of potassium conductance. When a cell is hyperpolarized, a depolarizing step within 10–20 ms that would normally trigger an action potential fails to do so in hippocampal cell bodies. The reason for this selective block is a $G_A$-like $K^+$ conductance present somewhere along the axon. If de-inactivated by long-lasting hyperpolarization, it filters out single isolated spikes. It could thereby act to enhance the signal-to-noise ratio of neuronal firing. To what extent this is a general mechanism or an exception to the rule that axons faithfully transmit action potentials from their site of initiation close to the cell body to their postsynaptic target structures remains to be seen.

Over the past several decades, the formalism introduced by Hodgkin and Huxley in 1952—voltage- and time-dependent activation and inactivation variables that determine the current value of the various membrane conductances—has become the de facto standard for modeling an amazing variety of phenomena, including adaptation, calcium-dependent conductances, plateau potentials, first- and second-order inactivation, oscillatory discharges, and several varieties of bursting.

# Axonal Path Finding

*Geoffrey J. Goodhill*

## Introduction

Many stages are involved in constructing a biological nervous system. Following the migration of neurons to their proper locations and their phenotypic specification, the initial pattern of connections forms between different regions (Sanes, Reh, and Harris, 2000). Making the right connections is crucial for proper function, and often requires axons to navigate over long distances with great precision (Tessier-Lavigne and Goodman, 1996). Until recently, relatively little was known about this process experimentally; however, the past decade has seen a dramatic increase in knowledge (at least qualitatively) concerning the molecules and mechanisms involved (Mueller, 1999). These insights are now being applied to understanding how axons can be made to regenerate to appropriate targets after injury to the adult nervous system, such as spinal cord injury.

Until now, the bulk of theoretical work in the neural network tradition has focused on changes in synaptic strengths within a fixed connectional architecture. Although local sprouting within the target has sometimes been considered (as has "sculpting," based on the assumption that when synaptic strengths go to zero, the physical connection is lost), how axons chart their initial path toward the correct target structure has generally not been addressed. An example is the mapping from the eye to more central targets in the brain. Abundant theoretical models address how topographic maps form once axons reach the tectum or visual cortex (see Development of Retinotectal Maps; Self-Organizing Feature Maps; and Ocular Dominance and Orientation Columns), but no theoretical work specifically addresses how retinal ganglion cell axons find the optic disc, how they then exit the retina, why they grow toward the optic chiasm, why some then cross at the midline while others do not, and so on. In recent years important insight into such issues has been gained through innovative experimental work, creating a body of knowledge that now has the potential to be framed and interpreted in terms of theoretical models. A crucial point is that, whereas work in neural networks has usually focused on processes such as synaptic plasticity that are dependent on neural activity, models for axon guidance must generally be phrased in terms of activity-independent mechanisms, particularly guidance by molecular gradients. In this article we first review some of the important experimental data regarding axon guidance, and then discuss some of the theoretical concepts that are relevant to this area.

## Experimental Data

Several basic types of mechanisms have been identified to guide axons. (For more detailed discussions of the data summarized in this section, see Tessier-Lavigne and Goodman, 1996; Mueller, 1999; and Song and Poo, 2001.) First, axons can be channeled in particular directions by boundaries of permissive or inhibitory molecules. For instance, a "railroad track" of a permissive molecule may lock an axon into a particular trajectory, or a "wall" of an inhibitory molecule may keep it away from an undesired region. Second, axons can be pushed or pulled by "vector" signals in the form of molecular gradients. These gradients are often established by diffusion of a soluble molecule away from the target region. Third, the path to a distant target may be broken into several short segments, each involving a different type of cue, thus simplifying the problem of long-range guidance. Fourth, once one "pioneering" axon has reached the target, it is often the case that following axons simply fasciculate with (stick to) the pioneering axon. In each of these cases the molecules involved may be substrate-bound (expressed on cell membranes or bound to cells or to the extracellular space) or diffusible (diffusing through the extracellular space).

In the last few years the number of molecules specifically implicated in axon guidance has jumped from virtually none to around 100, most of them previously unknown. (Note that we distinguish between *guidance factors* and *growth factors*: the latter category, which includes the neurotrophins, are often essential for axons to extend, but so far have mostly not been shown to play an active role in axon guidance in vivo.) Guidance factors can be organized into several main families based on their molecular structure, including the netrins, semaphorins, slits, and ephrins. There is an astonishing amount of evolutionary conservation in these familes. Homologous molecules perform analogous guidance functions in animals ranging from nematodes to flies to mammals, indicating that the basic molecular tools for wiring a nervous system were established hundreds of millions of years ago. Molecules involved in axon guidance are also often involved in the analogous chemotactic event of cell migration, and recent findings even suggest some commonality with the signal transduction mechanisms important for chemotaxis of leukocytes. Although it was originally thought that the different types of guidance mechanisms might be segregated between different families of molecules, it is now clear that this is not the case. For instance, the same molecule can be attractive in one context but repulsive in another, or it may normally be substrate-bound but have a soluble fragment that can diffuse.

Guidance signals for axons are detected and transduced by the growth cone, a dynamic and motile structure at the tip of the developing axon. This consists of a central region surrounded by weblike veils called lamellipodia, and long, finger-like protrusions called filopodia (Figure 1*A*). Receptors expressed on the surface of the growth cone can bind molecules of the families mentioned above. The resulting signals are then converted by complex internal transduction pathways into differential rates of actin polymerization in different parts of the growth cone so as to move it forward, left, or right. Dissection of the signaling networks responsible for converting a graded difference in receptor binding into directed movement is currently a very active area of research. One intriguing finding is that the concentration of cAMP within the growth cone

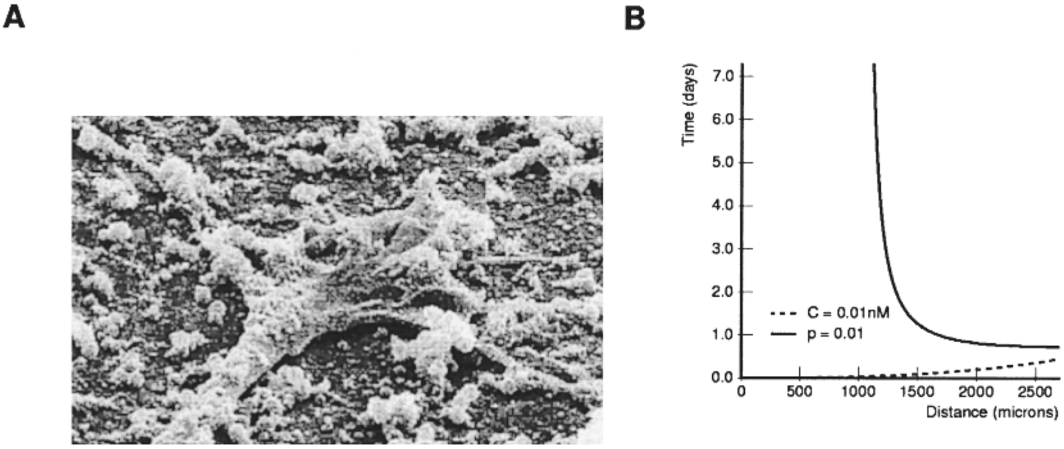

**Figure 1.** *A*, Electron micrograph of a growth cone at the end of an axon (here the growth cone is resting on a surface irregularly covered with coated beads). The long finger-like protrusions are filopodia. Growth cones are typically about 0.01 mm across. (From Rosentreter, S. M., Davenport, R. W., Löschinger, J. Huf, J., Jung, J., and Bonhoeffer, F., 1998, Response of retinal ganglion cell axons to striped linear gradients of repellent guidance molecules, *J. Neurobiol.*, 37:541–562. © 1998, John Wiley & Sons, Inc. Reprinted with permission.) *B*, Interaction of constraints for guidance by a target-derived diffusible factor. The graph shows, at each distance, the time at which two constraints are satisfied: the low concentration limit, where not enough receptors are bound for a gradient signal to be detected (assumed to be $K_D$/100, with $K_D = 1$ nM), and the fractional change constraint (assumed to be $\Delta C/C = 1\%$). The region between the two curves in each graph is where guidance is possible. The guidance limit imposed by the fractional change constraint once the gradient has stabilized is 1 mm. However, guidance range is extended at earlier times, when the fractional change constraint has yet to take full effect.

helps determine how the growth cone responds to a gradient cue: if the cAMP level is above a certain threshold, the growth cone is attracted; if the cAMP level is below that threshold, the growth cone is repelled.

## Theoretical Models

### *Gradient Detection*

Several different areas of theoretical development are relevant to the emerging picture of axon guidance. The general topic of chemotaxis has inspired a large body of theoretical analysis. However, most work has focused on bacteria and leukocytes, and it remains to be established how relevant these models are to axon guidance. Perhaps most important in this category are theories describing the fundamental physical limits on the minimum steepness of gradients detectable by *any* small sensing device. The key hypothesis, first rigorously formulated by Berg and Purcell (1977), is that gradient detection is limited by inherent statistical fluctuations in receptor binding. They calculated the statistical noise in a concentration measurement $\Delta C_{\text{noise}}$ by a small sensing device that arises from inevitable stochastic variations in the number of receptors bound at any instant. The fractional root mean square error in the measurement of a concentration difference between two spatially or temporally separated points is then $\sqrt{2}\Delta C_{\text{noise}}/C$, where $C$ is the average concentration at the sensing device. For a true gradient to be detected, it must be steep enough so that the actual concentration difference between the two points, $\Delta C_{\text{grad}}$, is such that $\Delta C_{\text{grad}} > \sqrt{2}\Delta C_{\text{noise}}$. $\Delta C_{\text{noise}}/C$ can be calculated from first principles using various simplifying assumptions. This approach has been applied to growth cones by Goodhill and Urbach (1999), who derived estimates for the minimum gradient steepness detectable by an axon for a diffusible gradient of order 1% and for a substrate-bound gradient of order 10%. The difference arises because of the lower encounter rate between receptor and ligand molecules for a bound versus a diffusible gradient. Goodhill and Urbach (1999) also showed that the movement of filopodia does not significantly increase the encounter rate, which suggests that filopodia increase gradient sensitivity only by increasing the effective size of the growth cone. However, this approach assumes that the receptor-ligand reaction is diffusion-limited, which may not be the case for the molecules involved in axon guidance. Theoretical work following Berg and Purcell (1977), while still generally founded on the basic assumption that gradient detection is limited by the signal-to-noise ratio, has attempted to relax this and some other assumptions, but these models have not yet been specifically applied to growth cones.

### *Growth Cones*

Theoretical models have been proposed to account for filopodial dynamics. Based on experimentally determined distributions for parameters such as rates of filopodial initiation, extension, and retraction, filopodial length, and angular orientation, Buettner and colleagues (e.g., Buettner, 1995) have developed simulation models describing filopodial structure as a function of time, and growth cone trajectories both during normal growth and when a target is encountered. Goodhill and Urbach (1999) presented a model of growth cone trajectories based on the assumption that each filopodium makes a noisy (in Berg and Purcell's sense) estimate of the concentration in the direction it is pointing, that more filopodia are generated in the direction of higher concentration, and that each filopodium exerts a pull on the growth cone. Other models have proposed hypotheses about how actin and microtubule dynamics lead to filopodia formation, though these models have yet to fully engage with what is known about these processes experimentally.

Another theoretically interesting aspect of growth cones is the signaling events that convert a small difference in receptor binding into a large directed movement. Meinhardt (1999) and others have proposed reaction-diffusion-type models in which a small inhomogeneity in an initially uniform system is amplified via the interaction of a short-range activator with a longer-range inhibitor. However, to return the system to a uniform state so that the directional preference of the growth cone can change with time, a second type of reaction with a longer time constant is invoked, and direct experimental evidence for such processes in growth cones is currently lacking. Tranquillo and Lauffenburger (1987), in the context of leukocyte chemotaxis, simulated and analyzed a model in which two pools of receptors (one on each side of the cell) communicated information about the degree of binding via a single intracellular messenger. This model was quite successful at accounting for various aspects of leukocyte movement, and subsequent versions by Tranquillo and colleagues have examined more complex assumptions regarding the internal signaling dynamics. Bacterial chemotaxis has been extensively studied from the perspective of signal transduction, and theoretical models have been effective at explaining the large amount now known experimentally about this system. A major focus of such models has been to explain the process by which bacteria adapt to background levels of ligand so that they can detect small changes in concentration over many orders of magnitude of absolute concentration. Although such analyses of signaling mechanisms in other chemotacting systems have the potential to be applied to growth cones, it is unclear how similar these systems really are. More generally there is increasing interest in mathematical modeling of the signal transduction pathways underlying cell behavior as a whole, although again, there is little application as yet of these theoretical ideas to axon guidance.

### *Diffusible Gradients and Optimal Gradients*

An important class of gradients for guiding axons both in vivo and in vitro consists of gradients established by diffusion. Hentschel and van Ooyen (1999) investigated a possible role for diffusion in controlling axon fasciculation. They considered a population of axons being guided by a target-derived diffusible factor, and hypothesized that in addition, each axon releases a diffusible attractant that pulls it toward the other axons, hence leading to fasciculation as they grow together toward the target. To account for defasciculation at the target, they hypothesized that each axon also releases a repulsive factor for other axons at a rate dependent on the concentration of the target-derived factor. As the axons approach the target, this repulsive force overcomes the attractive force, leading to defasciculation.

Another approach is to analyze the gradient shapes expected from diffusion processes in particular situations and how these constrain the spatiotemporal domains in which guidance is possible (see Goodhill, 1998, for a review). Goodhill considered a source releasing a diffusible factor at a constant rate into an infinite, spatially uniform three-dimensional volume, a problem for which there is a closed-form solution. As long as the gradient is not too steep, the fractional change in concentration $\Delta C/C$ across the growth cone width $a$ is $\Delta C/C = (\partial C/\partial r)(a/C)$, and can be straightforwardly calculated. It has the perhaps surprising characteristic that, for fixed $r$, $\Delta C/C$ *decreases* with $t$. That is, the largest fractional change at any distance occurs immediately after the source starts releasing factor. For large $t$, $\Delta C/C$ asymptotes at $a/r$. Thus: (1) At small times after the start of production the factor is very unevenly distributed. The concentration $C$ falls quickly to almost zero moving away from the source, the gradient is steep, and the percentage change across the growth cone $\Delta C/C$ is everywhere large. (2) As time passes, the factor becomes more evenly distributed. $C$ everywhere increases, but $\Delta C/C$ everywhere decreases. (3) For large times, $C$ tends to an inverse variation with the distance from the source $r$, while $\Delta C/C$ tends to $a/r$ independent of all other parameters. The equation for $\Delta C/C$ can be compared with the size of the smallest gradient the growth cone can detect to yield the regions of parameter space found in which guidance is possible (Figure 1*B*). Based on data for leukocyte chemotaxis it was assumed that gradient detection occurs when $\Delta C/C \geq p$ and $C \geq C_{\min}$, where $p$ is a threshold assumed independent of $C$. The positions and times for which the gradient calculated above satisfies these criteria were examined, given appropriate estimates for the relevant parameters. For large times (a few days) after the start of factor production, the maximum range is independent of the diffusion constant and is about 1 mm. This value fits well with both in vitro and in vivo observations. At earlier times, however, the factor is more unevenly distributed, being more concentrated around the source. This makes the fractional change larger than at later times, increasing the range over which guidance can occur. Depending on the parameters, the model predicts that guidance may be possible at distances of several millimeters before the distribution of factor equilibriates. It is conceivable that such a mechanism might be utilized in vivo to extend guidance range beyond the 1 mm limit imposed once the gradient has stabilized.

Similarly, one may inquire as to the optimal gradient shape, in the sense of the shape that guides an axon over the largest possible distance. Assuming the minimal fractional change is constant (not dependent on absolute concentration), the optimal shape is clearly exponential; the maximum guidance distance turns out to be about 1 cm (Goodhill, 1998). It is conceivable that substrate-bound gradients could achieve this shape, and in fact the size of the chick tectum at the time retinotectal maps are forming is about 1 cm. Assuming instead that the minimal fractional change varies with concentration, as predicted by Berg and Purcell, and also assuming a high concentration limit, the order of magnitude of the result remains at 1 cm (Goodhill and Urbach, 1999). More generally, this type of analysis raises the issue of overall scaling between different species. A guidance mechanism (e.g., target-derived diffusible gradient) that works for a small animal will not work in a large animal if the anatomy is simply scaled up. In general, the scale and structure of the anatomy of, say, the elephant nervous system at the time at which long-range navigation occurs are not known in sufficient detail to allow proper comparison with the same features in, say, the rat.

### *Retinotectal Maps*

The most well-developed area of axon guidance modeling concerns the formation of topographic maps in the optic tectum (reviewed in Goodhill and Richards, 1999). The hypothesis of chemospecificity, that graded distributions of molecules are somehow matched to graded distributions of complementary molecules in the tectum so as to form a topographic map, was first proposed qualitatively by Sperry (1963). Although a great deal of experimental work ensued to investigate how such gradients may actually operate, matched gradients of receptors in the retina and ligands in the tectum were discovered only in the mid-1990s. These receptors/ligands are of the Eph/ephrin family, which currently are under intense experimental investigation. Theoretical modeling started in the 1970s (e.g., Willshaw and von der Malsburg, 1979), and early models were based directly on molecular gradients. A key finding was that some kind of normalization is essential to prevent all axons from targeting the same part of tectum. Although modeling based on gradients has continued (e.g., Gierer, 1987), the focus of most modeling work changed to activity-dependent processes. Here only synaptic strength changes within a fixed architecture are generally considered, rather than the earlier stage of how axons traverse large expanses of the tectum. Data and models in this area are discussed in greater detail in Development of Retinotectal Maps (q.v.).

## Discussion

Current experimental work in axon guidance is dominated by techniques and hypotheses at the molecular level. The data are also rapidly evolving, with new molecules and mechanisms important for guidance being discovered at a very fast rate. However, many fundamental questions remain unresolved, and theoretical models have the potential to make an important contribution to answering these questions. What is the minimum gradient steepness detectable by a growth cone, and how does this vary with the properties of the receptor-ligand interaction and the internal state of the growth cone? How is a graded difference in receptor binding internally converted into a signal for directed movement? How do axons integrate multiple cues? And, perhaps most relevant to human health, how can regenerating axons be encouraged to grow toward and reconnect with appropriate targets after injury?

# Backpropagation: General Principles

*Michael A. Arbib*

## Introduction

Perceptrons are neural nets that use an *error-correction* rule to change the weights of each unit that makes erroneous responses to stimuli that are presented to the network. As already explained in PERCEPTRONS, ADALINES, AND BACKPROPAGATION (q.v.) and Section I.3: "Dynamics and Adaptation in Neural Networks," *backpropagation* is a family of methods for training a *multilayer perceptron*, a loop-free network that has its units arranged in layers, with each unit providing input only to units in the next layer of the sequence. The first layer comprises input units; there may then be several layers of trainable "hidden units" carrying an internal representation, and finally there is the layer of output units, also with trainable synaptic weights.

Rumelhart, Hinton, and Williams (1986) is the most influential paper on the error backpropagation method, providing a formula (see the Proposition below) for propagating back the gradient of error evaluation from a unit to the units that provide its inputs. Since the formulas involve derivatives, the input and output of each unit must take continuous values in some range, here taken to be [0, 1]. The response is a sigmoidal function of the weighted sum. Werbos (1995) provides a historical perspective on precursors of their paper. As a specific example of such a precursor, LEARNING AND STATISTICAL INFERENCE (q.v.) presents a general stochastic descent on-line learning procedure (Amari, 1967), which, when applied to the multilayer perceptron, yields the error backpropagation method.

*Proposition.* Consider a layered loop-free net with error $E = \Sigma_k(t_k - o_k)^2$, where $k$ ranges over designated output units, and let the weights $w_{ij}$ be changed according to the gradient descent rule

$$\Delta w_{ij} = -\frac{\partial E}{\partial w_{ij}} = 2 \sum_k (t_k - o_k) \frac{\partial o_k}{\partial w_{ij}}$$

Then the weights may be changed inductively, working back from the output units, by the rule $\Delta w_{ij}$ is proportional to $\delta_i o_j$, where

*Basis Step*: $\delta_i = (t_i - o_i)f'_i$ for an output unit.

*Induction Step*: If $i$ is a hidden unit, and if $\delta_k$ is known for all units that receive unit $i$'s output, then $\delta_i = (\Sigma_k \delta_k w_{ki})f'_i$, where $k$ runs over all units that receive unit $i$'s output. □

Thus the "error signal" $\delta_i$ *propagates* back layer by layer from the output units. In $\Sigma_k \delta_k w_{ki}$, unit $i$ receives error propagated back from a unit $k$ to the extent to which $i$ affects $k$.

The above proposition tells us how to compute $\Delta w_{ij}$ for the *on-line* backpropagation algorithm that adjusts the weights in response to each single input pattern, using the "local error" of the network with its current weight settings for that input. It does not guarantee that the above step size is appropriate to reach the minimum, nor does it guarantee that the minimum, if reached, is global. The backpropagation rule defined by this proposition is, thus, a heuristic rule, not one guaranteed to find a global minimum. The *batch* version of the algorithm cycles through a complete training set of input-output pairs $(x_1, y_1), (x_2, y_2), \ldots, (x_N, y_N)$, with gradient descent applied to the cumulative error of each cycle, until no further changes are required.

As the index to this *Handbook* attests, backpropagation has been perhaps the most diversely used adaptive architecture, especially in technological applications. The purpose of this article is neither to introduce the basics of backpropagation (again, see PERCEPTRONS, ADALINES, AND BACKPROPAGATION and Section I.3: Dynamics and Adaptation in Neural Networks) nor to survey its applications (see SPEECH RECOGNITION TECHNOLOGY for one example of a careful analysis of the pros and cons of using multilayer perceptrons), but instead to place backpropagation in a broader context by providing a road map for a number of contributions elsewhere in the *Handbook* that enrich our basic understanding of this adaptive architecture. The article also assesses the biological plausibility of backpropagation.

## Auto-Encoding

A basic application for backpropagation networks has been to find compressed representations. In this case, a network with one hidden layer is trained to become an *auto-encoder* or *auto-associator* by learning the identity function: making the desired states of the $N$ output units identical to the states of the $N$ input units for each input-output pair in the training sample. Data compression is achieved by making the number of hidden units $M < N$. Moreover, the features discovered by the hidden units may be useful for processing tasks, such as classification of the input patterns. However, as shown in UNSUPERVISED LEARNING WITH GLOBAL OBEJCTIVE FUNCTIONS, it may not be possible to relate the activities of individual hidden units to specific features that may be found by other means to characterize complicated input patterns. One way to constrain the hidden unit representation is to add extra penalty terms to the error function. For example, a penalty term on hidden unit activations can be chosen that causes these units to represent high-dimensional data as localized bumps of activity in a lower-dimensional constraint surface. This encourages the hidden units to form a map-like representation that best characterizes the input. Other penalty terms lead to other encodings, such as sparse or combinatorial representations (see MINIMUM DESCRIPTION LENGTH ANALYSIS).

RAAM networks (Pollack, 1990) are three-layer backpropagation networks whose input and output layers are each divided into regions. The network is trained to "auto-associate," i.e., to reproduce a given pattern of input on the output layer. The purpose of this training is to permit condensed, distributed encodings of $K$-tuples of information (i.e., the subpatterns presented to the $K$ regions of the input layer) to be developed on the hidden layer. Once such a distributed encoding has been developed for a given $K$-tuple of information, that encoding may later be presented as input to a single region of the input layer, while the remaining input regions receive similarly derived distributed encodings, so that the network then develops codes for $K$-tuples of information. The network may then be trained to auto-associate on this more complex set of input information. Iterating the procedure yields codes for $K$-tuples of $K$-tuples, and so on, thus making possible condensed distributed encodings for entire tree structures in the RAAM's hidden layer. SYSTEMATICITY OF GENERALIZATIONS IN CONNECTIONIST NETWORKS (q.v.) discusses the implications of such techniques for the ability, or otherwise, of connectionist models to capture human abilities for symbol processing.

## Stochasticity and Plateaus

STOCHASTIC APPROXIMATION AND EFFICIENT LEARNING (q.v.) notes that both on-line and batch backpropagation seek a weight vector $w$ that minimizes the error function, but stresses the statistical notion that inputs must follow some probability distribution so that what we really seek to minimize is the error as averaged over all examples. But should we average over the few examples available in the training set, or over all the complete probability distribution "given by Nature"? The first average is named *empirical risk* and measures only the training set performance. The second average is called the *expected risk* and measures the much more interesting generalization performance (Vapnik, 1998). The *Handbook* introduces a stochastic gradient descent algorithm in which each iteration consists of picking a single random example and updating the weight vector *w* accordingly. This stochastic gradient descent does not need to remember which examples were visited during the previous iterations, making this algorithm suitable for the on-line adaptation of deployed systems. In such a situation, the stochastic gradient descent directly optimizes the expected risk, since the examples are randomly drawn from the "ground truth" distribution. The stochastic gradient descent can also pick examples from a finite training set. This procedure optimizes the empirical risk. The number of iterations is usually larger than the size of the training set. The examples are therefore presented multiple times to the network.

Learning and Statistical Inference (q.v.) offers a general method, called *Fisher efficiency*, of assessing the success of an estimator relating input and output patterns. It then notes that, although backpropagation learning has been used widely, it is not Fisher efficient. Moreover, the method may converge to one of the local minima of the error landscape, which might be different from the global minimum. Intriguingly, convergence may be drastically slow because of "plateaus." The error decreases quickly at the beginning of learning, but its rate of decrease becomes extremely slow. After surprisingly many steps, the error again decreases rapidly. This is understood as showing that weights are trapped in a "plateau" that is not a local minimum but nonetheless provides a region of weight space that learning takes very long to escape from.

Saad and Solla (1995) used statistical mechanics to show that plateaus exist because of the "symmetry" in the hidden units: the output and hence the error measure is invariant under permutations of hidden units in the multilayer perceptron. Whereas this property leads to phase transitions in equilibrium batch training (see Statistical Mechanics of Generalization), the effect in on-line training is that the system approaches a symmetric state from generic initial conditions. Statistical Mechanics of On-line Learning and Generalization (q.v.) discusses how the properties of such plateaus can be investigated in detail by linearizing the dynamics close to the fixed point (Biehl, Riegler, and Wöhler, 1996). Figure 1 in Statistical Mechanics of On-line Learning and generalization (q.v.) provides a simple example of the breaking of permutation symmetry during learning, showing a typical learning curve in which the learning process is dominated by a pronounced plateau state in which hardly any progress is made while the number of examples increases. Only after an extended period of time does the system leave the plateau and approach its asymptotic state exponentially fast. In the case displayed in the figure, the system is very close to a perfectly symmetric configuration.

There are various acceleration methods for the backpropagation learning rule, but they cannot eliminate plateaus. Neuromanifolds and Information Geometry (q.v.) shows that the natural gradient method (Amari, 1998), based on the Riemannian structure of a neuromanifold, not only eliminates plateaus but is Fisher efficient.

## Recurrent Neural Networks

A feedforward network is just a static mapping of input vectors to output vectors, whereas our brain is a high-dimensional nonlinear dynamical system, replete with loops. This provides one motivation (another is technological) for the study of learning algorithms for recurrent neural networks, which have feedback connections and time delays. In a recurrent network, the state of the system can be encoded in the activity pattern of the units, and a wide variety of dynamical behaviors can be encoded by the connection weights. Network dynamics that converge to a minimum of an "energy" function (see Computing with Attractors) have proved important for associative memory tasks and optimization networks. However, steady-state solutions (fixed-point attractors) are only a limited portion of the capabilities of recurrent networks. A recurrent network can serve as a sequence recognition system or as a sequential pattern generator. Recurrent Networks: Learning Algorithms (q.v.) reviews the learning algorithms for training recurrent networks, focusing on supervised learning algorithms for recurrent networks, with only a brief overview of reinforcement and unsupervised learning algorithms.

Recurrent neural networks use the additional degree of freedom provided by a priori unlimited processing time in order to map the information appropriately. For example, simple recurrent networks (SRNs; Elman, 1990) augments the three-layer backpropagation network with a supplementary context layer of the same size as the hidden layer. Reciprocal links between the hidden layer and the context layer create a loop enabling any activation pattern currently present on the hidden layer to be merged with the activation pattern currently present in the context layer, and vice versa. An extension of the backpropagation algorithm trains these connections as well. Essentially, the activity in the context and hidden layers may be seen as an internal state, so that training serves to update both the definition of a "next-state function" as well as the reading of the output from the internal state in such a way as to enable the system to better and better approximate a training set, which now consists of pairs of input and output sequences, rather than one-shot input vectors and output vectors Constituency and Recursion in Language (q.v.) exemplifies the use of SRNs in connectionist linguistics.

## Other Perspectives

To create a neural network, a designer typically fixes a network topology and uses training data to tune its parameters, such as connection weights. The designer, however, often does not have enough knowledge to specify the ideal topology. In the case of a multilayer perceptron, the only free parameter in "topology space" is the number of hidden units. Too few hidden units and the current task is unlearnable; too many units and the network learns the noise as well as the task relationships. It is thus desirable to learn the topology from training data as well. Learning Network Topology (q.v.) looks at learning as a search in the space of topologies as well as in weight space. In particular, it provides a general measure of the "goodness" of a topology and some search strategies over the space of topologies to find the best one. This framework is applied to learning the topologies of both feedforward neural networks and Bayesian belief nets (see Bayesian Networks).

A basic strategy to avoid false minima is Boltzmann learning (see Simulated Annealing and Boltzmann Machines). Here the units respond in stochastic fashion to their inputs. The degree of "stochasticity" is controlled by a parameter *T*. As $T \to -\infty$, the unit becomes deterministic; as $T \to \infty$, the unit becomes very noisy. *T* is often referred to as "temperature," as part of the comparison of large neural networks with the systems treated by statistical mechanics (see Statistical Mechanics of Neural Networks). Convergence to the global optimum is aided by starting at high *T* and gradually lowering it—this is the process of "simulated annealing"—with the intuition being that the initial high noise "bumps the system out of the high valleys" of the error landscape, while the eventual low noise allows it to settle in the "low valleys."

Modular and Hierarchical Learning Systems (q.v.) replaces the training of a single network by the training of a set of networks that forms a "mixture of experts," the idea being that each network will become expert at processing inputs from a region of the input space, while a gating network will learn which experts to rely on for processing a given input. As an alternative to gradient methods, Jordan and Jacobs (1994) developed an Expectation-Maximization (EM) algorithm (McLachlan and Krishnan, 1997, give a general treatment of the EM algorithm) that is particularly useful for models in which the expert networks and gating networks have simple parametric forms. Each iteration of the algorithm consists of two phases: (1) a recursive propagation upward and downward in the tree of modules to compute posterior probabilities (the "E step"), and (2) solution of a set of local weighted maximum likelihood problems at the nonterminals and terminals of the tree (the "M step"). Jordan and Jacobs (1994) tested this algorithm on a nonlinear system identification problem (the forward dynamics of a 4-degrees-of-freedom robot arm) and reported that it converged nearly two orders of magnitude faster than backpropagation in a comparable multilayer perceptron network.

Graphical Models: Probabilistic Inference (q.v.) tells us that many neural network architectures are special cases of the general graphical model formalism that the article presents. Special cases of graphical models include essentially all of the models developed under the rubric of "unsupervised learning," as well as Boltzmann machines, mixtures of experts, and radial basis function networks. It is argued that many other neural networks, including the classical multilayer perceptron of the present article, can be analyzed profitably from the point of view of graphical models.

## Biological Considerations

Reinforcement Learning in Motor Control (q.v.) notes the importance of supervised learning in motor control, but stresses that reinforcement learning (in which positive reinforcement signals success on a task and increasing negative reinforcement gives a measure of increasingly poor performance, but where no explicit error signal for the network's output units is available) is more plausible in many situations involving motor learning; and, indeed, Dopamine, Roles Of (q.v.) shows that certain reinforcement learning methods seem to fit well with the action of dopamine in the brain.

However, Recurrent Networks: Neurophysiological Modeling (q.v.) argues for the utility of backpropagation as a tool for studying actual networks in the brain. The argument here is that backpropagation provides a means for the computational neuroscientist to adjust the parameters within a given neural network architecture to see whether there is indeed a parameter setting (whose robustness can then be studied) that yields a given type of behavior. The article presents backpropagation not as a model for biological learning, simply as an effective method of obtaining a solution. Biologically plausible learning algorithms will also find similar solutions, but usually take longer. For example, Mazzoni, Andersen, and Jordan (1991) argued that reinforcement learning gave a more biologically plausible learning rule than backpropagation in their study of a network model of cortical area 7a.

But what is the evidence that backpropagation is biologically implausible? Hebbian Synaptic Plasticity (q.v.) makes a *partial* case for biological plausibility. While conceding that there is no evidence that the backpropagation formula represents actual brain mechanisms, it summarizes new evidence suggesting that activity in one neuron may affect presynaptic neurons, and even neurons presynaptic to those. One might call this *qualitative backpropagation* to stress that the evidence says nothing about the quantitative plausibility of the generalized delta rule. The ability to patch (make local electrode recordings and current injections) at different distances from the soma of a biological neuron has suggested that action potentials propagate back from the soma into the dendrites as well as in the "conventional" direction, from dendrites to soma (see Dendritic Processing). Hebbian Synaptic Plasticity (q.v.) discusses three distinct mechanisms by which backpropagating spikes can be seen as the "binding signal" emitted by the soma to modify differentially synapses that are active within a precise temporal window. Moreover, the study of identified neurons and synapses in low-density hippocampal cultures has revealed extensive but selective spread of both long-term potentiation (LTP) and long-term depression (LTD) from the site of induction to other synapses in the network (see Bi and Poo, 2001, for a review). LTD induced at synapses between two glutamatergic neurons can spread to other synapses made by divergent outputs of the same presynaptic neuron, to synapses made by other convergent inputs on the same postsynaptic cell, and can even spread in a retrograde direction to depress synapses afferent to the presynaptic neuron (the evidence for qualitative backpropagation). In contrast, LTP can exhibit only lateral spread and backpropagation to the synapses associated with the presynaptic neuron.

## Discussion

Backpropagation has provided an effective and widely used architecture for the training of artificial neural networks. We recalled the generalized delta rule for multilayer perceptrons, illustrated its utility with two examples of auto-encoder networks, and showed how the methodology could be extended to recurrent networks. However, statistical analysis showed that backpropagation has problems—a particular example being the likelihood of backpropagation training of multilayer perceptrons getting trapped in plateaus—as well as advantages. We thus provided pointers to stochastic descent methods that avoided these pitfalls, as well as noting extensions of, and alternatives to, backpropagation that can usefully be added to the repertoire of those who train artificial neural networks.

As for biology, we saw that backpropagation may serve as a computational tool to estimate the parameters of a particular biological network even though it does not model the actual learning processes within that network. On the other hand, evidence of "spike backpropagation" provides inspiration for a family of subtle new learning rules that allow the activity of a neuron to affect the neurons presynaptic to its input neurons, but this offers no direct support for the specific formulas of the generalized delta rule. Finally, it should be noted that the modeling and theory summarized in this article are based on neurons with sigmoid outputs. Such units are useful both in artificial neural networks and in connectionist modeling. They can also be considered biological models if their real-valued output is seen to represent a moving-window mean of spiking frequency of the biological neurons (see Rate Coding and Signal Processing). However, there are cases in which it seems that a better fit to the biology can be obtained if the local temporal structure of spikes in the output of each neuron is taken into account (Spiking Neurons, Computation with). This suggests the importance of seeking to define learning rules that do take detailed spike placement, rather than local firing rates, into account. The data reviewed in Hebbian Synaptic Plasticity (q.v.) may lead brain modelers in the right direction but, unfortunately, no efficient learning algorithm for networks of spiking neurons, whether biological or not, has yet gained wide acceptance.

# Basal Ganglia

*Tony J. Prescott, Kevin Gurney, and Peter Redgrave*

## Introduction

Lying on either side of the forebrain/midbrain boundary, at the hub of the mammalian brain, the basal ganglia are a group of highly interconnected brain structures with a critical influence over movement and cognition. The importance of these nuclei for a cluster of human brain disorders, including Parkinson's disease, Huntington's disease, and schizophrenia, has produced a century or more of strong clinical interest, and a prodigious volume of neurobiological research. Given the wealth of relevant data, and a pressing need for a better functional understanding of these structures, the basal ganglia provide one of the most exciting prospects for computational modeling of brain function.

This article will begin by summarizing aspects of the functional architecture of the mammalian basal ganglia and will then describe the computational approaches that have been developed over the course of the past decade (see also Houk, Davis, and Beiser, 1995; Wickens, 1997; Gillies and Arbuthnott, 2000). An important task for an appraisal of computational models is to provide a framework for comparing pieces of work that can differ radically in their breadth of focus, level of analysis, computational premises, and methodology, and whose relative merits can consequently be difficult to ascertain (I.2. Levels and Styles of Analysis). Here, we first distinguish between models that attempt to incorporate appropriate biological data (anatomical and/or physiological) and those that attempt an explanation of function using generic neural network architectures. This review will discuss only those models that incorporate known neurobiological constraints and will consider some of the implications for these models of recent biological data. The models can be divided in two main categories: (1) those that work at a comparatively low level of detail (membrane properties of individual neurons and micro-anatomical features) and that restrict themselves to a single component of the basal ganglia nucleus; and (2) those that deal at the "system level" with the basal ganglia as a whole and/or with their interactions with related structures (e.g., thalamus and cortex). In this article we will also seek to classify system level models in terms of the primary computational role that is being addressed by the neural substrate.

The neuromodulator dopamine is known to play a vital role in regulating basal ganglia processing and also in mediating learning within the basal ganglia. Although some of the likely regulatory functions of dopamine will be considered in this article, a fuller discussion of this topic, including hypotheses and models concerned with the role of dopamine in learning from reinforcement, are the subject of a separate article (Dopamine, Roles of).

## Key Architectural Features

There have been many excellent summaries of the functional anatomy of the basal ganglia (e.g., Mink, 1996; Smith et al., 1998), the following therefore focuses on those aspects most relevant to understanding the models discussed in this article.

The principle structures of the rodent basal ganglia (Figure 1) are the striatum (consisting of the caudate, the putamen, and the ventral striatum), the subthalamic nucleus (STN), the globus pallidus (GP), the substantia nigra (SN), and the entopeduncular nucleus (EP) (homologous to the globus pallidus internal segment in primates). These structures are massively interconnected and form a functional subsystem within the wider brain architecture. There is a growing consensus that the basal ganglia nuclei can be regionally subdivided on the basis of their topographically organized connectivity with each other and with cortical and thalamic regions. Current views of information processing within the basal ganglia are heavily influenced by this suggestion of multiple parallel loops or channels.

The principle input components of the basal ganglia are the striatum and the STN. Afferent connections to both of these structures originate from virtually the entire brain, including cerebral cortex, many parts of the brainstem (via the thalamus), and the limbic system. Input connections provide phasic (intermittent) excitatory input.

The main output nuclei of the basal ganglia are the substantia nigra pars reticulata (SNr) and the entopeduncular nucleus (EP). Output structures provide extensively branched efferents to the thalamus (which project back to the cerebral cortex), and to premotor areas of the midbrain and brainstem. Most output projections are normally (tonically) active and inhibitory.

To make sense of the intrinsic connectivity of the basal ganglia it is important to recognize that the main projection neurons from the striatum (medium spiny cells) form two widely distributed populations differentiated by their efferent connectivity and neurochemistry.

One population comprises neurons with mainly D1-type dopamine receptors and projects to the output nuclei (SNr and EP). In the prevailing informal model of the basal ganglia (Albin, Young, and Penney, 1989) this projection constitutes the so-called *direct*

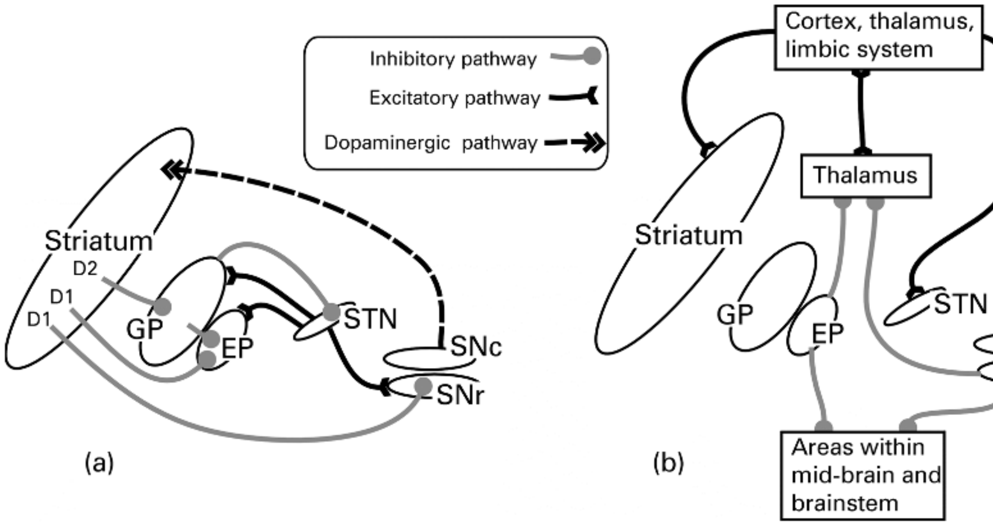

**Figure 1.** Basal ganglia anatomy of the rat: *A*. Internal pathways. *B*. External pathways. Excitatory and inhibitory pathways are denoted by solid and gray lines, respectively; not all connections are shown. See text for key to abbreviations.

*pathway* to the output nuclei (see Figure 2*A*). Efferent activity from these neurons suppresses the tonic inhibitory firing in the output structures, which in turn *disinhibits* targets in the thalamus and brainstem.

A second population of striatal output neurons has predominantly D2-type dopamine receptors. This group projects primarily to the globus pallidus (GP) whose tonic inhibitory outputs are directed both to the output nuclei (SNr and EP) and to the STN. The inhibitory projection from D2 striatal neurons constitutes the first leg of an *indirect pathway* to the output nuclei. Since this pathway has two inhibitory links (Striatum-GP, GP-STN), followed by an excitatory one (STN-EP/SNr), the net effect of striatal activity is to activate output nuclei, which increases inhibitory control of the thalamus and brainstem.

The main source of dopamine innervation to the striatum is the substantia nigra pars compacta (SNc). Interestingly, the D1 and D2 striatal populations respond differently to dopaminergic transmission, activation of D1 receptors having a predominantly excitatory effect while D2 receptor activation appears to be mainly inhibitory. This arrangement seems to provide dopaminergic control of a "push/pull" mechanism subserved by the direct (inhibitory) and indirect (net excitatory) basal ganglia pathways. Importantly, a key input to the SNc is from striatal areas known as striosomes (areas that project to EP/SNr are known as matri-

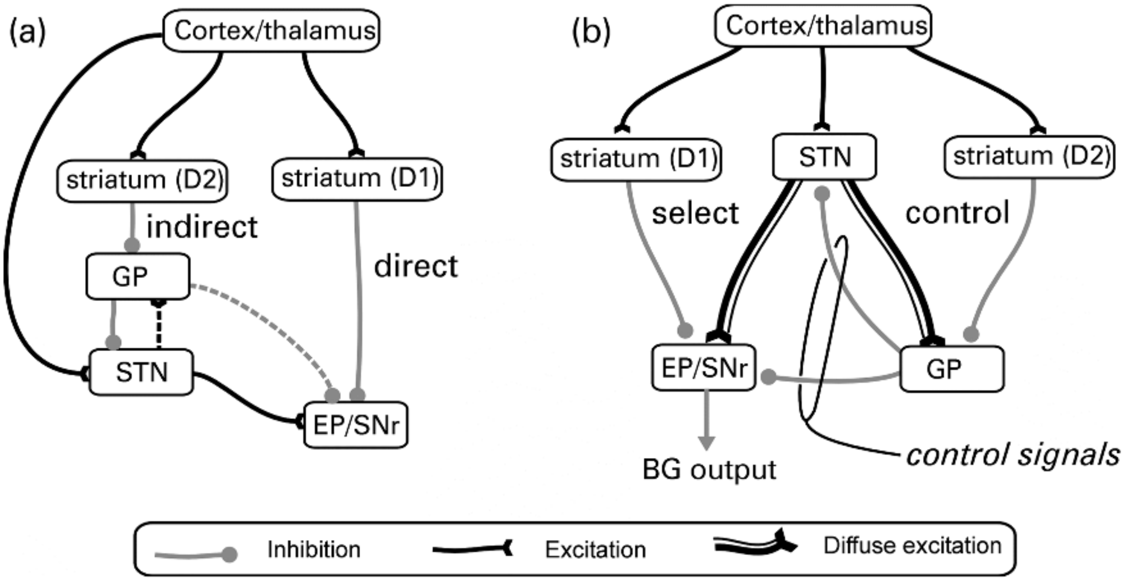

**Figure 2.** Functional interpretations of the basal ganglia: (a) *Informal* models stress the "direct" and "indirect" pathways and leave the functional consequences of their interactions ill-defined. Other pathways (indicated by dotted lines) have received less emphasis. (b) An alternative interpretation arising from *computational* modeling by Gurney et al. (2001) specifies specific functional roles for the various intrinsic basal ganglia connections summarized by the concept of "selection" and "control" pathways. See text for further explanation.

somes), thus the striatum is a major player in modulating its own dopaminergic input.

Although the preceding description focuses on pathways originating from the striatum, the STN, though much smaller in size, is increasingly recognized as a second important input structure within the basal ganglia functional architecture (see Mink, 1996). STN's excitatory outputs project to both the output nuclei (SNr and EP) and to the intermediary structure GP.

Recent anatomical data by Wu, Richard, and Parent (2000) has suggested that the "direct pathway" is actually branched with a significant output going to GP. Other new data shows the existence of additional inhibitory projections from GP to EP/SNr implying a multiplicity of indirect pathways (Smith et al., 1998). The proliferation of intrinsic basal ganglia circuitry in recent literature has highlighted the need for: (1) a radical reinterpretation of basal ganglia functional anatomy; and (2) an increasingly important role for computational modeling in interpreting the functional properties of the multiple interconnections and loops within the basal ganglia.

## Low-Level Models of Individual Basal Ganglia Nuclei

In contrast to the diverse nature of the brain regions projecting to the mammalian striatum, its internal organization appears surprisingly homogeneous. This finding offers hope that an understanding of striatal functioning in one local area could generalize across much of the entire structure. At any given moment the majority of striatal cells are in an inactive "down state," and can only be triggered into an active "up state" (in which they can fire action potentials) by a significant amount of coincident input. Since each neuron has a wide dendritic fan-in (with up to 30,000 synapses), but only a few synapses with any single source neuron, it must receive coincident signals from a large population of inputs to become active (see Wilson in Houk et al., 1995). This organization suggests that striatal spiny neurons may act as "context-specific filters," each one configured to match a specific pattern of activity distributed across multiple loci in one or more brain areas (Mink, 1996).

Recent studies have provided evidence for local inhibition within the striatum mediated either via local interneurones or by reciprocal inhibitory networks among the output cells themselves (see Oorschot et al. in Nicholson and Faull, 2002). Wickens and colleagues (see Wickens, 1997) have investigated the dynamics of such local neighborhoods of striatal neurons using network models. Under varying assumptions of topology and size, they concluded that reciprocal inhibition will usually lead to a network dynamic of competition, that is, the most active neurons will tend to suppress activity in their less active neighbors. This research also examined the effects of simulated dopamine inputs, showing that under circumstances of low dopamine, the dynamic of the network changes from competition to coactivation (where activity is uniformly distributed within the local population of neurons), a pattern that could provide a model for the muscular rigidity seen in dopamine-deficient Parkinson's patients. Using another variant of this model, Wickens explored the implications of dendritic asymmetries based on those observed in the early stages of Huntington's disease. Simulation of asymmetric interconnectivity generated slow traveling waves of activity (where normal symmetric configurations produce stationary activity patterns), suggesting that a similar abnormal network dynamic may underlie the sudden involuntary movements seen in Huntington's patients.

Apart from the striatum, relatively little attention has been given to modeling intrinsic processing within basal ganglia nuclei. One interesting exception is the work by Gillies and Willshaw (see Gillies and Arbuthnott, 2000) on a model of the STN. Having incorporated key physiological and anatomical properties, they showed that the widespread excitatory interconnectivity between STN neurons allows focused input to produce a widely distributed pulse of excitation to SNR and EP. Given that the output of the basal ganglia is largely inhibitory, phasic STN activity could serve to break established patterns of activity in basal ganglia targets thereby acting as a form of interrupt or "reset" mechanism.

The preceding models have as their starting point a wealth of low-level biological constraints with the rationale that the resulting model behavior must approximate observed biological data. Nevertheless, since the phenomena discussed are related to the ability to resolve localized competitions (in striatum) and to interrupt ongoing behaviors (STN), we would argue that these models may be thought of as addressing components of the overall computational problem of action selection (see further discussion later in this article).

## System Level Models of Basal Ganglia Circuits and External Functional Loops

Most of the effort so far directed at basal ganglia modeling has been concerned with simulating interactions between the various basal ganglia structures, and between the basal ganglia and other key brain regions such as cortex, thalamus, and brainstem. A comparatively high level of abstraction is usually adopted in this work, in which components of the basal ganglia are decomposed into functional units (e.g., multiple parallel channels). Most work to date has focused on a number of related computational hypotheses—that the basal ganglia function to (1) regulate the degree of action gating, (2) select between competing actions, (3) sustain working memory representations, and (4) store and enact sequences of behavior. These ideas will be the main focus of the remaining discussion.

### *Action Gating*

A key function of the striatum is to provide intermittent, focused inhibition (via the "direct pathway") within output structures that otherwise maintain inhibitory control over motor/cognitive systems throughout the brain. This architecture strongly suggests that a core function of the basal ganglia is to gate the activity of these target systems via the mechanism of disinhibition. Many basal ganglia models employ selective gating, however, that of Contreras-Vidal and Stelmach (1995) is particularly interesting as it explores gating operations in both normal and dysfunctional model variants. These authors coupled a simulation of basal ganglia intrinsic circuitry to a neural network that computed arm movements. Excitatory striatal input resulted in a smoothly varying signal to thalamic targets that provided the "Go" signal for the motor command, and also set its overall velocity. The time taken to execute movements decreased with increasing basal ganglia input thereby matching the results of striatal microstimulation studies. A "dopamine depleted" version of the model exhibited akinesia and bradykinesia similar to that observed in Parkinson's disease.

### *Selecting Between Competing Actions*

The proposal that the basal ganglia act to resolve action selection competitions is based on a growing consensus that a key function of these structures is to arbitrate between sensorimotor systems competing for access to the final common motor path. A computational hypothesis developed from this idea relies on the premise that afferent signals to the striatum encode the salience of "requests for access" to the motor system (Redgrave, Prescott, and Gurney, 1999). Multiple selection mechanisms embedded in the basal ganglia could resolve conflict between competitors and provide clean and rapid switching between winners. First, the up/down states of the striatal neurones may act as a first pass filter to exclude weakly supported "requests." Second, local inhibition within the striatum could selectively enhance the activity of the most salient channels.

Third, the combination of focused inhibition from striatum with diffuse (divergent) excitation from STN could operate as a feedforward, off-center/on-surround network across the basal ganglia as a whole (see Mink, 1996). Last, local reciprocal inhibition within the output nuclei could sharpen up the final selections.

Using the action selection hypothesis as an organizing principle, Gurney, Prescott, and Redgrave (2001) have proposed a reinterpretation of basal ganglia functional anatomy in which the direct/indirect classification is replaced by a new functional grouping based on *selection* and *control* circuits (Figure 2*B*). Specifically, the focused D1 inhibitory pathway from striatum to EP/SNr (originally the "direct pathway"), together with a *diffuse* excitatory pathway from STN to EP/SNr, form a primary feedforward *selection* circuit. A second group of intrinsic connections centered on the GP acts as a *control* circuit to regulate the performance of the main selection mechanism. Analytical and simulation studies of this model suggest two likely functional roles for this control circuit. First, the inhibition of STN by GP constitutes a negative feedback path that automatically scales the excitatory output of the STN with the number of channels. Second, GP inhibition of EP/SNr forms part of a mechanism that supports dopaminergic regulation of selection. Specifically, increased dopamine in these circuits promotes "promiscuous" selection in which channels are more easily disinhibited, while reduced dopamine results in a "stiffer" competition in which there are fewer winners and higher levels of general target inhibition. The adequacy of this model has been tested by embedding it in the control architecture of a mobile robot equipped with a small repertoire of animal-like behaviors (see Prescott, Gurney et al. in Nicholson and Faull, 2002). This work confirmed that the simulated basal ganglia can provide effective action selection in a real-world context requiring appropriate and timely behavioral switching. The robot model also provided an insight into the emergent consequences of abnormal dopamine modulation of action selection. For instance, and reminiscent of some motor symptoms of Parkinson's disease, reduced dopamine was found to cause failures to select appropriate behavior or to complete behaviors once selected.

An earlier model of the basal ganglia proposed by Berns and Sejnowski (1995) shared the "action selection" premise of Gurney et al., but emphasized possible timing differences between the direct and indirect pathways in a model that included just the feedforward intrinsic basal ganglia connections. An interesting feature of this model is that it incorporated a version of the dopamine hypothesis for reinforcement learning (Dopamine, Roles of) as a means for adaptively tuning the selection mechanism.

### *Sustaining Working Memory Representations*

The relationship between basal ganglia and cortex is characterized by relatively segregated parallel loops, in which cortical projections to the striatum are channeled through basal ganglia outputs to the thalamus and then back to their cortical areas of origin. The thalamic nuclei in this circuit also have reciprocal, net-excitatory, connections to their cortical targets. This architecture suggests a pattern of cortical-thalamic activity which, once initiated by disinhibitory signals from the basal ganglia, could be sustained indefinitely. Several authors have proposed that this circuit could act as a working memory store (see Houk et al., 1995). An example of this is provided by Arbib and Dominey's model of basal ganglia control of the primate saccadic eye movement system (see article in Houk et al., 1995). These authors modeled an experimental task in which a monkey is required to make a saccade to a remembered target location. They simulated circuits in which cortical cells in the frontal eye fields were activated by the target, which, in turn, excited a population of striatal neurons specialized for delayed saccades. The basal ganglia loops involving these cells disinhibited their thalamic targets so that the target location was maintained in the corticothalamic circuits until the saccade was made.

In our view, the selection and maintenance of specific working memory items can be viewed as an extension of action selection by the basal ganglia to the domain of cognition (selecting from a range of potential cognitive representations those which are to be sustained as working memory). It is interesting to speculate that deficits in this system may underlie the disorders of thought associated with schizophrenia, attention-deficit disorder, and obsessive-compulsive disorder.

### *Sequence Processing*

A plausible use for the working memory mechanism outlined previously would be to link successful selections during the development of behavioral/cognitive sequences. This idea has therefore become a central theme in a number of basal ganglia models. According to Beiser and Houk (1998), sequence encoding can be viewed as the task of translating a temporal ordering into a spatial pattern of neural activity. They propose that the initial item in a sequence selects the basal ganglia loop whose striatal neurons are most attuned to that context. When this channel is disinhibited, the item then becomes encoded as a self-sustaining pattern of corticothalamic activity. Later sequence elements are recorded in an identical way, except that, as each new item is added, the cortical activity triggered by its predecessors becomes part of its context (thereby implicitly encoding its position in the temporal order). Rather than recording sequences as spatially distributed patterns, Fukai (1999) has suggested a form of cortical short-term memory for sequences that uses patterns of fast (gamma) and slow (theta) oscillatory activity. Reciprocal inhibition between striatal neurons would allow the basal ganglia to select the first item in such a sequence, while other striatal neurons (and their corresponding basal ganglia outputs) would be recruited to maintain the selection of that item for as long as required. Finally, an excitatory burst from STN terminates the movement and signals the transition to the next item in the sequence. Although differing considerably in detail, these two models share the premise that the basal ganglia is specialized to "unpack" a cortical representation of sequential behavior by selectively gating each of the component movements. Sequence learning is another important theme in basal ganglia modeling. For instance, Dominey, Arbib, and Joseph (1995) have extended their model of delayed saccade control (described previously) to include a mechanism for associative and Sequence Learning (q.v.) based, again, on the hypothesis that dopamine provides a reinforcement learning signal.

## Discussion

The preceding summary demonstrates that basal ganglia modeling is still at the stage of exploring the space of alternative hypotheses, seeking to operationalize theoretical proposals while trying to match known neurobiological constraints. As a result, there is now a candidate set of "global" basal ganglia functions whose computational requirements we are beginning to understand. It remains to be seen to what extent proposed functions are mutually exclusive and to what extent one may be subsumed within another (for instance, action gating can be viewed as an essential component of action selection). Similar considerations apply when appraising models directed at different levels of basal ganglia function. For example, lower-level models of the striatum or STN may, in the future, be imported as fully functional components into higher-level models. However, some system level models are clearly in direct competition with each other as they ascribe different functional roles to local pathways and nuclei. We anticipate that models based on correct computational assumptions will find it comparatively easy to incorporate new biological constraints, which in most cases will improve their accuracy. In contrast, models making mistaken functional assignments will find it increasingly difficult to incorporate additional biological data while maintaining their functionality. Future work will therefore require ever-closer links between neurobiologists and modelers to refine the models, to formulate questions based on function, and to test the interesting and unforeseen predictions that can emerge from modeling studies.

# Bayesian Methods and Neural Networks

*David Barber*

## Introduction

An attractive feature of artificial neural networks is their ability to model highly complex, nonlinear relationships in data. However, choosing an appropriate neural network model for data is compounded by the difficulty of assessing the network's complexity. Since we are rarely certain about either our data measurements or model beliefs, a natural framework is to use probabilities to account for these uncertainties. How can we combine our data observations with these modeling uncertainties in a consistent and meaningful manner? The Bayesian approach provides a consistent framework for formulating a response to these difficulties, and is noteworthy for its conceptual elegance (Box and Tiao, 1973; Berger, 1985; MacKay, 1992). The fundamental probabilistic relationship required for inference is the celebrated Bayes rule, which, for general events $A$, $B$, $C$, is

$$p(A|B, C) = \frac{p(B|A, C)p(A|C)}{p(B|C)} \tag{1}$$

It is convenient to think of different levels of uncertainty in formulating a model. At the lowest level, we may assume that we have the correct model but are uncertain as to the parameter settings $\theta$ for this model. This assumption details how observed data are generated, $p(\text{data}|\theta, \text{model})$. The task of inference at this level is to calculate the posterior distribution of the model parameter. Using Bayes's rule, this is

$$p(\theta|\text{data, model}) = \frac{p(\text{data}|\theta, \text{ model})\ p(\theta|\text{model})}{p(\text{data}|\text{model})} \tag{2}$$

Thus, if we wish to infer model parameters from data, we need two assumptions: (1) how the observed data are generated under the assumed model, or the *likelihood* $p(\text{data}|\theta, \text{model})$, and (2) beliefs about which parameter values are appropriate before the data have been observed, or the *prior* $p(\theta|\text{model})$. (The denominator in Equation 2 is the normalizing constant for the posterior and plays a role in uncertainty at the higher model level.) That these two assumptions are required is an inescapable consequence of Bayes's rule, and forces the Bayesian to lay bare all necessary assumptions underlying the model.

### *Coin Tossing Example*

Let $\theta$ be the probability that a coin will land heads up. An experiment yields the data, $D = \{h, h, t, h, t, h, \ldots\}$, which contains $H$ heads and $T$ tails in $H + T$ flips of the coin. What can we infer about $\theta$ from these data? Assuming that each coin is flipped independently, the likelihood of the observed data is

$$p(D|\theta, \text{model}) = \theta^H(1 - \theta)^T \tag{3}$$

A standard approach in the statistical sciences is to estimate $\theta$ by maximizing the likelihood, $\theta^{ML} = \arg\max\theta p(D|\theta, \text{model})$. This approach is non-Bayesian, since it does not require the specification of a prior. Consequently, theories that deal with uncertainty in ML estimators are primarily concerned with the data likelihood, and not directly with posterior parameter uncertainty (see LEARNING AND GENERALIZATION: THEORETICAL BOUNDS). In the Bayesian approach, however, we need to be explicit about our prior beliefs $p(\theta|\text{model})$. These are updated by the observed data to yield the posterior distribution

$$p(\theta|D, \text{model}) \propto \theta^H(1 - \theta)^T p(\theta|\text{model}) \tag{4}$$

The Bayesian approach is more flexible than the maximum likelihood approach since it allows (indeed, *instructs*) the user to calculate the effect that the data have in modifying prior assumptions about which parameter values are appropriate. For example, if we believe that the coin is heavily biased, we may express this using the prior distribution in Figure 1*A*. The likelihood as a function of $\theta$ is plotted in Figure 1*B* for data containing 13 tails and 12 heads. The resulting posterior (Figure 1*C*) is bimodal, but less extreme than the prior. It is often convenient to summarize the posterior by either the maximum a posteriori (MAP) value or the mean, $\bar{\theta} = \int \theta p(\theta|D)d\theta$. Such a summary is not strictly required by the Bayesian framework, and the best choice of how to summarize the posterior depends on other loss criteria (Berger, 1985).

### *Model Comparison and Hierarchical Models*

The preceding discussion showed how we can use the Bayesian framework to assess which parameters of a model are a posteriori appropriate, given the data at hand. We can carry out a similar procedure at a higher, model level to asses which models are more appropriate fits to the data. In general, the model posterior is given by

$$p(M|D) = \underbrace{p(D|M)}_{\text{Model likelihood}} \quad \underbrace{p(M)}_{\text{Model prior}} /p(D) \tag{5}$$

If the model is parameterized by some unknown variable $\theta$, we need to integrate this out to calculate the model likelihood

$$p(D|M) = \int p(D|\theta, M)p(\theta|M)d\theta \tag{6}$$

Comparing two competing model hypotheses, $M_1$ and $M_2$, is straightforward:

$$\frac{p(M_1|D)}{p(M_2|D)} = \underbrace{\frac{p(D|M_1)}{p(D|M_2)}}_{\text{Bayes factor}} \frac{p(M_1)}{(M_2)} \tag{7}$$

In the coin example, we can use this to compare the biased coin hypothesis (model $M_1$ with prior given in Figure 1*A*) with a less unbiased hypothesis formed by using a Gaussian prior $p(\theta|M_2)$ with mean 0.5 and variance $0.1^2$ (model $M_2$). This gives a Bayes factor $p(D|M_1)/p(D|M_2) \approx 0.00018$. If we have no prior preference for either model $M_1$ or $M_2$, the data more strongly favor model $M_2$, as intuition would suggest. If we desired, we could continue in this way, forming a hierarchy of models, each less constrained than the submodels it contains.

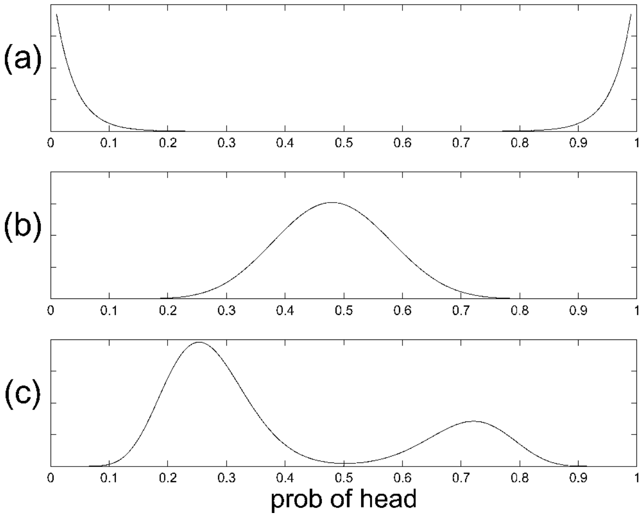

**Figure 1.** Coin tossing. *A*, The prior: this indicates our belief that the coin is heavily biased. *B*, The likelihood after 13 tails and 12 heads are recorded, $\theta^{ML} = 0.48$. *C*, The posterior: the data have moderated the strong prior beliefs, resulting in a posterior less certain that the coin is biased. $\theta^{MAP} = 0.25$, $\bar{\theta} = 0.39$.

## Bayesian Regression

Neural networks are often applied to a regression in which we wish to infer an unknown input-output mapping on the basis of observed data $D = \{(\mathbf{x}^\mu, t^\mu), \mu = 1, \ldots P\}$, where $(\mathbf{x}^\mu, t^\mu)$ represents an input-output pair. For example, fit a function to the data in Figure 2*A*. Since there is the possibility that each observed output $t^\mu$ has been corrupted by noise, we would like to recover the underlying clean input-output function. We assume that each (clean) output is generated from the model $f(\mathbf{x}; \mathbf{w})$, where the parameters $\mathbf{w}$ of the function $f$ are unknown, and that the observed outputs $t^\mu$ are generated by the addition of noise $\eta$ to the clean model output,

$$t = f(\mathbf{x}; \mathbf{w}) + \eta \tag{8}$$

If the noise is Gaussian distributed, $\eta \sim N(0, \sigma^2)$, the model $M$ generates an output $t$ for input $\mathbf{x}$ with probability

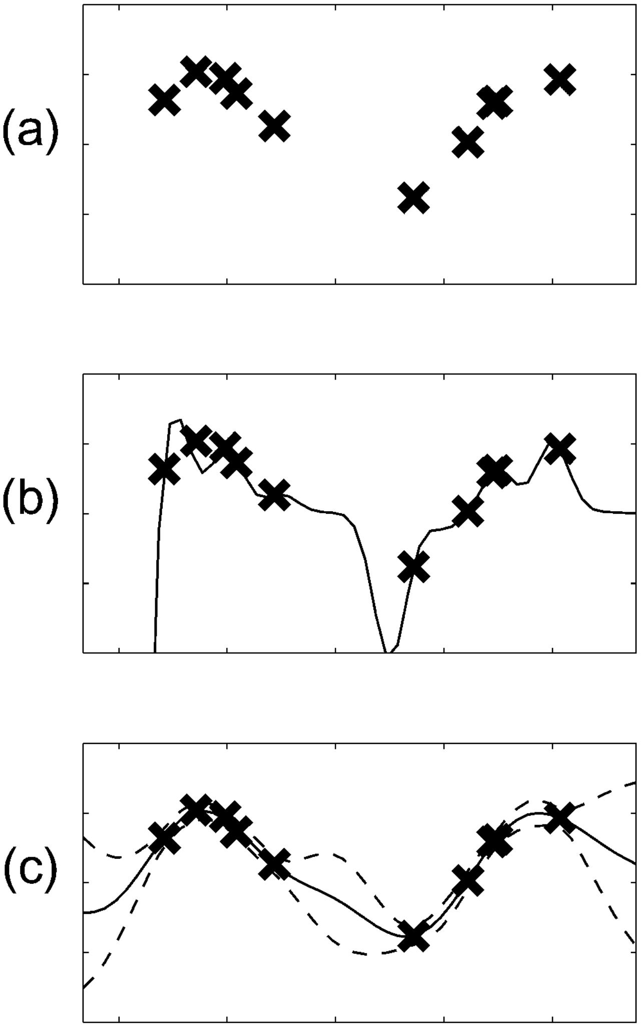

**Figure 2.** Along the horizontal axis we plot the input $x$ and along the vertical axis the output $t$. *A*, The raw input-output training data. *B*, Prediction using regularized training and fixed hyperparameters. *C*, Prediction with error bars, using ML-II optimized hyperparameters.

$$p(t|\mathbf{w}, \mathbf{x}, M) = \exp\left\{-\frac{1}{2\sigma^2}(t - f(\mathbf{x}; \mathbf{w}))^2\right\} \Big/ \sqrt{2\pi\sigma^2} \qquad (9)$$

If we assume that each data input-output pair is generated identically and independently from the others, the data likelihood is

$$p(D|\mathbf{w}, M) = \prod_{\mu=1}^{P} p(t^\mu|\mathbf{w}, \mathbf{x}^\mu, M) \qquad (10)$$

(Strictly speaking, we should write $p(t^1, \ldots, t^P|\mathbf{w}, \mathbf{x}^1, \ldots, \mathbf{x}^P, M)$ on the left-hand side of Equation 10. However, since we assume that the training inputs are fixed and non-noisy, it is convenient and conventional to write $p(D|\mathbf{w}, M)$.) The posterior distribution $p(\mathbf{w}|D, M) \propto p(D|\mathbf{w}, M)p(\mathbf{w}|M)$ is

$$\log p(\mathbf{w}|D, M) = -\frac{\beta}{2}\sum_\mu (t^\mu - f(\mathbf{x}^\mu; \mathbf{w}))^2 + \log p(\mathbf{w}|M) + \frac{P}{2}\log\beta + const. \qquad (11)$$

where $\beta = 1/\sigma^2$. Note the similarity between Equation 11 and the sum square regularized training error used in standard approaches to training neural networks (see GENERALIZATION AND REGULARIZATION IN NONLINEAR LEARNING SYSTEMS and Bishop, 1995). In the Bayesian framework, we can motivate the choice of a sum square error measure as equivalent to the assumption of additive Gaussian noise. Typically, we wish to encourage smoother functions so that the phenomenon of overfitting is avoided. One approach to solving this problem is to use a regularizer penalty term to the training error. In the Bayesian framework, we use a prior to achieve a similar effect. In principle, however, the Bayesian should make use of the full posterior distribution, not just a single weight value. In standard neural network training, it is good practice to use committees of networks, rather than relying on the prediction of a single network (Bishop, 1995). In the Bayesian framework, the posterior automatically specifies a committee (indeed, a distribution) of networks, and the importance attached to each committee member's prediction is simply the posterior probability of that network's weight.

## Radial Basis Functions and Generalized Linear Models

Generalized linear models have the form

$$f(x; w) = \sum_i w_i\phi_i(\mathbf{x}) \equiv \mathbf{w}^T\Phi(\mathbf{x}) \qquad (12)$$

Such models have a linear parameter dependence, but nevertheless represent a nonlinear input-output mapping if the basis functions $\phi(\mathbf{x})$, $i = 1, \ldots, k$ are nonlinear. Radial basis functions (see RADIAL BASIS FUNCTION NETWORKS) are an example of such a network (Bishop, 1995). A popular choice is to use Gaussian basis functions $\phi_i(\mathbf{x}) = \exp(-(\mathbf{x} - \mu^i)^2/(2\lambda^2))$. In this discussion, we will assume that the centers $\mu^i$ are fixed, but that the width of the basis functions $\lambda$ is a hyperparameter that can be adapted. Since the output is linearly dependent on $\mathbf{w}$, we can discourage extreme output values by penalizing large weight values. A sensible weight prior is thus

$$\log p(\mathbf{w}|\alpha) = -\frac{\alpha}{2}\mathbf{w}^T\mathbf{w} + \frac{k}{2}\log\alpha + const. \qquad (13)$$

Under the Gaussian noise assumption, the posterior distribution is

$$\log p(\mathbf{w}|\Gamma, D) = -\frac{\beta}{2}\sum_{\mu=1}^{P}(t^\mu - \mathbf{w}^T\Phi(x))^2 - \frac{\alpha}{2}\mathbf{w}^T\mathbf{w} + const. \qquad (14)$$

where $\Gamma$ represents the hyperparameter set $\{\alpha, \beta, \lambda\}$. (We drop the fixed model dependency wherever convenient.) The weight posterior is therefore a Gaussian, $p(\mathbf{w}|\Gamma, D) = N(\bar{\mathbf{w}}, \mathbf{S})$, where

$$\mathbf{S} = \left(\alpha\mathbf{I} + \beta\sum_{\mu=1}^{P}\Phi(\mathbf{x}^\mu)\Phi^T(\mathbf{x}^\mu)\right)^{-1}$$

$$\bar{\mathbf{w}} = \beta\mathbf{S}\sum_{\mu=1}^{P} t^\mu\Phi(\mathbf{x}^\mu) \qquad (15)$$

The mean predictor is straightforward to calculate: $\bar{f}(\mathbf{x}) \equiv \int f(\mathbf{x}; \mathbf{w})p(\mathbf{w}|D, \Gamma)d\mathbf{w} = \bar{\mathbf{w}}^T\Phi(\mathbf{x})$. Similarly, error bars are straightforward, $var(f(\mathbf{x})) = \Phi(\mathbf{x})^T\mathbf{S}\Phi(\mathbf{x})$ (predictive standard errors are given by $\sqrt{\text{var}(f) + \sigma_2}$). In Figure 2*B*, we show the mean prediction on the data in Figure 2*A* using 15 Gaussian basis functions with width $\lambda = 0.03$ spread out evenly over the input space. We set the other hyperparameters to be $\beta = 100$ and $\alpha = 1$. The prediction severely overfits the data, a result of poor choice of hyperparameters.

### *Determining Hyperparameters: ML-II*

How would the mean predictor be calculated if we were to include the hyperparameters $\Gamma$ as part of a hierarchical model? Formally, this becomes

$$\bar{f}(\mathbf{x}) = \int f(\mathbf{x}; \mathbf{w})p(\mathbf{w}, \Gamma|D)d\mathbf{w}d\Gamma = \int\left\{\int f(\mathbf{x}; \mathbf{w})p(\mathbf{w}|\Gamma, D)d\mathbf{w}\right\}p(\Gamma|D)d\Gamma \qquad (16)$$

The term in curly brackets is the mean predictor for fixed hyperparameters. We therefore weigh each mean predictor by the posterior probability of the hyperparameter $p(\Gamma|D)$. Equation 16 shows how to combine different models in an ensemble—each model prediction is weighted by the posterior probability of the model. There are other non-Bayesian approaches to model combinations in which the determination of the combination coefficients is motivated heuristically (see ENSEMBLE LEARNING).

Provided the hyperparameters are well determined by the data, we may instead approximate the above hyperparameter integral by finding the MAP hyperparameters $\Gamma^* = \arg\max_\Gamma p(\Gamma|D)$. Since $p(\Gamma|D) = p(D|\Gamma)p(\Gamma)/p(D)$, if the prior belief about the hyperparameters is weak ($p(\Gamma) \approx const.$), we can estimate the optimal hyperparameters by optimizing the hyperparameter likelihood

$$p(D|\Gamma) = \int p(D|\Gamma, \mathbf{w})p(\mathbf{w}|\Gamma)d\mathbf{w} \qquad (17)$$

This approach to setting hyperparameters is called ML-II (Berger, 1985; Bishop, 1995) and assumes that we can calculate the integral in Equation 17. In the case of GLMs, this involves only Gaussian integration, giving

$$2\log p(D|\Gamma) = -\beta\sum_{\mu=1}^{P}(t^\mu)^2 + \mathbf{d}^T\mathbf{S}^{-1}\mathbf{d} - \log|\mathbf{S}| + k\log\alpha + P\log\beta + const. \qquad (18)$$

where $\mathbf{d} = \beta\Sigma_\mu\Phi(\mathbf{x}^\mu)t^\mu$. Using the hyperparameters $\alpha$, $\beta$, $\lambda$ that optimize the above expression gives the results in Figure 2*C*, where we plot both the mean predictions and standard predictive error bars. This solution is more acceptable than the previous one in which the hyperparameters were not optimized, and demonstrates that overfitting is avoided automatically. A non-Bayesian approach to model fitting based on minimizing a regularized training error would typically use a procedure such as cross-validation to determine the regularization parameters (hyperparameters). Such approaches require the use of validation data (Bishop, 1995). An advantage of the Bayesian approach is that hyperparameters can be set without the need for validation data, and thus all the data can be used directly for training.

### *Relation to Gaussian Processes*

The use of GLMs can be difficult in cases where the input dimension is high, since the number of basis functions required to cover the input space fairly well grows exponentially with the input dimension—the so-called *curse of dimensionality* (Bishop, 1995). If we specify $n$ points of interest $\mathbf{x}^i$, $i \in 1, \ldots n$ in the input space, the GLM specifies an $n$-dimensional Gaussian distribution on the function values $f_1, \ldots, f_n$ with mean $\bar{f}_i = \bar{\mathbf{w}}^T\Phi(\mathbf{x}^i)$ and covariance matrix with elements $c_{ij} = c(\mathbf{x}^i, \mathbf{x}^j) = \Phi(\mathbf{x}^i)^T\Sigma\Phi(\mathbf{x}^j)$ (see GAUSSIAN PROCESSES). The idea behind a GP is that we can free ourselves from the restriction of choosing a covariance function $c(\mathbf{x}^i, \mathbf{x}^j)$ of the form provided by the GLM prior; any valid covariance function can be used instead. Similarly, we are free to choose the mean function $\bar{f}_i = m(\mathbf{x}^i)$. A common choice for the covariance function is $c(\mathbf{x}^i, \mathbf{x}^j) = \exp(-|\mathbf{x}^i - \mathbf{x}^j|^2)$. The motivation is that the function space distribution will have the property that for inputs $\mathbf{x}^i$ and $\mathbf{x}^j$, which are close together, the outputs $f(\mathbf{x}^i)$ and $f(\mathbf{x}^j)$ will be highly correlated, ensuring smoothness. This is one way of avoiding the curse of dimensionality, since the matrix dimensions depend on the number of training points, and not on the number of basis functions used. However, for problems with a large number of training points, computational difficulties can arise, and approximations again need to be considered.

## Multilayer Perceptrons

Consider the case of a single hidden layer neural network

$$f(\mathbf{x}; \mathbf{w}) = \sum_{i=1}^{H} v_i g(\mathbf{x}^T\mathbf{u}^i + b_i) \tag{19}$$

where $g(x)$ is a nonlinear sigmoidal transfer function, for example $g(x) = 1/(1 + \exp(-x))$. The set of all weights (parameters), including input-hidden weights $\mathbf{u}^i$, biases $b_i$, and hidden-output weights $v_i$, is represented by the vector $\mathbf{w}$. If the weights are small, the network function $f$ will be smooth, since only the near linear regime of the transfer function $g$ will be accessed. An appropriate prior to control complexity is therefore

$$\log p(\mathbf{w}|\alpha) = -\frac{\alpha}{2}\mathbf{w}^T\mathbf{w} + \frac{k}{2}\log\alpha + const. \tag{20}$$

where $k = dim(\mathbf{w})$. For the moment, we will assume that we know the value of the parameter $\alpha$. This gives the weight posterior as

$$\log p(\mathbf{w}|\alpha, \beta, D) = -\frac{\beta}{2}\sum_{\mu=1}^{P}(t^\mu - f(\mathbf{x}^\mu; \mathbf{w}))^2 - \frac{\alpha}{2}\mathbf{w}^T\mathbf{w} + const. \tag{21}$$

where $\beta = 1/\sigma^2$. In Figure 3 we show the result of using a six-hidden-unit network to fit the training data in Figure 3. With $\alpha = 0.1$ and $\beta = 1{,}000$, we drew a number of weight vectors $\mathbf{w}^l$, $l = 1, \ldots, 15$, from the weight posterior $p(\mathbf{w}|D)$, Equation 21 and considered the corresponding functions $f(\mathbf{x}; \mathbf{w}^l)$. The mean and standard error bars calculated from these samples are plotted in Figure 3. How these samples are obtained is discussed later. Note how the error bars automatically increase in regions of low data density.

### *Monte Carlo Sampling*

In general, the posterior distribution $p(\mathbf{w}|\Gamma, D)$ is non-Gaussian, and the integration required over the weight space to find, for example, the mean predictor

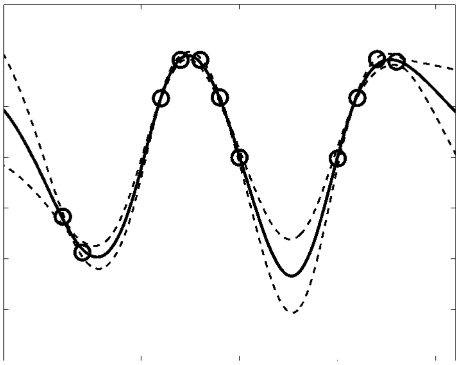

**Figure 3.** The raw input-output training data, with mean Bayesian MLP predictions (solid curve) and standard error bars (dashed curves). Note how the error bars increase away from the data.

$$\bar{f}(\mathbf{x}) = \int f(\mathbf{x}; \mathbf{w})p(\mathbf{w}|\Gamma, D)d\mathbf{w} \tag{22}$$

is difficult. An approximate solution is provided by Monte Carlo sampling (Bishop, 1995; Neal, 1996):

$$\int f(\mathbf{x}; \mathbf{w})p(\mathbf{w}|\Gamma, D)d\mathbf{w} \approx \frac{1}{L}\sum_{i=1}^{L} f(\mathbf{x}; \mathbf{w}^i) \tag{23}$$

where the sample weights $\mathbf{w}^i$ are drawn from the posterior distribution. In principle, this procedure is exact in the limit $L \to \infty$. The great difficulty, however, is in constructing a finite, representative set of samples $\{\mathrm{w}_i\}$, and it is easy to remain trapped in unrepresentative parts of the posterior distribution (Neal, 1996).

Consider the problem of drawing samples from a general distribution $p(\mathbf{x}) \propto \psi(\mathbf{x})$ (Figure 4). Let $\mathbf{x}^{\text{old}}$ be a sample point from $p(\mathbf{x})$. We propose a new sample point $\mathbf{x}^{\text{new}} = \mathbf{x}^{\text{old}} + \eta$ where each element $\eta_i$ is sampled from a zero-mean Gaussian distribution with variance $\tau^2$. We accept $\mathbf{x}^{\text{new}}$ if $\psi(\mathbf{x}^{\text{new}}) > \psi(\mathbf{x}^{\text{old}})$, since the new candidate sample point is more likely than the old sample point. However, this does not constitute a valid sampling scheme since we only accept increasingly likely points, targeting therefore only the modes of the distribution. To correct for this, we accept a less likely candidate with probability $\psi(\mathbf{x}^{\text{new}})/\psi(\mathbf{x}^{\text{old}})$. This valid sampling scheme is called the Metropolis method and forms the basis for many generalizations (Neal, 1993, 1996).

In high dimensions, Metropolis sampling can be inefficient, since it is unlikely that testing a new point a long way from the current sample point will result in a more likely point (if you stand on a mountain and jump, it is more likely that you will end up at a point lower than at your current point). Thus, only very small

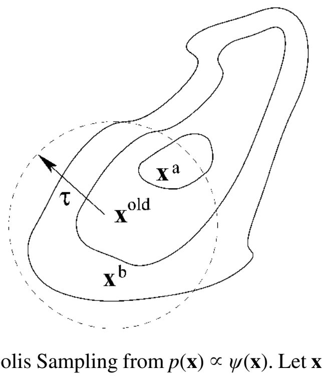

**Figure 4.** Metropolis Sampling from $p(\mathbf{x}) \propto \psi(\mathbf{x})$. Let $\mathbf{x}^{\text{old}}$ be a sample from the distribution $p(\mathbf{x})$. We propose a new candidate $\mathbf{x}^{\text{new}}$ by sampling from a Gaussian around $\mathbf{x}^{\text{old}}$ with width $\tau$. More likely candidates such as $\mathbf{x}^a$ are accepted. Less likely candidates such as $\mathbf{x}^b$ are accepted with probability $\psi(\mathbf{x}^b)/\psi(\mathbf{x}^{\text{old}})$.

jumps will be accepted in high-dimensional spaces, and many samples are required to form a good representation of the distribution. The hybrid Monte Carlo scheme attempts to improve sampling efficiency and allow larger jumps by exploiting gradient information about the distribution and has been successfully employed in Bayesian neural networks (Neal, 1996).

### *Laplace's Method*

Although sampling techniques can be attractive, convergence to a representative set of samples is difficult to assess and can be very slow. Laplace's method is a perturbation technique motivated by the fact that as the number $P$ of training data points is increased, the posterior distribution typically approaches a Gaussian (Walker, 1969) whose variance goes to zero in the limit $P \to \infty$ (we leave aside here the issues of inherent network symmetries). In order to calculate this Gaussian approximation, we consider the posterior distribution, Equation 21:

$$p(\mathbf{w}|D, \Gamma) \propto \exp(-\phi(\mathbf{w})) \tag{24}$$

and expand $\phi$ around a mode of the distribution, $\mathbf{w}_* = \arg\min \phi(\mathbf{w})$,

$$\phi(\mathbf{w}) \approx \phi(\mathbf{w}_*) + \tfrac{1}{2}(\mathbf{w} - \mathbf{w}_*)^T \mathbf{H}(\mathbf{w} - \mathbf{w}_*) \tag{25}$$

where

$$\mathbf{H} = \nabla\nabla\phi(\mathbf{w})|_{w_*} \tag{26}$$

is the local Hessian matrix. This local expansion defines a Gaussian approximation

$$p(\mathbf{w}|D, \Gamma) \approx \frac{|\mathbf{H}|^{1/2}}{(2\pi)^{k/2}} \exp\{\tfrac{1}{2}(\mathbf{w} - \mathbf{w}_*)^T \mathbf{H}(\mathbf{w} - \mathbf{w}_*)\} \tag{27}$$

The expected value of $f(\mathbf{x}; \mathbf{w})$ as required in Equation 22 can be evaluated by making a further local linearization of the function $f(\cdot, \mathbf{w})$ around the point $w_*$. In a practical implementation, a standard nonlinear optimization algorithm such as conjugate gradients is used to find a mode $w_*$ of the log posterior distribution (Bishop, 1995).

### *Determining Hyperparameters*

So far we have assumed that the hyperparameters of the MLP are fixed. In a fully Bayesian treatment we would define prior distributions of the hyperparameters, and then integrate them out. Since exact integration is analytically intractable, we can use ML-II to estimate specific values for the hyperparameters by maximizing the marginal likelihood $P(D|\Gamma)$ (Equation 17) with respect to $\Gamma$. Using MLPs, the integrand in Equation 17 is non-Gaussian and $p(D|\Gamma)$ needs to be approximated. This can be achieved using Laplace's method by locally expanding the integral to second order in the weights. This leads to simple reestimation formulas for the hyperparameters expressed in terms of the eigenvalue/eigenvector decomposition of the Hessian matrix. This treatment of hyperparameters is called the *evidence* framework (MacKay, 1995) and involves alternating the optimization of $\mathbf{w}$ (mode finding) for fixed hyperparameters with reestimation of the hyperparameters by reevaluating the Hessian matrix for the new value of $\mathbf{w}$. The various approximations involved in this approach improve as the number of data points $P \to \infty$. However, for a finite data set it can be difficult to assess the accuracy of the method. One obvious limitation is that it only takes account of the behavior of the posterior distribution at the mode.

### *The KL Variational Approach*

The Kullback Leibler divergence is a measure of the difference between two probability distributions $p(\mathbf{x})$ and $q(\mathbf{x})$ (Cover and Thomas, 1991)

$$KL(q, p) = \int \{q(\mathbf{x}) \log q(\mathbf{x}) - q(\mathbf{x}) \log p(\mathbf{x})\} d\mathbf{x} \tag{28}$$

This has the advantageous properties $KL \geq 0$ and $KL = 0$ if and only if $p \equiv q$. Consider the $KL$ divergence

$$KL(q(\mathbf{w}), p(\mathbf{w}|\Gamma, D)) \geq 0 \tag{29}$$

Finding the best distribution $q(\mathbf{w})$ in a restricted set of possible distributions by minimizing $KL(q, p)$ gives the best estimate (in the $KL$ sense) to the posterior distribution. From Equation 29 we immediately have the bound

$$\log p(D|\Gamma) \geq \int -q(\mathbf{w}) \log q(\mathbf{w}) d\mathbf{w} + \int q(\mathbf{w}) \log p(D|\Gamma, \mathbf{w}) p(\mathbf{w}) d\mathbf{w} \tag{30}$$

We can make use of this lower bound to carry out an approximate ML-II hyperparameter optimization by the following two-step procedure: First fix the hyperparameters $\Gamma$ and optimize the bound, Equation 30, with respect to $q(\mathbf{w})$. Then, for fixed $q(\mathbf{w})$, optimize the bound with respect to $\Gamma$. This scheme is a generalization of the Expectation-Maximization procedure (see Neal and Hinton in Jordan, 1998) and is also called *ensemble learning* (Barber and Bishop, 1997).

## Bayesian Pruning

To this point we discussed the idea of using a prior that encourages smoothness of the input-output mapping. Insofar as neural networks are nonlinear functions of a linear combination of inputs, it is reasonable to use a prior that encourages small weights, $p(\mathbf{w}) \propto \exp(-\mathbf{w}^T\mathbf{A}\mathbf{w}/2)$. Typically, only diagonal matrices $\mathbf{A}$ are considered. We can group weights into clusters containing one or more weights and associate with each cluster $c$ a common hyperparameter $\alpha_c$. The Bayesian approach results in a posterior distribution over these hyperparameters $\alpha_c$. Alternatively, we can optimize the hyperparameters using ML-II. If the posterior distribution favors large $\alpha_c$ values, then effectively the weight cluster $c$ is not contributing to the network and may be pruned. A useful choice of clustering is to group all the weights from a single input $x_i$ into the hidden units (note that these weights are different from the weights that fan in to a hidden node). If the hyperparameter $\alpha_i$ (after ML-II optimization) associated with the weights fanning out from input $x_i$ is large, the contribution of input $x_i$ is negligible and can be excluded. This is called *automatic relevance determination* (MacKay, 1995).

### *The Relevance Vector Machine*

In the discussion regarding GLMs, $f(\mathbf{x}) = \Sigma_i w_i \phi_i(\mathbf{x})$, we fixed the centers of the basis functions $\phi_i$. Similarly, in the relevance vector machine we use fixed basis functions (Tipping, 2001). By associating with each weight $w_i$ a regularizing prior $p(w_i) \propto \exp(-\alpha_i w_i^2/2)$, we can perform ML-II to optimize the hyperparameters $\alpha_i$. After optimization, typically many of the $\alpha_i$ will become very large, effectively removing the basis function $\phi_i$ from the model. This pruning procedure often results in a much sparser representation of the data in terms of only the "relevant" basis functions; this scheme is therefore particularly useful for compression. This sparseness effect is similar, although not equivalent, to the support vector machine (see SUPPORT VECTOR MACHINES), in which training points are effectively removed if they do not affect the prediction of the model.

## Classification

The previously described methods can be applied to classification, usually with only minor modification. For convenience, we consider here only problems with two classes. The data set is $D = \{(\mathbf{x}^{\mu}, t^{\mu}), \mu = 1, \ldots, P\}$, where $t^{\mu} \in \{0, 1\}$. In a probabilistic framework, we use the output of the network $f(\mathbf{x}; \mathbf{w})$ to represent the probability that the input is in class 1. In this case, the likelihood is

$$p(D|\mathbf{w}) = \prod_{\mu=1}^{P} f(\mathbf{x}^{\mu}; \mathbf{w})^{t^{\mu}}(1 - f(\mathbf{x}^{\mu}; \mathbf{w}))^{1-t^{\mu}} \tag{31}$$

For example, we could take $f(\mathbf{x}) = g(\mathbf{w}^T\mathbf{x})$, where $g(x) = 1/(1 + \exp(-x))$ (Bishop, 1995). In the Bayesian approach, we need to specify a prior belief about the weights. As before, a sensible choice is $p(\mathbf{w}) \propto \exp(-\alpha\mathbf{w}^T\mathbf{w}/2)$, since smaller weights will give less certain predictions. This results in a posterior distribution $p(\mathbf{w}|D) \propto p(D|\mathbf{w})p(\mathbf{w})$. For a novel input $\mathbf{x}$ the probability that it belongs to class 1 is

$$\begin{aligned} p(t = 1|\mathbf{x}, D) &= \int p(t = 1|\mathbf{x}, \mathbf{w})p(\mathbf{w}|D)d\mathbf{w} \\ &= \int g(\mathbf{w}^T\mathbf{x})p(\mathbf{w}|D)d\mathbf{w} \end{aligned} \tag{32}$$

Consider, for example, fitting the data in Figure 5*A*. The posterior distribution is given in Figure 5*D*. The decision boundary ($p(t = 1|\mathbf{x}, \mathbf{w}, D) = 0.5$) for the MAP solution is given in Figure 5*B* along with the 0.1 and 0.9 decision contours. Another decision boundary associated with the posterior weights $\mathbf{w}^A$ is plotted in Figure 5*B*. Because the decision boundaries are linear, the predictions of these single networks away from the data remain overly confident. The Bayesian prediction, Equation 32, is plotted in Figure 5*C* and has decision boundaries that properly account for the uncertainty in the predictions away from the training data.

Since the final integrand in Equation 32 depends only on the weight vector through the "activation" $a = \mathbf{w}^T\mathbf{x}$, we need only know the distribution of this one-dimensional quantity. A reasonable assumption is that the activation will be Gaussian distributed $p(a) = N(\bar{a}, \text{var}(a))$, and the resulting one-dimensional integration $p(t = 1|\mathbf{x}, D) = \int g(a)p(a)da$ can be efficiently performed using quadrature. The statistics of the activation are

$$\bar{a} = \bar{\mathbf{w}}^T\mathbf{x}, \quad \text{var}(a) = \mathbf{x}^T\Sigma\mathbf{x} \tag{33}$$

where $\bar{\mathbf{w}}$ and $\Sigma$ are the mean and covariance of the weight posterior $p(\mathbf{w}|D)$. It is convenient to approximate these statistics using Laplace's method.

## Discussion

The Bayesian framework deals with uncertainty in a natural, consistent manner by combining prior beliefs about which models are

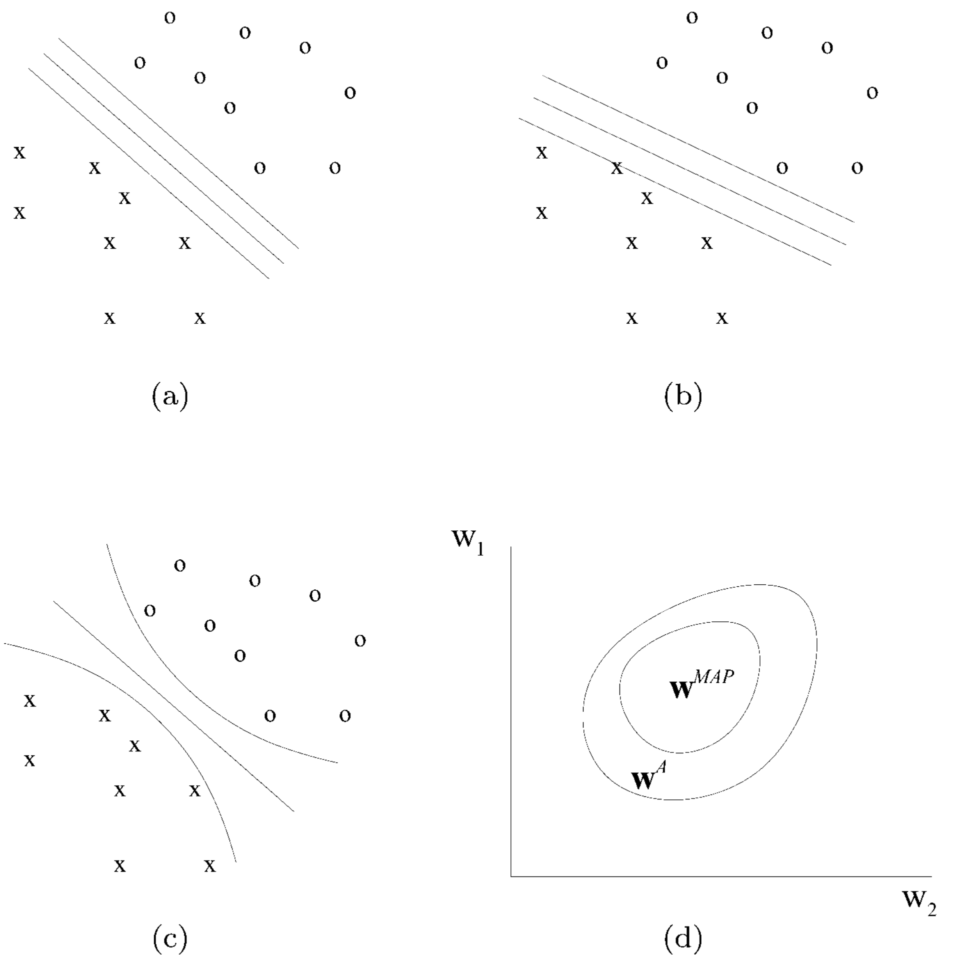

**Figure 5.** *A*, The decision boundary and 0.1, 0.9 decision contours for the most likely predictor $\mathbf{w}^{MAP}$. *B*, The predictions for $\mathbf{w}^A$. *C*, The posterior averaged predictors. *D*, The weight posterior distribution.

appropriate with how likely each model would be to have generated the data. This results in an elegant, general framework for fitting models to data, which, however, may be compromised by computational difficulties in carrying out the ideal procedure. There are many approximate Bayesian implementations, using methods such as sampling, perturbation techniques, and variational methods. Often these enable the successful approximate realization of practical Bayesian schemes. An attractive, built-in effect of the Bayesian approach is an automatic procedure for combining predictions from several different models, the combination strength of a model being given by the posterior likelihood of the model. In the case of models linear in their parameters, Bayesian neural networks are closely related to Gaussian processes, and many of the computational difficulties of dealing with more general stochastic nonlinear systems can be avoided.

Bayesian methods are readily extendable to other areas, in particular density estimation, and the benefits of dealing with uncertainty are again to be found (see Bishop in Jordan, 1998). Traditionally, neural networks are graphical representations of functions, in which the computations at each node are deterministic. In the classification discussion, however, the final output represents a stochastic variable. We can consider such stochastic variables elsewhere in the network, and the sigmoid belief network is an early example of a stochastic network (Neal, 1992). There is a major conceptual difference between such models and conventional neural networks. Networks in which nodes represent stochastic variables are called graphical models (see BAYESIAN NETWORKS) and are graphical representations of *distributions* (GRAPHICAL MODELS: PROBABILISTIC INFERENCE). Such models evolve naturally from the desire of incorporating uncertainty and nonlinearity in networked systems.

# Bayesian Networks

*Judea Pearl and Stuart Russell*

## Introduction

Probabilistic models based on directed acyclic graphs have a long and rich tradition, beginning with work by the geneticist Sewall Wright in the 1920s. Variants have appeared in many fields. Within statistics, such models are known as *directed graphical models*; within cognitive science and artificial intelligence (AI), they are known as *Bayesian networks*. The name honors the Reverend Thomas Bayes (1702–1761), whose rule for updating probabilities in light of new evidence is the foundation of the approach. The initial development of Bayesian networks in the late 1970s was motivated by the need to model the top-down (semantic) and bottom-up (perceptual) combination of evidence in reading. The capability for bidirectional inferences, combined with a rigorous probabilistic foundation, led to the rapid emergence of Bayesian networks as the method of choice for uncertain reasoning in AI and expert systems, replacing earlier, ad hoc rule-based schemes (Pearl, 1988; Shafer and Pearl, 1990; Jensen, 1996).

The nodes in a Bayesian network represent propositional variables of interest (e.g., the temperature of a device, the sex of a patient, a feature of an object, the occurrence of an event) and the links represent informational or causal dependencies among the variables. The dependencies are quantified by conditional probabilities for each node, given its parents in the network. The network supports the computation of the probabilities of any subset of variables given evidence about any other subset.

Figure 1 illustrates a simple yet typical Bayesian network. It describes the causal relationships among five variables: the season of the year ($X_1$), whether it's raining or not ($X_2$), whether the sprinkler is on or off ($X_3$), whether the pavement is wet or dry ($X_4$), and whether the pavement is slippery or not ($X_5$). Here, the absence of a direct link between $X_1$ and $X_5$, for example, captures our understanding that there is no direct influence of season on slipperiness;

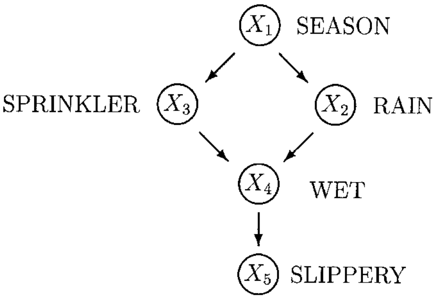

**Figure 1.** A Bayesian network representing causal influences among five variables. Each arc indicates a causal influence of the "parent" node on the "child" node.

the influence is mediated by the wetness of the pavement. (If freezing is a possibility, then a direct link could be added.)

Perhaps the most important aspect of Bayesian networks is that *they are direct representations of the world, not of reasoning processes*. The arrows in the diagram represent real causal connections and not the flow of information during reasoning (as in rule-based systems and neural networks). Reasoning processes can operate on Bayesian networks by propagating information in any direction. For example, if the sprinkler is on, then the pavement is probably wet (prediction); if someone slips on the pavement, that also provides evidence that it is wet (abduction, or reasoning to a probable cause). On the other hand, if we see that the pavement is wet, that makes it more likely that the sprinkler is on or that it is raining (abduction); but if we then observe that the sprinkler is on, that reduces the likelihood that it is raining (explaining away). It is this last form of reasoning, explaining away, that is especially difficult to model in rule-based systems and neural networks in any natural way, because it seems to require the propagation of information in two directions.

## Probabilistic Semantics

Any complete probabilistic model of a domain must, either explicitly or implicitly, represent the *joint distribution*—the probability of every possible event as defined by the values of all the variables. There are exponentially many such events, yet Bayesian networks achieve compactness by factoring the joint distribution into local, conditional distributions for each variable given its parents. If $x_i$ denotes some value of the variable $X_i$ and $pa_i$ denotes some set of values for $X_i$'s parents, then $P(x_i \mid pa_i)$ denotes this conditional distribution. For example, $P(x_4 \mid x_2, x_3)$ is the probability of wetness given the values of sprinkler and rain. The *global semantics* of Bayesian networks specifies that the full joint distribution is given by the product

$$P(x_1, \ldots, x_n) = \prod_i P(x_i \mid pa_i) \qquad (1)$$

In our example network, we have

$$\begin{aligned} &P(x_1, x_2, x_3, x_4, x_5) \\ &\quad = P(x_1)P(x_2 \mid x_1)P(x_3 \mid x_1)P(x_4 \mid x_2, x_3)P(x_5 \mid x_4) \qquad (2) \end{aligned}$$

Provided that the number of parents of each node is bounded, it is easy to see that the number of parameters required grows only linearly with the size of the network, whereas the joint distribution itself grows exponentially. Further savings can be achieved using compact parametric representations, such as noisy-OR models, decision trees, or neural networks, for the conditional distributions. For example, in *sigmoid* networks (see Jordan, 1999), the conditional distribution associated with each variable is represented as a sigmoid function of a linear combination of the parent variables; in this way, the number of parameters required is proportional to, rather than exponential in, the number of parents.

There is also an entirely equivalent *local semantics* that asserts that each variable is independent of its nondescendants in the network given its parents. For example, the parents of $X_4$ in Figure 1 are $X_2$ and $X_3$, and they render $X_4$ independent of the remaining nondescendant, $X_1$. That is,

$$P(x_4 \mid x_1, x_2, x_3) = P(x_4 \mid x_2, x_3)$$

The collection of independence assertions formed in this way suffices to derive the global assertion in Equation 1, and vice versa. The local semantics is most useful in *constructing* Bayesian networks, because selecting as parents *all* the direct causes of a given variable invariably satisfies the local conditional independence conditions (Pearl, 2000, p. 30). The global semantics leads directly to a variety of algorithms for reasoning.

## Evidential Reasoning

From the product specification in Equation 1, one can express the probability of any desired proposition in terms of the conditional probabilities specified in the network. For example, the probability that the sprinkler is on, given that the pavement is slippery, is

$$\begin{aligned} P(X_3 = on \mid X_5 = true) &= \frac{P(X_3 = on,\ X_5 = true)}{P(X_5 = true)} \\ &= \frac{\sum_{x_1, x_2, x_4} P(x_1, x_2, X_3 = on, x_4, X_5 = true)}{\sum_{x_1, x_2, x_3, x_4} P(x_1, x_2, x_3, x_4, X_5 = true)} \\ &= \frac{\sum_{x_1, x_2, x_4} P(x_1)P(x_2 \mid x_1)P(X_3 = on|x_1)P(x_4 \mid x_2, X_3 = on)P(X_5 = true \mid x_4)}{\sum_{x_1, x_2, x_3, x_4} P(x_1)P(x_2 \mid x_1)P(x_3 \mid x_1)P(x_4 \mid x_2, x_3)P(X_5 = true \mid x_4)} \end{aligned}$$

These expressions can often be simplified in ways that reflect the structure of the network itself. The first algorithms proposed for probabilistic calculations in Bayesian networks used a local, distributed message-passing architecture, typical of many cognitive activities (Kim and Pearl, 1983). Initially this approach was limited to tree-structured networks, but it was later extended to general networks in Lauritzen and Spiegelhalter's (1988) method of join-tree propagation. A number of other exact methods have been developed and can be found in recent textbooks (Jensen, 1996; Jordan, 1999).

It is easy to show that reasoning in Bayesian networks subsumes the satisfiability problem in propositional logic and, hence, is NP-hard. Monte Carlo simulation methods can be used for approximate inference (Pearl, 1988), giving gradually improving estimates as sampling proceeds. (These methods use local message propagation on the original network structure, unlike join-tree methods.) Alternatively, variational methods provide bounds on the true probability (Jordan, 1999).

## Uncertainty over Time

Entities that live in a changing environment must keep track of variables whose values change over time. Dynamic Bayesian networks, or DBNs, capture this process by representing multiple copies of the state variables, one for each time step (Dean and Kanazawa, 1989). A set of variables $\mathbf{X}_t$ denotes the world state at time $t$ and a set of sensor variables $\mathbf{E}_t$ denotes the observations available at time $t$. The *sensor model* $P(\mathbf{E}_t \mid \mathbf{X}_t)$ is encoded in the conditional probability distributions for the observable variables, given the state variables. The *transition model* $P(\mathbf{X}_{t+1} \mid \mathbf{X}_t)$ relates the state at time $t$ to the state at time $t + 1$. Keeping track of the world, known as *filtering*, means computing the current probability distribution over world states given all past observations, i.e., $P(\mathbf{X}_t \mid \mathbf{E}_1, \ldots, \mathbf{E}_t)$. Dynamic Bayesian networks include as special cases other temporal probability models, such as hidden Markov models (DBNs with a single discrete state variable) and Kalman filters (DBNs with continuous state and sensor variables and linear Gaussian transition and sensor models). For the general case, exact filtering is intractable, and a variety of approximation algorithms have been developed. The most popular and flexible of these is the family of *particle filtering* algorithms (see Doucet, de Freitas, and Gordan, 2001).

## Learning in Bayesian Networks

The conditional probabilities $P(x_i \mid pa_i)$ can be updated continuously from observational data using gradient-based or Expectation-Maximization (EM) methods that use just local information derived from inference (Binder et al., 1997; Jordan, 1999), in much the same way as weights are adjusted in neural networks. It is also possible to learn the structure of the network, using methods that trade off network complexity against degree of fit to the data (Friedman, 1998). As a substrate for learning, Bayesian networks have the advantage that it is relatively easy to encode prior knowledge in network form, either by fixing portions of the structure or by using prior distributions over the network parameters. Such prior knowledge can allow a system to learn accurate models from much less data than are required by *tabula rasa* approaches.

## Causal Networks

Most probabilistic models, including general Bayesian networks, describe a distribution over possible observed events, as in Equation 1, but say nothing about what will happen if a certain *intervention* occurs. For example, what if I *turn the sprinkler on*? What effect does that have on the season, or on the connection between wetness and slipperiness? A *causal network*, intuitively speaking, is a Bayesian network with the added property that the parents of each node are its direct causes, as in Figure 1. In such a network, the result of an intervention is obvious: the sprinkler node is set to $X_3 = on$, and the causal link between the season $X_1$ and the sprinkler $X_3$ is removed. All other causal links and conditional probabilities remain intact, so the new model is

$$P(x_1, x_2, x_3, x_4, x_5) = P(x_1)P(x_2 \mid x_1)P(x_4 \mid x_2, X_3 = on)P(x_5 \mid x_4)$$

Notice that this differs from *observing* that $X_3 = on$, which would result in a new model that included the term $P(X_3 = on|x_1)$. This mirrors the difference between seeing and doing: after observing that the sprinkler is on, we wish to infer that the season is dry, that it probably did not rain, and so on; an arbitrary decision to turn the sprinkler on should not result in any such beliefs.

Causal networks are more properly defined, then, as Bayesian networks in which the correct probability model after intervening to fix any node's value is given simply by deleting links from the node's parents. For example, *fire* → *smoke* is a causal network, whereas *smoke* → *fire* is not, even though both networks are equally capable of representing any joint distribution on the two variables. Causal networks model the environment as a collection of stable component mechanisms. These mechanisms may be reconfigured locally by interventions, with correspondingly local changes in the model. This, in turn, allows causal networks to be used very naturally for prediction by an agent that is considering various courses of action (Pearl, 2000).

## Functional Bayesian Networks

The networks discussed so far are capable of supporting reasoning about evidence and about actions. Additional refinement is necessary in order to process *counterfactual* information. For example, the probability that "the pavement would not have been slippery had the sprinkler been OFF, given that the sprinkler is in fact ON and that the pavement is in fact slippery" cannot be computed from the information provided in Figure 1 and Equation 1. Such counterfactual probabilities require a specification in the form of functional networks, where each conditional probability $P(x_i|pa_i)$ is replaced by a functional relationship $x_i = f_i(pa_i, \epsilon_i)$, where $\epsilon_i$ is a stochastic (unobserved) error term. When the functions $f_i$ and the distributions of $\epsilon_i$ are known, all counterfactual statements can be assigned unique probabilities, using evidence propagation in a structure called a "twin network." When only partial knowledge about the functional form of $f_i$ is available, bounds can be computed on the probabilities of counterfactual sentences (Pearl, 2000).

## Causal Discovery

One of the most exciting prospects in recent years has been the possibility of using Bayesian networks to discover causal structures in raw statistical data (Pearl, 2000)—a task previously considered impossible without controlled experiments. Consider, for example, the following *intransitive* pattern of dependencies among three events: $A$ and $B$ are dependent, $B$ and $C$ are dependent, yet $A$ and $C$ are independent. If you ask a person to supply an example of three such events, the example would invariably portray $A$ and $C$ as two independent causes and $B$ as their common effect, namely, $A \rightarrow B \leftarrow C$. (For instance, $A$ and $C$ could be the outcomes of tossing two fair coins, and $B$ could represent a bell that rings whenever either coin comes up heads.) Fitting this dependence pattern with a scenario in which $B$ is the cause and $A$ and $C$ are the effects is mathematically feasible but very unnatural, because it must entail fine tuning of the probabilities involved; the desired dependence pattern will be destroyed as soon as the probabilities undergo a slight change.

Such thought experiments tell us that certain patterns of dependency, which are totally void of temporal information, are conceptually characteristic of certain causal directionalities and not others. When put together systematically, such patterns can be used to infer causal structures from raw data and to guarantee that any alternative structure compatible with the data must be less stable than the one(s) inferred; namely, slight fluctuations in parameters will render that structure incompatible with the data.

## Plain Beliefs

In mundane decision making, beliefs are revised not by adjusting numerical probabilities but by tentatively accepting some sentences as "true for all practical purposes." Such sentences, called *plain beliefs*, exhibit both logical and probabilistic character. As in classical logic, they are propositional and deductively closed; as in probability, they are subject to retraction and can be held with varying degrees of strength. Bayesian networks can be adopted to model the dynamics of plain beliefs by replacing ordinary probabilities with nonstandard probabilities, that is, probabilities that are infinitesimally close to either zero or one (Goldszmidt and Pearl, 1996).

## Discussion

Bayesian networks may be viewed as normative cognitive models of propositional reasoning under uncertainty. They handle noise and partial information using local, distributed algorithms for inference and learning. Unlike feedforward neural networks, they facilitate local representations in which nodes correspond to propositions of interest. Recent experiments suggest that they accurately capture the causal inferences made by both children and adults (Tenenbaum and Griffiths, 2001). Moreover, they capture patterns of reasoning, such as explaining away, that are not easily handled by any competing computational model. They appear to have many of the advantages of both the "symbolic" and the "subsymbolic" approaches to cognitive modeling, and are now an essential part of the foundations of computational neuroscience (Jordan and Sejnowski, 2001).

Two major questions arise when we postulate Bayesian networks as potential models of actual human cognition. First, does an architecture resembling that of Bayesian networks exist anywhere in the human brain? At the time of writing, no specific work has been done to design neurally plausible models that implement the required functionality, although no obvious obstacles exist. Second, how could Bayesian networks, which are purely propositional in their expressive power, handle the kinds of reasoning about individuals, relations, properties, and universals that pervade human thought? One plausible answer is that Bayesian networks containing propositions relevant to the current context are constantly being assembled, as needed, from a more permanent store of knowledge. For example, the network in Figure 1 may be assembled to help explain why this particular pavement is slippery right now, and to decide whether this can be prevented. The background store of knowledge includes general models of pavements, sprinklers, slipping, rain, and so on; these must be accessed and supplied with instance data to construct the specific Bayesian network structure. The store of background knowledge must utilize some representation that combines the expressive power of first-order logical languages (such as semantic networks) with the ability to handle uncertain information. Substantial progress has been made on constructing systems of this kind (Koller and Pfeffer, 1998), but as yet no overall cognitive architecture has been proposed.

# Biologically Inspired Robotics

*Noel E. Sharkey*

## Introduction

At the beginning of the twenty-first century, living organisms have still not been successfully replicated by machines. Computers are much faster at number crunching than humans and can even beat the greatest at chess, and other machines can perform routine physical tasks faster than us and with a precision that we cannot approach. However, animals exhibit such remarkable capacities for flexible adaptation to novel circumstances that roboticists can only gaze in wonder. It is thus an important goal of modern robotics to learn from the way organisms are constructed biologically, and how this creates adaptive behaviors.

Biologically inspired robotics, also known as biomimetic robotics or biorobotics, refers to robotics research in which the life sciences, including biology, psychology, ethology, neuroscience, and evolutionary theory, play a key role in motivating the research. It is necessarily broad because the field is just beginning to emerge as a unified discipline, and so it still has fuzzy boundaries. Biorobotics research ranges from modeling animal sensors in hardware for guiding robots in target environments to investigating the interaction between neural learning and evolution in a variety of robot tasks. There are, however, common themes that will be explored here.

In the following sections, some of the major issues in biorobotics research and the aims of this approach are examined. First we briefly consider the historical roots of the core ideas. The seminal work of Grey Walter (1953) sets the scene and introduces some of the key elements of biologically inspired robotics. The re-introduction and development of the ideas in the 1980s occurred with Braitenberg's *synthetic psychology* and Brook's *behavior-based* robotics. In summarizing the breadth of the current work, we attempt a threefold classification of biologically inspired robotics.

## The Roots of Biologically Inspired Robotics

The roots of biologically inspired robotics date back to the early twentieth century, when Hammond constructed a heliotrope based on the biologist Loeb's tropism theory of animal behavior. Loeb proposed that animals are attracted and repelled by stimuli in the environment in a way similar to the phototropic responses of plants. Although Hammond's heliotrope did not model an animal, its mechanized movement toward light was sufficient to satisfy Loeb that his theory has physical plausibility (cf. Sharkey and Ziemke in Ziemke and Sharkey, 1998, pp. 361–392, for an account).

There were a number of robot learning studies during the first half of the twentieth century, before the birth of artificial intelligence (AI). However, the prototypical biorobotics work was conducted by Grey Walter (1953). He went far beyond Hammond in testing the mechanistic plausibility of animal tropism. His aim was to create a self-sustaining artificial life form that could adapt. This required the development of a robot that could seek out a source to recharge its batteries on demand.

Grey Walter used electromechanical robots equipped with two input "receptors": a photo-electric cell for sensitivity to light, and an electrical contact as a touch receptor. The controller, between sensors and motors, was a small artificial nervous system built from miniature valves, relays, condensers, batteries, and small electric motors—no computer. There was a hutch where a robot could drive in to have the battery automatically recharged.

Behavior resulted from the interaction of the internal states of the robot (battery level) and the intensity of light sources, as well as other environmental factors such as obstacles. When the battery levels were high, the robot was repelled by the bright light of the hutch and attracted by the moderate light in the room, where it "explored." With low battery levels, the robot was attracted to the bright light of the hutch for an automatic recharge. In this way Grey Walter demonstrated that mechanical tropism could work as a means of exploration and maintaining energy.

Grey Walter (1953) also investigated adaptation and showed how a simple learning mechanism could extend the behavior of a robot using the conditioned reflex analog (CORA) with a microphone for auditory input.

Biorobotics more or less died when Grey Walter moved on to other research in the 1950s. With the rise of AI and computing, the focus was on providing robots with human-inspired perception and cognition. The new robots had a series of modules, such as visual processing, planning, and reasoning, through which sensory information passed serially. Typically, a decision-making module controlled the output to the actuators. This was in contrast to the more direct control approach of Grey Walter, in which the only mediation between sensing and moving was provided by an artificial neural net consisting of two hardware neurons. Another difference was that whereas AI robotics focused on human cognition, Grey Walter focused on the question of how seemingly complex animal-like behavior could arise from simple mechanisms such as tropisms and reflexes.

Today the term *taxis* is used instead of tropism to refer to the movement of an animal directed by a stimulus, either negatively or positively. Examples of such stimulus-directed activity include chemotaxis (chemical taxis), geotaxis (gravity), phototaxis (light), and phonotaxis (auditory). Although Grey Walter worked only on individual taxes, biologists at the time (e.g., Fraenkel and Gunn; cf. Sharkey and Ziemke in Ziemke and Sharkey, 1998, pp. 361–392) proposed that the behavior of many organisms could be explained by a combination of taxes working together and in opposition. They cited Fraenkel's study of the coastal slug, *Littorina neritoides*. *Littorina* combines positive and negative phototaxis with negative geotaxis to feed and survive. Subsequently, combinations of taxes have been used as powerful explanations of many animal behaviors, from bacteria feeding to insect pheromone trailing to fish breeding and feeding.

These ideas began to emerge in a new wave of robotics during the 1980s as a result of two major influences. First, the neuroanatomist Valentino Braitenberg showed how a number of complex behaviors could emerge from a combination of very simple neural networks encoding different taxes (Braitenberg, 1984). Second, Rodney Brooks's development of subsumption architecture allowed autonomous control by a combination of taxes, and drove home the effectiveness of behavior-based robotics. His major papers from this period are reprinted in Brooks (1999). In this style of robotics, each behavior-producing module, such as *avoid obstacles* or *move toward light*, is encoded as a separate program module such that each is directly under the control of environmental circumstances rather than a central controller. For example, when there is light on the sensors, the *move toward light* module will be active until the light is occluded by an obstacle, at which point the *avoid obstacles* module takes over.

## Current Directions in Biorobotics

A large emerging body of research in robotics is making the connection between sensing and moving simple, and the relationship between robot and world tightly coupled. It was the dramatic increase in robotics research, riding on the back of the new behavior-based approach, that enabled biologically inspired robotics to flourish. Since the behavior-based approach grew directly from ideas in the life sciences, it was only natural that once the tools and techniques of the approach had been developed, they would be turned back to work on the source of inspiration.

In this article, biorobotics is divided into three main classes. Although these classes are mutually supportive and their paths often cross, the distinctions between them are nonetheless useful.

- The *generalized* approach follows from the lineage of ideas that inspired Grey Walter to use robots to investigate and extend general mechanistic theories of animal behavior and adaptation. This includes research using neural network adaptation through learning and/or evolutionary methods (see Reactive Robotic Systems).
- The *specific* approach uses methods from the generalized approach to investigate specific species or organisms. The research can range from studies of the physical plausibility of a simple neural explanation for some target behavior pattern to the physical modeling of a particular animal or some of its senses. Models can be evaluated by observing the target behavior of the robot interacting with the environment through sensing and moving. One of the main goals of specific biorobotics is to develop new methods for scientific modeling.
- The *theoretical* division is a mixed bag that provides an examination of the implications of the research for a number of disciplines. The issues range widely, from discussions of robot embodiment to the nature of life. Although all biorobotics has a theoretical component, the theoretical approach is distinct in not requiring empirical work.

The idea was to include only work that at least touched base with the life sciences with respect to the type of controllers and the method of adaptation used. Each of the classes is dealt with in more depth in the following three subsections.

### *Generalized Biorobotics*

The research impetus is to use broad notions derived from the life sciences for robot control. Many of these notions are in the form of implicit assumptions, such as deriving complex behavior from the simplest possible mechanisms or using the ideas of taxis or tropism for automated control. In this sense, Grey Walter's research was prototypical generalized biorobotics. His work on classical conditioning with the CORA architecture also foresaw the modern focus on adaptive techniques in robotics. The biological currency in the generalized biorobotics community mostly consists of abstract models of neural network learning, animal learning, or evolutionary processes, or a mixture. In the next two subsections, the main trends will be discussed.

*Evolution.* Evolutionary methods have been used for many applications since the 1950s when the first Genetic Algorithm (GA; see Evolution of Artificial Neural Networks) was developed by Friedman for his master's thesis on evolving control circuits for autonomous robots. These methods are particularly useful for constraining search in very large search spaces. However, from the perspective of biorobotics, the most important reason for employing evolutionary methods is that they are abstractly related to the Darwinian principle of natural selection and may be seen as analogous to real evolutionary theory; i.e., there is a fitness function to decide how fit a particular program is in the context of the problem it is to solve, and there are mutation and crossover to operate on the computer equivalent of gene strings. Given the intended relationship between the behavior of biorobots and natural biological behavior, the development of an *evolutionary robotics* is a very important step.

A fairly typical example of evolutionary methods for single robots is Nolfi's garbage collector (in Sharkey, 1997, pp. 187–198). The connection weights were evolved to control a miniature robot equipped with distance sensors and a gripper. The task was to "clean" an arena by picking up objects and dropping them off outside. To do this, the robot had to move around the arena, avoid obstacles, locate an object, pick it up, move toward the walls, and release the object outside the arena. After 1,000 generations, robot controllers were evolved that performed the cleaning task to a high degree of accuracy.

Most evolutionary robotics research relies on using a fixed neural network architecture on which the weights are evolved. Another interesting approach is to let the evolutionary method decide on the type of connectivity between the units in the net; i.e., the pattern of connectivity is "genetically" represented (see Husbands et al. in Ziemke and Sharkey, 1998, pp. 185–210).

An important reasearch area in biorobotics is concerned with how the environment and other species co-evolve with a given organism, resulting in an *evolutionary arms race*. This issue has been taken up in the simple form of evolving two competing robot controllers at the same time. For example, Floreano and Nolfi (1997) co-evolved the controllers for predator and prey behavior for two different "species" as part of each other's environment. One of the main problems was that in one generation the predators would win but in the next generation the prey would win because a counterstrategy was evolved. This instability has been overcome by introducing neural network learning during the lifetime of the individuals. In this way the predators were able to adapt to the new evolved strategies of the prey.

The approach of combining the two adaptive techniques of evolutionary methods and neural network learning is proving to be a very effective adaptation technique that has a naturalistic flavor. Much of the research on combining has focused on how learning can help guide evolution—the *Baldwin effect*. The idea is that if the genotype of an individual is close to an optimal combination of genes, learning can allow that individual to increase its suitability for its environment, thereby increasing its probability of survival and reproduction. This could lead to a larger "basin" of fitness around optimal genotypes, channeling evolution toward optimal solutions (see Nolfi and Floreano, 1999, for a review).

*Learning.* One of the most widely used learning techniques in biorobotics is reinforcement or reward learning (RL) (see, e.g., Krose, 1995). RL has been studied psychologically since the beginning of the twentieth century. An advantage of RL techniques in robotics is that the learner needs only occasional reinforcement. RL is therefore unlike supervised learning, which requires a trainer to provide the learner with an exact target action in every time step, suited for use in unknown environments or tasks (but see Sharkey, 1998, on the use of innate controllers for training supervised learning).

More recently there has been a move toward using the *operant conditioning* techniques developed in the 1940s for studies of animal learning. Operant conditioning involves the shaping of pregiven behaviors. In particular, animals can be trained to produce an experimenter-required behavior when they are rewarded for successive approximations to that behavior. For example, to begin training a rat to press a bar for food, rewards are given for any reaching movement. Then successive approximations to the goal are rewarded until the target behavior is observed. In robotics, this has also been called behavior editing by Dorigo and Colombetti (1998), who have conducted most of the experimental work on this technique. An extension of this work to include incremental shaping is discussed by Urzelai et al. (in Zimke and Sharkey, 1998, pp. 341–360).

In a realistic approach, Saksida et al. (in Sharkey, 1997, pp. 231–249) successfully used operant conditioning to modify the interaction between behaviors that had been preprogrammed into a robot. This departure from using reinforcement learning as a trial-and-error approach to modify existing behaviors is a step toward real animal training. Furthermore, unlike most RL work, the training was conducted by a human trainer rather than a programmed reinforcer. Initially, the robot has three categories of objects: a bright orange jacket, green and pink plastic dog toys, and blue plastic recycling bins. One of its innate behaviors was to approach the plastic dog toys and pick them up. Successful (fast) shaping was shown for a number of new behaviors, including *Follow the Trainer, Recycling*, and *Playing Fetch.*

### Specific Biorobotics

One of the attractions of robotics is that there is strong potential for testing the relationship between a model and some hypothesized behavioral consequences in the physical world. When Hammond built his heliotrope in the early twentieth century to test Loebian theory, it was essentially the physical plausibility of the theory that was under scrutiny. This was generalized biorobotics in that the hypotheses were about all animals. One of the goals of specific biorobotics is to extend such physical testing to test specific hypotheses about specific species. The motivation is that mathematical specification and computer simulation provide only a weak test of a model in that the inputs are typically chosen by the researcher and the outputs are designed to be interpretable as data points or graphs. The central idea of specific biorobotics is to test the model by situating the robot in a physical environment that provides the main features of the world of the target species.

There are a number of dangers with this approach, and a number of wrinkles will have to be ironed out before such modeling reaches maturity as a test methodology in biology and psychology. For example, with complex neural networks such as brains, it is not always possible to isolate a mechanism and test its behavioral consequences. Although robotics can offer a window on the possible behaviors resulting from particular models, a model cannot generally be used directly as a robot controller; a number of "gaps" between the sensors, the model, and motor output have to be filled in. This can be advantageous in forcing the theorist to extend the theoretical mechanisms, but care must be taken to ensure that mechanisms outside the theoretical framework do not play a causal role in the robot behavior.

Robotic modeling of living systems has taken a number of different forms, from behavioral modeling (see, e.g., Webb in Gaussier, 1996, pp. 117–134, on cricket phonotaxis; Grasso et al. in Chang and Guadiano, 2000, pp. 115–131 on lobster chemotaxis) to neuroscientific modeling (e.g., Burgess et al. in Ziemke and Sharkey, 1998, pp. 291–300, and Recce et al. in Sharkey, 1997, pp. 393–406, on the rat hippocampus; van der Smagt in Ziemke and Sharkey, 1998, pp. 301–320, on the human cerebellum for arm control) to modeling animal sensing (e.g., Lambrinos et al. in Chang and Guadiano, 2000, pp. 39–64, on ant solar compass sensing; Blanchard et al. in Chang and Guadiano, 2000, pp. 17–38, on locust sensing of approach; Rucci in Chang and Guadiano, 2000, pp. 181–193, on localization of auditory and visual structures in the barn owl) to biomechanics (e.g., Delcomyn and Nelson in Chang and Guadiano, 2000, pp. 5–15, and Quinn and Ritzman in Ziemke and Sharkey, 1998, pp. 239–254, on hexapod walking in the cockroach).

One of the most successful attempts at behavioral modeling has been the work of Webb and her associates (e.g., Webb in Gaussier, 1996, on mate selection in the female cricket). A wheeled robot was used to physically model a female cricket locating a conspecific male by following its calls. The robot was equipped with an auditory system capable of selectively localizing the sound of a male cricket stridulating (rubbing its wings together rapidly to produce a sound that attracts potential mates).

A similar approach has been taken by Lambrinos et al. (in Chang and Gaudiano, 2000, pp. 39–64) for modeling the sensors of the desert ant *Cataglyphus*, which maintains its heading across a largely featureless desert using polarized light sensing. Lambrinos et al. built special-purpose polarized light sensors based on what is known about the neural mechanisms of polarization that the honey bee *Apis mellifera*, the field cricket *Gyrllus campestris*, and the desert ant *Cataglyphus bicolor* use to determine the position of the sun. The sensors were mounted on a wheeled robot and used to test different models of how *Cataglyphus* maintains its heading with polarized light. The research has been successfully conducted on a mobile robot in the ant's natural habitat with a homing performance similar to that of the ant.

As in Webb's work, the "ant robot" was used to model only a small part of the whole process of finding the direction to the nest. It did not, for example, accommodate the movement of the sun across the sky during the day (although this information was used to make corrections to the data). The sun moves relative to Earth at an average of 15° per hour (this figure varies greatly according to the time of day). In the early part of the twentieth century, this fact was used to show that ants both memorized the position of the sun and compensated for its movement. When the ants are imprisoned in a dark box for 2½ hours and released, they deviate from their original bearing by approximately the same number of degrees as the sun moved during their imprisonment. These findings reveal that *Cataglyphus* keeps track of the azimuth during the day and uses this information in maintaining a course.

Another important aspect of robotics used for modeling concerns legged locomotion. This leads to a two-way interaction between model testing and engineering. A number of researchers have turned to insect locomotion as a way to find a type of gait for a legged robot. Quinn and Ritzmann (in Ziemke and Sharkey, 1998, pp. 239–254) have designed and built a hexapod robot based on detailed neurobiological and kinematic observations of the locomotion of the death's head cockroach, *Blaberus discoidalis*. As a result, the robot's kinematics are remarkably similar to those of the real cockroach, and issues addressed in controlling the artificial cockroach have actually lead to new understanding of its natural counterpart.

Moving onto the mammalian nervous system, Burgess, Donnett, and O'Keefe (in Ziemke and Sharkey, 1998, pp. 291–300) used a miniature mobile robot equipped with a camera to test a neuronal model of how internal and external sensory information contribute to the firing of place cells in the rat hippocampus, and how these cells contribute to rat navigation behavior. They tested hypotheses based on their earlier neurophysiological work on the rat hippocampus using single-cell recording techniques. The robot experiments showed that the information provided by the robot's onboard video, odometry, and proximity sensors was sufficient to allow reasonably accurate return to an unmarked goal location. Similar robot modeling work has also been carried out by Recce et al. (in Sharkey, 1997, pp. 393–406) using the hippocampus as a method of absolute localization.

Research in specific biorobotics is gathering momentum as robot and sensing technology continues to improve. There are still many modeling issues to be worked out in conjunction with biology. The next step would be to get the morphology of robots to more accurately model the bodies and movement of the target species and to work continuously toward the goal of modeling whole animals, rather than installing patches to cover the missing bits. Like computational modeling, great care must be taken to ensure that the patches do not have a causal role in the target behavior.

## *Theoretical Biorobotics*

Theoretical biorobotics is the most abstract level of biologically inspired robotics. Essentially, theoretical biorobotics is an all-encompassing category for work that does not involve implementation on a robot but rather addresses metaquestions about robotics. Although wide-ranging, the main theoretical focus of biologically inspired robotics concerns biological and psychological issues. Many of these issues draw on detailed philosophical reasoning. Here we will confine ourselves to setting out some of the main points and referencing more detailed works in the literature.

A strong impetus for the new wave in biologically inspired robotics was the way it differed from traditional AI. Rodney Brooks, one of the prime movers in the mid-1980s, was concerned with the inadequacy of the prevailing methods used in AI for robotics (see, e.g., Brooks, 1999). Based mainly on the cognitivist conception of human intelligence, the sensory input to robots went through a number of strategic stages such as perception, planning, and reasoning before each move. All of the information was presented to a central controller, which decided how to act. This slowed performance to a single small move about every 15 minutes.

Rejecting cognitivism, theoretical biorobotics views intelligence as *embodied* in the machine and in its interactions with the world in which it is situated. Extreme cognitivists hold that mind is essentially a computer program, a language of thought, that could be run on any machine capable of running it. Mind is simply linked to the machine running it and the external world through transducers. Extreme bioroboticists might claim that mind is inseparable from the individual machine and the more encompassing environmental machine of which the individual machine is a part. That is, the robot is *situated* in the world and is an *embodied* or *physically grounded* intelligence.

Varela, Thompson, and Rosch (1991) provide an insightful discussion of the details of embodiment in robots and its relation to life and mind. These authors are primarily interested in how living systems are embodied and how they are situated in their interactions with the world. Their purpose is to urge cognitive science to reject the vacuity of ungrounded thought. However, Sharkey and Ziemke (in Ziemke and Sharkey, 1998), while going along with some of the account by Varela et al. of living systems, argue for a weak embodiment in robotics, i.e., that robots can be used to *model* embodiment without themselves being embodied (see Philosophical Issues in Brain Theory and Connectionism).

Another idea that has received considerable attention is that of *emergence* or *emergent behavior*. This is the notion that we can get something for nothing (or very little). One analogy is that from a collection of many molecules of water a cloud emerges that is greater than the sum of the parts. Perhaps a better example is the emergence of collective behavior in insects when each insect carries out very simple behaviors. For example, it is argued that the extraordinary structures that termites build in the desert emerge from very simple behaviors. Clark (1997) provides an in-depth discussion of emergent behavior and describes the two rules required by the termites: "If not carrying anything and you bump into a wood chip, pick it up"; and "If carrying a wood chip and you bump into another one, put it down." The resultant piling behavior emerges from the interplay between simple rules and the constraints of the environment.

The idea, then, is that coherent behavior emerges from a collection of simple taxes working together at the same time. This was an outright rejection of the notion of a central controller for action that was prevalent in AI. The idea in AI was to provide the robot with a model of the world, whereas one of the favorite slogans of the new roboticists is "the world is its own model." Nonetheless, Sharkey and Ziemke (2001) caution that even the taxes are emergent in the sense that they are in the eye of the beholder; i.e., they are distal descriptions of behavior.

One of the healthiest signs in the field is that some mainstream biologists and psychologists have begun to write about the relationship between specific biological findings and robotics. Navigation, for example, is an important topic in both biology and robotics, and biologists (e.g., Collett in Ziemke and Sharkey, 1998, pp. 255–270; Etienne in Ziemke and Sharkey, 1998, pp. 271–290; Franz and Mallot in Chang and Guadiano, 2000, pp. 133–153) have discussed the relation between different aspects of navigation from an insect and mammalian perspective. Moreover, psychologists are beginning to take robot studies using animal learning techniques seriously enough to write detailed discussions of the relationship between the natural and the metallic (e.g., Savage in Ziemke and Sharkey, 1998, pp. 321–340).

## Conclusions

The field of biologically inspired robotics has been classified into the three separate subfields of generalized, specific, and theoretical. General and theoretical biorobotics has a long but patchy history that is now a considerable and growing field. Specific biorobotics has gradually emerged from the other two and is fast making headway toward the goal of accurately modeling specific animal species. With the ever-increasing improvements in materials, sensors, and computing equipment, we can look forward to many exciting new developments over the coming decade and the transfer of the findings into engineering.

# Biophysical Mechanisms in Neuronal Modeling

*Lyle J. Graham*

## Introduction

Models of single neurons span a wide range, with more or less fidelity to biological facts (see Perspective on Neuron Model Complexity; Single-Cell Models; Mechanisms in Neuronal Modeling). So-called biophysically detailed compartmental models of single neurons typically aim to quantitatively reproduce membrane voltages and currents in response to some sort of "synaptic" input. We may think of them as Hodgkin-Huxley-Rall models, based on the hypothesis of the neuron as a dynamical system of nonlinear membrane channels (e.g., conductances described by Hodgkin-Huxley kinetics; see Ion Channels: Keys to Neuronal Specialization; Axonal Modeling) distributed over an electrotonic cable skeleton (e.g., as described by Rall dendritic cable theory; see Dendritic Processing).

Such models can incorporate as much biophysical detail as desired (or practical), but, in general, all include some explicit assortment of voltage-dependent and transmitter-gated (synaptic) membrane channels. Many Hodgkin-Huxley-Rall models also include some system for describing intracellular $Ca^{2+}$ dynamics, for example, to account for the gating of $Ca^{2+}$-dependent $K^+$ channels. Modeling these dynamics involves not only $Ca^{2+}$ channels but often associated buffer systems and membrane pumps as well.

This article summarizes the application of the more common mathematical models of these basic biophysical mechanisms (Borg-Graham, 1999; Koch, 1999). The models for each of these mechanisms are at an intermediate level of biophysical detail, appropriate for describing macroscopic variables (e.g., membrane currents, ionic concentrations) on the scale of the entire cell or anatomical compartments thereof.

First, we will discuss general issues regarding model formulations, and data interpretation for contructing models of biophysical mechanisms. We will then describe models for nonlinear channel properties, including Hodgkin-Huxley and Markov kinetic descriptions of voltage and second-messenger-dependent ion channels. Similar models aimed particularly for synaptic mechanisms are covered in Synaptic Interactions. We will then discuss concentration systems, including models of membrane pumps and concentration buffers. Finally, examples of model definitions are illustrated using the Surf-Hippo Neuron Simulation System (Graham, 2002), pointing out an essential and minimal syntax that facilitates model documentation and analysis.

## General Issues for Constructing Biophysical Models

### Phenomenological and Mechanistic Models

A first consideration in choosing a mathematical model for a given cellular mechanism is whether the model is intended only to capture an empirical relationship between an independent variable (the input or signal) and a dependent variable (the output or response), or whether the model represents an explicit mechanistic hypothesis. Phenomenological models may be instantiated by a function with few (e.g., a low-dimensional polynomial fit) or many (e.g., look-up table) degrees of freedom, depending on the nature of the problem.

Of course, a mechanistic model can also have few or many parameters, but explanatory power tends to dimish with the number of parameters. The mechanistic and phenomenological model alternatives are not mutually exclusive, since the former may incorporate the latter, and in some ways the distinction between them is rather ad hoc.

### *Static (Instantaneous) and Dynamic (Kinetic) Models*

Another basic consideration is whether the relation between signal and response is instantaneous on the time scale relevant to the entire system at hand. In some cases an instantaneous mechanism may permit analysis by exploiting separation of variables, for example assuming instantaneous activation for $Na^+$ currents relative to $K^+$ currents during spiking (see OSCILLATORY AND BURSTING PROPERTIES OF NEURONS). For cellular models that are solved by explicit integration over time, however, instantaneous relationships between state variables can introduce troublesome numerical instabilities unless there are intervening kinetics with slow time constants (relative to the time scale of the integration) that serve to "decouple" element dynamics at the faster time scale.

### *Deterministic and Stochastic Models*

A stochastic component, or "noise," in experimental measures is ubiquitous, for example, in the trial-to-trial variability of spike responses to deterministic stimuli, or in membrane voltage or membrane current fluctuations (especially in vivo). There is accumulating experimental and theoretical evidence that noise places an important constraint on information processing under some conditions while conversely serving a useful computational role in others.

Some system noise can be traced to the inherent stochasticity of molecular kinetics at the cellular level, and there is increasing interest in analyzing single-neuron models that explicitly consider this contribution. For example, simulations with stochastic Hodgkin-Huxley-type channel models can show functional dynamics that would be completely missed by deterministic models. A deterministic approximation should be valid when the number of channels is very large, the usual assumption, but the actual number in a local region of the neuron membrane may be rather low, considering both realistic estimates of channel densities and, especially, the small number of open channels near spike threshold (Schneidman, Freedman, and Segev, 1998).

### *The Experimenter's Model Versus the Theorist's Model*

Every model is based on some empirical data set, but an often overlooked point is how the theorist's model relates to, or rather is constrained by, that of the experimentalist. It may be a bit surprising to discover there is such a thing as an experimentalist's model (which is not the same thing as an *experimental* model). However, in reality, experimental data are never arbitrary but reflect the experimenter's explicit or implicit notion of either the necessary and sufficient parameters of a phenomenon, the functionally relevant mappings between signal and response, what is experimentally tractable (no one is able to do his or her "dream" experiment!), or some combination of all three. The first issue, in particular, is essentially equivalent to assuming some hypothetical model, but importantly, the associated experiments are not normally designed for *testing* that hypothesis (since it is taken as an a priori). Examples include electrophysiological reports on whole-cell current kinetics, which usually focus on voltage-dependent activation and inactivation characteristics according to the classical model of Hodgkin and Huxley (described below). However, this paradigm, while practical, may miss crucial functional characteristics, basically by not sufficiently characterizing certain important dynamical trajectories. We shall return to this point later in discussing Markov channel models.

## Channel Models

Membrane channels underlie both intrinsic neuronal excitablility and the direct postsynaptic action of synaptic transmission. The channel current $I$, assuming some permeant ion $X$, may be expressed as the product of a conduction term $f(V, \Delta[X])$ and a gating term $h(V, t, \ldots)$:

$$I = f(V, \Delta[X])h(V, t, \ldots)$$

where $V$ is the membrane voltage, $t$ is time, and $\Delta[X]$ represents the concentration gradient of $X$ across the cell membrane. The ellipsis in the argument of $h()$ stands for the various ligand-dependent processes, for example, $Ca^{2+}$ dependence or the action of synaptic neurotransmitters.

### *Ohmic and Permeation Conduction Models*

The two common models of the conduction term $f()$ are the ohmic model (thermodynamic equilibrium conduction) and the constant-field permeation model (nonequilibrium conduction). In the ohmic model, current is proportional to the difference of the membrane voltage and the reversal potential for $I$:

$$f(V, \Delta[X]) = \bar{g}_X(V - E_X)$$

where $\bar{g}_X$ is the maximum conductance. The reversal potential $E_X$ for the ion $X$ is given by the Nernst equation:

$$E_X = \frac{-RT}{zF} \text{Log} \frac{[X]_{out}}{[X]_{in}}$$

where $R$ is the gas constant, $F$ is Faraday's constant, and $T$ is temperature in degrees Kelvin. $[X]_{in}$ and $[X]_{out}$ are the intracellular and extracellular concentrations, and $z$ is the valence of the permeant ion $X$. For more than one permeant ion (all with the same valence) and under some assumptions, the similar Goldman-Hodgkin-Katz voltage equation (e.g., Hille, 2002) may be used. Note that if the effect of channel current on $[X]$ is considered (see section on concentration integration), then the ohmic $f()$ is in fact implicitly nonlinear.

As the conducting ion moves farther from equilibrium (specifically the case for $Ca^{2+}$), the ohmic model becomes less accurate. A widely used nonequilibrium model is the constant field model, described by the Goldman-Hodgkin-Katz current equation. In this equation (Jack, Noble, and Tsien, 1983; Hille, 2002), the nonlinearity of permeation is explicit:

$$f(V, \Delta[X]) = \bar{p}_X \frac{Vz^2F^2}{RT} \frac{[X]_{in} - [X]_{out} \exp(-zFV/RT)}{1 - \exp(-zFV/RT)}$$

where $\bar{p}_X$ is the permeability (*not* the conductance) of the channel (typically in $cm^3/s$). Note that at membrane potentials far from the reversal point (e.g., $< -20$ mV for $Ca^{2+}$ channels) the Goldman-Hodgkin-Katz current equation becomes linear, and thus the ohmic model may suffice if the model voltages are appropriately bounded.

### *Channel Gating à la Hodgkin and Huxley: Independent Voltage-Dependent Gating Particles*

Hodgkin and Huxley (1952) described channel gating as an interaction between independent two-state (open and closed) elements or "particles," all of which must be in the open state for channel conduction (see ION CHANNELS: KEYS TO NEURONAL SPECIALIZATION; AXONAL MODELING). The state dynamics of each particle are described with first-order kinetics:

$$x_C \overset{\alpha(V),\beta(V)}{\rightleftharpoons} x_O \tag{1}$$

where $x_C$ and $x_O$ represent the closed and open states of gating particle $x$, respectively. $\alpha(V)$ and $\beta(V)$ are the forward and backward rate constants of the particle as a function of voltage, respectively.

## *An Extended Hodgkin and Huxley Model*

While Hodgkin and Huxley hypothesized that the steady-state behavior of each particle fit a Boltzmann distribution, their underlying rate equations were essentially ad hoc fits to the experimental data. Although taken as a canonical form by countless cell models, one consequence is that there is not an obvious relationship between the equations' parameters and the more "observable" steady-state, $x_\infty(V)$, and time-constant, $\tau_x(V)$, functions associated with Equation 1.

The Hodgkin-Huxley model can be recast in more explicit form by considering parameters of a single-barrier kinetic model for each particle (Jack et al., 1983; Borg-Graham, 1991, 1999). In its basic form this formulation has five parameters for each particle, compared to six parameters in the Hodgkin-Huxley model. Nevertheless, this formulation may be readily fitted to the original Hodgkin-Huxley equations of squid axon $I_{Na}$ and $I_K$; the error is comparable to the error between the original equations and the data to which they were fit (cf. Figures 4, 7, and 9 in Hodgkin and Huxley, 1952).

We first derive the expressions the forward, $\alpha'_x(V)$, and backward, $\beta'_x(V)$, rate constants of the single-barrier transition. The parameter $z$ (dimensionless) is the *effective* valence of the gating particle: when positive (negative), the particle opens (closes) with depolarization; thus it is an "activation" ("inactivation") particle. The effective valence is the product of the actual valence of the particle and the proportion of the membrane thickness that the particle moves through during state transitions. $\gamma$ (dimensionless, between 0 and 1) is the asymmetry of the gating particle voltage sensor within the membrane (symmetric when $\gamma = 0.5$). $K$ is the leading rate coefficient of both $\alpha'_x(V)$ and $\beta'_x(V)$. This term can be described in terms of Eyring rate theory, but here we just take $K$ as a constant. $V_{1/2}$ is the voltage for which $\alpha'_x(V)$ and $\beta'_x(V)$ are equal. The final equations for $\alpha'_x(V)$ and $\beta'_x(V)$ are then:

$$\alpha'_x(V) = K \exp\left(\frac{z\gamma(V - V_{1/2})F}{RT}\right)$$

$$\beta'_x(V) = K \exp\left(\frac{-z(1 - \gamma)(V - V_{1/2})F}{RT}\right)$$

An additional parameter, $\tau_0$ (*not* the passive membrane time constant), is crucial for fitting the expressions to the original Hodgkin-Huxley equations. $\tau_0$ represents a rate-limiting step in the state transition, for example, "drag" on the particle conformation change (similar considerations have been explored for other, more general, kinetic schemes; e.g., Patlak, 1991), and may be incorporated directly into the expression for the time constant $\tau_x(V)$. $x_\infty(V)$, however, is not affected by $\tau_0$:

$$\tau_x(V) = \frac{1}{\alpha'_x(V) + \beta'_x(V)} + \tau_0$$

$$x_\infty(V) = \frac{\alpha'_x(V)}{\alpha'_x(V) + \beta'_x(V)}$$

Two additional parameters, $\alpha_0$ and $\beta_0$, may be considered in some cases, although they are not necessary in reproducing the original Hodgkin-Huxley equations. These parameters are voltage-independent forward and backward rate constants, respectively, of parallel state transitions. If considered, these transitions will change the final forms of $\tau_x(V)$ and $x_\infty(V)$.

The parameters of this form have clear relationships to the corresponding $x_\infty(V)$ and $\tau_x(V)$ functions. Thus, the $V_{1/2}$ parameter gives the midpoint and $z$ sets the steepness of the $x_\infty(V)$ sigmoid. The symmetry parameter $\gamma$ determines the skew of $\tau_x(V)$: $\gamma = 0.5$ gives a symmetric bell-shaped curve for $\tau_x(V)$, which otherwise bends to one side or the other as $\gamma$ approaches 0 or 1. $z$ sets the width of $\tau_x(V)$, unless $\gamma$ is equal to either 0 or 1, in which case $\tau_x(V)$ becomes sigmoidal and thus $z$ sets the steepness as for $x_\infty(V)$.

With this scheme a particle with a voltage-independent rate constant can be represented by setting $1/K \ll \tau_0$ (and $\alpha_0 = \beta_0 = 0$), thus making $\tau_0$ the effective time constant. Likewise, both the time constant and steady state become voltage independent by setting $K = 0$ and choosing the appropriate $\alpha_0$ and $\beta_0$.

## *Determining the Number of Particles in Hodgkin-Huxley Models*

The Hodgkin-Huxley paradigm includes the possibility of multiple gating particles of a given type associated with a given channel. Some experimental papers report fitting integer powers of hypothetical gating particles to the observed kinetics, but more typically steady-state activation or inactivation data are simply the observed macroscopic behavior (that is, reflecting the steady state of the ensemble of particles). Thus, gating particle powers for channel models can often be considered as a free parameter.

Gating particle powers greater than 1 have several kinetic consequences, including a sigmoidal "delayed" time course of activation (Hodgkin and Huxley, 1952), a more rapid approach to 0 in the steady-state characteristic as a function of voltage, and a shift in either the peak (when $0 < \gamma < 1$) or inflection point (when $\gamma = 0$ or 1) of $\tau_x(V)$ in the direction of voltage for which $x_\infty(V)$ tends to 0.

## *Channel Gating as Dynamical Systems à la Markov Models*

The independence and simplicity of the Hodgkin-Huxley gating particle models have at least two advantages: model kinetics can be predicted in an intuitive way, and their numerical evaluation is efficient (Hines, 1984). In addition, as mentioned, electrophysiological measures of whole-cell currents are often guided by this model. The two-state gating model can also be readily adapted to include factors such as intracellular [Ca$^{2+}$], by using the appropriate functions for $\alpha$ and $\beta$ (see below).

On the other hand, the independence of the two-state Hodgkin-Huxley particles constrains the equivalent state space description (e.g., allowed state transitions) given by the more general Markovian model (see Synaptic Interactions). General Markov kinetic models are standard for detailed biophysical analysis of single-channel kinetics, but there have been relatively few applications in the neural modeling literature. One practical limitation is that Markov models are often much more computationally expensive than the Hodgkin-Huxley model. Nevertheless, the richer dynamics of Markov models may prove necessary for capturing functional properties of some channel types, including subthreshold steady-state Na$^+$ channel rectification (Figure 4), delay of activation for Na$^+$ and K$^+$ currents, and the coupling between opening of K$^+$ channels by Ca$^{2+}$ entering during the action potential and subsequent inactivation (Borg-Graham, 1999).

Although the Markovian framework puts no restrictions on the functions that define state transitions (other than the no-memory condition), the form presented above of the $\alpha(V)$ and $\beta(V)$ functions for the extended Hodgkin-Huxley model is convenient and very general. Another form is the following squeezed exponential formula for the transition rate $\alpha_{ij}(V)$ from state $i$ to state $j$:

$$\alpha_{ij}(V) = \left(\tau_{min} + \left((\tau_{max} - \tau_{min})^{-1} + \exp\left(\frac{(V - V_{1/2})}{k}\right)\right)^{-1}\right)^{-1} \tag{2}$$

where the inverse of $\tau_{min}$ (analogous to $\tau_0$ in the extended Hodgkin-Huxley model) and $\tau_{max}$ put upper and lower bounds, respectively, on the rate constant $\alpha_{ij}(V)$. Note that there is an implicit coefficient of the exponential term of 1/ms (same units as either $1/\tau_{min}$ or $1/\tau_{max}$) in this equation.

### *$Ca^{2+}$-Dependent Gating*

Neural models have used a variety of explicit relationships between the concentration of some second messenger and the activation state of the target mechanism. Here we consider a range of examples that have been used to describe $\mathrm{Ca}^{2+}$-dependent $\mathrm{K}^+$ channels.

A simple instantaneous model for $\mathrm{Ca}^{2+}$-dependent gating is given by a static rectified power function of concentration with some threshold $\theta_{\mathrm{Ca}}$, reminiscent of firing rate models:

$$w = K \times \sigma([\mathrm{Ca}^{2+}]^n - \theta_{\mathrm{Ca}})$$

where $\sigma(x) = 0$ for $x < 0$, and $\sigma(x) = x$ otherwise, for the gating variable $w$.

A simple kinetic model for $\mathrm{Ca}^{2+}$-dependent gating can be described by the following reaction. Assume that $w_C$ and $w_O$ represents the closed and open probabilities, respectively, of a $\mathrm{Ca}^{2+}$-dependent gating particle $w$ with forward and backward rate constants $\alpha$ and $\beta$, respectively:

$$w_C + n\mathrm{Ca}^{2+} \overset{\alpha,\beta}{\rightleftharpoons} w_O$$

Note that the open state $w_O$ is bound to $n$ $\mathrm{Ca}^{2+}$ ions. One can also imagine a similar but reverse reaction for the description of $\mathrm{Ca}^{2+}$-dependent inactivation, as has been reported for some $\mathrm{Ca}^{2+}$ channels. In the more general Markovian framework, $w_C$ and $w_O$ refer to two adjacent states out of the entire state space. This scheme assumes that binding with $\mathrm{Ca}^{2+}$ ions is cooperative: either all binding sites are occupied or none are. We may also consider a $\tau_0$ parameter as in the extended Hodgkin-Huxley model. If we assume that the binding of $\mathrm{Ca}^{2+}$ in this reaction does not appreciably change $[\mathrm{Ca}^{2+}]$, then the steady-state value for $w$, $w_\infty$, and the time constant for the kinetics, $\tau_w$, are given by:

$$w_\infty = \frac{\alpha}{\alpha + \beta[\mathrm{Ca}^{2+}]_{in}{}^{-n}}$$

$$\tau_w = \frac{1}{\alpha[\mathrm{Ca}^{2+}]_{in}{}^{n} + \beta} + \tau_0$$

An important distinction is whether or not a $\mathrm{Ca}^{2+}$-dependent channel is also dependent on voltage. For example, in recordings of the large-conductance $\mathrm{Ca}^{2+}$-dependent $\mathrm{K}^+$ (BK) channel, Barrett, Magleby, and Pallotta (1982) found an approximate third-power relationship between channel open times and $[\mathrm{Ca}^{2+}]$ that was strongly facilitated by depolarization. At a membrane voltage of 10 mV, channels became open with a $[\mathrm{Ca}^{2+}]$ threshold of about 1 $\mu$M.

If the dependences are separable, it may be convenient to consider a product of voltage-only and $\mathrm{Ca}^{2+}$-only gating terms, for example according to the formulations presented earlier. Otherwise, a single gating "particle" must take into account both voltage and $\mathrm{Ca}^{2+}$. A direct voltage dependence of the simple kinetic scheme above can be added in a number of ways, for example by adding a voltage-dependent term to the forward rate constant, now defined as $\alpha(V, [\mathrm{Ca}^{2+}]_{in})$:

$$\alpha(V, [\mathrm{Ca}^{2+}]_{in}) = \alpha_V(V) \times \alpha[\mathrm{Ca}^{2+}]_{in}{}^{n}$$

where, e.g., $\alpha_V(V)$ is the squeezed exponential function of voltage in Equation 2, such that the forward reaction speeds up with depolarization.

Moczydlowski and Latorre (1983) proposed a detailed Markovian kinetic scheme for the $\mathrm{Ca}^{2+}$- and voltage-dependent gating of the BK channel, which has been interpreted in several neuron models. The essential dynamics are captured by a two-state scheme as in Equation 1, with rate constants dependent on both voltage and $\mathrm{Ca}^{2+}$, thus:

$$\beta(V, [\mathrm{Ca}^{2+}]_{in}) = \beta_0\left(1 + \frac{k_1(V)}{[\mathrm{Ca}^{2+}]_{in}}\right)^{-1}$$

$$\alpha(V, [\mathrm{Ca}^{2+}]_{in}) = \alpha_0\left(1 + \frac{[\mathrm{Ca}^{2+}]_{in}}{k_4(V)}\right)^{-1}$$

where

$$k_i(V) = k_i(0) \times \exp\left(\frac{-V\delta_i FZ}{RT}\right)$$

## Ionic Concentration Dynamics

An inevitable consequence of channel currents is that the concentrations on either side of the membrane will change as a function of electrical activity. In addition to the negative feedback on channel currents already mentioned (as a result of a reduction in driving force), such changes can have a variety of other functional consequences. These include the activation of intracellular or extracellular receptors, the most important being those that underlie the myriad $\mathrm{Ca}^{2+}$-dependent pathways (including the $\mathrm{Ca}^{2+}$-dependent channel gating just described). We may also consider the role of the membrane pumps, which tend to maintain ionic gradients (see Mechanisms in Neuronal Modeling), and of the intracellular buffer systems. In the following discussion we emphasize $\mathrm{Ca}^{2+}$ dynamics, but similar considerations are relevant for other ions.

### *Concentration Integrators*

Most neuron models that consider concentration changes rely on some partition of the extracellular and intracellular space into a set of well-mixed compartments (e.g., "shells"), with or without an "inifinite" compartment with a fixed concentration. Simple diffusion is normally assumed between compartments, according to the geometry of the partitioning and assumptions about the diffusion coefficient for the free ion, $D$. Compartments adjacent to the cell membrane also take into account ion flow across the membrane, e.g., due to channels and pumps. The physical partitioning into compartments depends on the question being addressed, with the simplest system being a single intracellular compartment (extracellular concentration being assumed constant).

Any model of $[\mathrm{Ca}^{2+}]$ must take into account not only the influx of $\mathrm{Ca}^{2+}$ but also some mechanism for the removal of $\mathrm{Ca}^{2+}$. The simplest method is to include a steady-state term in the differential equation(s) describing $[\mathrm{Ca}^{2+}]$. In the general case this value is associated with a second parameter corresponding to the time constant for concentration decay.

### *Membrane Pump Models*

More explicit models of ion removal includes mechanisms, such as membrane-bound pumps, that transport $\mathrm{Ca}^{2+}$, $\mathrm{K}^+$, $\mathrm{Na}^+$, and other ions against their respective concentration gradients. A general pump model may be described with a Michaelis-Menton mechanism, assuming no appreciable change in the extracellular $[\mathrm{Ca}^{2+}]$:

$$J_{\mathrm{Ca}^{2+}} = V_{max}\frac{[\mathrm{Ca}^{2+}]_{in}}{K_d + [\mathrm{Ca}^{2+}]_{in}} - J_{leak}$$

where $J_{\mathrm{Ca}^{2+}}$ is the removal rate of $\mathrm{Ca}^{2+}$ per unit area, $V_{max}$ is the maximum flux rate per unit area, and $K_d$ is the half-maximal $[\mathrm{Ca}^{2+}]_{in}$. $J_{leak}$ compensates for the resting pump rate and is typically adjusted so that there is no net pump current at rest, given some resting activation of $\mathrm{Ca}^{2+}$ channels.

For example, the spine model by Zador, Koch, and Brown (1990) included two $\mathrm{Ca}^{2+}$ pumps with Michaelis-Menton kinetics: one high-affinity, low-capacity, corresponding to a Ca ATPase-driven mechanism, and the other low-affinity, high-capacity, corresponding to a $\mathrm{Ca}^{2+}/\mathrm{Na}^{+}$ exchange mechanism (see also Koch, 1999). These pumps were treated as separate currents in the $[\mathrm{Ca}^{2+}]$ differential equation. Other models have incorporated a pump that binds to intra- and extracellular $\mathrm{Ca}^{2+}$ with various rate constants. These reactions are then solved simultaneously with another binding reaction between $[\mathrm{Ca}^{2+}]_{in}$ and a buffer.

### *Buffer Models*

Endogenous intracellular $\mathrm{Ca}^{2+}$ buffers have a strong effect on free intracellular $[\mathrm{Ca}^{2+}]_{in}$. Cell models that consider $\mathrm{Ca}^{2+}$ dynamics have incorporated buffer mechanisms of varying complexities, including solving the dynamical equations for the buffer-$\mathrm{Ca}^{2+}$ reaction during the course of the simulation. Note that in some models an explicit (instantaneous) buffer mechanism is replaced by adjusting $\mathrm{Ca}^{2+}$ sensitivities of $\mathrm{Ca}^{2+}$-dependent mechanisms, such as $\mathrm{Ca}^{2+}$-dependent $\mathrm{K}^{+}$ channels.

A simple way to treat intracellular buffering of $\mathrm{Ca}^{2+}$ is to assume a nonsaturated buffer (i.e. $[\mathrm{Bu}] \gg [\mathrm{Ca}^{2+}]_{in}$, where [Bu] is the concentration of buffer binding sites) with instantaneous kinetics. The key parameter, $\beta_{\mathrm{Bu}}$, in this mechanism equals the ratio of the concentration of bound $\mathrm{Ca}^{2+}$ and free $\mathrm{Ca}^{2+}$:

$$\beta_{\mathrm{Bu}} = \frac{[\mathrm{Ca}^{2+}]_{in}^{bound}}{[\mathrm{Ca}^{2+}]_{in}^{free}}$$

and thus is a function of [Bu]. This mechanism implies that the *measured* $[\mathrm{Ca}^{2+}]_{in}$ is equal to the total $[\mathrm{Ca}^{2+}]_{in}$ divided by $(\beta_{\mathrm{Bu}} + 1)$. For nondiffusional models of $[\mathrm{Ca}^{2+}]_{in}$ (e.g., where there is one $\mathrm{Ca}^{2+}$ compartment per electrical compartment), this is the only role of the instantaneous buffer. For multiple-compartment systems, the effective diffusion constant $D'$ applied to the difference in $[\mathrm{Ca}^{2+}]$ between compartments must also be adjusted to take into account the instantaneous buffer, by setting $D'$ equal to $D/(\beta_{\mathrm{Bu}} + 1)$. A variation on this scheme would be to assume that $\beta_{\mathrm{Bu}}$ is a function of each compartment. In this case the diffusion equation between compartments would reference the original $D$, with the concentration difference between any two compartments determined by the difference of the total concentrations, weighted by the appropriate $\beta_{\mathrm{Bu}}$s.

```

**Figure 1.** The Surf-Hippo definitions of the classical Hodgkin-Huxley model of the squid axon $\mathrm{Na}^{+}$ channel and the associated M-activation gating particle. The plethora of parentheses may seem daunting; however, all formatting (including indentation) is done automatically by Lisp-savvy editors (such as Emacs). The last line in the `CHANNEL-TYPE-DEF` form specifies three `M-HH` and one `H-HH` gating particles. Surf-Hippo model definitions allow concise inclusion of arbitrary functions, in this case for the `ALPHA` and `BETA` rate constants (refer to equations of the Hodgkin-Huxley $\mathrm{Na}^{+}$ channel in Axonal Modeling, q.v.) in the `PARTICLE-TYPE-DEF` form. The `LAMBDA` symbol denotes the beginning of a function definition. In the context of gating particle definitions, Surf-Hippo assumes only that the rate functions take a single `VOLTAGE` argument (in millivolts), and return a rate value (in $\mathrm{ms}^{-1}$). Comments are indicated with a semicolon. Expression precedence is unambiguous with the prefix notation of Lisp. The first element of each (parenthesized) list defines the operation applied to the rest of the list, and in nested lists everything is evaluated from the inside out: e.g., `(+ A (* B C) D)` is $A + BC + D$.

## Practical Aspects of Coding Biophysical Models

The translation of experimental data on some biophysical mechanism into simulator code, within the framework of a given mathematical model, and the reverse process (which is a necessary step in formulating experimental predictions from a model) have received little attention. However, these steps have many practical aspects, not the least of which is that as models become more and more complex, the opportunity for errors becomes more and more serious. For this reason it is useful to consider model *syntax* (see Neurosimulation: Tools and Resources; GENESIS Simulation System; NEURON Simulation Environment; NSL Neural Simulation Language).

In most situations, it is desirable that a simulator program act essentially as a "black box," so that model analysis concerns only the input (some collection of model definition files) and the output (numerical data, usually time sequences). Thus, when composing the model definition, one should ideally be able to focus on the model algorithms and their parameters, rather than on their implementation. Model syntax should therefore allow the expression of mathematical (and symbolic, if appropriate) relationships in as close to a "natural" syntax as possible. In other words, one should be able to simply "write down the equations" defining the model. Certainly a practical consequence of such a syntax is that the learning curve for the simulator is reduced, but more important over the long term is simply that if model definitions are easier to read, they are also easier to verify, document, and change.

To illustrate these ideas, here we present examples of biophysical model definitions taken from the Surf-Hippo Neuron Simulation System (Graham, 2002). This system is written in Lisp, an important point, since the system exploits many advantages of this truly high-level language that are well known to the AI community (at the same time having a numerical performance on par with languages such as C). In particular, Lisp supports an emphasis on more

     (C1 C2 (SQUEEZED-EXPONENTIAL VOLTAGE :V-HALF -60 :K -1 :TAU-MAX 100 :TAU-MIN 1)))))
```

**Figure 3.** The Surf-Hippo definition of a Markovian gating particle for a hippocampal pyramidal cell Na$^+$ channel model (Borg-Graham, 1999). Transition rates between states, in ms$^{-1}$, are defined with either constants (for example, 3 ms$^{-1}$ for the transition from state O to state I) or functions of voltage (as indicated by the "dummy" variable VOLTAGE). The SQUEEZED-EXPONENTIAL function (Equation 2) is built into Surf-Hippo (when :TAU-MAX is not specified, then the mininum rate is 0).

declarative descriptions (emphasizing *what* kind of model is desired), rather than imperative ones (emphasizing *how* to construct a model). Thus, model syntax in Surf-Hippo is designed to minimize the actual code for mechanism specification: correspondingly, these examples illustrate the necessary and sufficient parameters for each mechanism, avoiding "overhead" code that would be simulator specific. Surf-Hippo also includes automatic generation of mechanism definition code, for example, allowing capture of the "state" of a given mechanism model that has been modified on-line during automatic or manual parameter exploration. This capability, which is facilitated by both the minimal requirements for model specification and the relative ease with which Lisp programs may be able to write Lisp code, is important for avoiding errors when documenting model results.

Figure 1 illustrates the definitions of the classical Hodgkin-Huxley model of the squid axon Na$^+$ channel and the associated M-activation gating particle, showing in particular how arbitary functions are represented. Once the basic syntax of Lisp is grasped, the human readability of this format is enhanced because it includes only the essential kinetic parameters. As a comparison, the equivalent source code in similar simulation systems such as GENESIS and NEURON is about two to three times larger.

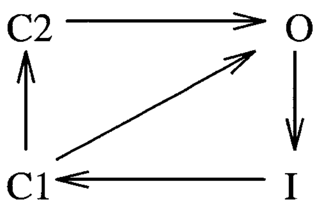

**Figure 4.** State diagram of a hypothetical Markov gating model used for $I_{Na}$ in a model of hippocampal pyramidal cells (Borg-Graham, 1999). From the single inactivated state $I$, the two closed states $C_i$ are reached with increasing hyperpolarization. The $C_i \rightarrow O$ transitions implement in effect distinct thresholds, occuring at progressively lower potentials with increasing $i$. Likewise, the $I \rightarrow C_1$ and $C_1 \rightarrow C_2$ transitions occur at voltages hyperpolarized to the associated $C_1 \rightarrow O$ and $C_2 \rightarrow O$ transitions, respectively, somewhat like a rachet mechanism. The $O \rightarrow I$ transition is voltage independent. The arrows denote the dominant transitions during spike depolarization/repolarization. One important aspect of this model is that the inactivation state is reached only after channel opening, as reported from studies of single Na$^+$ channels (Patlak, 1991; Hille, 1992). Such coupling contradicts the central assumption of independent activation and inactivation kinetics in the Hodgkin-Huxley model.

Several parameterized models of biophysical mechanisms are included in Surf-Hippo, including those discussed in this article. For example, Figure 2 shows the definition for the extended Hodgkin-Huxley model of the Na$^+$ channel M-gating particle. Markov models for particle gating are also readily represented in this system. As an example, Figure 3 illustrates the definition of a Markovian gating particle for a hippocampal pyramidal cell Na$^+$ channel model (Borg-Graham, 1999); the state diagram is shown in Figure 4.

## Discussion

Biophysical details are likely to be crucial for understanding neural computation (see Mechanisms in Neuronal Modeling). This process entails an informed trade-off between incorporating every known experimental nuance of a given cellular mechanism and the practical application of abstractions and simplifications that capture essential dynamic relationships between biological molecules and various neuronal signals. In this article we have presented some of the more commonly used mathematical descriptions for these relationships. We note in closing that an increasingly important (and unavoidable) problem with complicated neural models that rely on these sorts of mechanisms is the lack of formal or analytic verification. This situation calls for alternative methods, in particular the cross-validation of numerical results using several tools of similar capability (e.g., NEURON, GENESIS, Surf-Hippo). Practical aspects of coding biophysical models, such as the minimal model syntax discussed here, should facilitate such efforts.

# Biophysical Mosaic of the Neuron

*Lyle J. Graham and Raymond T. Kado*

## Introduction

In this article we broadly review the biophysical mechanisms of neurons that are likely to be relevant to computational function (Table 1). These mechanisms operate within the complex three-dimensional anatomy of the single neuron and are manifested by electrical and chemical interactions between ions on either side of the cell membrane and the diverse proteins and other molecules embedded in the membrane and within the cytoplasm (Figure 1). The signals mediating these interactions may be defined by the voltage across the cell membrane or by concentrations of specific molecules in specific conformational or metabolic states. The first case relies on the voltage sensitivity of various membrane proteins; the second relies on a vast multitude of receptor proteins that link the functional state of neuronal proteins with the external or internal concentrations of ions and molecules.

**Table 1.** Neuronal Biophysical Mechanisms Relevant to Computational Function

| |
|---|
| Ion channels |
| Control by intrinsic signals (membrane voltage, intracellular molecules) |
| Control by extrinsic signals (extracellular molecules, e.g., released from presynaptic terminals) |
| Receptors |
| Ionotropic: Direct control of ion channels |
| Metabotropic: Indirect control of ion channels and other internal systems |
| External binding sites (synaptic and pancrinic) |
| Internal binding sites associated with neuronal and organelle membranes |
| Control of internal biochemical systems |
| Enzymes (kinases and phosphatases, which determine the state of most proteins; others) |
| Gap junctions |
| Pumps, transporters, exchangers (electrogenic and nonelectrogenic) |
| Organelles |
| $Ca^{2+}$ sequestering and release (endoplasmic recticulum, mitochondria) |
| Protein synthesis and metabolism |
| Maintenance and modulation of three-dimensional structure (spines, dendritic morphology) |
| Transmitter sequestering and release (synaptic vesicles) |
| Cytoplasmic biochemical systems |
| Transmitter synthesis and degradation |
| G proteins: Initiate second messenger release after receptor activation |
| Second messengers: Diffusible molecules linking various stages of internal biochemical systems |
| Effectors: Targets of second messengers, including channels and enzymes (kinases, phosphatases) |
| Three-dimensional structure |
| Macroscopic anatomy (soma, dendritic and axonal trees) |
| Microscopic anatomy (spines, synaptic junctions, variations in dendritic or axonal dimensions) |
| "Electrotonic" anatomy (modulated by state of local membrane) |
| Geometrical synaptic and channel distribution |
| Functional synaptic localization (e.g., retinotopic, tonotropic) |
| Computational synaptic localization (e.g., on-the-path interactions, coincidence detection) |

It may be noted that none of these cellular mechanisms is unique to neurons. For example, essentially all the mechanisms discussed in this article may be relevant when considering a possible computational role of the neuroglia network (Laming et al., 2000). By the same token, neurons (and glial cells) include the essential mosaic of biochemical systems found in all cells required for metabolism, reproduction, growth, and repair. The complexity is daunting. Here we focus on the better-known elements most clearly linked to the reception, processing, and transmission of neuronally represented information. It may seem that there are so many such elements, and an even larger number of unknown relationships, that it would not be possible for a theory to take all of the actual dynamic behaviors into consideration. Nevertheless, it also seems likely that an oversimplification of these interactions—for example, in the extreme case by describing single neuron function as an abstracted trigger device—may put fundamental limits to the explanatory and predictive power of any neural model. The challenge remains, then, to develop a description of single neuron function that can serve as the foundation for a practical yet sufficient neural theory.

We start with a metaphor, the mosaic neuron. A *mosaic* is a collection of discrete parts, each with unique properties, fitted together in such a way that an image emerges from the whole in a nonobvious way. Similarly, the neuronal membrane is packed with a diversity of receptors and ion channels and other proteins with a recognizable distribution. In addition, the cytoplasm is not just water with ions, but a mosaic of interacting molecular systems that can directly affect the functional properties of membrane proteins. Whether for the developing or for the mature neuron, this mosaic is not stationary. To begin with, neuronal proteins are constantly recycled, as is the case for all cells. Furthermore, on both long and short time scales, most mechanistic theories for learning and memory implicate physical changes in various cellular constituents. On time scales of seconds or less, different signaling systems impinging on the neuron from the network or present in the cytoplasm can modify the properties of the mosaic elements, and in some cases their distribution within the cell (see ACTIVITY-DEPENDENT REGULATION OF NEURONAL CONDUCTANCES). Thus, just as a mo-

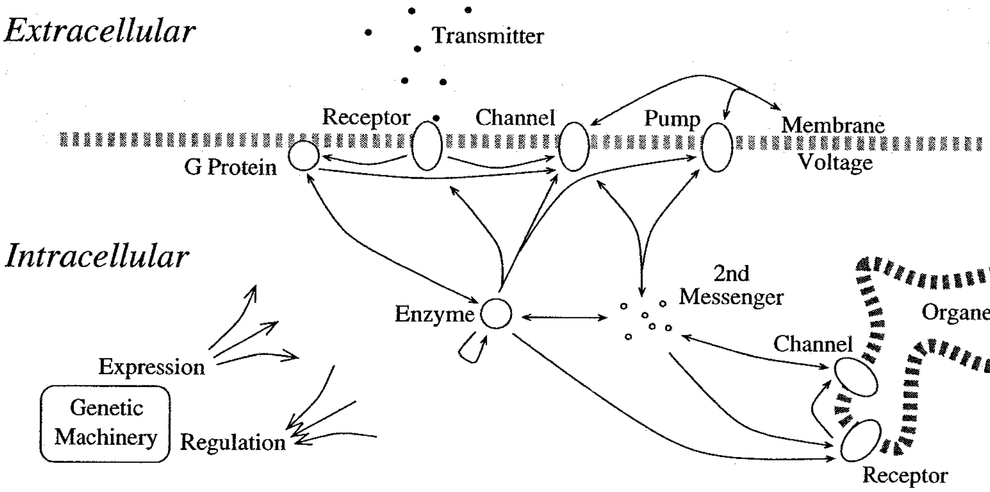

**Figure 1.** Sketch of the molecular circuit underlying the neuron's biophysical mosaic. This caricature outlines the many interrelated control paths among the molecular elements that determine the functional properties of the neuron. For example, activation of an ionotropic synapse starts with the binding of extracellular transmitter to the membrane receptor, which then directly turns on an associated ion channel. Alternatively, activation of a metabotropic synapse is initiated by transmitter binding to a receptor, which then activates a G protein, which turns on an enzyme, which raises the concentration of a second messenger, which, finally, activates a target ion channel. Many control pathways are immediately bidirectional: current through an ion channel changes the membrane voltage, which in turn can control the gating of that same channel. Some elements can even control themselves, for example autophosphorylating enzymes.

saic painting provokes perception of a complete image out of a maze of individually diversified tiles, current thinking holds that a given neuron performs a well-defined computational role that depends not only on the network of cells in which it is embedded but also to a large extent on the dynamic distribution of macromolecules throughout the cell.

## The Minimal Essential Model and the Biophysical Mosaic

It remains an open question as to what constitutes a minimal neuron model for reproducing functional neuronal computation (Meunier and Segev, 2000; see also Canonical Neural Models). This is in part because to date, only a handful of neuron circuit models come close to predicting known experimental data in any nontrivial way. The question of finding a minimal model is hardly an academic one, as can be appreciated by reviewing the dimensionality of the mosaic neuron (Table 2).

Whatever the minimal essential model turns out to be, a detailed knowledge of neuronal biophysics is most likely necessary for understanding the system behavior (even if this understanding is not sufficient). The clearest evidence for this point of view comes from psychopharmacology: although we lack a clear understanding of the mechanisms, we know that adding certain chemicals to the brain parenchyma can qualitatively alter cognitive behavior. We know that the direct action of psychotropic drugs is probably to change one or more biophysical properties at the microscopic cellular level, such as blocking an ion channel, altering the binding kinetics of a receptor, modulating a biochemical pathway, and so on, rather than acting at a more macroscropic systems level, such as cleanly disconnecting a circumscribed subcircuit from the entire network. We know that physical access to the brain is necessary for this action (preventing a drug from crossing the blood-brain barrier eliminates its effect), and we also know, in many cases, that some neurons have highly specific membrane receptors for a given psychotropic molecule that are often localized in very restricted areas at the level of brain substructures and even at the single-cell level. Often there is direct evidence of a drug's effect in electrophysiological measurements of single cells, when a change in intrinsic response properties or synaptic dynamics is seen after a given chemical is added to the fluid bathing the nervous tissue.

## The Mosaic's Tiles

We will now review the major proteins that compose the neuron mosaic and discuss some basic implications of their diversity and complexity. These macromolecules include ion channels, receptors (described along with the molecules that activate them), enzymes, gap junctions, pumps, exchangers, and transporters. Note that these classifications can sometimes overlap. For example, an ionotopic receptor is a protein multimer that includes both a receptor part and a channel part.

Several texts may be consulted for more detail on these mechanisms (Johnston and Wu, 1995; Weiss, 1996; Koch and Segev, 1998; Fain, 1999; Hille, 2002). In particular, the textbook by Koch (1999) provides an explicit foundation for the computation/algorithm/implementation trinity that is fundamental for understanding brain function.

### *Ion Channels*

Ion channels are membrane-spanning proteins that, owing to their conformational states which allow the passage of ionic current, are the primary basis for the dynamical electrical behavior of neurons (see Ion Channels: Keys to Neuronal Specialization). The permeability of the conducting states and the kinetics governing state transitions (generally referred to as channel gating) can be affected by a variety of factors, principally the membrane voltage and the intra- and extracellular concentrations of the permeable ions and other specific molecules. Sensitivity to extracellular molecules is generally mediated by either direct action on the channel or various receptor proteins (e.g., in response to neurotransmitters), as discussed below. Molecules that affect channel gating from the inside include second messengers. The kinetic relationship between membrane voltage, the concentration of neurotransmitters, second messengers, and a channel's conductance state can be quite complex, a point we return to later.

**Table 2.** Quantitative Summary of the Neuron's Biophysical Mosaic Relevant to Computational Function

- Spatial scales (voltage and concentration transients): <1 to thousands of microns
- Temporal scales
  - Kinetics of gating, binding, and diffusion: <1 ms to seconds
  - Gene expression: days to years?
- Anatomy
  - Tens to hundreds of dendritic and axonal branches
  - Models of electrotonic structure can require thousands of compartments
- Synapses and channels
  - Thousands of pre- and postsynaptic sites
  - Five major categories of charge carriers: $Na^+$, $K^+$, $Ca^{2+}$, $Cl^-$, other (e.g., "cationic," proton, etc.)
  - Tens of types for each category, several of which may be expressed in a single neuron
- Receptors and associated agonists (neurotransmitters, second messengers, etc.)
  - Approximately 30 major types, several of which may be expressed in a single neuron
  - Possibly tens of identified subtypes for some major receptor types

A brute force map of a single neuron would be very large indeed. For example, compartmental models of the dendritic tree can require hundreds or thousands of coordinates, corresponding to spatial scales relevant for representing gradients of membrane voltage or of the concentration of intracellular molecules. A given neuron may have thousands of synaptic inputs, each associated with one of several types of receptors, and the cell membrane can include tens of types of ion channels. Furthermore, the different synaptic receptor and channel types are typically scattered inhomogeneously over the neuron. It is also important to consider the stationarity of the map. For computations over hundreds of milliseconds or less, the map may properly be thought to be static, but at longer time scales it may be necessary to consider a dynamic layout of the mosaic. For another *carte du monde* of computational cellular mechanisms and their spatial and temporal scales, see Figure 21.2 in Koch, 1999.

Since channels are the most direct mechanism determining the basic firing properties of the cell (e.g., regular adapting, bursting, fast spiking), and since channels are subject to functional modulation on a variety of time scales, it is not surprising that a given neuron can exhibit more than one "stereotypical" firing behavior, depending on the conditions (see NEOCORTEX: BASIC NEURON TYPES).

### *Receptors and Their Agonists and Antagonists: Neurotransmitters, Neuromodulators, Neurohormones, and Second Messengers*

Receptors are membrane proteins whose functional action is triggered by the reversible binding of specific molecules called ligands (Cooper, Bloom, and Roth, 1996; see NMDA RECEPTORS: SYNAPTIC, CELLULAR, AND NETWORK MODELS). A given molecule may be a ligand for more than one kind of receptor, with very different or even opposite functional effects; likewise, a given receptor may be able to be activated by more than one endogenous (or artificial, that is, experimental or pharmaceutical) ligand. A ligand that tends to upregulate the functional activity of a receptor protein is called an agonist for that receptor. Conversely, antagonists are molecules that inhibit the activity of a receptor.

There are two basic types of receptors, ionotropic and metabotropic. Ionotropic receptors are directly associated with an ion channel whose gating is controlled by the presence of the receptor agonist. The action of metabotropic receptors is more complex: upon binding to an agonist, these receptors activate a G protein (so named because their action involves the conversion between guanosine diphosphate and guanosine triphosphate), which may directly control channel gating or may initiate a biochemical cascade mediated by second messengers. The end point of this "chain reaction" can be, for example, the opening of a channel, or the phosphorylation of a receptor by the activation of a kinase.

Agonists are properly called neurotransmitters when released by the presynaptic terminal of an axon (or possibly a dendrite) arising from another neuron (see NEOCORTEX: CHEMICAL AND ELECTRICAL SYNAPSES). Extracellular agonists also include neuromodulators and neurohormones, with the latter distributed through the vasculature as well as the perineuronal space (see NEUROMODULATION IN MAMMALIAN NERVOUS SYSTEMS and NEUROMODULATION IN INVERTEBRATE NERVOUS SYSTEMS). From a functional viewpoint, the main difference between these agonists and neurotransmitters is that neurotransmitters generally mediate synaptic communication between two specific pre- and postsynaptic cells, whereas the release of a neuromodulator or neurohormone into the extracellular space mediates *pancrinic* transmission, affecting a local region of tissue rather than a single postsynaptic site. Another, somewhat arbitrary, difference is that neuromodulators and neurohormones tend not to overtly excite or inhibit their targets, but rather shape the response of a neuron to classical synaptic transmitters in various and subtle ways (Kaczmarek and Levitan, 1987). Note that a given molecule can be assigned more than one of these roles (e.g., neurotransmitter versus neuromodulator), depending on the cell type or region in the nervous system.

Intracellular second messengers are called such because their concentration is often subsequent to the message delivered by neurotransmitters (e.g., after activation of a metabotopic receptor). Second messengers may have direct actions or, as mentioned, may participate in more complicated reaction schemes. Depending on the complexity of the reaction, the functional action of second messengers can be quite delayed and last for minutes if not longer. In addition, the more complicated the biochemical cascade, the more opportunities there are for interactions with modulatory pathways.

The most well-known second messenger is the $Ca^{2+}$ ion, which modulates various membrane channels and biochemical cascades, including many neurotransmitter release systems, and whose intracellular concentration is mediated by a variety of $Ca^{2+}$-permeable channels, pumps, buffers, and intracellular stores (involving as well the extensive endoplasmic recticulum network, which may support regenerative intracellular $Ca^{2+}$ waves [Berridge, 1998]).

There is a vast array of receptor types, some of which are associated with classical point-to-point synaptic transmission, others that mediate pancrinic transmission, and still others that function as links along intracellar pathways. Presynaptic membrane may also express extracellular receptors whose agonist is either the transmitter released by the same terminal (and thus implementing an immediate feedback loop) or another substance, which then may modulate the presynaptic terminal properties. A given neuron may express many different types of receptors in response to the signaling molecules released from other cells, normally in a nonuniform distribution over its surface. In contrast, the number of neuroactive compounds that a single neuron releases itself is usually one, probably (according to current knowledge) at most two or three.

### *Enzymes*

Among the wide variety of enzymes distributed in the neuron's cytoplasm, the most important types for signal processing include kinases and phosphatases, as well as those involved in the metabolism of signaling molecules (e.g., synthases and lipases). The kinases and phosphatases respectively phosphorylate (add a phosphate group) and dephosphorylate specific target proteins, as a result modifying the functional properties of the target. This is the most common mechanism of regulating the activity of neuronal proteins, for example, by altering the responsiveness of a receptor to an agonist, or the voltage dependency or conductance of an ion channel.

### *Gap Junctions*

Gap junctions are membrane proteins that form a direct electrical path between two neurons, essentially as a nonlinear, nonselective ion channel (see NEOCORTEX: CHEMICAL AND ELECTRICAL SYNAPSES). Thus, on the one hand, these connections are like conventional synapses in that they mediate information flow from cell to cell, but on the other hand, they are quite unlike conventional synapses in that this flow is (more or less) reciprocal and instantaneous. As with essentially all the other neuronal elements, gap junctions can be functionally modulated, typically by $Ca^{2+}$ or other second messengers.

### *Pumps, Exchangers, and Transporters*

Pumps, exchangers, and transporters are membrane proteins responsible for the active maintenance of concentration gradients of different ions and molecules crucial for neural signal processing, and thus are able to modify the membrane potential, either directly or indirectly.

For example, the enzyme Na/K ATPase maintains the characteristic $Na^+$ and $K^+$ gradients across all cell membranes; related proteins include the calcium and proton pumps. The action of these pumps depends on the hydrolysis of adenosine triphosphate (ATP) to adenosine diphosphate (ADP), and thus they are tightly coupled to the metabolic machinery of the neuron. Since these cations directly or indirectly contribute to the membrane potential, and since the kinetics of the pump can be modulated, a pump can set the neuron's long-term electrical behavior.

In addition to driving channel currents, the $Na^+$ and $K^+$ gradients across the cell membrane also provide the energy for exchangers and transporters. Exchanger proteins move ions such as $Ca^{2+}$ and protons out of the neuron, against their gradients, in exchange for $Na^+$ moving down its gradient. The exchangers react faster than pumps and thus provide early protection against excessive accumulation of various ions. Transporter proteins move molecules such as glutamate and GABA (respectively the principal excitatory and inhibitory neurotransmitters in the central nervous system) back into the neuron (and into surrounding glia as well) after being released into the extracellular space during synaptic transmission.

The activity of some of these proteins is electrogenic. For example, the Na/K pump cycles two $K^+$ ions in for three $Na^+$ ions out, and therefore directly generates a net outward current that can cause a hyperpolarization of many millivolts, depending on conditions. Although not always inherently electrogenic, there is an indirect link between the activity of exchangers and transporters and the membrane potential. Since they are driven by the inward movement of $Na^+$, an increase in exchanger or transporter activity leads to an increase in the cytoplasmic concentration of $Na^+$, which will then be countered by increased Na/K ATPase activity and its attendent electrogenic effect.

### *Implications of Neuronal Macromolecule Diversity and Complexity*

Channels, receptors, pumps, enzymes, and so on are comprised of one or several individual proteins, called subunits, each of which is coded by a specific gene. For any given type of channel (etc.) there may be many variations of the complete ensemble, or *multimer*, as one subunit substitutes for another, which often imparts different peculiarities to the functional properties of the multimeric protein (binding sites, effect on kinetics, etc.—in fact, the same sort of properties that may be affected by protein phosphorylation). Thus, a particular $Ca^{2+}$ channel type, for example, may have ten or so identified variants or subtypes (with the strong likelihood that more remain to be discovered). There are as yet but few demonstrations, either by explicit functional studies or by model prediction, that these differences between subtypes are relevant for neural computation. Nevertheless, correlations are increasingly being found between particular disease states and subtle functional alterations of cellular elements, or, in the opposite sense, functional (e.g., behavioral) expressions of genetic manipulation (e.g., knockout) protocols. Thus, the reality of subtype diversity suggests an important limitation for models that employ a single stereotypical kinetic model of a given type of neural protein.

Subunit substitution in a receptor, channel, or other neural protein can, among other things, determine different endogenous modulatory agonists or antagonists. Since there are many candidates for pancrinic pathways at most neurons, this mechanism is important for understanding circuitry dynamics in the intact brain. This functional diversity also has extremely important implications for clinical pharmacology: different subunits can also impart sensitivities to different exogenous compounds, allowing the eventual possibility of targeting very specific synapses or other cellular elements with the appropriately chosen (or designed) drug.

Individual proteins are comprised of contorted chains of thousands of amino acids. This fundamental complexity allows for, in principle, several mechanisms by which a protein may be influenced by its local environment. Thus, there may be an important location dependence of the functional properties of a particular kind of protein, reflecting subtle variations in the protein's microenvironment. For the same reason, it is not surprising that the behavior of a channel, for example, may be modified by the membrane voltage or by binding with a signaling molecule. In this context, we may note that quantitative experimental measurements of a given channel or receptor type in different cell types are inevitably different, beyond what would be expected from experimental variability. Sometimes such differences are seen even between different locations of a single cell type (in particular somatic versus dendritic). Thus, there are at least two possible explanations for such differences: they may be intrinsic to the neural protein under investigation (i.e., a difference in subunit composition), or they may reflect how different local environments, specific to different cell types or location within a single cell, can influence the protein's behavior.

## Neuron Models and the Biophysical Mosaic

We now return to the question of neuron models and how they might relate to cellular details. In the most general sense, a single neuron provides a dynamic mapping from a spatiotemporal pattern of pulsed inputs impinging on its dendrites and soma, into a single sequence of output spikes at the axon hillock, which may then be further altered by distinct mechanisms in the axonal tree and presynaptic boutons. Overall, the neuron models employed by theorists describe the time-varying three-dimensional biophysical mosaic underlying this complex signal processing to varying degrees (see PERSPECTIVE ON NEURON MODEL COMPLEXITY and SINGLE-CELL MODELS).

At the simplest level, an extreme abstract model might be a point integrator whose output is passed through a static sigmoid transfer function, where the scalar output is analogous to the firing rate of a spiking neuron. Here the biophysical basis is essentially limited to the resistive nature of the neuron membrane and the spike threshold. As a next step, the basic temporal characteristics of neuronal function may be represented by a leaky integrate-and-fire model that captures the resistive-capacitive nature of the neuron membrane and the action potential–based point process communication between neurons (see Integrate-and-Fire Neurons and Networks). Among other things, this scheme allows for encoding by both firing rate and higher-order statistics of spike trains, as well as a more tractable analysis of generalized stochastic mechanisms (see Adaptive Spike Coding, Rate Coding and Signal Processing, and Sensory Coding and Information Transmission).

A more explicit description of biophysical mechanisms might start with the characteristics of membrane channels and dendritic cables (see Dendritic Processing). For example, a single neuron model may include transmitter-gated synaptic conductance inputs distributed on a linear (or "passive") cable tree topology, with conductance-based (i.e., voltage-dependent channels) spike generation at a central somatic node. An anatomically based dendritic cable structure provides an explicit basis for synaptic weights via different coupling impedances to the soma, as well as cable-dependent (e.g., "on-the-path") nonlinear synaptic interactions. Simple channel models can capture basic spike firing properties such as absolute and relative refractory period, adaptation, or nonzero minimum firing rates.

A model with increased biophysical realism could include voltage-dependent membrane properties distributed throughout the cell (Stuart, Spruston, and Häusser, 1999; see Dendritic Processing). Intrinsic and synaptic mechanisms can be modeled with less or more sophisticated kinetic descriptions, either deterministic or stochastic (see Biophysical Mechanisms in Neuronal Modeling; Temporal Dynamics of Biological Synapses, Synaptic Interactions; and Synaptic Noise and Chaos in Vertebrate Neurons). Further details of functional properties may require descriptions of the microphysiology of extra- and intracellular systems, and thus explicit modeling of biochemical dynamics, including $Ca^{2+}$ diffusion, buffering, sequestration, and release; protein conformations; and enzyme activation/inactivation. Finally, the most faithful cellular model would require a four-dimensional construct whose biophysical properties vary with both space and time, in particular depending on past activity, or "experience" (see Hebbian Synaptic Plasticity).

## State Variables and Functional Compartments of the Mosaic Neuron

The many cellular elements we have described suggest a similar number of variables that characterize the functional state of a neuron as a signal processing device, each of which may be thought of as representing information. The most classical variable, of course, is the membrane voltage, which defines the immediate integration of synaptic input onto the dendritic tree and soma and, eventually, the action potential output of the cell. However, it may be argued that for predicting spike output, the first derivative of the membrane voltage may be nearly as important as the actual value of the voltage, a behavior that is easily predicted by Hodgkin-Huxley-type models (see Axonal Modeling; Biophysical Mechanisms in Neuronal Modeling; and Ion Channels: Keys to Neuronal Specialization). Other variables that may be important include the concentration of ions and various neuroactive molecules (e.g., transmitters and second messengers) both inside and outside the cell, and the metabolic or conformational state of various membrane and intracellular proteins. Finally, it may be useful to consider structural or anatomical parameters of the single neuron as functional state variables, such as number and distribution of spines or postsynaptic sites.

All of these state variables are determined by complex relationships between the cellular constituents. For example, the membrane voltage at any given point in the neuron is determined by the spatial distribution of electrically conducting membrane channels and their reversal potentials, the membrane capacitance, and the electrical coupling to the rest of the cell as determined by the three-dimensional branching cable structure and cytoplasmic resistivity. In turn, the ion concentration gradients that underlie channel reversal potentials are determined by an interplay between the currents through the appropriate channels (which tend to reduce the gradients) and membrane pumps, exchangers, transporters, and intracellular buffer and sequestering systems (which in general tend to maintain the gradients). Finally, in some cases ions passing through a given membrane channel can subsequently bind with and then modulate the conduction state of either the same or possibly other types of channels. Clearly, feedback pathways are the rule rather than the exception in the mosaic's interactions (see Figure 1).

The state variables of a neuron can be associated with a variety of functional compartments, with spatial scales that range from less than a micron to the entire cell. These compartments may correspond to the spatial gradients of voltage (e.g., as determined by dendritic cable properties) or second messenger concentration (e.g., determined by diffusion constant and geometry of the intracellular space), or to the localization of a given biochemical pathway, or to an explicit subcellular structure (e.g., a dendritic spine, an organelle, the cell nucleus). In summary, for most state variables the neuron is far from a classical "well-mixed" system. Rather, an extreme internal heterogeneity is usually the case: a single cell thus becomes a cell of cells.

### *Emergent State Properties of Intracellular Chemical Systems*

Recent work has demonstrated the possibility of various stable arrangements between the concentrations of certain intracellular molecules or the metabolic states of certain proteins, all of which in turn can participate in various biochemical pathways, including those regulating membrane properties and plasticity (Weng, Bhalla, and Iyengar, 1999). From an information processing viewpoint, these combinations can be thought of as essentially distinct states that partially define the functional input-output properties of the neuron. It has also been proposed that changes in cellular properties on even longer time scales may be due to self-stabilizing conformational states of proteins such as CAM kinase II or others. Of course, any mechanism underlying a long-lasting modification of the neuronal transfer function is a candidate for the molecular basis of memory (see Invertebrate Models of Learning: *Aplysia* and *Hermissenda*).

## Discussion: How Much Biophysics Needs to Be Known for a Compelling Brain Theory?

Where does the complexity of the mosaic neuron leave us in terms of formulating a theory for the brain? In particular, how detailed does a model of the neuron have to be, and how does the power of current methods compare with the computational complexity inherent at various levels of biophysical description? These open questions have a very practical importance, since there are few opportunities for formal analyses of these nonlinear dynamical systems. Furthermore, the increasing experimental knowledge of neuronal cellular mechanisms is daunting. The details seem to have an almost fractal quality; no matter what level is being examined, underneath any given mechanism there is another Pandora's box of parameters waiting to be described. Today, so many biophysical properties are known to be present in the neuron membrane that the biggest risk is to choose to include only those that will give the model the properties desired. This leads to a model that is unlikely to fail, and therefore unlikely to teach us anything that we did not know before.

The brute force strategy is to construct a bottom-up, biophysically detailed cell model in order to cover as much as possible the high-order interactions between various mechanisms. Once the map has been laid out, sufficiently rich deterministic or stochastic kinetic equations for the membrane elements and intracellular dynamics may then be assigned. Such maps can be evaluated, at least in principle, since all known biophysical mechanisms can be described by nonlinear partial differential equations, and thus are amenable to standard numerical integration techniques.

However, it may appear that at some point there will be too many equations with too many free parameters for practical evaluation or, more important, for true *understanding*. (On the other hand, the rapid evolution of computing power suggests that the threshold for "impractical" is hard to define.) An optimistic view is that once a sufficiently elaborate biophysical cellular model is constructed, its behavior may be well enough understood so that a more abstract model that captures the functional essentials with considerably less computational expense may be derived. But until there are some formal criteria for establishing what exactly "essential" means, this process will inevitably be an iterative one, moving back and forth between an analysis of detailed cell models in isolation and in nontrivial networks (limited most probably by the available tools) and an analysis of more abstract neural networks. The fundamental challenge to theorists, then, is to go beyond this sort of "reverse engineering" approach and develop a method that is at once commensurate with the complexity of the brain, yet can produce a bona fide theory whose detail avoids that of the actual biological reality.

# Brain Signal Analysis

*Jeng-Ren Duann, Tzyy-Ping Jung, and Scott Makeig*

## Introduction

Artificial neural networks (ANNs) have now been applied to a wide variety of real-world problems in many fields of application. The attractive and flexible characteristics of ANNs, such as their parallel operation, learning by example, associative memory, multifactorial optimization, and extensibility, make them well suited to the analysis of biological and medical signals. In this study, we review applications of ANNs to brain signal analysis, for instance, for analysis of the electroencephalogram (EEG) and magnetoencephalogram (MEG) or electromyogram (EMG), and as applied to computed tomographic (CT) images and magnetic resonance (MR) brain images, and to series of functional MR brain images (i.e., fMRI).

Most ANNs are implemented as sets of nonlinear summing elements interconnected by weighted links, forming a highly simplified model of brain connectivity. The basic operation of such artificial neurons is to pass a weighted sum of their inputs through a nonlinear hard-limiting or soft "squashing" function. To form an ANN, these basic calculating elements (artificial neurons) are most often arranged in interconnected layers. Some neurons, usually those in the layer farthest from the input, are designated as output neurons. The initial weight values of the interconnections are usually assigned randomly.

The operation of most ANNs proceeds in two stages. Rules used in the first stage, training (or learning), can be categorized as supervised, unsupervised, or reinforced. During training, the weight values for each interconnection in the network are adjusted either to minimize the error between desired and computed outputs (supervised learning) or to maximize differences (or minimize similarities) between the output categories (unsupervised or competitive learning). In reinforced learning, an input-output mapping is learned during continued interaction with the environment so as to maximize a scalar index of performance (Haykin, 1999). The second stage is recall, in which the ANN generates output for the problem the ANN is designed to solve, based on new input data without (or sometimes with) further training signals.

Because of their multifactorial character, ANNs have proved suitable for practical use in many medical applications. Because most medical signals of interest usually are not produced by variations in a single variable or factor, many medical problems, particularly those involving decision making, must involve a multifactorial decision process. In these cases, changing one variable at a time to find the best solution may never reach the desired objective (Dayhoff and DeLeo, 2001), whereas multifactorial ANN approaches may be more successful. In this article, we review recent applications of ANNs to brain signal processing, organized according to the nature of brain signals to be analyzed and the role that ANNs play in the applications.

## Roles of ANNs in Brain Signal Processing

To date, ANNs have been applied to brain data for the following purposes:

- *Feature extraction, classification, and pattern recognition.* ANNs in this application serve mainly as nonlinear classifiers. The inputs are preprocessed so as to form a feature space. ANNs are used to categorize the collected data into distinct classes. In other cases, inputs are not subjected to preprocessing but are given directly to an ANN to extract features of interest from the data.
- *Adaptive filtering and control.* In this application, ANNs operate within closed-loop systems to process changing inputs, adapting their weights “on the fly” to filter out unwanted parts of the input (adaptive filtering), or mapping their outputs to parameters used in on-line control (adaptive control).
- *Linear or nonlinear mapping.* In this application, ANNs are used to transform inputs to outputs of a desired form. For example, an ANN might remap its rectangular input data coordinates to circular or more general coordinate systems.
- *Modeling.* ANNs can be thought of as function generators that generate an output data series based on a learned function or data model. ANNs with two layers of trainable weights have proved capable of approximating any nonlinear function.
- *Signal separation and deconvolution.* In this application, ANNs separate their input signals into the weighted sum or convolution of a number of underlying sources using assumptions about the nature of the sources or of their interrelationships (e.g., their independence).
- *Texture analysis and image segmentation.* Image texture analysis is becoming increasingly important in image segmentation, recognition, and understanding. ANNs are being used to learn spatial or spatial-frequency texture features and, accordingly, to categorize images or to separate an image into subimages (image segmentation).
- *Edge detection.* In an image, an edge or boundary between two objects can be mapped to a dark band between two lighter areas (objects). By using the properties of intensity discontinuity, ANNs can be trained to recognize these dark bands as edges, or can learn to draw such edges based on contrast and other information.

## Application Areas

In this section, we describe some applications of ANNs to brain signals by means of examples involving neurobiological time series and brain images. Neurobiological signals of clinical interest recorded noninvasively from humans include electroencephalographic (EEG), magnetoencephalographic (MEG), and electromyographic (EMG) data. Research in brain imaging includes the analysis of structural brain images, mainly focused on the extraction of three-dimensional (3D) structural information, from various kinds of brain images (e.g., magnetic resonance images, or MRIs), as well as the analysis of functional brain imaging series that mainly reveal changes in the brain state during cognitive tasks using medical imaging techniques (e.g., functional MRI, or fMRI, and positron emission tomography, or PET). These examples by no means cover all the applications in the field.

### *Neurobiological Signals*

*EEG and MEG.* EEG provides a noninvasive measure of brain electrical activity recorded as changes in the potential difference between two points on the scalp. MEG is the magnetic counterpart of EEG. In accordance with the assumption that the ongoing EEG can be altered by stimulus or event to form respectively the event-related potential (ERP) or the evoked potential (EP), these changes, though tiny, can be recorded through the scalp. It is possible for researchers to apply pattern recognition algorithms to search for the differences in brain status while the brain is performing different tasks. Thus, Peters, Pfurtscheller, and Flyvbjerg (2001) applied an autoregressive model to four-channel EEG potentials to obtain features that were used to train an ANN using a backpropagation algorithm to differentiate the subject’s intention to move the left or right index finger or right foot. They suggested that the framework might be useful for designing a direct brain-computer interface. In the study of Zhang et al. (2001), ANNs were trained to determine the stage of anesthesia based on features extracted from the middle-latency auditory-evoked potential (MLAEP) plus other physiological parameters. By combining power spectral estimation, principal component analysis (PCA), and ANNs, Jung et al. (1997) demonstrated that continuous, accurate, noninvasive, and near real-time estimation of an operator’s global level of alertness is feasible using EEG measures recorded from as few as two scalp sites. The results of their ANN-based estimation compared favorably with results obtained using a linear regression model applied to the same PCA-reduced EEG power spectral data.

Sun and Sclabassi (2000) employed an ANN as a linear mapping device to transform the EEG topography obtained from a forward solution in a simple spherical model to a more realistic spheroidal model whose forward solution was difficult to compute directly. In that study, a backpropagation learning algorithm was used to train an ANN to convert spatial locations between spherical and spheroid models. Instead of computing the infinite sums of the Legendre functions required in the asymmetric spheroidal model, the calculations were carried out in the spherical model and then converted by the ANN to the more realistic model for display and evaluation.

Recently, ANNs have made a substantial contribution to the analysis of EEG/MEG by separating the problem of EEG/MEG source identification from that of source localization, a mathematically underdetermined problem: any scalp potential distribution can be produced by a limitless number of potential distributions within the head. Because of volume conduction through cerebrospinal fluid, skull, and scalp, EEG and MEG data collected from any point on the scalp may include activity arising in multiple locally synchronous but relatively independent neural processes within a large brain volume. This has made it difficult to relate EEG measurements to underlying brain processes and to localize the sources of EEG and MEG signals. Progress has been made by several groups in separating and identifying the distinct brain sources from their mixtures in scalp EEG or MEG recordings, assuming only their temporal independence and spatial stationarity (Makeig et al., 1997; Jung et al., 2001), using a class of independent component analysis (ICA) or blind source separation algorithms.

*Muscle and movement signals.* From recordings of muscle stretching (mainly the EMG), it is possible to predict the intent of subjects to perform actions such as hand or finger movements, or to judge the disability of a specific bundle of muscle cells. For example, Khalil and Duchene (2000) used wavelet coefficients obtained from uterine EMG to train ANNs to separate the inputs into four labeled categories: uterine contractions, fetal movements, Alvarez waves, and long-duration low-frequency band waves. They reported that the system was useful for maintaining preterm births. On the other hand, Stites and Abbas (2000) used an ANN as a pattern shaper to refine the output patterns of a functional neuromuscular stimulation system that served as a pattern generator of control signals for cyclic movements to help the paraplegic patient stand using functional neuromuscular stimulation.

### Brain Images

*Structural images.* In structural brain image analysis, ANNs may play roles in image segmentation, image labeling, or edge detection. Image segmentation is the first and probably the most important step in digital image processing. Segmentation may be a labeling problem in which the goal is to assign, to each voxel in a gray-level image, a unique label that represents its belonging to an anatomical structure. The results of image segmentation can be used for image understanding and recognition, 3D reconstruction, visualization, and measurements, including brain volume changes in developmental brain diseases such as Alzheimer's disease and autism. The rapid pace of development of medical imaging devices such as MRI and computed tomography permits a better understanding of anatomical brain structure without, prior to, or even during neurosurgery. However, the results are highly dependent on the quality of the image segmentation processes.

Here we give some examples using ANNs in image segmentation: Dawant et al. (1991) presented a backpropagation neural network approach to the automatic characterization of brain tissues from multimodal MR images. The ability of a three-layer backpropagation neural network to perform segmentation based on a set of MR images (T1-weighted, T2-weighted, and proton density-weighted) acquired from a patient was studied. The results were compared with those obtained using a maximum likelihood classifier. Dawant et al. found no significant difference in the results obtained by the two methods, although the backpropagation neural network gave cleaner segmentation images. Using the same analysis strategy, Reddick et al. (1997) first trained a self-organizing map (SOM) on multimodal MR brain images to efficiently extract and convert the 3D inputs (from T1-, T2- and proton density-weighted images) into a feature space and utilized a backpropagation neural network to separate them into classes of white matter, gray matter, and cerebrospinal fluid. Their work demonstrated high intraclass correlation between the automated segmentation and classification of tissues and standard radiologist identification, as well as high intrasubject reproducibility.

*Functional images.* Today, not only are medical imaging devices able to provide impressive spatial resolution and details of the fine structure of the human brain, they can also reveal changes in brain status in awake subjects who are performing a task or even daydreaming, by measuring ongoing metabolic changes, including cerebral blood flow, cerebral blood volume (by PET), and blood oxygenation level–dependent signal levels (by fMRI). We will give some examples, mainly from fMRI analysis.

Functional brain imaging emerged in the early 1990s, based on the observation that increases in local neuronal activity are followed by local changes in oxygen concentration. Changing the amount of oxygen carried by hemoglobin changes the degree to which hemoglobin disturbs a magnetic field, as a result of which in vivo changes in blood oxygenation could be detected by MRI (Ogawa et al., 1992). The subsequent changes in the MRI signal became known as the blood oxygenation level–dependent or BOLD signal. This technique was soon applied to normal humans during functional brain activation (the subjects performed cognitive tasks), giving birth to the rapid growing field of fMRI.

Theoretically, the fMRI BOLD signal from a given brain voxel can be interpreted as a linear combination of different sources with distinguishable time courses and spatial distributions, including use-dependent hemodynamic changes, blood, or CSF flows, plus subject movement and machine artifacts. Recently, ANNs (especially those using ICA), applied to fMRI data, have proved to be a powerful method for detecting and separating task-related activations with either known or unanticipated time courses (McKeown et al., 1998) that could not be detected using standard hypothesis-driven analyses. Duann et al. (2002) have given further details of applying ICA to the fMRI BOLD signal. They showed that the hemodynamic response to even widely spaced stimulus presentations may be dependent on the trial, site, stimulus, and subject. Thus, the standard regression–based method of applying a fixed hemodynamic response model to find stimulus- or task-related BOLD activations needs to be reconsidered.

## Discussion

The use of ANNs as classifiers currently dominates their applications in the field of brain signal analysis. This includes classification of brain or related signals as exhibiting normal or abnormal features or processes. Not surprisingly, published studies report promising results.

If the measurements can be modeled as an additive mixture of different sources, including task-related signals and artifacts, applying blind source separation prior to the further processing, visualization, or interpretation may better reveal the underlying physical phenomena (such as different brain processes), which in the raw data could be contaminated or overwhelmed by other processes of no interest.

A survey of relevant papers shows that the most popular architecture for ANNs is the multilayer perceptron (MLP). The MLP architecture is both simple and straightforward to implement and use. In MLPs, information flows in one direction except during training, when error terms are backpropagated. Backpropagation updates network weights in a supervised manner. Although it cannot guarantee a globally minimal solution, backpropagation at least arrives at a local minimum through gradient descent. Various techniques have been derived in an attempt to avoid overfitting to a local minimum. Once the network weights have been learned and fixed, feedforward networks can be implemented in hardware and made to run in real time. All of these characteristics make the backpropagation algorithm most popular in biomedical applications.

In some applications, target outputs may not be available or may be too expensive to acquire. In these cases, unsupervised learning algorithms may be used. Among unsupervised learning algorithms, self-organizing maps (SOMs) are the most popular for biomedical applications. During training, SOMs attempt to assign their input patterns to different output regions. Often SOMs may converge after only few learning cycles.

## Application Issues

Although most published papers have concluded that ANNs are appropriate for their domain of interest, many issues still have to be resolved before ANNs can be claimed to be the general method of choice. Unfortunately, most published studies have not gone beyond demonstrating application to a very limited amount of data. As with any type of method, ANNs have their limitations that should be carefully considered:

- Every study should provide a rationale for the data chosen as input. For example, ANN-based computer-aided diagnostic systems may give misleading results if the ANNs are not given adequately representative features and sufficient naturally occurring data variations in their training data. With ANNs, any input may yield some sort of output, correct and useful or not ("garbage in, garbage out"). Therefore, the keys to success of ANN applications are not only to pick an appropriate architecture or learning algorithm, but also to choose the right data and data features to train the network.
- Although methods of applying ANNs to biomedical signals have already shown great promise, great care must be taken to examine

the results obtained. The issue of trust in the outputs of ANNs always deserves informed as well as statistical consideration. Since medical diagnosis is nearly always a multifactorial and multidisciplinary problem, medical experts should always evaluate network outputs in light of other direct or indirect convergent evidence before making final decisions affecting the health of patients.

- Before practical implementation is planned, ANN methods should be compared to more direct ways of obtaining the same answers, as these might sometimes prove more accurate or cost effective.

## Model Mining

Since the first wave of popularization of backpropagation networks nearly two decades ago, an ever greater number and variety of ANN models have been devised to tackle an ever greater variety of problems. The overall insight that ANNs both embody and exemplify is perhaps that our human intelligence is multifactorial and highly adaptable to using whatever forms of information are available to us. In this spirit, we suggest that researchers always attempt to interpret the physiological meaning both of the features of their input data and of the data models that their trained ANNs represent. Too often ANNs have been treated like black boxes. We believe it is time to open the black boxes and interpret what is happening inside them. Such interpretations might even yield new insights into the nature of the biomedical signals, or suggest new or more efficient ways to look at the input data. It is also possible that the ANN models and methods might suggest more efficient methods to collect input data. Such "model mining" might even prove to be the most rewarding result of applying ANNs. Researchers who simply recount classification accuracy may ignore nuggets of novel information about brain processes hidden in the ANN models that they and the data have jointly constructed.

# Brain-Computer Interfaces

*José del R. Millán*

## Introduction

There is a growing interest in the use of physiological signals for communication and operation of devices for the severely motor disabled as well as for able-bodied people. Over the last decade evidence has accumulated to show the potential of analyzing brainwaves on-line to derive information about the subject's mental state that is then mapped into some external action such as selecting a letter from a virtual keyboard or moving a robotics device. A *brain-computer interface (BCI)* is an alternative communication and control channel that does not depend on the brain's normal output pathway of peripheral nerves and muscles (Wolpaw et al., 2000).

Most BCI systems use electroencephalogram signals (EEG and MEG Analysis) measured from scalp electrodes that do not require invasive procedures. Although scalp EEG is a simple way to record brainwaves, it does not provide detailed information on the activity of single neurons (or small clusters of neurons) that could be recorded by implanted electrodes in the cortex (Prosthetics, Neural). Such a direct measurement of brain activity may, in principle, enable faster recognition of mental states and even more complex interactions.

A BCI may monitor a variety of brainwave phenomena. Some groups exploit evoked potentials generated in response to external stimuli (see Wolpaw et al., 2000, for a review). Evoked potentials are, in principle, easy to pick up but are constrained by the fact that the subject must be synchronized to the external machinery. A more natural and practical alternative is to rely on components associated with spontaneous mental activity. Such spontaneous components range from slow cortical potentials of the EEG (e.g., Birbaumer et al., 1999), to variations of EEG rhythms (e.g., Wolpaw and McFarland, 1994; Kalcher et al., 1996; Anderson, 1997;

Roberts and Penny, 2000; Millán et al., 2002b), to the direct activity of neurons in the cortex (e.g., Kennedy et al., 2000; Wessberg et al., 2000).

## Direct Brain-Computer Interfaces

Direct BCIs involve invasive procedures to implant electrodes in the brain (Prosthetics, Neural). Apart from ethical concerns, a major difficulty is to obtain reliable long-term recordings of neural activity. Recent advances have made it possible to develop direct BCIs with animals and even human beings.

Kennedy and colleagues (2000) have implanted a special electrode into the motor cortex of several paralyzed patients. These electrodes contain a neurotrophic factor that induces growth of neural tissue within the hollow electrode tip. With training, patients learn to control the firing rates of the multiple recorded neurons to some extent. One of them is able to drive a cursor and write messages.

Wessberg et al. (2000) have recorded the activity of ensembles of neurons with microwire arrays implanted in multiple cortical regions involved in motor control, as monkeys performed arm movements. From these signals they have obtained accurate real-time predictions of arm trajectories and have been able to reproduce the trajectories with a robot arm. Although these experiments do not describe an actual BCI, they support the feasibility of controlling complex prosthetic limbs directly by brain activity. In addition, earlier work by Nicolelis and colleagues showed that neural predictors can be derived for rats implanted with the same kind of microelectrodes (see Nicolelis, 2001, for details and reference). The rats were trained to press a bar to move a simple device delivering water, and later learned to operate this device through neural activity only.

For a more detailed analysis and prospects of this area, see Nicolelis (2001).

## Noninvasive Brain-Computer Interfaces

Noninvasive BCIs are based on the analysis of EEG phenomena associated with various aspects of brain function. Thus, Birbaumer et al. (1999) measure slow cortical potentials (SCP) over the vertex (top of the scalp). SCP are shifts in the depolarization level of the upper cortical dendrites and indicate the overall preparatory excitation level of a cortical network. Other groups look at local variations of EEG rhythms. The most commonly used rhythms are related to the imagination of movements and are recorded from the central region of the scalp overlying the sensorimotor cortex. In this respect, there exist two main paradigms. Pfurtscheller's team works with event-related desynchronization (ERD, EEG and MEG Analysis) computed at fixed time intervals after the subject is commanded to imagine specific movements of the limbs (Kalcher et al., 1996; Obermaier, Müller, and Pfurtscheller, 2001). Alternatively, Wolpaw and co-workers analyze continuous changes in the amplitudes of the $\mu$ (8–12 Hz) or $\beta$ (13–28 Hz) rhythms (Wolpaw and McFarland, 1994). Finally, in addition to motor-related rhythms, Anderson (1997) and Millán et al. (2002b) also analyze continuous variations of EEG rhythms, but not only over the sensorimotor cortex and in specific frequency bands. The reason is that a number of neurocognitive studies have found that different mental tasks—such as imagination of movements, arithmetic operations, or language—activate local cortical areas to different extents. The insights gathered from these studies guide the placement of electrodes to obtain more relevant signals for the different tasks to be recognized. In this latter case, rather than looking for predefined EEG phenomena as in the previous paradigms, the approach aims at discovering EEG patterns embedded in the continuous EEG signal associated with different mental states.

Most of the existing BCIs are based on synchronous experimental protocols in which the subject must follow a fixed repetitive scheme to switch from one mental task to the next (Wolpaw and McFarland, 1994; Kalcher et al., 1996; Wolpaw and McFarland, 1994; Birbaumer et al., 1999; Obermaier et al., 2001). A trial consists of two parts. A first cue warns the subject to get ready and, after a fixed period of several seconds, a second cue tells the subject to undertake the desired mental task for a predefined time. The EEG phenomena to be recognized are time locked to the last cue and the BCI responds with the average decision over the second period of time. In these synchronous BCI systems, the shortest trial lengths that have been reported are 4 s (Birbaumer et al., 1999) and 5 s (Obermaier et al., 2001). This relatively long time is necessary because the EEG phenomena of interest, either SCP or ERD, need some seconds to recover. On the contrary, other BCIs rely on more flexible asynchronous protocols where the subject makes self-paced decisions on when to stop doing a mental task and start immediately the next one (Roberts and Penny, 2000; Millán et al., 2002b). In this second case, the time of response of the BCI goes from 0.5 s (Millán et al., 2002b) to several seconds (Roberts and Penny, 2000).

EEG signals are characterized by a poor signal-to-noise ratio and spatial resolution. Their quality is greatly improved by means of a Surface Laplacian (SL) derivation, which requires a large number of electrodes (normally 64–128). The SL estimate yields new potentials that represent better the cortical activity originated in radial sources immediately below the electrodes (for details see McFarland et al., 1997; Babiloni et al., 2001; and references therein). The superiority of SL-transformed signals over raw potentials for the operation of a BCI has been demonstrated in different studies (e.g., McFarland et al., 1997). Although significant progress has been obtained (and will still continue) with studies using a high number of EEG electrodes (from 26 to 128), today's practical BCI systems should have a few electrodes (no more than 10) to allow their operation by laypersons, as the procedure of electrode positioning is time consuming and critical. Most groups have developed BCI prototypes with a limited number of electrodes that, however, do not benefit from SL transformations. On the contrary, Babiloni et al. (2001) and Millán et al. (2002b) compute SL derivations from a few electrodes, using global and local methods, respectively.

Wolpaw and McFarland (1994) as well as Birbaumer et al. (1999) have demonstrated that some subjects can learn to control their brain activity through appropriate, but lengthy, training in order to generate fixed EEG patterns that the BCI transforms into external actions. In both cases the subject is trained over several months to modify the amplitude of either the SCP or $\mu$ rhythm, respectively. A few other groups follow machine learning approaches to train the classifier embedded in the BCI. These techniques range from linear classifiers (Babiloni et al., 2001; Obermaier et al., 2001), to compact multi-layer perceptrons and Bayesian neural networks (Anderson, 1997; Roberts and Penny, 2000), to variations of LVQ (Kalcher et al., 1996), to local neural classifiers (Millán, 2002; Millán et al., 2002b). Most of these works deal with the recognition of just two mental tasks (Roberts and Penny, 2000; Babiloni et al., 2001; Obermaier et al., 2001), or report classification errors bigger than 15% for three or more tasks (Kalcher et al., 1996; Anderson, 1997). An exception is Millán's approach that achieves error rates below 5% for three mental tasks, but correct recognition is 70% (Millán, 2002; Millán et al., 2002b). Obermaier et al. (2001) reports on a single disabled person who, after several months of training, has reached a performance level close to 100%. It is also worth noting that some of the subjects who follow Wolpaw's approach are able to control their $\mu$ rhythm amplitude at four different levels. These classification rates, together with the number of recognizable tasks and duration of the trials, yield bit rates from approximately 0.15 to 2.0.

Some approaches are based on a mutual learning process in which the user and the brain interface are coupled together and adapt to each other (Roberts and Penny, 2000; Obermaier et al., 2001; Millán, 2002; Millán et al., 2002b). This should accelerate the training time. Thus, Millán's approach has allowed subjects to achieve good performances in just a few hours of training (Millán, 2002; Millán et al., 2002b). Analysis of learned EEG patterns confirms that for a subject to operate a personal BCI satisfactorily, the BCI must fit the individual features of the user (Millán et al., 2002a).

Another important concern in BCI is the incorporation of rejection criteria to avoid making risky decisions for uncertain samples. This is extremely important from a practical point of view. Roberts and Penny (2000) apply Bayesian techniques for this purpose, while Millán et al. (2002b) use a confidence probability threshold. In this latter case, more than ten subjects have experimented with their BCI (Millán, 2002; Millán et al., 2002b). Most of them were trained for a few consecutive days (from three to five). Training time was moderate, around half an hour daily. Experimental results show that, at the end of training, the correct recognition rates were 70% (or higher) for three mental tasks. This figure is more than twice random classification. This modest rate is largely compensated by two properties: wrong responses were below 5% (in many cases even below 2%) and decisions were made every half-second. Some other subjects have undertaken consecutive training sessions (from four to seven) in a single day. None of these subjects had previous experience with BCIs and, in less than two hours, all of them reached the same excellent performance as noted previously. It is worth noting that one of the subjects was a physically impaired person suffering from spinal muscular atrophy.

## Brain-Actuated Applications

These different BCI systems are being used to operate a number of brain-actuated applications that augment people's communication capabilities, provide new forms of education and entertainment, and also enable the operation of physical devices. There exist virtual keyboards for selecting letters from a computer screen and writing a message (Birbaumer et al., 1999; Obermaier et al., 2001; Millán, 2002). Using these three different approaches, subjects can write a letter every 2 minutes, every 1 minute, and every 22 seconds, respectively. Wolpaw's group has also its own virtual keyboard (Wolpaw, personal communication). A patient who has been implanted with Kennedy and colleagues' special electrode has achieved a spelling rate of about three letters per minute using a combination of neural and EMG signals (Kennedy et al., 2000).

On the other hand, it is also possible to make a brain-controlled hand orthosis open and close (see references in Wolpaw et al., 2000; Obermaier et al., 2001) and even guide in a continuous manner a motorized wheelchair with on-board sensory capabilities (Millán, 2002). In this latter case, the key idea is that users' mental states are associated with high-level commands that the wheelchair executes autonomously (ROBOT NAVIGATION). Another critical aspect for the control of the wheelchair is that subjects can issue high-level commands at any moment, as the operation of the BCI is self-paced and does not require waiting for specific events.

Finally, Millán (2002) illustrates the operation of a simple computer game, but other educational software could have been selected instead.

## Discussion

Despite recent advancements, BCI is a field still in its infancy and several issues must be addressed to improve the speed and performance of BCI. One of them is the exploration of local components of brain activity with fast dynamics that subjects can consciously control. For this we will need increased knowledge of the brain (where and how cognitive and motor decisions are made) as well as the application of more powerful digital signal processing (DSP) methods than those commonly used currently. In addition, extraction of more relevant features, by means of these DSP methods, together with the use of more appropriate classifiers, will improve BCI performance in terms of classification rates and the number of recognizable mental tasks. It may be possible to apply recurrent neural networks to exploit temporal dynamics of brain activity. However, a main limitation in scaling up the number of recognizable mental tasks is the quality—signal-to-noise ratio (SNR)—and resolution of the measured brain signals. This is especially true in the case of EEG-based BCIs, in which the SNR is very poor and we cannot get detailed information on the activity of small cortical areas unless we use a large number of electrodes (64, 128, or more). It is thus crucial to develop better electrodes that are also easy to position, thereby enabling the use of a large number of electrodes even by laypersons. Finally, another key concern is to keep the BCI constantly tuned to its owner. This requirement arises because, as subjects gain experience, they develop new capabilities and change their EEG patterns. In addition, brain activity changes from one session (with which data the classifier is trained) to the next (where the classifier is applied). The challenge here is to adapt the classifier on-line while the subject operates a brain-actuated application, even if the subject's intention is not known until later. In this respect, local neural networks are better suited for on-line learning (STATISTICAL MECHANICS OF ON-LINE LEARNING AND GENERALIZATION) than other methods, due to their robustness against catastrophic interference. This list of topics is not exhaustive, but space limits prevent further discussion (see Wolpaw et al., 2000, for additional details on these and other issues).

Although the immediate application of BCI is to help physically impaired people, its potentials are extensive. Ultimately, they may lead to the development of truly adaptive interactive systems that, on the one hand, augment human capabilities by giving the brain the possibility to develop new skills and, on the other hand, make computer systems fit the pace and individual features of their owners. Most probably, people will use BCI in combination with other sensory interaction modalities (e.g., speech, gestures) and physiological signals (e.g., electromyogram, skin conductivity). Such a multimodal interface will yield a higher bit rate of communication with better reliability than would occur if only brainwaves were utilized. On the other hand, the incorporation of other interaction modalities highlights a critical issue in BCI, namely the importance of filtering out from the recorded brain signals non-CNS artifacts originated by movements of different parts of the body. INDEPENDENT COMPONENT ANALYSIS (q.v.) is a method of detecting and removing such artifacts.

# Canonical Neural Models

*Frank Hoppensteadt and Eugene M. Izhikevich*

## Introduction

Mathematical modeling is a powerful tool for studying the fundamental principles of information processing in the brain. Unfortunately, mathematical analysis of a certain neural model could be of limited value, because the results might depend on the particulars of that model: various models of the same neural structure could produce different results. For example, if an investigator obtains results with a Hodgkin-Huxley-type model (see AXONAL MODELING) and then augments the model by adding more parameters and variables to take into account more neurophysiological data, would similar results emerge? A reasonable way to circumvent this problem is to derive results that are largely independent of the model and that can be observed in a class or a family of models.

Having understood the importance of considering families of neural models instead of a single model, we carry out this task by reducing an entire family of Hodgkin-Huxley-type models to a canonical model (for precise definitions, see Section 4.1 in Hoppensteadt and Izhikevich, 1997). Briefly, a model is *canonical* for a family if there is a continuous change of variables that transforms any other model from the family into this one, as we illustrate in Figure 1. For example, the entire family of weakly coupled oscillators of the form in Equation 1 can be converted into the canonical phase model described by Equation 6, where $H_{ij}$ depend on the particulars of the functions $f_i$ and $g_{ij}$. The change of variables does not have to be invertible, so the canonical model is usually lower dimensional, simple, and tractable. Yet it retains many important features of the family. For example, if the canonical model has multiple attractors, then each member of the family has multiple attractors.

The major advantage to considering canonical models is that one can study universal neurocomputational properties that are shared by all members of the family, since all such members can be put into the canonical form by a continuous change of variables. Moreover, an investigator need not actually present such a change of variables explicitly, so that derivation of canonical models is possible even when the family is so broad that most of its members are given implicitly, e.g., in the abstract form of Equation 1. For example, the canonical phase model in Equation 6 reveals universal computational abilities (e.g., oscillatory associative memory) that are shared by all oscillatory systems, regardless of the nature of each oscillator or the particulars of the equations that describe it. Thus, the canonical model approach provides a rigorous way to obtain results when only partial information about neuron dynamics is known. Many examples are given subsequently in this article.

The process of deriving canonical neural models is more an art than a science, because a general algorithm for doing so is not known. However, much success has been achieved when we consider weakly connected networks of neurons whose activity is near a bifurcation, a situation that often occurs when the membrane potential is near the threshold value (see DYNAMICS AND BIFURCATION IN NEURAL NETS and PHASE-PLANE ANALYSIS OF NEURAL NETS). We review such bifurcations and corresponding canonical

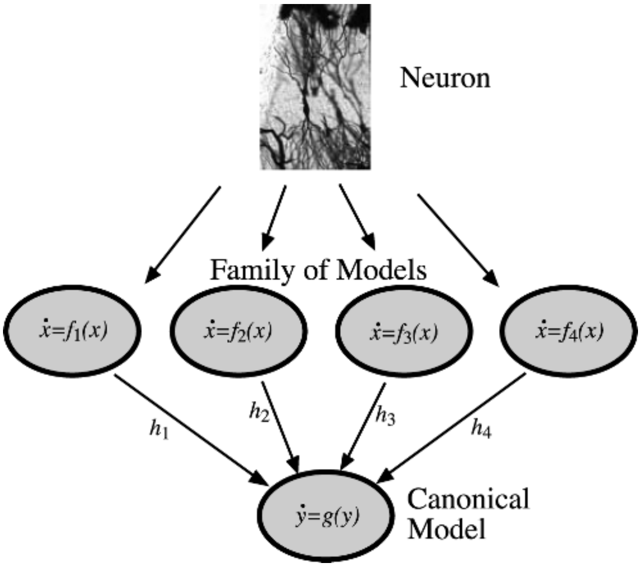

**Figure 1.** Dynamical system $\dot{y} = g(y)$ is a canonical model for the family $\{f_1, f_2, f_3, f_4\}$ of neural models $\dot{x} = f(x)$ because each such model can be transformed into the form $\dot{y} = g(y)$ by the continuous change of variables $h_i$.

models. Their rigorous derivation and detailed analysis can be found in Hoppensteadt and Izhikevich (1997).

## Weakly Connected Neural Networks

The assumption of weak neuronal connections is based on the observation that the typical size of a postsynaptic potential is less than 1 mV, which is small in comparison with the mean size necessary to discharge a cell (around 20 mV) or the average size of the action potential (around 100 mV) (for a detailed review of relevant electrophysiological data, see Hoppensteadt and Izhikevich, 1997, chap. 1). From the mathematical point of view, this results in neural models of "weakly connected" form

$$\dot{x}_i = f(x_i, \lambda_i) + \varepsilon \sum_{j=1}^{n} g_{ij}(x_i, x_j, \varepsilon) \qquad (1)$$

where each vector $x_i \in \mathbb{R}^m$ describes membrane potential, gating variables, and other electrophysiological variables of the $i$th neuron (see Ion Channels: Keys to Neuronal Specialization). Each vector $\lambda_i \in \mathbb{R}^l$ denotes various biophysical parameters of the neuron. The function $f$ describes the neuron's dynamics, and the functions $g_{ij}$ describe connections between the neurons. The dimensionless parameter $\varepsilon \ll 1$ is small, reflecting the strength of connections between neurons.

## Bistability and Hysteresis

Bistable and hysteretic dynamics are ubiquitous in neural models, and they may play important roles in biological neurons. The cusp bifurcation depicted in Figure 2 is one of the simplest bifurcations leading to such dynamics. For example, the sigmoidal neuron

$$\dot{x} = -x + aS(x), \quad S(x) = 1/(1 + e^{-x})$$

is at a cusp bifurcation point $x = 0.5$ when $a = 4$. It is bistable when $a > 4$. If each neuron in the weakly connected network described by Equation 1 is near a supercritical cusp bifurcation, then the entire network can be transformed into the canonical form (Hoppensteadt and Izhikevich, 1997)

$$y_i' = r_i - y_i^3 + \sum_{j=1}^{n} s_{ij} y_j \qquad (2)$$

where each scalar $y_i \in \mathbb{R}$ describes rescaled dynamics of the $i$th neuron. Particulars of the functions $f$ and $g_{ij}$ and the value of the parameters $\lambda_i$ do not affect the form of the canonical model. They only affect the parameters $r_i$ and $s_{ij}$. Thus, by studying the canonical model in Equation 2 one can gain some insight into the neurocomputational behavior of any neural model near a cusp bifurcation, whether it is a simple sigmoidal neuron or a biophysically detailed conductance-based (Hodgkin-Huxley-type) neuron.

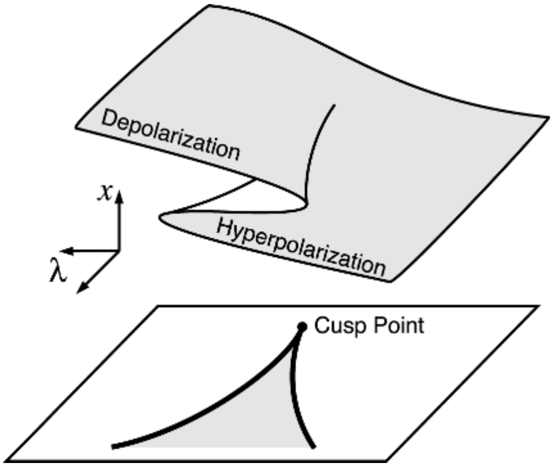

**Figure 2.** Cusp surface.

The canonical model in Equation 2 is quite simple: each equation has only one nonlinear term, namely, $y_i^3$, and two internal parameters, $r_i$ and $s_{ii}$. Still, the Cohen-Grossberg-Hopfield convergence theorem applies, which means that the canonical model has the same neurocomputational properties as the standard Hopfield network (see Computing with Attractors).

### *Theorem 1 (Cohen-Grossberg-Hopfield Convergence Theorem)*

If the connection matrix $S = (s_{ij})$ is symmetric, then the canonical neural network of Equation 2 is a gradient system.

One can easily check that

$$E(y) = -\sum_{i=1}^{n} (r_i y_i - ¼\, y_i^4) - ½ \sum_{i,j=1}^{n} s_{ij} y_i y_j$$

is a potential function for Equation 2 in the sense that $y_i' = -\partial E/\partial y_i$ (see also Energy Functionals for Neural Networks).

## Small-Amplitude Oscillations

Many biophysically detailed neural models can exhibit small-amplitude (damped) oscillations of the membrane potential, especially when the system is near transition from rest state to periodic activity. In the simplest case this corresponds to the supercritical

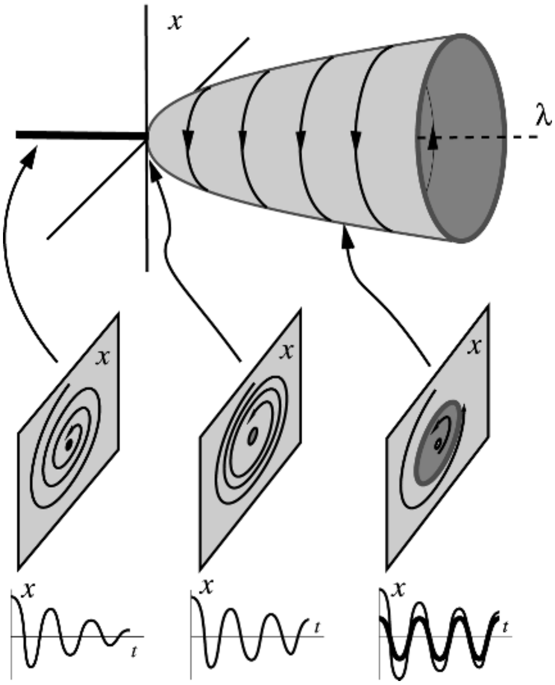

**Figure 3.** Supercritical Andronov-Hopf bifurcation in $\dot{x} = f(x, \lambda)$. On the left, the rest state is stable. In the middle, the rest state is losing stability, giving birth to a stable limit cycle corresponding to periodic activity. On the right, the system exhibits periodic activity.

Andronov-Hopf bifurcation in Figure 3. Many weakly connected networks (in the form of Equation 1) of such neurons can be transformed into the canonical model

$$z_i' = (r_i + i\omega_i)z_i - z_i|z_i|^2 + \sum_{j=1}^{n} c_{ij}z_j \tag{3}$$

by a continuous change of variables (Aronson, Ermentrout, and Kopell, 1990). Here $i = \sqrt{-1}$, and each complex variable $z_i \in \mathbb{C}$ describes oscillatory activity of the $i$th neuron. Again, particulars of the form of the functions $f$ and $g_{ij}$ in Equation 1 affect only the values of the parameters $r_i$ and $\omega_i$ and the complex-valued synaptic coefficients $c_{ij} \in \mathbb{C}$.

Even though the canonical model in Equation 3 exhibits oscillatory dynamics, one can still prove the following analogue of the Cohen-Grossberg convergence theorem, which implies that the canonical model in Equation 3 has oscillatory associative memory; that is, it can memorize and retrieve complex oscillatory patterns (Hoppensteadt and Izhikevich, 1996) (Figure 4).

### *Theorem 2 (Synchronization Theorem for Oscillatory Neural Networks)*

If in the canonical neural network in Equation 3 all neurons have equal frequencies $\omega_1 = \ldots = \omega_n$ and the connection matrix $C = (c_{ij})$ is self-adjoint, i.e.,

$$c_{ij} = \bar{c}_{ji} \quad \text{for all } i \text{ and } j \tag{4}$$

then the network always converges to an oscillatory phase-locked pattern; that is, the neurons oscillate with equal frequencies and constant, but not necessarily identical, phases. There could be many such phase-locked patterns corresponding to many memorized images.

The proof follows from the existence of an orbital energy function

$$E(z) = -\sum_{i=1}^{n} (r_i|z_i|^2 - ½\,|z_i|^4) - \sum_{i,j=1}^{n} c_{ij}\bar{z}_i z_j$$

for Equation 3 (see Energy Functionals for Neural Networks).

The self-adjoint synaptic matrix arises naturally when one considers complex Hebbian learning rules (Hoppensteadt and Izhikevich, 1996):

$$c_{ij} = \frac{1}{n}\sum_{s=1}^{k} \xi_i^s \bar{\xi}_j^k \tag{5}$$

where each vector $\xi^s = (\xi_1^s, \ldots, \xi_n^s) \in \mathbb{C}^n$ denotes a pattern of phase relations between neurons to be memorized (see also Hebbian Synaptic Plasticity). Notice that the problem of negative (mirror) images does not arise in oscillatory neural networks, since both $\xi^k$ and $-\xi^k$ result in the same phase relations.

The key difference between the Hopfield-Grossberg network and the oscillatory network (Equation 3) is that memorized images correspond to equilibrium (point) attractors in the former and to limit cycle attractors in the latter. Pattern recognition by an oscillatory neural network involves convergence to the corresponding limit cycle attractor, which results in synchronization of the network activity with an appropriate phase relation between neurons, as in Figure 4 (see also Computing with Attractors).

## Large Amplitude Oscillations

Suppose that neurons in the weakly connected network described by Equation 1 exhibit periodic spiking (Figure 5; see also Chains of Oscillators in Motor and Sensory Systems, Collective Behavior of Coupled Oscillators, and Phase-Plane Analysis of Neural Nets). If they have nearly equal frequencies, then the network can be transformed into the phase canonical model

$$\varphi_i' = \omega_i + \sum_{j=1}^{n} H_{ij}(\varphi_j - \varphi_i) \tag{6}$$

where each $\varphi_i \in \mathbb{S}^1$ is a one-dimensional (angle) variable that describes the phase of the $i$th oscillator along the limit cycle attractor corresponding to its periodic spiking (see Figure 5), and each $H_{ij}$ is a function that depends on $f$ and $g_{ij}$ that can be explicitly computed using Malkin's theorem (Theorem 9.2 in Hoppensteadt and Izhikevich, 1997).

The phase canonical model (Equation 6) describes frequency locking, phase locking, and synchronization properties of the original system in Equation 1. Therefore, to understand these and other nonlinear phenomena that might take place in oscillating neural

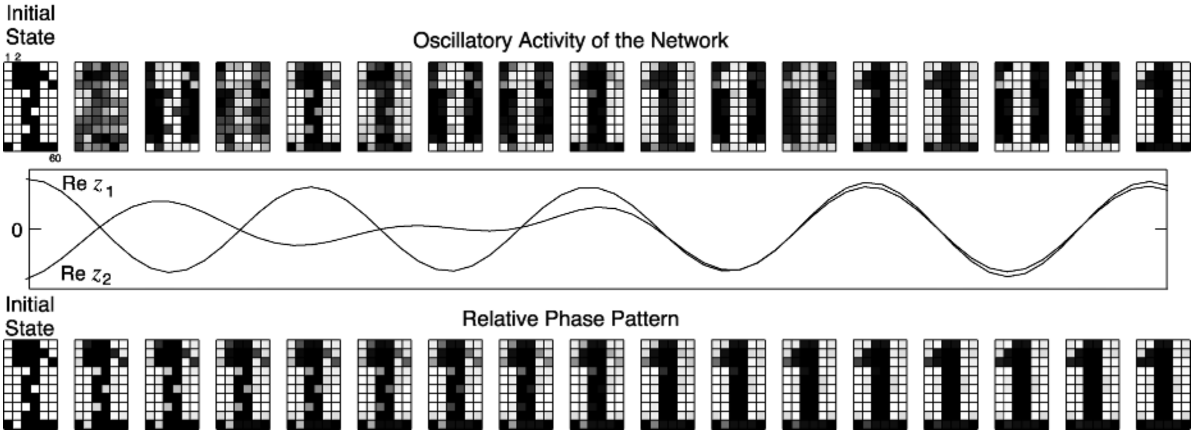

**Figure 4.** Pattern recognition via phase locking by the oscillatory canonical model (Equation 3). Complex Hebbian learning rule (5) was used to memorize patterns "1," "2," and "3." When the distorted pattern "1" is presented as an initial state, the neurons synchronize with the phase relations corresponding to the memorized pattern "1."

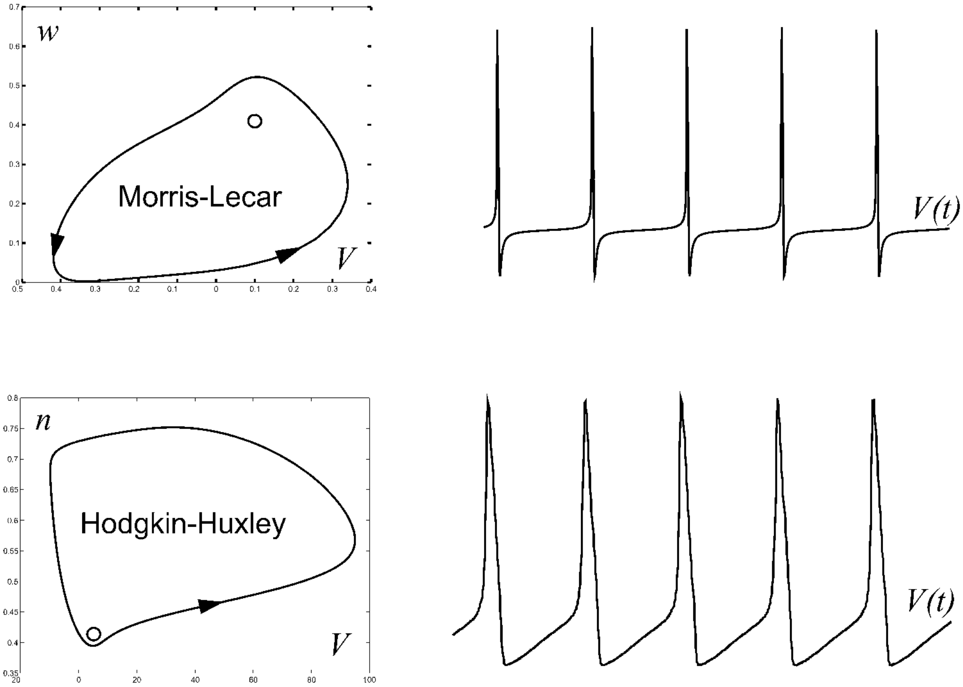

**Figure 5.** Examples of large-amplitude limit cycle attractors corresponding to periodic spiking in two biophysically detailed neural models, Morris and Lecar (1981) and Hodgkin and Huxley (1952).

networks, it usually suffices to consider the phase model. In particular, one can glimpse the universal computational abilities that are shared by all oscillatory systems, regardless of the nature of each oscillator or the particulars of the equations that describe it. Indeed, one can prove the following analogue of Theorem 2.

### *Theorem 3 (Synchronization Theorem for Oscillatory Neural Networks)*

If all oscillators in Equation 6 have equal frequencies, i.e., $\omega_1 = \ldots = \omega_n$, and the connection functions $H_{ij}$ have pairwise odd form, i.e.,

$$H_{ij}(-\psi) = -H_{ji}(\psi) \tag{7}$$

for all *i* and *j*, then the canonical phase model in Equation 6 converges to a phase-locked pattern $\varphi_i(t) \to \omega_1 t + \phi_i$ for all *i*, so the neurons oscillate with equal frequencies ($\omega_1$) and constant phase relations ($\varphi_i(t) - \varphi_j(t) = \phi_i - \phi_j$). In this sense the network dynamic is synchronized. There could be many stable synchronized patterns corresponding to many memorized images.

The proof is based on the observation that the phase canonical model in Equation 6 has the energy function

$$E(\varphi) = \tfrac{1}{2} \sum_{i,j=1}^{n} R_{ij}(\varphi_j - \varphi_i)$$

where $R_{ij}$ is the antiderivative of $H_{ij}$; that is, $R'_{ij} = H_{ij}$ (see Theorem 9.15 in Hoppensteadt and Izhikevich, 1997, and Energy Functionals for Neural Networks).

For example, Kuramoto's (1984) model

$$\varphi'_i = \omega_i + \sum_{j=1}^{n} s_{ij} \sin(\varphi_j + \psi_{ij} - \varphi_i) \tag{8}$$

has such an oscillatory associative memory when $\omega_1 = \ldots = \omega_n$:

$$s_{ij} = s_{ji} \quad \text{and} \quad \psi_{ij} = -\psi_{ji}$$

for all *i* and *j*. If we denote $c_{ij} = s_{ij} e^{i\psi_{ij}}$, then these conditions have the form shown by Equation 4. The energy function for Kuramoto's model is

$$E(\varphi) = -\tfrac{1}{2} \sum_{i,j=1}^{n} s_{ij} \cos(\varphi_j + \psi_{ij} - \varphi_i)$$

There are various estimates of the storage capacity of the network, as discussed by Vicente, Arenas, and Bonilla (1996). In particular, those authors found a time scale during which oscillatory networks can have better performance than Cohen-Grossberg-Hopfield-type attractor neural networks.

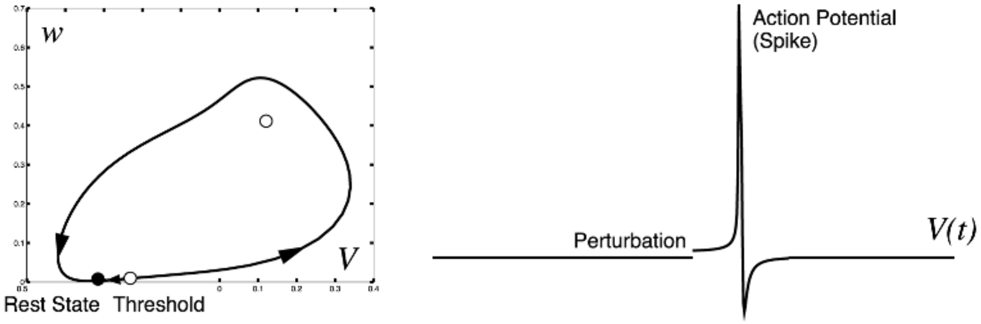
Since neither the form of the functions *f* and $g_{ij}$ nor the dimension of each oscillator in Equation 1 were specified, one could take the above result to the extreme and claim that *anything that can oscillate can also be used for computing*, as for associative pattern recognition, etc. The only problem is how to couple the oscillators so that Equation 7 is satisfied.

## Neural Excitability

An interesting intermediate case between rest and periodic spiking behavior is when a neural system is *excitable*; that is, it is at rest, but can generate a large-amplitude spike in response to a small perturbation (Figure 6) (see Phase-Plane Analysis of Neural Nets and Oscillatory and Bursting Properties of Neurons). A simple but useful criterion for classifying neural excitability was suggested by Hodgkin (1948), who stimulated cells by applying currents of various strengths. When the current is weak the cell is quiet. When the current is strong enough, the cell starts to fire repeatedly. He suggested the following classification according to the emerging frequency of firing (Figure 7):

- *Class 1 neural excitability*: Action potentials can be generated with arbitrarily low frequency. The frequency increases as the applied current is increased.
- *Class 2 neural excitability*: Action potentials are generated in a certain frequency band that is relatively insensitive to changes in the strength of the applied current.

**Figure 6.** Neural excitability in Morris and Lecar (1981) neuron having fast $Ca^{2+}$ and slow $K^{+}$ voltage-gated currents. The rest state (solid circle) is stable, but small perturbations can push the voltage beyond the threshold (open circle), thereby causing a large-amplitude excursion, or action potential. The voltage variable changes slowly near the rest states but fast during the generation of action potentials.



Their class of excitability influences neurocomputational properties of cells (see review in Izhikevich, 2000). For example, class 1 neural systems have a well-defined threshold manifold for their state variables, beyond which they generate a large-amplitude spike. They generate an all-or-none response, and they act as *integrators*, meaning that the higher the frequency of the incoming pulses, the sooner they fire. In contrast, class 2 neural systems may not have a threshold manifold. They could generate spikes of arbitrary intermediate amplitude, and they could act as *resonators*. That is, they respond to certain resonant frequencies of the incoming pulses. Increasing the incoming frequency may delay or even terminate their response.

A canonical model for class 1 excitable systems is described in the next section. The canonical model for class 2 systems has yet to be found.

### *Class 1 Excitable Systems*

Class 1 excitable systems are understood relatively well (Rinzel and Ermentrout, 1989; Ermentrout, 1996; Hoppensteadt and Izhikevich, 1997; Izhikevich, 2000). The transition from rest to periodic spiking in such systems occurs via a saddle node on invariant circle bifurcation, as shown in Figure 8 (see also DYNAMICS AND BIFURCATION IN NEURAL NETS and OSCILLATORY AND BURSTING PROPERTIES OF NEURONS). A weakly connected network of such neurons can be transformed into a canonical model, which can be approximated by

$$\vartheta_i' = 1 - \cos\vartheta_i + (1 + \cos\vartheta_i)\left(r_i + \sum_{j=1}^{n} s_{ij}\delta(\vartheta_j - \pi)\right) \quad (9)$$

where $\vartheta_i \in \mathbb{S}^1$ is the phase of the $i$th neuron along the limit cycle corresponding to the spiking solution. Again, particulars of the functions $f$ and $g_{ij}$ in Equation 1 do not affect the form of the canonical model in Equation 9, but only affect the values of the parameters $r_i$ and $s_{ij}$, which can be computed explicitly (Hoppensteadt and Izhikevich, 1997, chap. 8). Notice that the canonical model in Equation 9 is pulse coupled, whereas the original weakly coupled network in Equation 1 is not. The qualitative reason for pulse coupling is that the voltage changes are extremely slow most

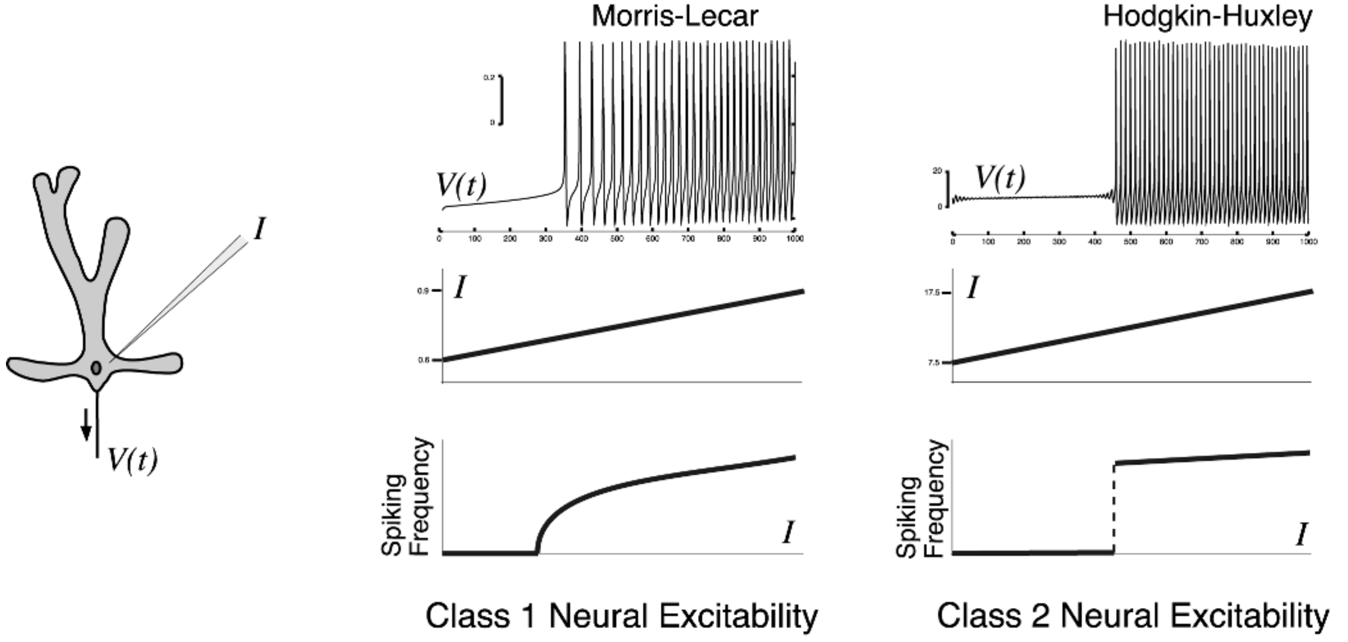


**Figure 7.** Transition from rest to repetitive spiking in two biophysical models when the strength of applied current, *I*, increases. The neural excitability is classified according to the frequency of emerging spiking.

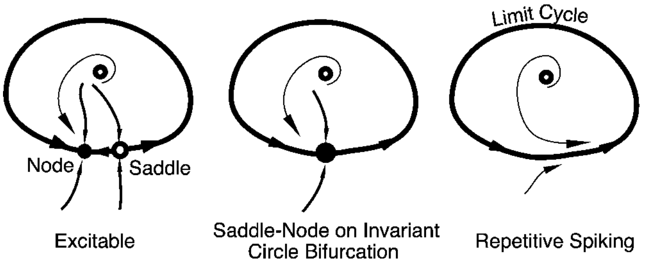

**Figure 8.** Class 1 neural excitability via saddle node on invariant circle bifurcation: The threshold state (saddle) approaches the rest state (node), they coalesce and annihilate each other leaving only limit cycle attractor. The oscillation on the attractor has two time scales: slow transition through the "ghost" of the saddle-node bifurcation and fast rotation along the rest of the limit cycle.

of the time because of the proximity to the rest state, but they are relatively instantaneous during the generation of an action potential. Hence the duration of coupling looks infinitesimal on the slow time scale.

The neuron is quiescent when $r_i < 0$ (Figure 8, left) and fires periodically when $r_i > 0$ (Figure 8, right). It fires a spike exactly when $\vartheta_i$ crosses the value $\pi$, which results in a step-like increase in the phases of other neurons. Hence, the canonical model in Equation 9 is a *pulse coupled neural network* (Izhikevich, 1999). It has many important physiological features, including absolute and relative refractory periods (Figure 9). Indeed, the effect of every incoming pulse depends on the internal state of the neuron, since it is multiplied by the function $(1 + \cos\vartheta_i)$. The effect is maximal when the neuron is near rest, since $(1 + \cos\vartheta_i) \approx 2$ when $\vartheta_i \approx 0$. It is minimal when the neuron is generating a spike, since $(1 + \cos\vartheta_i) \approx 0$ when $\vartheta_i \approx \pi$.

A canonical model for *slowly* connected class 1 excitable neurons with spike frequency adaptation has the form (Izhikevich, 2000):

$$\begin{aligned} \vartheta_i' &= 1 - \cos\vartheta_i + (1 + \cos\vartheta_i)\left(r_i + \sum_{j=1}^{n} s_{ij} w_j\right) \\ w_i' &= \delta(\vartheta_i - \pi) - \eta w_i \end{aligned}$$

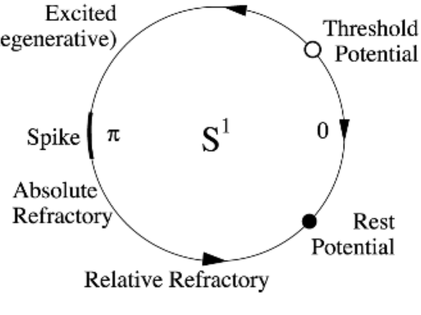

**Figure 9.** Diagram of the canonical model in Equation 9 for class 1 neural excitability. (From Hoppensteadt and Izhikevich, 1997.)

where $w_i$ describes slow synaptic processes. The term $s_{ii}w_i$ denotes not a self-synapse but a slow spike frequency adaptation ($s_{ii} < 0$) or facilitation ($s_{ii} > 0$) process.

## Discussion

The canonical model approach to computational neuroscience provides a rigorous way to derive simple yet accurate models that describe single-cell or network dynamics (see Single-Cell Models). Such a derivation is possible even when no assumptions are made regarding the detailed form of equations describing neural activity. Indeed, we specify neither *f* nor $g_{ij}$ in Equation 1. The only assumptions we make are those concerning the dynamics of each neuron—whether it is quiescent, excitable, periodic spiking, and so on. Nevertheless, any such neural system can be transformed into a canonical model by a piecewise continuous change of variables.

The derivation of canonical models can be a daunting mathematical task. However, once found, the canonical models provide invaluable information about universal neurocomputational properties shared by a large family of neural systems. For example, studying the canonical model in Equation 9 sheds light on the behavior of *all* class 1 excitable systems and their networks, regardless of the details of equations describing their dynamics.

# Cerebellum and Conditioning

*Jeffrey S. Grethe and Richard F. Thompson*

## Introduction

For many years, psychologists and neurobiologists have been searching for the substrates underlying learning and memory. Aristotle hypothesized that learning involved the association of ideas with one another. Pavlov (1927, cited in Gormezano, Kehoe, and Marshall, 1983) combined the concepts of learning and association with the production of reflexes (see CONDITIONING). Classical conditioning (CC) has been extremely useful in examining the substrates underlying learning and memory. The standard CC paradigm (Figure 1) consists of pairing a neutral stimulus, the conditioned stimulus (CS), with an aversive stimulus, the unconditioned stimulus (US). At the beginning of training, the only response to the stimuli is the unconditioned response (UR) to the US. Over repeated pairings of the stimuli, an association is formed between the CS and US, resulting in the performance of a conditioned response (a response that resembles the UR).

By varying stimulus parameters, a large number of behavioral-conditioning phenomena can be observed (Gormezano et al., 1983). Eye-blink conditioning can occur with a CS-US interstimulus interval (ISI) ranging from 100 ms to well over 1 s. The rate of learning and asymptotic response level are optimal at an ISI of about 250 ms. After 100–200 training trials at the optimal ISI, rabbits give CRs on more than 90% of trials. The CR onset initially develops near the US onset, gradually begins earlier in the trial over the course of training, and generally peaks near the US onset (Figure 1). More complex conditioning phenomena can also be observed (see CONDITIONING).

## Cerebellar Substrates of Classical Eye-Blink Conditioning

Current evidence from extensive anatomical, lesion, and physiological studies argues very strongly that the essential memory trace for the classically conditioned nictitating membrane response is formed and stored in the cerebellum (Thompson et al., 1997). This research has identified much of the network subserving classical conditioning (Figure 2). Information regarding the US is transmitted by the dorsal accessory olive to the cerebellum through the climbing fibers. Stimulation of the dorsal accessory olive, in place of a corneal airpuff, has been shown to be an effective US. If the dorsal accessory olive is lesioned before paired presentations of the CS and US, learning of the conditioned response is prevented. In addition, the interpositus provides inhibitory feedback to the inferior olive, and over the course of learning, the inhibitory feedback increases, thereby decreasing the output of the inferior olive. This evidence points to the olivary climbing fiber system as being the essential reinforcing pathway that transmits an error signal to the cerebellum. Information regarding the CS is transmitted to the cerebellum from the pontine nuclei by the mossy fibers. Stimulation of the pontine nuclei or mossy fibers has been shown to be an effective CS. The CR pathway consists of the anterior interpositus nucleus, magnocellular red nucleus, and finally the accessory abducens nucleus and the facial (seventh) nucleus. This circuit points to the cerebellum as the site of convergence where associative learning may take place. Experimental evidence supports this view, since lesions of the cerebellum, including the critical regions of the interpositus nucleus, completely abolish the conditioned response without affecting the UR.

One of the first theories to detail how associative memories could be formed in the cerebellum was proposed by Albus (1971). The most striking aspect of this model was that the parallel fiber synapses on Purkinje cells were modifiable. This theory of parallel fiber–Purkinje cell plasticity now has considerable experimental support. In addition, Albus predicted the occurrence of long-term depression at this synapse (see CEREBELLUM: NEURAL PLASTICITY). Furthermore, Albus predicted that climbing fiber spikes are the US and that mossy fiber activity patterns are the CS, predictions that are now supported by the conditioning literature. However, this theory does not account for the temporal dynamics of the CR. One of the more interesting features of classical conditioning is that of the well-timed response. Over the course of training, the timing of the response to the CS becomes more precise (i.e., the CR predicts the onset of the US). Most models of the cerebellum and its involvement in the classically conditioned eye-blink response focus on the production of this well-timed CR.

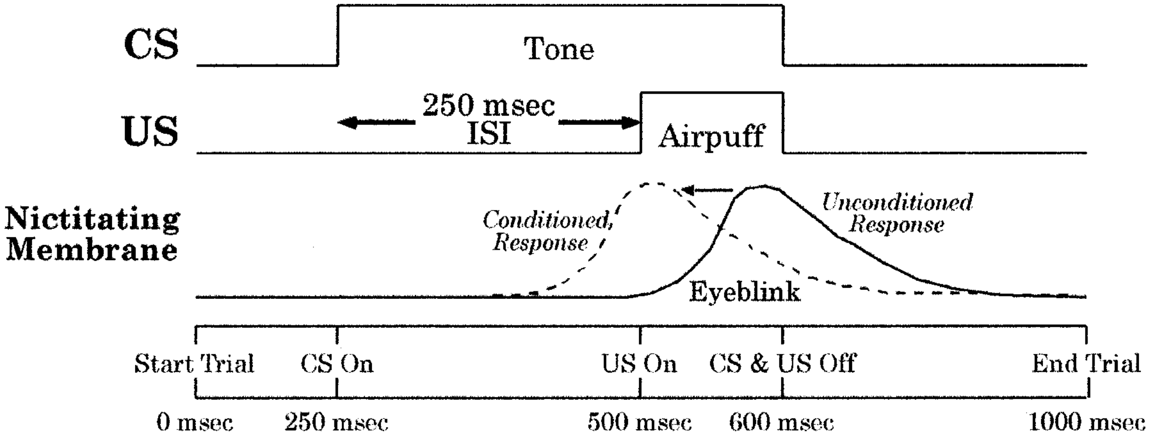

**Figure 1.** Standard delay conditioning paradigm. The CS is a 350-ms tone and the US is a 100-ms airpuff directed at the cornea. Early in training, the animal responds to the airpuff (UR). Over time, the animal learns to associate the tone with the airpuff, and produces a defensive blink that coincides with the airpuff (CR).

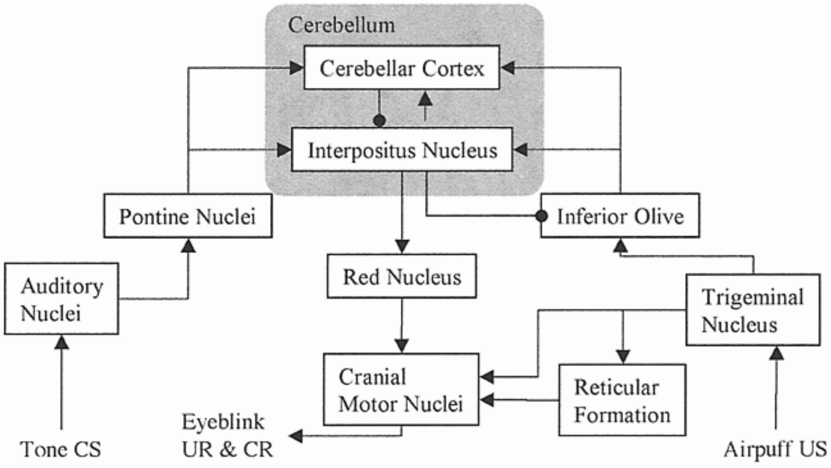

**Figure 2.** Essential circuitry for the classically conditioned nictitating membrane response.

## Modeling the Role of the Cerebellum in Classical Conditioning

One of the first theories as to how the cerebellum could control movement timing was proposed by Braitenberg (1961). He suggested that parallel fibers could act as tapped delay lines, with the conduction time of the parallel fibers yielding movement timing. However, this theory cannot account for movements with time scales on the order of hundreds of milliseconds; it can only account for delays on the order of a few milliseconds. Many current models, however, still rely on this notion.

Moore, Desmond, and Berthier (1989) constructed a model of the cerebellum based on an earlier adaptive network model. In order to temporally associate the CS and US, the CS inputs are not discrete events but rather stimulus traces that persist for some time after the CS is gone (see CONDITIONING). Learning is then allowed to occur when the CS trace and the US coincide. In the cerebellar implementation the adaptive unit is the Purkinje cell, whereas the Golgi cell learns to gate an image of the CR from the brainstem to the Purkinje cell. Purkinje and Golgi cell plasticity, combined with the model's tapped delay lines, yields anticipatory CRs for delay and trace conditioning at all ISIs. The learning rules follow the form of Rescorla and Wagner's (1972) model and thus account for the same stimulus context effect. One problem with this model is that the tapped delay lines must be on the order of hundreds of milliseconds, and no physiologically plausible mechanism has been suggested for this. Another problem is the existence of the CR image: the model does not include learning of this hypothesized image. Moore et al. have hypothesized that this image is located around the trigeminal nucleus. Learning-induced models of the CR are present in the region bordering the trigeminal; however, evidence has shown that this model is relayed to the trigeminal from the interpositus via the red nucleus. It is interesting to note that a cerebellar implementation of the Sutton and Barto tapped delay model (Moore and Choi, 1997) also requires feedback from extracerebellar structures. In order to properly determine the difference between the predicted reinforcement and actual reinforcement, the model uses an efference copy of the conditioned response from the red nucleus and spinal trigeminal nucleus.

Jaffe (1990) proposed a model that moved the tapped delay lines from the network and placed them at the level of the neuron. The model proposed that single interpositus neurons can generate the full range of delays for CRs by adjusting their input weights and exploiting the phenomenon of delayed inhibitory rebound. The most significant problem with this model is that the interpositus cell must be quiescent at CS onset and cannot fire through the delay period. However, most neurons in the interpositus are spontaneously active, and it seems unlikely that a few neurons silent during the delay could account for the production of the CR.

Fiala, Grossberg, and Bullock (1996) also developed a neuron-centered tapped delay line model of the metabotropic glutamate receptor (mGluR) second-messenger system (see CEREBELLUM: NEURAL PLASTICITY), which is responsible for the well-timed CR. Temporal correlation between the CS (parallel fiber–induced mGluR response) and US causes a phosphorylation of AMPA receptors and calcium-dependent potassium channels. Phosphorylation of the calcium-dependent potassium channels results in a reduction in Purkinje cell firing during the CS-US interval. This model is very interesting in that it explores possible biochemical mechanisms for production of the well-timed response. However, for this model to produce responses across the full range of timing, the variety in the density of mGluR receptors on dendritic spines must be highly variable, which may not be physiologically plausible.

In addition to tapped delay line models, researchers began investigating how dynamical network processes within the cerebellum could yield precise timing. Buonomano and Mauk (1994) developed a semirealistic population model of the cerebellar cortex. The CS activates a subset of mossy fibers, which in turn excites a population of granule cells. Both the mossy fibers and the granule cells excite a population of Golgi cells. The resulting Golgi inhibition of the granule cells produces a varying pattern of granule cell activity over time in which different subsets of granule cells are active at different times. Learning of the CR would occur through weakening of the parallel fiber synapses that were active around the occurrence of the US. An extension of this model (Mauk and Donegan, 1997) includes two sites of plasticity within the cerebellum, the cerebellar cortex and interpositus nucleus. More important, the model showed that long-term depression of the parallel fiber–Purkinje cell synapses, coupled with recurrent projections between the interpositus and inferior olive, produces a stable learning system. The most pressing problem with these models is extreme sensitivity to noise. If there is a substantial amount of noise in the network or if the input pattern varies during the CS, the Purkinje cell timing would be disrupted due to the changes in the granule cell activity pattern.

Bartha (1992) developed a network simulation of the cerebellum and associated circuitry that stressed the input and output representation of the cerebellum. The input representation was constrained by known properties of the mossy fibers and the output representation was modeled through detailed information on the CR pathway and oculomotor plant. The cerebellar model consists of two populations of granule cells, one responsive to the tone CS and one unresponsive. The Golgi cell's inhibitory influence on the tone-unresponsive granule cells is to produce a variety of firing patterns so that the granule cells display differing periods of depression. The Purkinje cell then selects the granule cells (through long-term depression) that display the proper time interval of depression to produce a properly timed eye-blink. With realistic single-neuron parameters, the model is able to reproduce many aspects of CR timing and form. One concern with the model lies with the Golgi cells. For the Golgi cell to be able to produce the proper spectrum of delays for short ISIs, the time constant of the Golgi cells' influence on the granule cells must fall within the 100 ms to 250 ms range, which can be considered physiological. However, to produce properly timed blinks of longer latencies, the time constant of this inhibitory effect must be considerably longer, which does not seem physiologically plausible.

Grethe (2000) developed a model that focuses on the cerebellar microcomplex as a Hebbian cell assembly (a highly interconnected group of neurons that forms a reverberatory circuit that can sustain activity). Each microcomplex contains a set of Purkinje cells and their related nuclear neurons. The cerebellar cortex receives mossy fiber input from both pontine nuclei and recurrent projections from the interpositus nucleus. This basic architecture allows the recurrent excitation in the excitatory interpositus cells to be modulated by the Purkinje cells in the cerebellar cortex. The architecture of the model tries to preserve the topographic projections between the cerebellar cortex and the deep nuclei as well as the beam-like organization of Purkinje cells receiving input from the parallel fibers. Local reverberations in the cerebellum, between the cerebellar cortex and deep nuclei, are responsible for the response topography and timing. Long-term depression at the parallel fiber–Purkinje cell synapse is responsible for the precise timing of the response. The reverberations are controlled by the anatomical connectivity, the bistability of Purkinje neurons, and the process of synaptic fatigue. One interesting aspect of the model is the effect of stimulation intensity on the response timing of the assembly. Since the timing of the model is inherently dependent on the recurrent projections, this timing process can be sped up by increasing the stimulation intensity of the CS, which has been found experimentally.

Gluck and associates (2001) developed a connectionist-level model of classical eye-blink conditioning incorporating basic features of the essential cerebellar circuitry, based on the Rescorla-Wagner model, a most successful trial-level behavioral formulation of classical conditioning. The Rescorla-Wagner model assumes that the change in association between a neutral CS and a response-evoking US is a function of the difference between the US and an animal's *expectation* of the US, given all CSs present in the trial. Because the discrepancy, or "error," between the animal's expectations and what actually occurs drives learning in this theory, the theory is referred to as an "error-correcting" learning procedure.

Thirty years after its publication, the Rescorla-Wagner model stills as the most influential and powerful model in psychology for describing and predicting animal learning behavior in conditioning studies. Moreover, its influence has extended far beyond animal conditioning. The model's basic error correction principle has been rediscovered within cognitive psychology and cognitive neuroscience in the form of connectionist network models, many of which rely on the same principle. In addition, the most commonly used connectionist learning procedure, back propagation (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION), along with its simpler predecessor, the delta rule (see CONDITIONING), both are generalizations of the Rescorla-Wagner model.

Although the Gluck et al. model does not attempt to model neuronal processes, it includes two key features of cerebellar circuitry: positive feedback via the pontine nuclei and negative feedback via inhibition of the inferior olive. This rather simple connectionist model successfully predicts a wide range of behavioral phenomena of classical conditioning, including, in particular, adaptive timing of the CR and blocking. In the model, adaptive timing depends on positive feedback; if this feedback is blocked, adaptive timing no longer occurs. The model circuitry predicts that inhibition of the inferior olive-climbing fiber input system is necessary for the behavioral phenomenon of blocking. This prediction was empirically verified by Kim, Krupa, and Thompson (1998), who showed that blocking interpositus-evoked GABA inhibition of the inferior olive during compound-stimulus training completely prevented behavioral blocking.

## Discussion

Currently, no model accounts for all the data on cerebellar neurobiology and conditioning. However, models of conditioning that take into account the neurobiology of the cerebellum can pose questions that researchers may be able to examine. For example, in order to experimentally test some of the network models presented, single-unit recordings from the granule would be necessary. These recordings are difficult because granule cells are small and closely spaced. Moreover, it would be difficult to obtain these recordings while the task is being performed. The predictions from several of the models regarding granule cells are all different:

- Buonomano and Mauk predict that a subset of granule cells will exhibit nonperiodic activity.
- Bartha predicts that the subset of granule cells will primarily show depressions in activity at all conditionable intervals after the presentation of a CS.
- Grethe predicts that activation of the granule cells in the cell assembly should occur in a wave-like fashion as the cell assembly's reverberating activity increases.

The future will bring new experiments that test these and future models, which in turn will lead to further experiments and models.

## Introduction

Fast, smooth, and coordinated movements cannot be achieved by basic feedback control alone because delays associated with feedback loops are long (about 200 ms for visual feedback and 100 ms for somatosensory feedback) and feedback gains are low. Additionally, feedback controllers such as the commonly used PID (proportional, integral, and derivative) controllers do not incorporate predictive dynamic or kinematic knowledge of controlled objects or environments. Two major feedforward control schemes have been proposed: the equilibrium point control hypothesis and the inverse dynamics model hypothesis (see Equilibrium Point Hypothesis and Motor Control, Biological and Theoretical). Some versions of the former scheme advocate that the central nervous system (CNS) can avoid inverse dynamics computation by relying on the spring-like properties of muscles and reflex loops. For this mechanism to work efficiently, the mechanical and neural feedback gains, which can be measured as mechanical stiffness in perturbation experiments, must be quite high. The low stiffness of the arm, which was measured during visually guided point-to-point multijoint movements (Gomi and Kawato, 1996), suggests the necessity of inverse dynamics models in these well-practiced and relaxed movements. The internal models in the brain must be acquired through motor learning in order to accommodate the changes that occur with the growth of controlled objects such as hands, legs, and torso, as well as the unpredictable variability of the external world.

Where in the brain are internal models of the motor apparatus likely to be stored? First, the locus should exhibit a remarkable adaptive capability, which is essential for acquisition and continuous update of internal models of the motor apparatus. A number of physiological studies have suggested important functional roles of the cerebellum in motor learning and remarkable synaptic plasticity in the cerebellar cortex (Ito, 1984, 2001). Second, the biological objects of motor control by the brain, such as the arms, speech articulators, and the torso, possess many degrees of freedom and complicated nonlinear dynamics. Correspondingly, neural internal models should receive a broad range of sensory inputs and possess a capacity high enough to approximate complex dynamics. Extensive sensory signals carried by mossy fiber inputs and an enormous number of granule cells in the cerebellar cortex seem to fulfill these prerequisites for internal models. (See Figure 1 for cerebellar circuitry and its connection to the cerebellar nucleus in the case of the lateral cerebellum.) Finally, the cerebellar symptoms usually classified as the "triad" of hypotonia, hypermetria, and intention tremor could be understood as degraded performance when control is forced to rely solely on primitive feedback control after internal models are destroyed or cannot be updated. This is because precise, fast, coordinated movements can be executed if accurate internal models of the motor apparatus can be utilized during trajectory planning, coordinate transformation, and motor control, while primitive feedback controllers with long feedback delays and small gains can attain only poor performance in these computations and usually lead to oscillatory instability for forced fast movements.

Miall et al. (1993) grouped into classes many theories regarding the role of the cerebellum (such as coordination, studied by Flourens; comparators, studied by Holmes; gain controllers; associative learning). The most complete class of theories, these authors suggested, comprises theories in which the cerebellum forms an internal model of the motor system; such theories can encompass all the alternative theories, while fitting many of the known facts of cerebellar organization. These theories require that the cerebellum be an adaptive system capable of learning and of updating a model as the behavior of the motor system changes. They also require that the cerebellum store relevant parameters of the motor system, as these parameters form part of the description of the motor system behavior. Another requirement is timing capabilities: the motor system is dynamic, so a useful model will also need dynamic (i.e., time-dependent) behavior. How might internal models be acquired in the cerebellum through motor learning?

## Marr-Albus Model and Synaptic Plasticity

Purkinje cells are the only output neurons from the cerebellar cortex. They receive two major synaptic inputs, from parallel fibers and from climbing fibers (Figure 1). Waveforms of neuronal spikes generated by the two kinds of synaptic inputs are different and can be discriminated even on extracellular recordings: simple spikes are triggered by parallel fibers and complex spikes are triggered by climbing fibers. Modularity is the basic design principle in the cerebellum. In the spinocerebellum, somototopic fractured maps have been identified for parallel fiber inputs to the cerebellar cortex. Furthermore, microzones as long as several centimeters along the longitudinal axis of the cerebellar folia and as wide as 0.2 mm have been identified for climbing fiber inputs (Ito, 1984).

Marr (1969) and Albus (1971) proposed a detailed model of the cerebellum, according to which the cerebellum can form associative memories between particular patterns on parallel fiber inputs and Purkinje cell outputs. The basic idea is that the parallel fiber–Purkinje cell synapses can be modified by input from the climbing

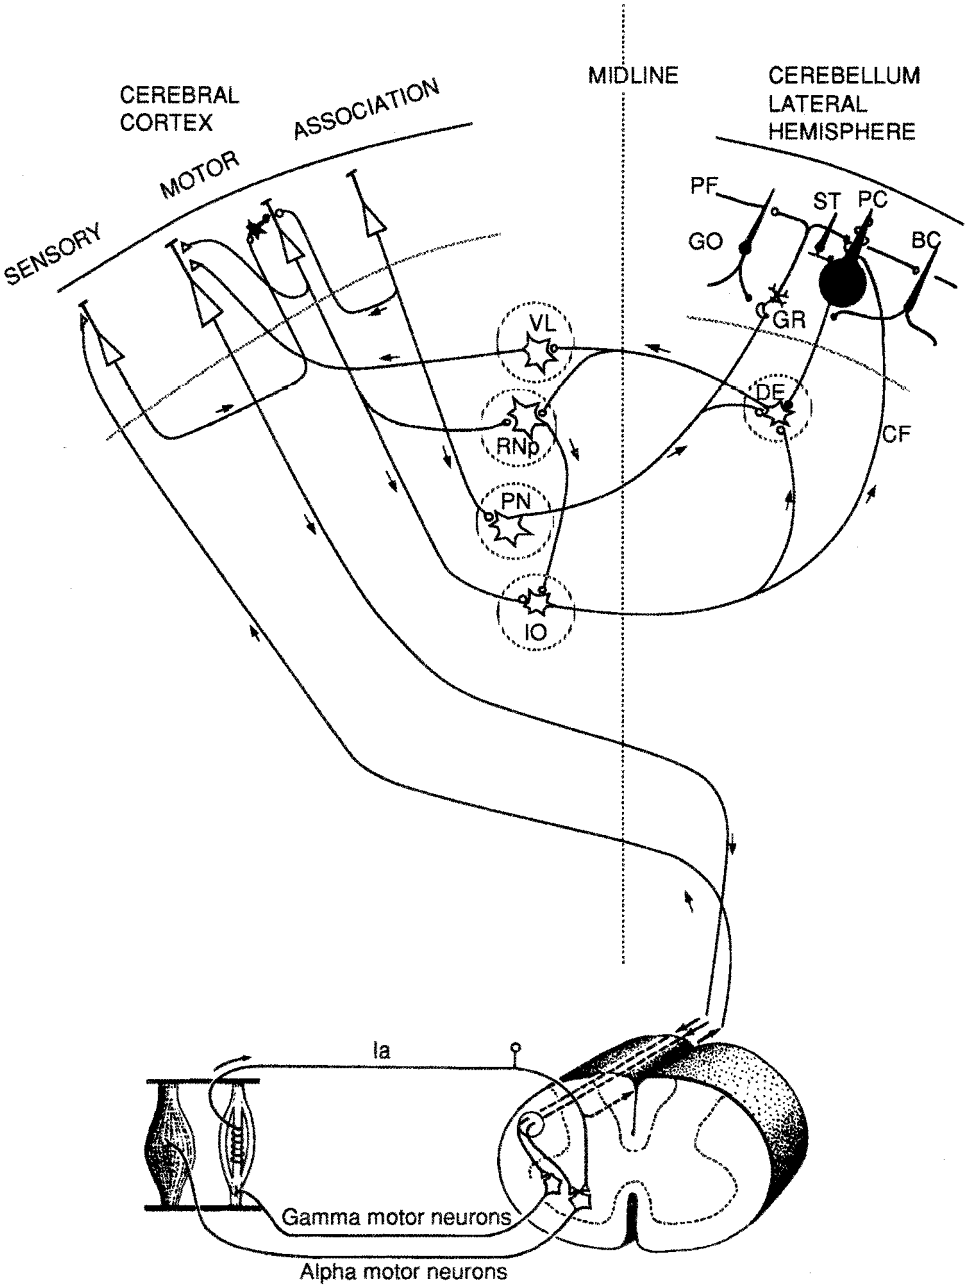

**Figure 1.** Schematic diagram of a neural circuit for voluntary movement learning control by a cerebrocerebellar communication loop (see Ito, 1984, for details). Although the lateral part of the cerebellum hemisphere is shown and the input and output of other cerebellar regions are vastly different, the neural circuit of the cerebellar cortex is rather the same and uniform. It must be emphasized that only one climbing fiber makes contact with a single Purkinje cell, whereas parallel fibers make 200,000 synapses on a single Purkinje cell. The number of granule cells, the origin of parallel fibers, is about $10^{11}$. CF, climbing fiber; BC, basket cell; GO, Golgi cell; GR, granule cell; MF, Mossy fiber; PC, Purkinje cell; PF, parallel fiber; ST, stellate cell; DE, dentate nucleus; IO, inferior olivary nucleus; PN, pontine nuclei; RNp, parvocellular red nucleus; VL, ventrolateral nucleus of the thalamus.

fibers. In the perceptron models, the efficacy of a parallel fiber–Purkinje cell synapse is assumed to change when there exists a parallel fiber and climbing fiber input conjunction. The presence of the putative heterosynaptic plasticity of Purkinje cells was demonstrated as a long-term depression (LTD) (Ito, 2001).

The original Marr-Albus model did not take into account the dynamic and temporal characteristics of sensorimotor integration and was inappropriate in proposing simple associative memories for motor control problems. More satisfactory dynamic modeling in cerebellar learning was started by Fujita (1982). An associative LTD found in Purkinje cells can be modeled as the following heterosynaptic plasticity rule (Fujita, 1982): the rate of change of the synaptic efficacy of a single parallel fiber synapse is proportional to the negative product of the firing rate of that synapse's input and the increment of the climbing fiber firing rate from its spontaneous level:

$$\tau dw_i/dt = -x_i(F - F_{\text{spont}}) \tag{1}$$

where $\tau$ is the time constant, $w_i$ is the synaptic weight of the $i$th parallel fiber–Purkinje cell synapse, $x_i$ is the firing frequency of the $i$th parallel fiber–Purkinje cell synapse, $F$ is the firing frequency of the climbing fiber input, and $F_{\text{spont}}$ is its spontaneous level. This single rule reproduces both the LTD and the long-term potentiation (LTP) found in Purkinje cells. When the climbing fiber and the parallel fiber are stimulated simultaneously, the parallel fiber synaptic efficacy decreases. In contrast, the parallel fiber synaptic efficacy increases when only the parallel fiber is stimulated (that is, when the climbing fiber firing frequency is lower than its spontaneous level). From a computational viewpoint, if the Purkinje cell output is the linear weighted summation of the parallel fiber inputs, Equation 1 can be regarded as the steepest descent of the error function defined as the square of the second factor. That is, this equation could provide a supervised learning rule if and only if the climbing fiber firing rate encodes an error signal.

Although early-day cerebellar models (Marr, 1969; Albus, 1971) were epoch-making in proposing Purkinje cell plasticity as a basis of cerebellar learning at the hardware level, they were not satisfactory at the representational and computational theory levels. What is actually learned and stored in the cerebellum? What neural representations are used in inputs and outputs of the Purkinje cells? Recent models and experimental efforts point to answers entirely different from those suggested by the early-day models.

## Models of Limb Motor Control in the Cerebellum

Boylls (1975) proposed that the spatiotemporal neural firing patterns formed by the excitatory loop due to the cerebellar reverberating circuit and the inhibitory loop via the Purkinje cells are computationally beneficial for the generation of rhythmic interlimb coordination patterns in locomotion. In Boylls's theory, the purpose of cerebellar computation is to create synergically meaningful excitation profiles on a cerebellar nucleus, whose profiles are subsequently transmitted via an "output nucleus" to spinal levels. Boylls's model was later extended by Houk and Barto (1992) to accommodate motor learning in the cerebellum as an adjustable pattern generator (APG) model of the cerebellum. Temporal patterns of movement are acquired through motor learning, based on the LTD of Purkinje cells in combination with the reverberating circuit. Artificial neural network models with recurrent connections that can learn and generate arm trajectories were the computational bases of their model. The learning scheme proposed is mathematically based on associative reward-penalty learning (see Reinforcement Learning in Motor Control). One of its attractive features is that a temporal movement pattern is selected and generated, which is impossible with a simple internal forward or inverse model. Correspondingly, however, learning is more difficult.

## Cerebellar Feedback-Error-Learning Model

Internal models can be largely classified into forward models and inverse models (see Sensorimotor Learning). Forward models predict the sensory consequences of movements from an efference copy of issued motor commands. Inverse models compute necessary feedforward motor commands from desired movement information. Both kinds of internal models are assumed to be located in the cerebellum (Kawato, 1999). However, the evidence for the forward models is much more circumstantial than is the evidence for the inverse models (see Motor Control, Biological and Theoretical). Learning forward models are generally much easier than inverse models because actual sensory feedback can be utilized as a teaching signal in the supervised learning equation (Equation 1), except for the difficulty associated with the delay in sensory feedback. Miall et al. (1993) proposed that the cerebellum forms two types of forward internal models. One model is a forward model of the motor apparatus. The second is a forward model of the transport time delays in the control loop (due to receptor and effector delays, axonal conductance, and cognitive processing delays). The second model delays the copy of prediction made by the first model so that it can be compared in temporal registration with actual sensory feedback from the movement. The second model resolves the difficulty of a temporal mismatch between the sensory signal delayed by the feedback loop and the output calculated by forward internal models.

Acquiring an inverse dynamics model through motor learning is computationally difficult because the necessary teaching signal for the desired motor command, which is the output of the inverse dynamics model, is not available. Several computational learning schemes to resolve this difficulty have been proposed (see Sensorimotor Learning). Kawato and colleagues (Kawato, 1999) proposed a cerebellar feedback-error-learning model (CBFELM; Figure 2), which turned out to be the most biologically plausible of the various proposals as a model of the cerebellum. In this model, simple spikes (SS) represent feedforward motor commands and the parallel fiber inputs represent the desired trajectory as well as the sensory feedback of the current status of the controlled object. A microzone of the cerebellar cortex constitutes (part of) an inverse model of a specific controlled object such as an eye or an arm. Most important climbing fiber inputs are assumed to carry a copy of the feedback motor commands generated by a crude feedback control circuit. Thus, the complex spikes (CS) of Purkinje cells activated by climbing fiber inputs are predicted to be sensory error signals already expressed in motor command coordinates. The supervised learning equation (Equation 1) allows an interpretation that a crude feedback controller could generate approximation to the necessary error signal in motor commands. Stability and convergence of the CBFELM have been proved mathematically in the recent control theory literature.

## Experimental Supports for the Cerebellar Feedback-Error-Learning Model

The CBFELM model was directly supported by neurophysiological studies in the ventral paraflocculus (VPFL) of monkey cerebellum

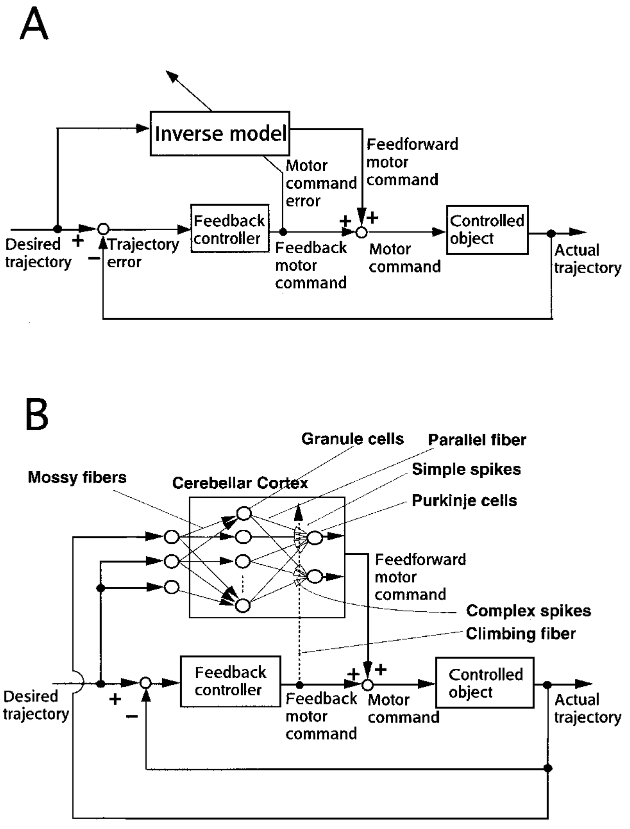

**Figure 2.** *A*, The general feedback-error-learning model. *B*, The cerebellar feedback-error-learning model (CBFELM) (Kawato, 1999). The "controlled object" is a physical entity that needs to be controlled by the CNS, such as the eyes, hands, legs, or torso.

during ocular following responses (OFRs) (Shidara et al., 1993; Kawato, 1999; Yamamoto et al., 2002). OFRs are tracking movements of the eyes evoked by movements in a visual scene and are thought to be important for the visual stabilization of gaze. The phylogenetically older, crude feedback circuit of the CBFELM is comprised of the retina, the accessory optic system (AOS), and the brainstem. The phylogenetically newer, more sophisticated feedforward pathway and the inverse dynamics model of the CBFELM correspond to the cerebral and cerebellar cortical pathway and the cerebellum, respectively.

During OFRs, the temporal waveforms of SS firing frequency of VPFL Purkinje cells show complicated patterns. However, they (Figure 3, thin curve) were quite accurately reconstructed by using an inverse dynamics representation of the eye movement (Figure 3, thick curve; Shidara et al., 1993). The model fit was good for the majority of the neurons studied under a wide range of visual stimulus conditions. The same inverse dynamics analysis of firing frequency was applied to neurons in the area MST and dorsolateral pontine nucleus (DLPN), which provide visual mossy fiber inputs to the VPFL. In this area neural firing patterns were not well reconstructed. Taken together, these data suggest that the VPFL is the major site of the inverse dynamics model of the eye for OFRs.

The CBFELM model assumes that motor commands, which are conveyed by SS, are directly modified and acquired through synaptic plasticity by motor command errors, which are conveyed by climbing fiber inputs. For this to work, the motor commands and climbing fiber inputs must have comparable temporal and spatial characteristics, but the ultra-low discharge rates of the latter (1–2 spikes/s) would appear to rule this out. This apparently discrete and intermittent nature of climbing fiber inputs once suggested a reinforcement learning type of theory of cerebellar learning. However, if thousands of trials were averaged to compute firing frequencies of the climbing fiber inputs, the firing rates actually conveyed very accurate and reliable temporal waveforms of motor command error (Figure 3*C*b). Because the LTD is a rather slow process of several tens of minutes of time constants, the averaging over many trials can actually be conducted by the LTD dynamics itself. Consequently, the firing probability of climbing fiber inputs aligned with the stimulus motion onset had high-frequency temporal dynamics matching those of the dynamic command signals. Thus, the most critical assumption of the CBFELM model was satisfied.

The preferred directions of MST and DLPN neurons were evenly distributed over 360 degrees. Thus, the visual coordinates for OFRs are uniformly distributed over all possible directions. On the other hand, the spatial coordinates of the extraocular muscles lie in either the horizontal or vertical directions, and are entirely different from the visual coordinates. The preferred directions of Purkinje cell SS were either downward or ipsilateral, and at the site of each recording, electrical stimulation of a Purkinje cell elicited eye movement toward the preferred direction of the SS of that Purkinje cell. This observation indicates that the SS coordinate framework is already that of the motor commands. Thus, at the parallel fiber–Purkinje cell synapse, a drastic visuomotor coordinate transformation occurs. Hence, the neural representation dramatically changes from population coding in MST and DLPN to firing rate coding of Purkinje cells at the parallel fiber–Purkinje cell synapse. What is the origin of this drastic transformation? According to the CBFELM model, the CS and eventually the AOS are the source of this motor command spatial framework. The preferred directions of pretectum neurons are upward, and those of nucleus of optic tract neurons are contralateral, and they are propagated to the inferior olive neurons and the CS of Purkinje cells. Yamamoto et al. (2002) reproduced all these experimental findings of Purkinje cell firing characteristics during OFRs based on CBFELM, thus providing quite strong evidence for the theory.

Although direct and rigorous support of the CBFELM model was limited to a small portion of the cerebellum and to only several types of eye movements (OFR, VOR, OKR, smooth pursuit), because the neural circuit of different parts of the cerebellum is uniform and LTD is ubiquitous, we believe that the computational principle and the neural architecture demonstrated are common to all parts of the cerebellum. Recent physiological and brain imaging experiments provided further support of the CBFELM model in visually guided arm reaching movements (Kitazawa, Kimura, and Yin, 1998) and in the learning of a new tool (Imamizu et al., 2000).

## Discussion

Humans can manipulate a vast number of tools, and exhibit an almost infinite number of behaviors in different environments. Given this multitude of contexts for sensorimotor control, there are two qualitatively distinct strategies to motor control and learning. The first is to use a single controller that uses all the contextual information in an attempt to produce an appropriate control signal. However, such a controller would have to be enormously complex to allow for all possible scenarios. If this controller were unable to encapsulate all the contexts, it would need to adapt every time the context of the movement changed before it could produce appropriate motor commands. This would produce transient but possibly large performance errors. Alternatively, a modular approach could be used in which multiple controllers coexist, with each controller suitable for one or a small set of contexts. Depending on the current context, only those appropriate controllers should be active to generate the motor command.

The modular approach has several computational advantages over the nonmodular approach. First, by using multiple inverse models, each of which might capture the motor commands necessary when interacting with a particular object or within a particular environment, we could achieve an efficient coding of the world. In other words, the large set of environmental conditions in which we are required to generate movement requires multiple behaviors or sets of motor commands, each embodied within a module. Second, the use of a modular system allows individual modules to adapt through motor learning, without affecting the motor behaviors already learned by other modules. Third, many situations that we encounter are derived from combinations of previously experienced contexts, such as novel conjoints of manipulated objects and environments. By modulating the contribution to the final motor command of the outputs of the inverse modules, an enormous repertoire of behaviors can be generated. With as few as 32 inverse models, in which the output of each model either contributes or does not contribute to the final motor command, we have $2^{10}$ behaviors—sufficient for a new behavior for every second of one's life. Therefore, multiple internal models can be regarded conceptually as *motor primitives*, which are the building blocks used to construct intricate motor behaviors with enormous vocabulary (see MOTOR PRIMITIVES).

Based on the benefits of a modular approach and the experimental evidence for modularity in observed behaviors, Wolpert and Kawato (1988) have proposed that the problem of motor learning and control is best solved using multiple controllers—that is, inverse models. At any given time, one or a subset of these inverse models will contribute to the final motor command (Figure 4 gives the details of the model). However, if there are multiple controllers, then there must also be some scheme to select the appropriate controller or controllers at each moment in time. The basic idea is that multiple inverse models exist to

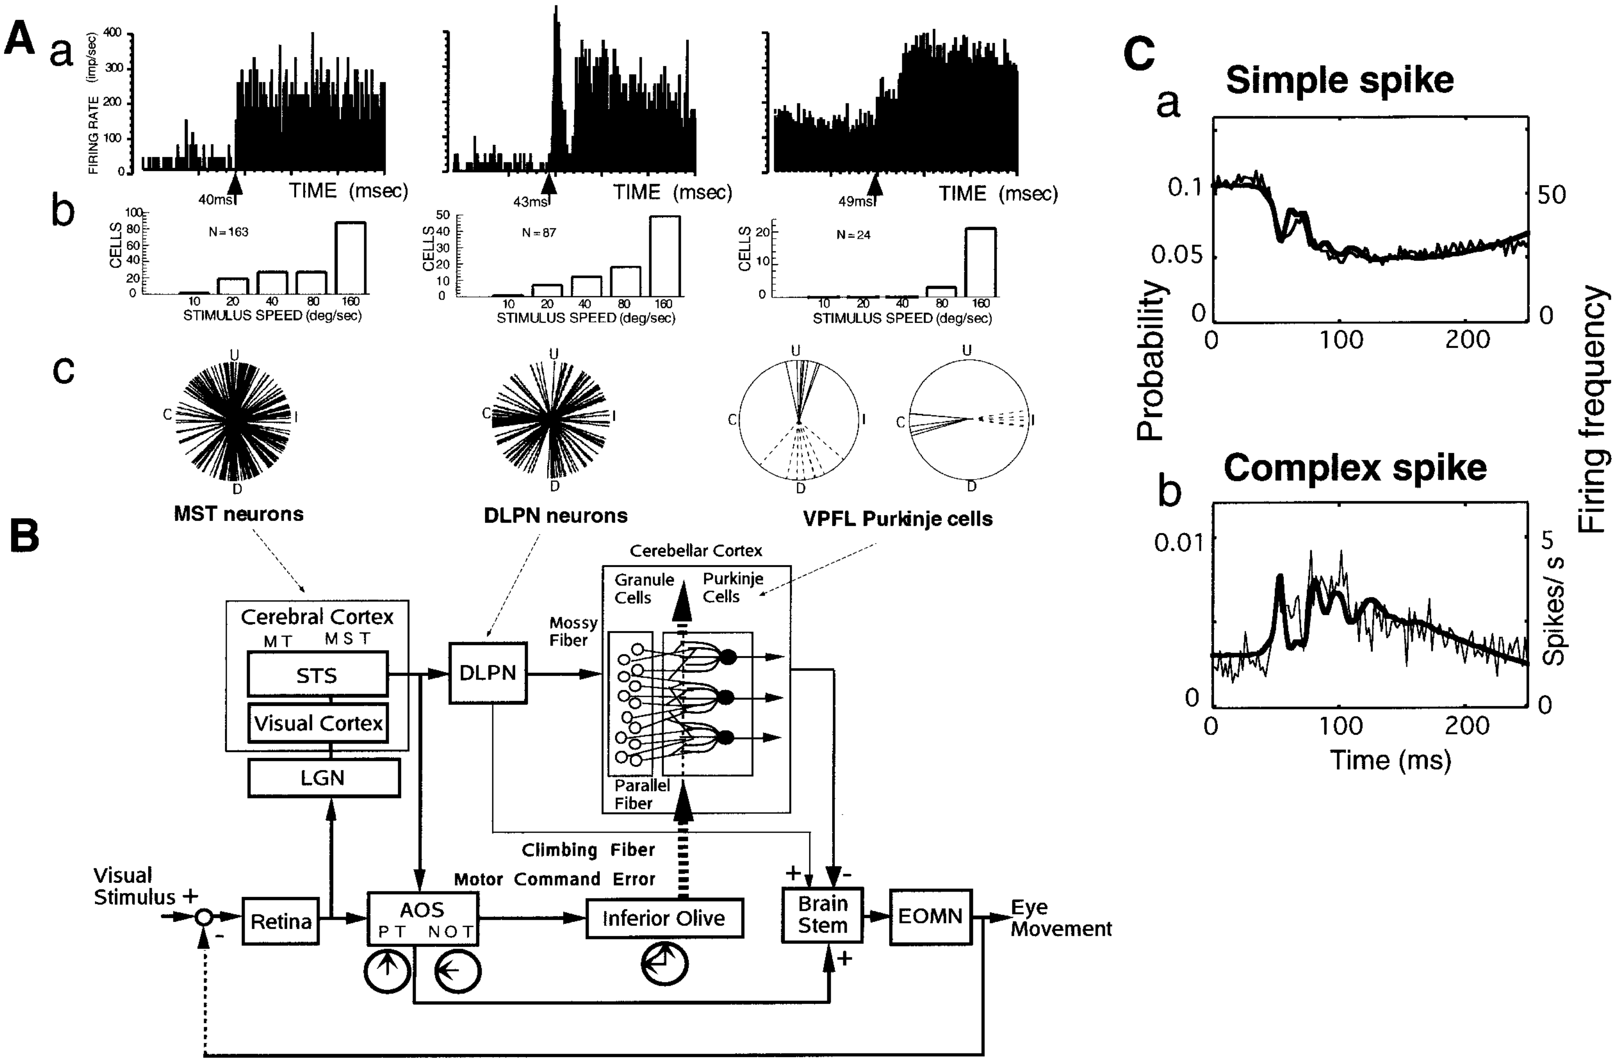

**Figure 3.** Change of neural codes and learning of inverse dynamics model in the cerebellum for ocular following responses (OFRs) (see Yamamoto et al., 2002, for a model reproduction of this experimental data). *A*, The firing characteristics of MST, DLPN, and VPFL neurons. *B*, A schematic neural circuit for OFR. *C*, The temporal firing patterns of VPFL Purkinje cells in upward eye movements induced by upward visual motion. In *A*, the left, middle, and right columns are for MST, DLPN, and VPFL neurons. In *a*, post-stimulus-time histograms of the firing rates of a typical neuron in each of the three areas are shown. The origin of time is the onset of visual stimulus motion. In *b*, histograms of a number of cells within a given range of the optimum stimulus speeds are shown. In *c*, polar plots of optimum stimulus directions are shown. U, C, D, and I indicate upward, contralateral, downward, and ipsilateral, respectively. VPFL Purkinje cells were classified into two groups, vertical cells and horizontal cells, based on simple spike (dotted line) and complex spike (solid line) optimum directions. *B*, The circuit can be divided into two main pathways. The upper part shows the corticocortical (the cerebral cortex to the cerebellar cortex) pathway, which corresponds to the feedforward arc of the feedback-error-learning model. The lower part shows the phylogenetically older feedback pathway containing the accessory optic system, which corresponds to a crude feedback controller in the feedback-error-learning scheme. *C*, Temporal firing patterns of nine Purkinje cells accumulated (thin curves) and their reconstruction based on an inverse-dynamics model (bold curves). The model predicts that the temporal firing patterns of simple spikes (*a*) and complex spikes (*b*) should be mirror images of each other, and this was confirmed experimentally. MST, medial superior temporal area; DLPN, dorsolateral pontine nucleus; VPFL, ventral paraflocculus; AOS, accessory optic system; PT, pretectum; NOT, nucleus of optic tract; MT, middle temporal area; STS, superior temporal sulcus; LGN, lateral geniculate nucleus; EOMN, extraocular motor neurons.

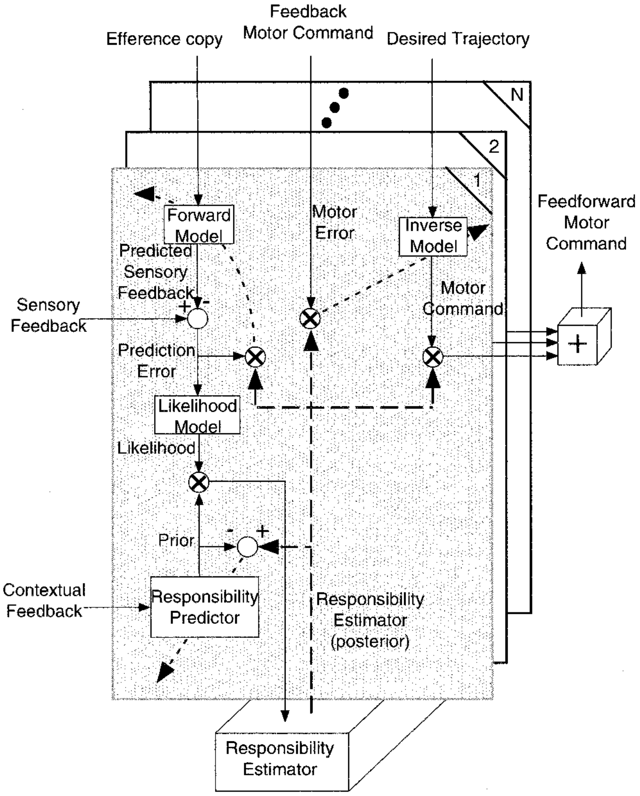

**Figure 4.** A schematic of the MOSAIC model (Wolpert and Kawato, 1998). *N*-paired modules are shown as stacked sheets (the dotted lines represent training signals and three-signal multiplication). The details of the first module are shown. Interactions between modules take place through the responsibility estimator. Each module consists of three interacting parts. The first two, the forward model and the responsibility predictor, are used to determine the responsibility of the module. This responsibility signal reflects the degree to which the module captures the current context and should, therefore, participate in control.

control the system, and each is augmented with a forward model that determines the responsibility each controller should assume during movement. This responsibility signal reflects, at any given time, the degree to which each pair of forward and inverse models should be responsible for controlling the current behavior. Within each module, the inverse and forward internal models are tightly coupled during their acquisition, through motor learning. This ensures that the forward models learn to divide up experience so that at least one forward model can predict the consequence of actions performed in any given context. By coupling the learning of the forward and inverse models, the inverse models learn to provide appropriate control commands in contexts in which their paired forward model produces accurate predictions. The model was once called the multiple paired forward and inverse models, but it was later renamed MOSAIC (MOdular Selection And Identification Control). MOSAIC is a version of the mixture-of-experts architecture (see Modular and Hierarchical Learning Systems).

Recent human brain imaging studies have started to accumulate evidence supporting multiple internal models of tools in the cerebellum (Imamizu et al., 2000, and successive studies). Other imaging studies suggest forward models in the cerebellum as well as inverse models. Each modular internal model in MOSAIC could have good anatomical correspondence with microzones. MOSAIC is capable of learning to produce appropriate motor commands in a variety of contexts and can switch rapidly between controllers as the context changes. These features are important for a full model of motor control and motor learning, as it is clear that the human motor system is capable of very flexible, modular adaptation. Furthermore, MOSAIC has the potential to explain many human cognitive capabilities such as thinking, communication, and language. This point is intriguing, since the cerebellum was shown to be involved in these uniquely human cognitive activities.

# Cerebellum: Neural Plasticity

*Hervž Daniel and Francis Crepel*

## Introduction

The participation of the cerebellum in motor learning was postulated by Brindley as early as 1964 and then formalized by Marr and Albus (see Cerebellum and Motor Control for details) around 1970. Purkinje cells (PCs) are the only output neurons of the cerebellar cortex. Each PC receives two excitatory synaptic inputs displaying distinct characteristics. The first and most powerful one-to-one synaptic input corresponds to climbing fibers (CFs) that originate from neurons in the contralateral inferior olive and make multiple synapses on primary and secondary dendrites of PCs. The second, weaker excitatory input corresponds to parallel fibers (PFs) that originate from cerebellar granule cells; 80,000 PFs converge onto tertiary dendrites of each PC, where each PF makes few synapses. PFs and CFs are likely to use the excitatory amino acid glutamate (Glu) as a neurotransmitter.

Given the dual arrangement of these excitatory synaptic inputs and taking into account current models of memory, it has been proposed that during motor learning, the gain of synaptic transmission at PF-PC synapses changes if and only if these synapses are repetitively activated at low rates in conjunction with CF impinging on the same PC. In this scheme, the CF acts as an external teacher to instruct PF-PC synapses to change their gain to adapt the cerebellar cortex output to the motor command (see Cerebellum and Motor Control). Thus, Marr's theory of motor learning predicts that repeated coincident activation of CFs and PFs leads to a long-term potentiation (LTP) of the PF synaptic inputs. However, Albus proposed instead that a long-term depression (LTD) occurs rather than LTP at PF-PC synapses during motor learning, to avoid saturation of neuronal networks.

The first experimental support in favor of this theory was provided by Ito and co-workers in a series of in vivo experiments on rabbits (Ito, Sakurai, and Tongroach, 1982). They demonstrated that LTD is associative, since only concomitant stimulation of PFs at low frequency (1–4 Hz) and of the CF impinging on the same PC leads to LTD of synaptic transmission at PF-PC synapses. In contrast, activation either of the CF or of PFs alone has no long-term effect. In addition, this long-term change in synaptic strength is restricted to PF-PC synapses activated in conjunction with CFs and is thus considered to be input specific. This is a crucial point for deciphering the mechanisms involved in motor learning (Ito et al., 1982). With the experimental advantages of in vitro brain slices and culture preparations, more recent studies have elucidated, at least in part, the complex processes of glutamate receptor activation and subsequent second-messenger cascades controlling the induction and the expression of this form of synaptic plasticity. The present article presents a detailed review of the findings of many experimentalists. Since space does not allow a comprehensive bibliography, the reader is referred to Daniel, Levenes, and Crepel (1998) and Daniel et al. (1999) for a full bibliography and citation of these many researchers.

## Glutamatergic Receptors Involved in LTD Induction

We first examine the components in Figure 1. In marked contrast to most other neurons in the brain, PCs in the mature brain do not bear functional *N*-methyl-D-aspartate (NMDA) ionotropic receptors (see NMDA Receptors: Synaptic, Cellular, and Network Models). As such, fast excitatory synaptic transmission at PF-PC synapses is entirely mediated by non-NMDA ionotropic receptors, mostly of the AMPA type. These synapses also possess type-1$\alpha$ metabotropic glutamatergic receptors (mGluR1) coupled to phospholipase C, the activation of which leads to the production of inositol 1,4,5-triphosphate ($IP_3$) and of diacylglycerol (DAG, a protein kinase C (PKC) activator). There is now wide agreement that LTD induction of PF-mediated synaptic responses in PCs in acute slices and of Glu-induced currents in cultured PCs requires the activation of these two receptor groups. In cultured PCs, evidence for AMPA receptor participation in LTD has been provided by Linden and co-workers (1991). They have shown that iontophoretic application of quisqualate (an agonist of both mGluRs and AMPA receptors) induces LTD of quisqualate-mediated excitatory currents when combined with PC depolarization sufficient to produce $Ca^{2+}$ entry through voltage-gated $Ca^{2+}$ channels (VGCCs). This LTD is blocked by bath application of CNQX (a selective antagonist of AMPA receptors) during the pairing protocol (Linden et al., 1991). Likewise, using acute slices, other workers demonstrated that application of CNQX during a classical pairing protocol (PC depolarization/PF stimulation) prevents induction of LTD of PF-EPSCs but not its expression.

Concerning mGluRs, it was shown that application of mGluR1-inactivating antibodies or of the mGluR antagonist MCPG completely blocks LTD induction, while LTD induced by a classical pairing protocol is significantly impaired in knockout (KO) mice lacking functional mGluR1s. Moreover, LTD in mGluR1-null mutant mice can be rescued either by bypassing the disrupted m-GluR1s with direct pharmacological activation of downstream intracellular cascades (activation of IP3 signal transduction pathway by photolytic release of IP3) (Daniel et al., 1999) or by transfecting

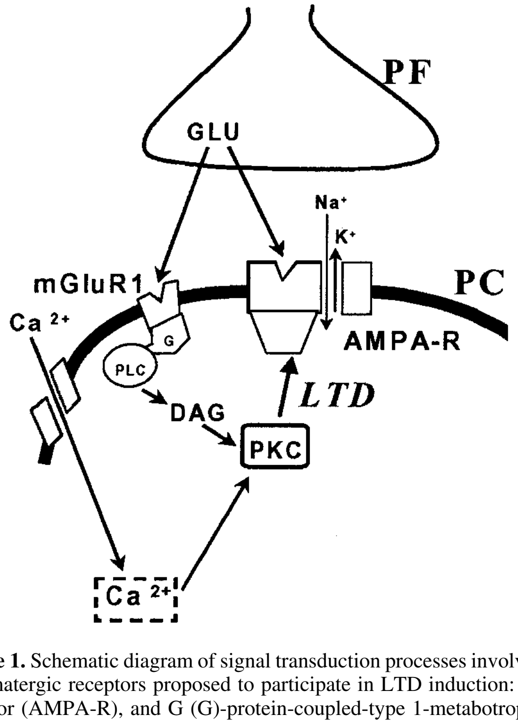

**Figure 1.** Schematic diagram of signal transduction processes involving the glutamatergic receptors proposed to participate in LTD induction: AMPA receptor (AMPA-R), and G (G)-protein-coupled-type 1-metabotropic glutamate receptor (mGluR1), which is positively coupled to phospholipase C (PLC) and can therefore lead to the production of 1,2-diacylglycerol (DAG), a protein kinase C (PKC) activator. Other abbreviations: GLU: Glutamate, PC: Purkinje cell, PF: parallel fiber.

functional mGluR1s in these KO mice under the control of the PC-specific L7 promoter (Ichise et al., 2000). Thus, these studies demonstrate the key role of mGluR1 in PCs for LTD induction, as they rule out the possibility that impairment of LTD in mGluR1 KO mice is due to some indirect developmental defects.

## Involvement of Increases in Intracellular $Ca^{2+}$ in LTD Induction

The crucial role of increases in $Ca^{2+}$ resulting from VGCC activation for LTD induction was initially demonstrated in acute slices maintained in vitro with induction of LTD of PF-mediated synaptic responses by concomitant stimulation of PFs and CF impinging on the same PC prevented when PC intracellular free $Ca^{2+}$ is buffered by 1,2-*bis*(2-aminophenoxy)ethane-N,N,N,N′-tetra-acetic acid (EGTA). The involvement of $Ca^{2+}$ increases following VGCC activation in LTD induction was also evidenced in this same preparation, where LTD of PF-mediated responses was consistently induced by pairing these synaptic responses with direct depolarization of PCs sufficient to produce $Ca^{2+}$ entry through VGCCs, thus mimicking activation of CFs. Likewise, as shown by Crepel and Krupa (1988) in acute slices and by Linden et al. (1991) in cultured PCs, LTD of responses elicited in PCs by iontophoretic application of Glu in their dendritic fields is also induced when these responses are combined with membrane depolarization, giving rise to $Ca^{2+}$ spike firing. Finally, in patch-clamped PCs in acute slices, combining recordings of synaptic currents with fluorometric measurements of intracellular $Ca^{2+}$ concentration directly demonstrates that PF stimulation paired with depolarization-induced $Ca^{2+}$ transients is sufficient to induce LTD (see Figure 2).

In addition to $Ca^{2+}$ entry through VGCCs, it was hypothesized that the cascade of events leading to LTD in PCs may involve $Ca^{2+}$ release from IP3- or ryanodine-sensitive internal stores (Daniel et al., 1998). However, in acute slices, the extent to which this process is involved seems to depend crucially on experimental conditions. Two groups have shown that both inhibition of $Ca^{2+}$ release from IP3-sensitive stores with heparin (an antagonist of IP3 receptors) or with a specific antibody against IP3-receptor type 1 block LTD induced by a classical pairing protocol. Likewise, slices prepared from mice with a disrupted IP3-receptor type 1 gene, which is predominantly expressed in PCs, lack LTD induced by the same pairing protocol. Finally, and as mentioned before, the impairment of LTD induced by a classical pairing protocol in mGluR1-deficient PCs is pharmacologically rescued by photolysis of a caged IP3-compound. Along the same line, LTD can be rescued in transgenic mice with defective IP3-mediated $Ca^{2+}$ signaling in spines, by local photolysis of a caged $Ca^{2+}$ compound. Taken together, these data seem to establish that $Ca^{2+}$ release from internal stores are critical for LTD induction in slices, at least in certain experimental conditions, but they do not reveal the precise mechanisms of their involvement in more physiological conditions. Indeed, synaptically driven $Ca^{2+}$ mobilization from internal stores by PF stimulation has been now detected in PC spines and dendritic microdomains with confocal microscopy as well as with the use of two-photons laser scanning microscopy.

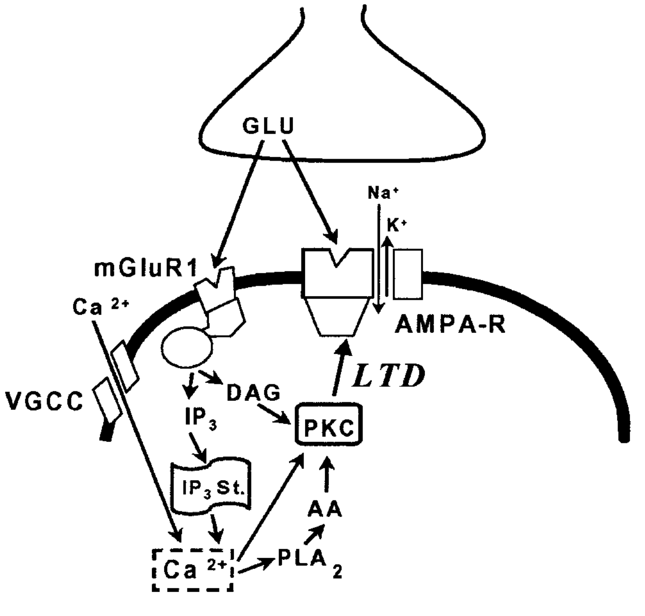

**Figure 2.** Schematic diagram of signal transduction processes proposed to participate in LTD induction involving increase in intracellular calcium, resulting from voltage-gated calcium channel (VGCC) activation and/or from calcium release from Inositol-1,4,5-trisphosphate (IP3)-internal stores (IP3 St), and involving the full PKC activation which requires in addition to the intracellular cascade leading to DAG production, the activation of the calcium-dependent enzyme phospholipase $A_2$ ($PLA_2$) leading to arachidonic acid (AA) production. Other abbreviations as in Figure 1.

The problem of the participation of $Ca^{2+}$ release from internal stores in LTD induction has been recently elucidated in an elegant series of experiments using two-photon laser scanning microscopy. In particular, it has been shown that with conjunctive activation of CF and of small number of PFs, both $Ca^{2+}$ signals and LTD are confined to the activated synapses and require $Ca^{2+}$ release from IP3-sensitive stores. In contrast, with co-activation of CF and of a large number of PFs, $Ca^{2+}$ signals spread to dendritic shafts, and LTD induced in these conditions is now entirely mediated by VGCC-dependent $Ca^{2+}$ entry. These results may reconcile previous conflicting findings regarding the involvement of $Ca^{2+}$ release from internal stores in LTD induction in acute slices. Indeed, depletion of internal $Ca^{2+}$ stores with thapsigargin blocks induction of LTD of PF-EPSPs induced by PC depolarization/bath application of mGluR agonist (1S-3R ACPD) without PF stimulation but does not prevent the induction of LTD by a classical pairing protocol (PC depolarization/PF stimulation).

In cultured PCs, the results are also puzzling, since certain studies have reported that inhibition of $Ca^{2+}$ release from ryanodine or IP3-sensitive internal $Ca^{2+}$ stores blocks LTD induced by Glu/depolarization conjunctive stimulation. In contrast, others have shown that LTD induction appears to be independent from $Ca^{2+}$ release from IP3-sensitive stores. Thus, the potential involvement of $Ca^{2+}$ release from internal stores in LTD induction in these reduced preparations is unclear, especially in the light of a recent study demonstrating that $Ca^{2+}$ release from internal stores in PCs maintained in culture is impaired (Womack, Walker, and Khodakhah, 2000).

## Second Messengers and LTD Induction: Cascades Involving PKC Activation and Nitric Oxide (NO)-cGMP-Dependent Protein Kinase (PKG) Activation

### *PKC Pathway*

We now examine other aspects of the pathway shown in Figure 2. It is now well accepted that the second-messenger cascades following rises in internal $Ca^{2+}$ involve PKC activation. Since PKC$\gamma$ is abundantly expressed in PCs (Daniel et al., 1998) and mGluR1 activation also results in DAG production (see above), it was tempting to postulate that the cascade of events leading to LTD involves the activation of PKC by $Ca^{2+}$ entry through VGCCs and DAG produced by mGluR activation following Glu release from PFs (Crepel and Krupa, 1988). Indeed, studies by Crepel and Krupa

(1988) in acute slices and later studies in cultures showed that direct activation of PKC by phorbol esters induces LTD of the responsiveness of PCs to exogenously applied Glu or quisqualate, whereas inactive analogs are without effect. Moreover, studies in acute cerebellar slices have shown that the potent protein kinase inhibitor polymixin B or the selective PKC inhibitory peptide PKC[19-36] abolishes LTD induction by conventional pairing protocols (PC depolarization/PF stimulation). Likewise, PKC[19-36] also blocks LTD induction by Glu/depolarization conjunction in cultured PCs. Moreover, in this reduced preparation, full activation of PKC is required to induce LTD and involves activation of the calcium-dependent enzyme phospholipase $A_2(PLA_2)$ leading to arachidonic acid (AA) production, in addition to the intracellular cascade leading to DAG production. Such an involvement of $PLA_2$ in LTD induction was also evidenced more recently in acute slices by Reynolds and Hartell (2001). Finally, the crucial role of PKC activation in the cellular mechanisms leading to LTD induction was recently supported by the introduction of an additional player in the game, that is, the corticotropin-releasing factor that is contained in CFs and is critical for LTD induction in cerebellar slices, probably acting by enhancing activation of PKC.

However, and surprisingly enough, mice with null mutation in protein kinase C$\gamma$ exhibit apparently normal cerebellar LTD and this LTD is still abolished by specific PKC inhibitors. These puzzling results suggest that compensatory processes involving other subtypes of PKC are activated in these mutants to sustain LTD or, as was recently proposed, PKC$\alpha$ and/or PKC$\beta_1$ but not PKC$\gamma$ are involved in LTD induction (Hirono et al., 2001). More straightforward results were obtained by using transgenic mice selectively expressing the pseudosubstrate PKC inhibitor, PKC[19-31] in PC, since no LTD could be produced in these cells either in cultures or (Goossens et al., 2001) in acute slices. Thus, altogether, there is now a wide agreement that induction of cerebellar LTD requires PKC activation in in vitro brain slices and in culture preparations.

### *NO-cGMP-PKG Pathway*

Further mechanisms are summarized in Figure 3. Inhibition of postsynaptic protein phosphatase activity through a cascade involving nitric oxide (NO), cGMP production, and cGMP-dependent protein kinase (PKG) activation is also required for LTD induction. In neurons, increases in intracellular $Ca^{2+}$ can induce the formation of NO from arginine, by activating calmodulin-dependent NO-synthase (NO-S). As early as 1990, it was shown, in acute slices, that LTD of PF-mediated EPSPs induced by a conventional pairing protocol is prevented by bath application of NO-S inhibitors and furthermore that this blocking effect is reversed by addition of an excess of arginine in the bath. In the same year, it was shown that, again in acute slices, bath application of NO-S inhibitor prevents enduring desensitization of AMPA receptors of PCs resulting from successive exposures of slices to quisqualate. Moreover, it was shown later on that an LTD-like phenomenon can be induced by bath application of NO donors or by dialyzing such NO donors in the recorded cell through the recording patch pipette. However, neuronal nitric oxide synthase (nNO-S) has not been identified in PCs, even following RT-PCR analysis of mRNAs directly harvested from these neurons during patch-clamp experiments. In contrast, nNO-S is highly expressed in neighboring elements such as PFs and basket cells. Further studies, with NO-sensitive electrodes inserted into the molecular layer of cerebellar slices, have shown that protocols that are known to induce LTD lead to NO release, most probably originating from PFs. Finally, it has been shown that photolytic release of NO and $Ca^{2+}$ inside PCs could replace the conjunctive PF stimulation and depolarization, respectively, required for LTD induction, suggesting that NO release is sufficient to replace PF stimulation. If this finding underlines the potential role of NO in LTD induction, it is somewhat puzzling, as it contradicts previous experiments demonstrating that activation of AMPA receptors and of mGluRs are necessary for LTD induction (see the previous section). This apparent discrepancy could be due to the use of the photolytic release of NO, which is a powerful pharmacological tool but may exaggerate the participation of this NO pathway in LTD induction, which otherwise might be much less prominent in physiological conditions. Nevertheless, taken together, data obtained in acute slices are entirely consistent with a role for NO in LTD induction in PCs.

The target for NO is likely to be the soluble enzyme guanylate cyclase (sGC), which is abundantly expressed in PCs. Indeed, it is now indirectly established (by measurements of cGMP-dependent activation of phosphodiesterases) that NO, either pharmacologically applied or endogenously released following electrical stimulation of the molecular layer, triggers cGMP production in Purkinje cells (Hartell et al., 2001). Numerous studies have examined the potential role of cGMP on LTD induction. A long-lasting depression of PF-mediated responses is induced by direct dialysis of cGMP into the recorded PCs through the recording patch-pipette or by bath application of 8-bromo-cGMP (a membrane-permeative cGMP analog). In addition, this cGMP-induced LTD-like phenomenon partially occludes subsequent induction of LTD by classical pairing protocols. Moreover, LTD induced by a classical pairing protocol is totally inhibited by intracellular injection of the selective and potent inhibitor of sGC, 1H-(1,2,4)oxadiazolo(4,3-a)quinoxalin-1-one (ODQ), confirming that the sGC of PCs is the target of NO.

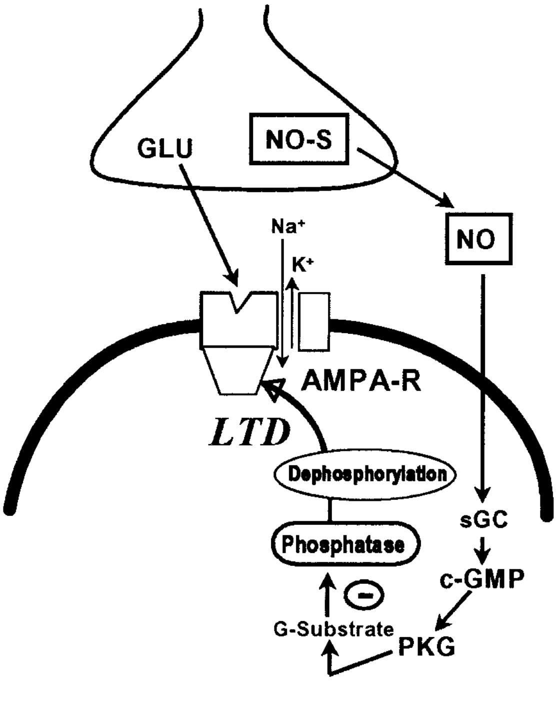

**Figure 3.** Schematic diagram of signal transduction processes involving the NO-cGMP-PKG pathway proposed to participate in LTD induction: Nitric oxide (NO), produced by NO-synthase (NO-S), activates synthesis of cyclic guanosine monophosphate (cGMP) by the catalytic action of the soluble guanylate cyclase (sGC); cGMP production in turn activates Protein kinase G (PKG), a cGMP-dependent protein kinase, thereby allowing phosphorylation of its specific endogenous "G-substrate," which is, in the phoshorylated state, a powerful inhibitor of protein phosphatase. Other abbreviations as in Figure 1.

In keeping with these findings, Ito and Karachot suggested in 1992 that cGMP production would in turn activate a cGMP-dependent protein kinase (PKG), thereby allowing phosphorylation of its specific endogenous G-substrate, which is, in the phoshorylated state, a powerful inhibitor of protein phosphatases. In keeping with such a hypothesis, it has been shown that selective inhibition of PKG blocks LTD induced by co-activation of PFs and CFs or LTD induced by PF stimulation paired with PC depolarization (Reynolds and Hartell, 2001). In addition, it has been reported that bath application of the protein phosphatase inhibitor calyculin A induces LTD in acute slices.

All these experiments support the view that the NO-cGMP-PKG pathway participates in cellular events leading to LTD. Because of its ability to diffuse over large distances, the role of NO in LTD cannot be to bring synapse specificity for this change in synaptic strength. Rather, this compound might allow recruitment of additional synapses into the pool of those exhibiting LTD following co-activation of PFs and CFs, thus increasing the signal-to-noise ratio of this process.

While the involvement of NO-cGMP signaling in LTD induction in cerebellar slices is now firmly established, the induction of LTD of glutamate-evoked currents in cultured PCs is unaffected by treatments that stimulate or inhibit this signaling pathway. This discrepancy might be due to the fact that in reduced preparations, putative NO donors such as PFs and basket cells are more scarcely represented. Alternatively, it is also conceivable that mechanisms of LTD induction are different in neurons grown in dissociated cultures versus those in acute brain slices from young adult animals.

## Changes in the Functional Characteristics of Postsynaptic AMPA Receptors During LTD Expression

In early in vivo experiments, Ito and co-workers showed that co-activation of PCs by CF stimulation and iontophoretic Glu application into their dendritic fields induced a long-lasting decrease in their responsiveness to this agonist (Ito et al., 1982). This result led Ito to propose that induction of LTD might ultimately lead to a long-term desensitization of PC postsynaptic ionotropic Glu receptors. Consistent with this view, experimental evidence based on the use of the coefficient of variation (CV) applied to PF-EPSCs suggests that LTD of PF-EPSCs, induced either by a classical pairing protocol or by bath application of NO donors in acute slices, is entirely expressed at a postsynaptic level. Moreover, a true modification of Glu receptor properties during LTD expression has been also suggested in acute slices. Indeed, it has been shown that aniracetam, a compound that is known to markedly reduce desenzitization of AMPA receptors, has a larger potentiating effect on PF-EPSCs after induction of LTD than before, which suggests that LTD involves a true desenzitization of postsynaptic AMPA receptors at PF-PC synapse. These results support the view that this change in long-term synaptic efficacy involves a genuine change in the functional characteristics of postsynaptic AMPA receptors.

## Redistribution of AMPA Receptors and LTD Expression

In addition to functional modifications of AMPA receptors, recent studies have shown that trafficking of these receptors could play a crucial role in the expression of LTD (see Xia et al., 2000). Indeed, LTD expression in cultured PCs is associated with a rapid endocytotic-dependent decrease in the number of GluR2-containing synaptic AMPA receptors. This internalization requires clathrin-complex-mediated endocytosis, since peptides that interfere with this complex block LTD. Additionally, this process depends on the intracellular carboxy-terminal domain of AMPA receptor subunit GluR2(/3), which has been identified as a likely candidate region to interact with proteins of the postsynaptic density, allowing their intracellular anchoring. These latest studies have made substantial advance toward a molecular understanding of LTD expression by establishing a potential link between the internalization of AMPA receptors and PKC activation (see above). Indeed, phosphorylation of Ser 880 in the C-terminal domain of GluR2(/3) by pharmacological PKC activation is accompanied by a reduction in the binding affinity of this subunit to an anchoring protein of the postsynaptic density termed "glutamate receptor interacting protein" (GRIP) (Figure 4), thereby leading to significant disruption of postsynaptic GluR2 clusters (Matsuda et al., 2000). In addition, treatments that disrupt the interaction between the carboxy-terminal of GluR2(/3) and PICK1 (another protein component of the postsynaptic density interacting with protein kinase C) (Figure 4) strongly attenuated both LTD induced by glutamate/depolarization pairing and a LTD-like phenomenon produced by exogenous application of PKC-activating phorbol ester (Xia et al., 2000). Taken together, these findings demonstrate that expression

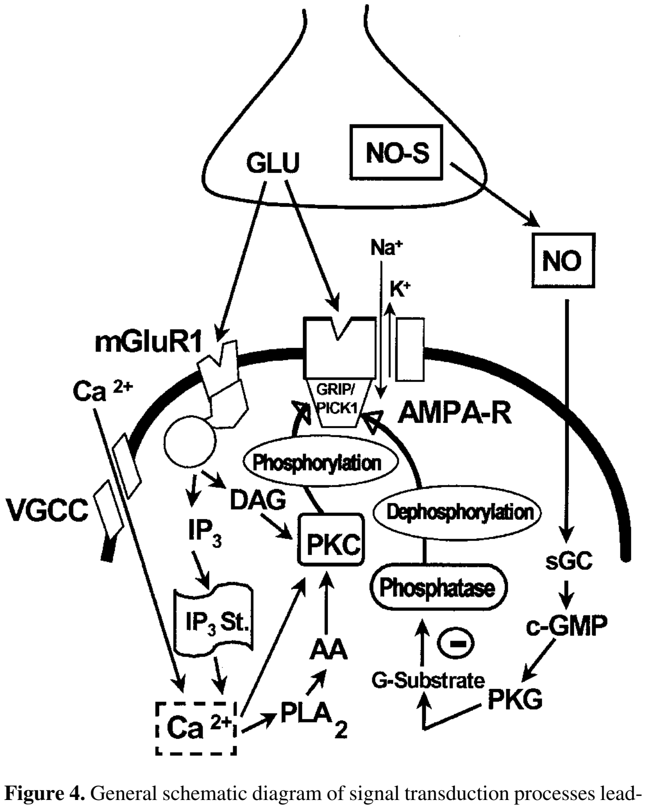

**Figure 4.** General schematic diagram of signal transduction processes leading to the phosphorylation and internalization of AMPA receptors, proposed to participate in LTD induction (glutamate receptor interacting protein (GRIP) and protein interacting with protein kinase C (PICK1) are proteins of the postsynaptic density interacting with AMPA receptors). Other abbreviations as in previous figures (Abbreviations: AA: arachidonic acid, AMPA-R: AMPA receptor, cGMP: cyclic guanosine monophosphate, DAG: 1,2-diacylglycerol, G: G protein, GLU: glutamate, GRIP: glutamate receptor interacting protein, $IP_3$: inositol-1,4,5-trisphosphate, $IP_3$ St.: inositol-1,4,5-trisphosphate internal $Ca^{2+}$ stores, mGluR1: type-1 metabotropic glutamate receptor, NO: nitric oxide, NOS: nitric oxide synthase, PC: Purkinje cell, PF: parallel fiber, PICK1: protein interacting with C-kinase 1, PKC: protein kinase C, PKG: protein kinase G, $PLA_2$: phospholipase $A_2$, PLC: phospholipase C, sGC: soluble guanylate cyclase.)

of cerebellar LTD requires PKC-regulated interaction between the carboxy terminal of GluR2(/3) and specific proteins of the postsynaptic density. Ultimately, internalization and/or changes in the properties of AMPA receptors could then create a disturbance in the postsynaptic density, which might in turn initiate a cascade of events that leads to a reorganization of the dendritic cellular cytoskeleton, thereby creating a permanent imprint of LTD.

## Transcription Factors, Protein Synthesis, and LTD Expression

Recent findings have demonstrated that the mechanisms involved in the maintenance phase of LTD (which may underlie long-term memory) include the expression of transcription factors and require protein synthesis in addition to modifications of AMPA receptor properties and/or changes in their distribution. The experimental protocols that are known to induce LTD trigger expression of the immediate-early genes c-Fos and Jun-B, suggesting that the expression of these genes may help to establish cerebellar long-term depression. Moreover, translational inhibitors that were perfused immediately after the induction protocol abolished LTD of glutamate responsiveness in cultured PCs only after a delay of 45 minutes, suggesting that postsynaptic protein synthesis is specifically involved in the establishment of the late phase of LTD. However, Karachot et al. (2001) have reported more recently that translational inhibitors entirely abolish the LTD induced by conjunctive stimulation of PFs and CF in acute slices, including its early phase, even if this early phase is less sensitive to these inhibitors.

## Discussion

After two decades of research, the understanding of the cellular and molecular mechanisms pathways underlying LTD has made rapid progress. Although part of the signal transduction pathways remains obscure, the stable phosphorylation of AMPA receptors appears to play a key step for expressing LTD (Figure 4). Thus, taking into account the experimental data available so far, Kuroda and coworkers have recently established a very interesting computational model that links kinetics of phosphorylation of AMPA receptors with different phases of LTD expression (Kuroda, Schweighofer, and Kawato, 2001).

Despite remaining uncertainties in the current understanding of the cellular and molecular mechanisms underlying the induction and expression of LTD, this associative and input specific form of synaptic plasticity has been proposed as the cellular basis for error-driven learning and memory in the motor system (see MOTOR CONTROL, BIOLOGICAL AND THEORETICAL). In particular, recent in vivo experiments point toward a role of LTD in the adaptation of the vestibulo-ocular reflex (VOR). This conclusion has been strengthened by the observations that selective expression of PKC inhibitors in PCs not only blocks cerebellar LTD without affecting PC excitability in alert transgenic mice, but also is accompanied by a lack of VOR adaptation in these animals (Goossens et al., 2001). Such a correlation between impairment of LTD and deficiency of associative learning of eyeblink conditioning has also been consistently found in other types of transgenic mice, such as mice that are deficient in mGluR1 (Aiba et al., 1994, in Daniel et al., 1998) or GFAP (Shibuki et al., 1996, in Daniel et al., 1998). Thus, there is now a growing consensus to support the notion that the associative nature of LTD makes it an attractive candidate for the cellular substrate underlying motor learning in the cerebellum. Moreover, the timing conditions for LTD induction may account for the temporal specificity of cerebellar motor learning. In this respect, an important future development in the field will be to study developmental aspects of LTD in relation to acquisition of motor skills.

# Chains of Oscillators in Motor and Sensory Systems

*Nancy Kopell and G. Bard Ermentrout*

## Introduction

Collections of oscillators that send signals to one another can phase-lock with many patterns of phase differences. This article discusses a set of examples that illustrate how those phases emerge from the oscillator interactions. Much of the work was motivated by spatiotemporal patterns in networks of neurons that govern undulatory locomotion. The original experimental preparation to which this work was applied is the lamprey central pattern generator (CPG) for locomotion (see SPINAL CORD OF LAMPREY: GENERATION OF LOCOMOTOR PATTERNS). However, the mathematics is considerably more general, and can be used to gain insight into other systems. In addition to the lamprey CPG, we will briefly discuss related pattern generators in the crayfish swimmeret system (Skinner, Kopell, and Mulloney, 1997) and the leech network of swimming (Friesen and Pearce, 1993), as well as waves of activity in other oscillatory neural tissue (Kleinfeld et al., 1994). For relationships to other patterns in the nervous system, see SYNCHRONIZATION, BINDING AND EXPECTANCY; OLFACTORY BULB; and OLFACTORY CORTEX.

Though much has been written about chains of oscillators in the context of physical problems, very little of that literature is relevant to chains of biological oscillators. Much of the the physics literature depends on the existence of certain conserved quantities that are irrelevant in a biological setting. Biological oscillators have other structure that is important to the behavior of collections of such oscillators. For example, unlike models of mechanical oscillators, models of biological oscillators have stable limit cycles (see PHASE-PLANE ANALYSIS OF NEURAL NETS). In the context of locomotion, each "oscillator" is likely to be a local subnetwork of neurons that produces rhythmic patterns of membrane potentials. Since the details of the oscillators often are not known and difficult to obtain, the object of the mathematics is to find the consequences of what is known, and to generate sharper questions to motivate further experimentation.

## Physical Models and Phase Models

Each of the examples we describe below can be considered, roughly, as an array of oscillators. In the absence of knowledge of details, it is desirable to keep the oscillator description as general as possible. Thus, we assume only that the local network can be described by some (possibly high-dimensional) system of ordinary differential equations having a stable limit cycle, with no concern for the mechanistic origin of that oscillation.

In general, the behavior of interacting oscillators can be arbitrarily complex (Guckenheimer and Holmes, 1983, chap. 6). However, in some circumstances, the network behaves like a much more simply described collection of units. For example, suppose that the coupling is (sufficiently) weak. Then the collection of oscillators acts as if there were a well-defined "phase" to each oscillator, and the signals between the oscillators become dependent only on the differences of the phases (Kopell, 1987). The form of the equations is then

$$\theta_j' = \omega_j + \sum H_{jk}(\theta_k - \theta_j) \tag{1}$$

Here $\theta_j$ is the phase of the $j$th oscillator and $\omega_j$ is its frequency when uncoupled. The interaction functions $H_{jk}(\phi)$ measure how much the $j$th oscillator is sped up or slowed down by the interaction with the $k$th oscillator; they can be computed from the original, more complicated equations by averaging the effects of the coupling terms over a cycle, and depend on the properties of the oscillators as well as the coupling (Guckenheimer and Holmes, 1983, chap. 4). There are also other computational ways of producing (at least the relevant parts of) the coupling functions, including a method that can in principle be done in the absence of explicit knowledge of the equations (see SPINAL CORD OF LAMPREY: GENERATION OF LOCOMOTOR PATTERNS).

The existence of this reduction procedure allows us to come back to questions about how details of the oscillators or the coupling can affect the network behavior via their effects on the functions $H_{jk}$. The simple description in Equation 1 can also be valid in some circumstances relevant to CPGs in which the coupling is strong. For example, if each oscillator is itself a composite of cells and emits coupling signals several times per cycle, the system can behave like the averaged one (see Cohen et al., 1992, for reference).

## Mechanisms for the Production of Traveling Waves

We now consider arrays of oscillators, of which nearest-neighbor coupled chains are the simplest example. When the above reduction is valid, the equations have the form

$$\theta_j' = \omega_j + H_A(\theta_{j+1} - \theta_j) + H_D(\theta_{j-1} - \theta_j) \tag{2}$$

Here $H_A$ and $H_D$ are the functions that represent the coupling in the ascending and descending directions of the chain. There are at least two different mechanisms that can produce waves in Equation 2. One of these relies on differences in natural frequency along the chain and the other on properties of the coupling.

The first mechanism is easy to illustrate, using the simple choice of coupling functions $H_A(\phi) = H_D(\phi) = \sin(\phi)$, where $\phi$ denotes the relevant phase difference. Such functions arise from the reduction procedure when the differential equations producing the oscillations have, for example, odd symmetry and the interaction is via the standard mathematical description of diffusion between compartments (Ermentrout and Kopell, 1984). In this case, if the natural frequencies are all equal, the synchronous solution ($\theta_j = \theta_k$ for all $j$, $k$) is the stable output of the chain. If the frequencies are not all the same, however, other behavior is produced. For example, a gradient in frequencies produces a traveling wave of activity from the oscillator with the highest frequency to the one with the lowest (Cohen, Holmes, and Rand, 1982), but not one with constant phase lags (i.e., independent of position along the chain).

Waves induced by frequency differences are important in the electrical activity produced by smooth muscle of the intestines, where there is a linear gradient in the uncoupled frequencies (Ermentrout and Kopell, 1984). They are also known to exist in the leech CPG for swimming (Friesen and Pearce, 1993) and appear to be the mechanism underlying waves in *Limax* (Ermentrout, Flores, and Gelperin, 1998). There is no evidence for such a gradient in the lamprey or crustacean swimmeret system.

A variation on the frequency gradient idea has an oscillator at one or both ends of the chain with a different frequency than the ones in the middle. Even with symmetric coupling such as $H_A(\phi) = H_D(\phi) = \sin(\phi)$, there can be waves of activity. In this case, the waves can have constant phase lags.

Another mechanism that produces traveling waves in chains of locally coupled oscillators relies on the properties of the coupling, allowing the frequencies to be identical. The essential property for $H_A$ or $H_D$ is that, if there is one-way coupling using either of these functions, the oscillators would lock with a non-zero phase difference. A simple example of such a coupling function is $H_A(\phi) =$

$\alpha \sin\phi + \beta\cos\phi$, with $\beta \neq 0$, while $H_B(\phi) = 0$. We note that for almost all kinds of coupling between two oscillators (in particular for models of chemical synapses), $H(0) \neq 0$. An important special exception is the mathematical description of simple diffusion across a membrane, which is a standard model of electrical synapses.

To understand how this mechanism works, consider a chain of oscillators coupled only in one direction, e.g., the ascending direction. Then the equations take the form

$$\begin{aligned} \theta_j' &= \omega + H_A(\phi_j);\ j \neq N \\ \theta_N' &= \omega \end{aligned} \tag{3}$$

where $\phi_j = \theta_{j+1} - \theta_j$. The hypothesis about $H_A$ implies that $H_A(0) \neq 0$, i.e., that the zero $\phi_0$ of $H_A$ satisfies $\phi_0 \neq 0$. Since all equations with $j \neq N$ are the same, we get equal phase lags $\phi_j = \phi_0$. This corresponds to a wave traveling at constant speed determined by $\phi_0$. The direction of the wave depends on the sign of $\phi_0$; if $\phi_0 > 0$, the wave travels in the ascending direction; if $\phi_0 < 0$, the wave travels in the opposite direction. Thus, the direction of the coupling does not determine the direction of the wave.

If the coupling is in both directions, and/or if the frequencies are not uniform, the outcome can still be calculated (Kopell and Ermentrout, 1986). We will say more about this later in the context of particular applications. One of the applications (to *Limax*) uses a generalization of the ideas of coupling-induced waves. In that example, there is a gradient of coupling strength, so the equations have the form

$$\theta_j' = \omega_j + s_j H_A(\theta_{j+1} - \theta_j) + s_j H_D(\theta_{j-1} - \theta_j) \tag{4}$$

Here $s_j$ denotes the strength of the connections to the $j$th cell; a gradient in coupling strength corresponds to the $s_j$ changing monotonically with $j$.

## The Lamprey Central Pattern Generator for Swimming

This CPG is described in more detail in Spinal Cord of Lamprey: Generation of Locomotor Patterns (q.v.). The most striking aspect of the lamprey CPG for undulatory locomotion is the linear geometry of the network. That is, the network can be portrayed crudely as a chain of oscillators (Cohen et al., 1982). The linear geometry provides important constraints on the behavior of the network, making it possible to use the theory described above. It is also important that the number of oscillators associated with the circuit be fairly large: there are approximately 100 segments, and small numbers (at least two) of isolated segments are known to be able to oscillate. The general theory in (Kopell and Ermentrout, 1986) is addressed to understanding the behavior of such long chains of oscillators; as we will see in the section on crayfish, CPGs that correspond to small numbers of oscillators must have a different construction in order to have a similar behavior. Although long fibers are known to exist in the lamprey cord, we consider first only local coupling; this was remarkably successful in explaining the behavior of the spinal cord. For references to the long fibers, see Cohen et al. (1982).

The first issue to be addressed about this preparation is the mechanism for producing the traveling wave that is observed in the spinal cord (see Spinal Cord of Lamprey: Generation of Locomotor Patterns). This wave has a constant speed (i.e., the phase lag between adjacent oscillators is independent of position along the chain). For the large class of equations for which the representation in Equation 2 is valid, the general theory of Kopell and Ermentrout (1986) tells us what properties of the oscillators and coupling are necessary to produce this constant speed wave.

In general, if there are frequency differences among the oscillators, the wave speed is not constant along the chain. (This can be mitigated by creating coupling that connects each oscillators to multiple neighbors; see Cohen et al., 1992.) Thus, frequency gradients do not provide the basis for waves in the lamprey. Chains with differences in frequency for the first and last oscillators do produce constant speed waves. However, small sections from any portion of the isolated lamprey cord produce local phase differences identical to the differences produced in the whole cord, invalidating the hypothesis that the ends of the cord are intrinsically different from the rest.

The edges of a piece of cord *are* different, not because of their intrinsic properties but because of their placement, and this can produce waves driven by edge effects. We saw in the previous section that one-way coupling provides constant speed waves if the uncoupled frequencies of the oscillators are equal; in that mechanism, the relevant edge is the oscillator that gets no input.

The theory of Kopell and Ermentrout (1986) proves the surprising fact that, even with two-way coupling, a long but finite chain in general behaves like one with only one-way coupling. (For this, the coupling must be asymmetric.) That is, for the purpose of determining the phase lags between any two points on the chain, one of the two directions of coupling is dominant over the other; the output is almost as if the other coupling were silent. The phase lags among the oscillators are affected by the nondominant coupling only near one end of the chain, where there is a "boundary layer" of phase lags different from those in the rest of the chain. (This occurs only for long chains; when the chain is short, as in the swimmeret system discussed later, the boundary layer can be most of the chain.) This dominance can be understood from a linearized version of the equations (see Spinal Cord of Lamprey: Generation of Locomotor Patterns); however, the linearized equations do not reproduce other effects elicited by experimental perturbations. An important result of the theory is that the lags depend only on the coupling functions; changes in the frequency uniformly along the chain do not change the expression of phase lags.

Three sets of experiments have been done with the isolated lamprey spinal cord to test the ideas described above. Theory based on Kopell and Ermentrout (1986) and other mathematical work was used in each case to predict an effect that should be seen only if one direction of the coupling was dominant, and to determine the dominant direction. In one of these experiments, a small motor was attached to one end of an otherwise pinned-down cord and used to wag the cord periodically at measured frequencies; the predicted effect concerned the range of frequencies over which the cord could be entrained by the forcing at either end of the cord. In another set of experiments, the local frequency of the intrinsic circuits was manipulated to be different in different parts of the cord; the mathematics makes predictions about changes in phase lags due to the frequency perturbations. The third set of experiments concerned the existence of "boundary layers" in phase lags at one end of the chain. In each case, the predicted effect was found, and the data revealed that the dominant direction of coupling is caudal to rostral (ascending), though the wave itself is descending.

For more information on the the experiments and interpretation, see Spinal Cord of Lamprey: Generation of Locomotor Patterns and Cohen et al. (1992) and the references therein; the Cohen article has the references to the mathematical work. We note that if the edge effects needed to create the waves are produced by changing the frequencies of the first and last oscillators in a chain that would otherwise display synchrony, the mathematics says that the consequences of the experimental perturbation would not be as observed.

The central question that motivated the lamprey work concerned the constancy of the phase lags as swimming speed is increased. In vivo, the swimming speed of an animal is proportional to the frequency of the local oscillators of the spinal cord. In the isolated spinal cord, the frequency can be manipulated directly; changing the oscillatory frequency uniformly does not change the phase lags along the cord. The theory described above provides a first step toward explaining this constancy; it says that changing the frequencies uniformly along the cord should not change the phase lags, provided that the zero of the dominant coupling does not change. In the lamprey spinal cord, changes of frequency may be achieved in ways that also change the coupling. Thus, the theory raises the sharper question of how the local network is constructed so that the excitation that increases the frequency leaves unchanged the relevant zero crossing.

## Swimmeret Systems of Crayfish

The swimmeret system of crayfish is another example of modular control of motor behavior via oscillatory components. The swimmerets are four paired, jointed limbs in the abdomen of the animal that move rhythmically to propel the animal through the water. Each swimmeret is controlled by a local oscillatory neural circuit in a ganglion containing motor neurons that innervate the swimmeret and interneurons that produce the rhythm (Skinner and Mulloney, 1998).

During a bout of swimming, the circuits all oscillate with the same frequency and maintain a constant phase relationship. The left and right sides are synchronized and there is approximately a quarter-cycle phase difference between neighboring circuits, with a posterior circuit leading its anterior neighbor. Thus, the chain of circuits produces a traveling wave whose direction is opposite to that of the lamprey. As in the lamprey, the wave produced has a wavelength approximately that of the body length, and the phase lag between adjacent segments is the same between any pair of segments. Other parallels with the lamprey swimming CPG are (1) there is no evidence for frequency differences between uncoupled local circuits, and (2) pharmacologically induced uniform changes in frequency of the circuits do not affect the phase lags.

In the swimmeret system, intersegmental coordination between the local circuits is accomplished by interneurons projecting to neighboring circuits. The details of connectivity and how the rhythms are produced are not known. Thus, as in the lamprey investigation, it is useful to consider the network behavior from a more abstract point of view, to understand what constraints on the bidirectional connectivity and local oscillators are necessary to reproduce key experimental observations. Based on recordings from isolated ganglia bathed in nicotinic agonists to produce swim-like patterns, some observations are as follows: (1) when anterior or posterior ganglia are selectively excited, a significant change in phase lag occurs at the excitation boundary, and (2) the frequency of the swimmeret pattern increases with an increase in the number of ganglia excited.

A model having the same form as Equation 2 can reproduce the basic findings about normal phases and perturbations in phase and frequency due to experimental perturbations (see Skinner and Mulloney, 1998, for references). However, in order for this to be so, there are critical differences from the lamprey work in assumptions about the coupling. For the lamprey, the length of the chain of oscillators allows one direction of coupling to dominate; the other direction makes its presence known (at least with respect to the phase lags) only in a small boundary layer. For a short chain (four oscillators), both directions of coupling contribute significantly, and must be coordinated in order for the phase lags to be appropriate. The mathematical theory suggests that the two coupling directions must be constructed so that each, by itself, would produce the appropriate lag of 90 degrees. Since the lags are measured in a fixed direction (e.g., $(j+1)$-st to $j$th ganglion), this requires a zero crossing for the ascending coupling to be 90 degrees, and that for the descending coupling to be $-90$ degrees. That is, the coupling in the two directions must be asymmetric in a very particular way. If they have the same strength and that asymmetry, all the experimental observations follow Skinner et al. (1997).

## The Leech Central Pattern Generator for Swimming

The 21 segmental ganglia of the leech are responsible for producing the traveling wave that enables the animal to swim. A small number of neurons in each ganglion have been identified as responsible for producing the rhythms. These can be crudely divided into three groups according to the phase in the cycle when they fire: (1) $-10°$ to 70°, (2) 130° to 180°, and (3) 220° to 260°. Most of the interactions are inhibitory, and the three groups essentially divide the cycle into 120° subgroups. The fact that the coupling signals occur at different phases in the cycle motivated the idea of temporal averaging that was used to create the phase models described in the preceding sections for the lamprey circuits.

In the leech, the coupling appears to be important in the creation of the oscillations: an isolated ganglion is able to produce a crude oscillatory rhythm, but the rhythm is much more regular in the intact chain. The coupling within the leech CPG has many long-range connections. While the lamprey also has such connections, the success of the simple nearest-neighbor models in explaining many of the details of the lamprey swim pattern suggests that the long-range connections are not as important as they are in the leech. The length of the coupling is important in the formation of the phase lags for the leech CPG; unlike the lamprey CPG, the intersegmental phase lags are smaller for the intact cord than for pieces of the cord. This can be understood from mathematical work showing that coupling to multiple neighbors in general decreases the phase lag (see Cohen et al., 1992, for a reference).

In this CPG, there is a systematic gradient in the intrinsic frequency of each of the ganglia; the gradient is opposite the direction of the wave, which is rostrocaudal. The general mathematical theory in Kopell and Ermentrout (1986) shows that there can be waves in locally coupled chains with both frequency gradients and asymmetric coupling. However, the theory does not address the effects of the significant conduction delays in the leech cord, or the effects of coupling that might extend for a large fraction of the cord. Thus, the creation of the phase lags is less understood in the leech than in the other two examples presented above.

## The Procerebral Lobe of *Limax*

Waves in the nervous system occur not only in locomotor activities but in sensory processing as well. A well-studied example occurs in the procerebral (PC) lobe of the *Limax*, or common garden slug, that is responsible for the olfactory processing of the slug. The PC lobe can be isolated from the animal along with the sensory apparatus. Under resting conditions, optical imaging of the lobe reveals a regular slow oscillatory wave that travels from the distal region of the lobe to the basal region (Kleinfeld et al., 1994). The frequency is about a half a cycle per second and the velocity is about 250 $\mu$m per second. The lobe itself is about 500 $\mu$m, so that, as in the lamprey, at any given point in time, there is only one wave on the lobe. When the animal is exposed to a novel odor, the oscillations quickly synchronize for several cycles and then return to the traveling waves. The reasons for the waves and the synchronization are not known, although it is believed that they may be crucial in odor learning and recognition. Blocking the oscillations impairs the animal's ability to be conditioned to odor stimuli.

In a recent paper, Ermentrout, Flores, and Gelperin (1998) developed a minimal model for the oscillations and waves in the lobe under a variety of experimental conditions. As in the lamprey work, the intent was to suggest a general model that was not dependent on biophysical details that are not known for the PC lobe. Since the lobe consists of many coupled intrinsically oscillating cells, modeling it as a network of coupled oscillators is natural.

The lobe consists of two layers, the cell layer and the neuropil. The source of the waves appears to be intrinsically oscillatory bursting cells in the cell layer. There are many interneurons that send processes into the neuropil and are likely important in the maintenance of the wave and the switch to synchrony. The double layer of cells is an important part of the anatomical structure to be retained in the model. One layer represents the locally connected bursting neurons and the other represents the diffusely coupled interneurons. Interneuron connections, believed to be an important part of the odor associative memory, are globally coupled, while the bursting neurons are coupled locally. Each layer consists of an $N \times m$ array of oscillators, with $N$ representing the apical-basal axis (the direction of wave propagation) and $m$ representing the axis parallel to the wave fronts. Each bursting cell influences only the interneuron in its immediate neighborhood, while each interneuron influences every bursting cell. The interneuron coupling is very weak during the resting state; the odor stimulus induces greater activity in the interneurons, which is modeled by an increase in their coupling strength.

In the PC lobe, the mechanism for wave production was hypothesized by Ermentrout et al. (1998) to be a gradient in the coupling strength, with the neurons in the basal end having stronger coupling than the neurons in the apical end. The reason for this choice is that the basal end is thicker and broader than the apical end, so that there could be more neurons involved in the rhythm at the thicker end. The interaction function for each layer was

$$H(\phi) = C + K \sin(\phi - \xi) \tag{5}$$

with slightly different values of $C$ and $K$ for the two layers. The layer with the locally connected bursting neurons is responsible for producing the waves, while the other layer has connections that collapse the wave to synchrony when there is an odor stimulant. Considering a slice in the direction of the waves, the relevant form of the full set of equations for the layer of oscillators is given by Equation 4.

As in the simpler Equation 2, without a gradient in coupling strengths, there is a dominant direction of coupling that determines the phase lags. The major role of the gradient is to determine which coupling direction is dominant. (It is the one with coupling from the larger strengths to the weaker ones if the ascending and descending coupling is the same.) In particular, the coupling strengths do not change the phase lags. This can be deduced from the general equations in Kopell and Ermentrout (1990), and can be seen easily from equations for one-way coupling, as in Equation 3, with coupling strengths included.

An interesting feature of a model in which the dominance is determined by coupling gradients is that it mimics one feature of a frequency gradient while still producing constant speed waves: If a chain of oscillators has a frequency gradient, splitting the chain at some point produces two smaller chains having different locked frequencies; this is also true if the chain has a gradient in coupling strengths. This feature is seen in the *Limax* preparation.

## Long-Range Coupling

The theory discussed in the previous sections deals only with local coupling (nearest neighbor and multiple neighbor, but still short compared to the length of the chain). There have been few studies so far on the effects of long-range coupling (see Cohen et al., 1992, for some references). One of these (Ermentrout and Kopell, 1994a) was motivated by trying to understand why the wavelength of the traveling wave in lamprey (and other anguiliform species that swim by undulation) is approximately one body length. Although the theory discussed above provides a framework for understanding how the wavelength can stay constant when the swimming speed changes, it does not provide any clues to why that wavelength should be related to the body length.

Ermentrout and Kopell showed that long coupling between the ends and an interior region, adjusted so that the coupling produces antiphase between the oscillators directly coupled, can create traveling waves that have the correct wavelength. With the same architecture, but changes in the relative strengths of the ends-to-middle coupling versus middle-to-ends coupling, a new, stable pattern can emerge: the chain displays a standing wave, characteristic of the spinal cord of amphibia during a trotting gait. Thus, this architecture is a substrate for both swimming movements (traveling wave) and trotting movements in an amphibian (Ermentrout and Kopell, 1994a). The long fibers cannot be essential to the production of the phase lags in adult lamprey, since the waves form in small portions of the animal. It is possible that a mechanism involving long fibers is responsible for creating the appropriate phase lags in young animals, and that learning mechanisms then enable this information to be encoded in local synapses, which can then work without global connectivity (Ermentrout and Kopell, 1994b).

## Phase Oscillators and Relaxation Oscillators

Equation 1 is derived from a physical description of oscillators and their interactions by a reduction procedure described in a previous section. When the reduction procedure is not valid, the emergent behavior of the collection of oscillators can be very different from that of the chains described in the preceding sections.

One such situation in which the reduction procedure is not generally valid involves relaxation oscillators coupled using models of excitatory chemical synapses (see Phase-plane Analysis of Neural Nets). Such oscillators have critical differences in the mechanisms by which the phase lags are determined. For interactions mimicking fast chemical synapses, Somers and Kopell (1995) described a coupling scheme they called fast threshold modulation, or FTM. In that mathematical description, at sufficiently high or low voltages of the presynaptic cell, the synaptic conductance saturates, so that the postsynaptic cell receives a current that is (on the high or low branch) independent of the trajectory of the presynaptic cell. Thus, the postsynaptic cell is essentially uncoupled from the presynaptic one, but has its voltage equation (and so its effective threshold for firing) changed during the input.

The different mechanisms lead to some important contrasts in properties. One is that variations in frequency or in inputs among relaxation oscillators coupled by FTM need not lead to phase differences among the oscillators, as occurs for Equation 2 (Somers and Kopell, 1995). This provides a potential mechanism to be used in constructing a network whose phase lags are well regulated even if the frequencies are not. A second difference concerns speed of locking: long chains of oscillators of the form of Equation 2 can take many, many cycles to approach the locked solution, with the time increasing with the length of the chain. By contrast, a long chain of relaxation oscillators can lock within a couple of cycles (Somers and Kopell, 1995).

It is difficult to obtain traveling waves in a chain of such oscillators; the usual outcome is approximate synchrony unless the coupling is very weak (in which case the averaging procedure is relevant). Indeed, changes in gating of synapses or voltage range of the presynaptic cell can change the mechanism of the interaction from that of phase oscillator-like behavior to that of FTM, changing waves into almost synchronous cell assemblies. Thus, a generalized signal in the network that changes, e.g., the threshold or sharpness of the synapses can provide a stimulus-induced change in mechanism, and hence of emergent behavior (Somers and Kopell, 1995). We saw in the *Limax* example how a stimulus produced change from waves to synchrony; this provides another kind of mechanism for such a change.

In a recent paper, Izhikevich (2000) has shown that it is possible to derive coupled-phase models derived from relaxation oscillators. The corresponding interaction functions, $H(\phi)$, have a discontinuity at the origin. This implies that a reciprocally coupled pair will synchronize even if there is a difference in the intrinsic frequencies. Thus, in theory one can connect fast-threshold modulation with phase models and obtain the properties of the former by using the easily analyzed formalism of the latter.

Chains of relaxation oscillators have also featured in models of a single dendrite of the basal ganglia dopaminergic neuron. Based on the experiments and models of Wilson and Callaway, Medvedev and Kopell modeled the compartments of the dendrite as a chain of coupled relaxation oscillators. (For a reference to the work of Wilson and Callaway, see Medvedev and Kopell, 2001.) The aim of the work was to understand the origin of long transients in frequency observed in slice preparations and biophysical models. The model was able to explain how the electrical coupling between the compartments can produce a spiking rate decreasing over many cycles; this decrease is analogous to spike frequency adaptation, but does not use any unusual currents normally associated with adaptation.

More complicated local circuits, with several different elements within a local circuit, may have some features of each type. The properties of such composite oscillators were studied in the context of the swimmeret CPG system (Skinner and Mulloney, 1998). In that system, the theory using averaged coupling is successful in understanding phase lags in normal and perturbed settings. A model based on the biophysical underpinnings of the component cells allows one to address finer questions relating to control of burst durations and frequency.

# Chaos in Biological Systems

*Leon Glass*

## Introduction

Chaotic dynamics, i.e., *aperiodic dynamics in deterministic systems displaying sensitivity to initial conditions*, has emerged from a relatively obscure topic of mathematics to an area that is of great current interest among scientists as well as the general public. The important characteristics of chaos are the apparent irregularity of time traces and the divergence of the trajectories over time (starting from two nearby initial conditions) in a system that is deterministic. Although the rhythm is irregular, the underlying deterministic equations can lead to structure in the dynamics (Figure 1).

Deterministic chaotic dynamics is different in principle from what is commonly known as random dynamics. In random dynamics, prediction is intrinsically impossible, except in a statistical sense. A natural system believed to be random is the radioactive decay of isotopes, leading to random time intervals between decay events.

Chaotic dynamics is now well-documented in a variety of different mathematical models, physical systems, and biological systems (Cvitanovic, 1989). Introductions to chaotic dynamics suitable for biology include Glass and Mackey (1988), Kaplan and Glass (1995), Strogatz (1994), and Liebovitch (1998). Research in biology has extended from studies of dynamics in well-controlled model systems to analysis of spontaneous dynamics in organisms. Although all agree that spontaneous activity is very complicated, reflecting the interactions of the intrinsic physiological control mechanisms with the fluctuating environment, the extent to which concepts developed in simpler chaotic systems can be applied is controversial. The word *chaos* has been used with so many different nuances of meaning and operational definitions that the original technical meaning (i.e., the highlighted phrase in the opening sentence of this article) can no longer be assumed. However, in this article, I will stick to this original technical definition of chaos.

## Identifying Chaos

### Chaos in Deterministic Systems

In a deterministic system there is a definite equation governing the dynamics. Biological systems have been modeled by difference

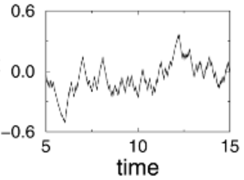

**Figure 1.** Dynamics from a deterministic high-dimensional ordinary differential equation representing a highly interconnected gene or neural network. The extremely irregular dynamics reflect deterministic chaos rather than random noise, but it would be difficult to develop criteria to determine this without huge amounts of data. The network is of the sort discussed in Mestl et al. (1997) with 32 model "neurons," each of which has 15 randomly chosen inputs. The graph shows the values of one of those variables as a function of time.

equations, differential equations, delay-differential equations, and partial differential equations that display chaotic dynamics. As long as one is dealing with deterministic equations, the signature of deterministic chaos is clear. It is easy to numerically integrate the equations starting from two nearby initial conditions and to watch the evolution. Chaotic systems display aperiodic dynamics with the same statistical properties (such as density histograms) for both trajectories. In addition, the trajectories should diverge but remain in a bounded region. Many equations also show characteristic bifurcations (changes in qualitative dynamics) as parameters change that are representative of well-studied routes to chaos. Perhaps the best known of these, the "period doubling route to chaos," has been found in a variety of simple equations and experimental systems. As a parameter of an equation changes, the period of an oscillation undergoes successive doublings. For example, if the period of an oscillation was initially 1 s, as a parameter changed the period would have doubled to 2 s, then as the parameter changed a bit more the period would have doubled to 4 s, and so forth. However, the parameter range over which each successively doubled period persists decreases geometrically, so that in practice it is very difficult to observe experimentally more than two or three of the successive doublings. The period doublings lead eventually to chaotic dynamics, which arise after a parameter crosses a threshold (Cvitanovic, 1989).

When dealing with dynamics in experimental systems or in natural systems, it is much more problematic to figure out the dynamic origins of complicated rhythms that are not periodic. Such rhythms will usually arise from the interaction between a deterministic system and random noise, and it is difficult to dissect out the relative effects of the determinism and the noise (Ruelle, 1994). Since there is no clear operational definition for chaos in experimental data, analyses generally focus on other properties of time series that can be defined operationally. However, if chaos has property $C$, and a time series has a property $C$, it does not follow that the time series is chaotic. Several books and web sites deal with time-series analysis methods and their pitfalls (Ott, Sauer, and Yorke, 1994; Abarbanel, 1996; Kantz and Schreiber, 1997; Goldberger et al., 2000).

I now summarize many features that are assessed in analyses of time series.

*Power spectrum.* The power spectrum of a time series can be easily determined using fast Fourier transform algorithms. However, since one can always construct random models that have the same power spectrum as a deterministic model, the power spectrum is not a good measure for defining chaos.

*Dimension.* Grassberger and Procaccia (1983) defined the correlation dimension of a set of points embedded in $d$ dimensions. The set of points could be generated in a variety of ways, including discrete time processes (e.g., time intervals between neural spikes or outputs of a difference equation) or continuous processes (e.g., recording from an electroencephalogram or a continuous differential equation). Call $r$ the distance away from a given point. The point correlation function, $C_i(r)$ is proportional to the number of points lying within a radius $r$ of a point $i$. The spatial correlation function, $C(r)$, is an average of the $C_i(r)$ over all points. Then the correlation dimension is $\nu$, if $C(r) = kr^{\nu}$ for small values of $r$. For random points distributed in $d$ dimensions, $C(r) = kr^{d}$, so that the dimension is an integer equal to the dimension of the space in which points are distributed. Thus a line has dimension 1, a plane has dimension 2, and so forth. However, some sets of points, called *fractals*, have a fractional dimension. Some workers take a fractional correlation dimension as a definition for deterministic chaos, since many chaotic dynamical systems have attractors with a fractional dimension. However, there are many pitfalls associated with determining the dimension, and not all chaotic systems have a fractional dimension. Consequently, a fractional correlation dimension cannot be accepted as a definition for chaos.

*Lyapunov exponent.* The Lyapunov exponent measures the rate at which trajectories diverge. A negative Lyapunov exponent indicates convergence of trajectories and a positive Lyapunov exponent indicates divergence of trajectories. Therefore, for a time series a positive Lyapunov exponent is a necessary condition for chaotic dynamics. However, the numerical algorithms for determination of the Lyapunov exponent may yield a positive exponent for periodic oscillations with large first derivatives, or in noisy systems. Therefore, a positive Lyapunov exponent found using numerical methods from naturally occurring data cannot be taken as a definition for chaos.

*Poincaré map.* Certain difference equations display period doubling bifurcations and chaos. An example is the quadratic map in which the value of a variable at one time is a quadratic function of the value at the previous time. The period doubling route to chaos is observed as the height of the quadratic function is increased. Some experimental data can be plotted so that the value of a variable at one time is plotted as a function of its value at the preceding time. For example, given a sequence of interspike intervals, it is possible to plot one interspike interval as a function of the preceding interval. If data plotted in this fashion clearly fall on a one-dimensional curve that is known to give chaotic dynamics, then this is good evidence for chaotic dynamics in the data. However, most biological examples in which data are plotted in this fashion do not give such clear-cut results, but rather give clouds of points.

*Determinism and prediction.* Since chaotic dynamics are generated by deterministic equations, in chaotic systems it should be possible either to demonstrate determinism or to predict dynamics that will occur in the proximate future. Several methods have been developed to try to make predictions based on past dynamics without necessarily knowing the equations of motion. A confounding factor of prediction tests is that random inputs to linear and nonlinear systems lead to correlations for short times that enable prediction even though the system is not deterministic and hence not chaotic. Random signals in which there are brief randomly inserted segments, all of which have the same waveform, would also be expected to show short-term predictability, but the underlying signal would not be chaotic.

*Surrogate data.* None of the above measures can be simply applied to determine if a given data set displays deterministic chaos. Consequently, several people have advocated generating "surrogate" data sets that have similar statistical properties to a given data set but are generated from a random process (Kantz and Schreiber, 1997). For example, it is a simple matter to generate a random time series that has an identical power spectrum to a given time series. Statistical analyses are then carried out using the time series under investigation and surrogates. The results of the analysis of the surrogate data are compared with the analysis of the original data. The origins of significant differences are then analyzed. They may be due to deterministic chaos, although other hypotheses, such as failure to capture some important aspect in the surrogate data set, need to be entertained. Application of this technique has led to the recognition that many earlier claims for deterministic chaos were in error.

## Chaos at Subcellular and Cellular Levels

Carefully controlled experiments, in which it is possible to generate large amounts of high-quality data while varying critical control parameters, have demonstrated chaotic dynamics in chemical, electronic, and hydrodynamic systems (Cvitanovic, 1989). Observations of chaotic dynamics in biological systems are more problematic. I will briefly review some of the areas in which there have been claims for chaotic dynamics.

### *Subcellular Dynamics: Ion Channels*

The basis for neural activity lies in the changes of conductance of specialized protein molecules called ion channels that allow ions to pass between the intracellular and the extracellular medium. For example, action potentials of nerve cells are usually associated with the opening of sodium ion channels. Classical intracellular electrophysiological techniques record the average activity over the thousands of ion channels present on a single nerve cell. Macroscopic ionic models describe this average activity and its dependence on the membrane voltage. An important technological advance, called the patch clamp, enabled researchers to measure directly the conductance of a single ion channel during its open state. Experimental recording of a single ion channel typically shows a complex switching behavior in which the channel makes transitions between open and closed states in a seemingly random manner. Most researchers believe that this switching is random and have developed appropriate theoretical descriptions. However, deterministic chaotic models may show the same statistical features as the random models (Liebovitch, 1998). At the current time, new information about the structural properties of ion channels is accumulating, and this should yield new insights into the molecular basis of the conformational changes that underlie the channel activity. Independent of the outcome of that endeavor, the observation that subcellular ion channel events are following a random (or perhaps chaotic) dynamics raises a conceptual problem: Why is it possible to study cellular or supercellular processes using deterministic ionic models? Presumably, the thousands of channels in a single cell, and the millions and billions in collections of cells, enable an averaging, so that macroscopic equations are valid, with fluctuations being small.

### *Cellular Activity in Single Cells*

The electrical activity of single cells can be easily measured using intracellular or extracellular microelectrodes, either in vitro or in vivo. The activity can be measured during spontaneous activity or in response to manipulation of environmental parameters. In my opinion, the most convincing demonstrations of chaotic dynamics in biological systems have been carried out in this scale of preparation. Periodic stimulation of oscillatory or excitable biological systems, such as nerve or cardiac tissue, has identified chaotic dynamics over restricted ranges of stimulation parameters (Glass and Mackey, 1988). Over other stimulation ranges there are regular rhythms in which there are repeating sequences of stimuli and action potentials. This work is placed on a firm footing by extensive theoretical analyses and numerical simulation mathematical models. Depending on the stimulation parameters, the theoretical models display periodic behavior or deterministic chaos in agreement with experimental observations. Moreover, in the chaotic region, plotting the stimulus phase as a function of the preceding stimulus phase to generate the Poincaré map can give a plot that is similar to the quadratic map (Glass and Mackey, 1988), further supporting the identification of chaos. However, there is no clear functional role for chaos at a cellular level.

## Complex Dynamics in Biological Networks

### *Chaos in Complex Networks*

One of the outstanding characteristics of biological systems is that they are characterized by complex networks of interacting elements. Thus, schematic diagrams of biological systems controlling metabolism, hormone secretion, gene activation, hormone secretion, motor activity, and heart rate are notable for being incredibly complex, with multiple feedbacks. Mathematical models developed for complex biological networks often demonstrate chaotic dynamics (Arbib, Érdi, and Szentágothai, 1997; Goldbeter, 1997; Mestl, Bagley, and Glass, 1997; Glass and Mackey, 1988; Sreenivasan, Pradhan, and Rapp, 1999). However, because there are no well-established operational tests for chaos, analyses that claim chaos in experimental or clinical data are often subject to alternative interpretations. Thus, the extent to which data such as heart rate variability or electroencephalographic data reflect deterministic chaos has been hotly debated. In recent years, there have been suggestions that many biological time series that had previously been called chaotic are not chaotic but may be better described using other adjectives (1/*f* long-range scaling, fractal, multifractal). However, these terms do not have clear implications with regard to the underlying mechanisms. Independent of the detailed mechanisms of fluctuations, a variety of studies have suggested implications for the study of health and disease.

### *Chaos and Health*

Although early studies of biological control networks often emphasized that they served to maintain homeostasis—a relatively constant internal environment—there is now increasing recognition that normal, healthy individuals can be expected to show complex fluctuations in important physiological functions (Goldberger, 1996). Many diseases can be characterized by qualitative changes in dynamics in biological control systems. Since these changes may be associated with bifurcations in appropriate mathematical models of the physiological systems, Mackey and I proposed the term “dynamical disease” to capture the dynamic aspects of disease (Glass and Mackey, 1988).

There are many examples of altered physiological dynamics associated with disease. Diminished heart rate variability is associated with a higher risk of sudden cardiac death. However, since patients do not die from reduced heart rate variability, it is important to clarify the underlying mechanisms. One hypothesis is that impaired cardiac function leads to increased sympathetic nervous activity associated with elevated levels of circulating chemicals (catecholamines). This in turn will increase the heart rate and lead to less variability. Further, since circulating catecholamines are pro-arrhythmic, there can be an increased risk of arrhythmia. In addition, patients with impaired heart function are also more likely to be taking drugs that blunt fluctuations in heart rate, or may even have implanted artificial pacemakers that might lead to a more regular rhythm. Clinical studies that associate higher risk for sudden cardiac death with decreased heart rate variability do not always address these potentially confounding factors. Independent of the mechanism, since low heart rate variability is associated with a higher risk for sudden cardiac death, the analysis of heart rate variability in the clinic has practical utility.

In a similar vein, in neurology, there have been claims that time-series analysis techniques can be useful in predicting the occurrence of an epileptic episode (Schiff, 1998). These types of claims are often hard to validate, since the data sets and the analysis algorithms often are not readily available. However, the recently established Research Resource for Complex Physiologic Signals (Goldberger et al., 2000) may provide an important avenue for publishing both data sets and data analysis packages.

Another practical direction is to apply to biological systems (Moss and Gielen, 2000) methods that can successfully control chaotic dynamics in mathematical models and in physical systems (Ott et al., 1994). Control methods have been applied to control comparatively simple rhythms associated with deterministic dynamics in model experimental systems. However, in cases in which the rhythms are more complex and not definitely associated with deterministic dynamics, further research is needed to validate the utility of chaos control methods.

## Discussion

Theoretical studies have demonstrated chaotic dynamics in mathematical models of biological systems ranging from the subcellular level to the organismal level. The most convincing experimental observations of chaotic dynamics in biological systems are associated with the response of biological systems in vitro to periodic stimulation of comparatively well-defined cells or assemblies of cells. The high dimensions of biological systems, the fluctuating environment (leading to nonstationarity), and the subtleties of the numerical methods are factors that make convincing demonstration of chaos in vivo a difficult matter. Therefore, although it might not be surprising that clear demonstrations of deterministic chaos in biology are rare, it is surprising that exaggerated claims founded on weak experimental evidence have been widely accepted without sufficient critical analysis.

Insofar as real biological systems (as opposed to computer models of these systems) are exposed to random thermal and other fluctuations and are composed of large numbers of interacting elements (i.e., they are high-dimensional), it is not easy to decide the appropriate class of theoretical model for a given system. Another difficult issue is to understand the biological significance, if any, of the observed fluctuations. Consider complex fluctuations in the timing between spikes of a neuron: does the neuron function well despite these irregularities, or are the irregularities essential to its task? And if the irregularities are essential for the task, is there any reason to expect that deterministically chaotic irregularities would be better than random ones? Although there have been several interesting speculations about an association of chaos with health and a possible role for chaos in information processing (for a summary, see Arbib et al., 1997), convincing demonstrations of the function of chaos are not yet available. Probably what drives many in brain theory is to understand the neural correlates of the human mind: higher cognitive function, originality, and free will. Humans behave neither in a random manner nor in a totally predictable manner. Although it seems inevitable that the mathematical concept of chaos will help us interpret the human brain, definite results pointing in that direction are still meager.

# Chaos in Neural Systems

*Kazuyuki Aihara*

## Introduction

From the viewpoint of dynamical systems theory, biological neurons and neural networks can be understood as nonlinear dynamical systems. Therefore, research on neural systems is a combination of brain science and nonlinear science.

The progress of nonlinear science in the twentieth century deepened our understanding of interesting dynamical phenomena called *deterministic chaos*, or simply chaos, although the research history of chaos can be traced back at least to Poincaré's work on the three-body problem in celestial mechanics 100 years ago. Chaotic phenomena, in which a deterministic law generates complicated, nonperiodic, and unpredictable behavior, exist in many real-world systems and mathematical models. Chaos has many intriguing characteristics, such as a sensitive dependence on initial conditions, or the so-called butterfly effect (i.e., the influence of a small perturbation in the initial condition diverges with time), and fractal geometrical structure (i.e., chaotic behavior is represented by a strange attractor with a noninteger dimension in the state space) (Ott, Sauer, and Yorke, 1994; see also CHAOS IN BIOLOGICAL SYSTEMS; DYNAMICS AND BIFURCATION IN NEURAL NETS).

In this article, the nonlinear behavior of neural systems is considered with respect to deterministic chaos. Although many of the neural systems that have been studied so far for neural computation have simple dynamics that converge into a steady state corresponding to an equilibrium point or a limit cycle, neural systems with chaotic dynamics produce much more dynamical behavior that may be functional from the viewpoint of information processing (see also COMPUTING WITH ATTRACTORS).

## Neurodynamics and Chaos

The nonlinear dynamics of a single neuron can naturally generate deterministic chaos under some conditions. For example, nerve membranes of squid giant axons respond to periodic forcing, such as sinusoidal and periodic pulse stimulation, not only periodically but also chaotically, depending on parameter values of the frequency and the strength of the force and states of nerve membranes (Aihara, 2002). Figure 1 demonstrates a chaotic response observed experimentally in squid giant axon. Chaotic and various other neuronal responses, which provide possible mechanisms of synaptic coding, are also observed in biological neurons stimulated through synapses (Segundo et al., 1998; see also SYNAPTIC NOISE AND CHAOS IN VERTEBRATE NEURONS). Thus, the behavior of a single neuron is essentially very dynamical, although some computational aspects of excitable neurodynamics can be reduced to static and logical calculations typically modeled by the McCulloch-Pitts neuron. Furthermore, chaotic dynamics in neural systems may also be discussed both in the more microscopic level of ion channels and in the mesoscopic and more macroscopic levels of neural networks (Elbert et al., 1994; Freeman, 2000; see also CHAOS IN BIOLOGICAL SYSTEMS).

Although chaotic behavior appears extremely irregular and complicated, it differs entirely from stochastic randomness because chaos is generated according to a definite deterministic rule. This deterministic dynamics enables control, short-term prediction, and change through bifurcation of chaotic behavior. On the other hand, because real neural systems operate in noisy environments, it is an important and delicate problem to clarify the effects of noise on chaotic neurodynamics (Freeman, 2000; Kaneko and Tsuda, 2000; Tsuda, 2001).

## Models of Chaotic Neural Networks

Can deterministic chaos in neural systems play a useful role? Biologically based answers to this question are few (Glass, 2001; see also CHAOS IN BIOLOGICAL SYSTEMS), but possible functions of chaos have been explored using theoretical models of chaotic neural networks.

Various models of neurons and neural networks with chaotic dynamics, in both discrete time and continuous time, have been proposed (Aihara, Takabe, and Toyoda, 1990; Lewis and Glass, 1992; Nara et al., 1995; van Vreeswijk and Sompolinsky, 1996; Rabinovich and Abarbanel, 1998; Freeman, 2000; Kaneko and Tsuda, 2000; Tsuda, 2001). For example, chaos in nerve membranes can be well described by continuous-time nerve equations like the Hodgkin-Huxley and FitzHugh-Nagumo equations (Aihara, 2002). It is an important research subject to extend such biologically realistic neuronal models by considering difference of excitability types (see CANONICAL NEURAL MODELS) and input effects through both chemical and electrical synapses (see NEOCORTEX: CHEMICAL AND ELECTRICAL SYNAPSES; TEMPORAL DYNAMICS OF BIOLOGICAL SYNAPSES).

On the other hand, simpler neuron models are desirable for elucidating possible principles of information processing with chaotic dynamics in large-scale neural networks both mathematically and numerically. For this purpose, a simple discrete-time model of chaotic neural networks has been proposed in which the neuronal elements qualitatively reproduce chaotic responses experimentally observed in squid giant axons (Aihara et al., 1990; Aihara, 2002). This model, based on the earlier Caianiello's neuronic equations and the Nagumo-Sato model with refractoriness, considers spatiotemporal external inputs from outside the network, spatiotemporal feedback inputs through mutual interactions among constituent neurons in the network, and refractory effects as a general discrete-

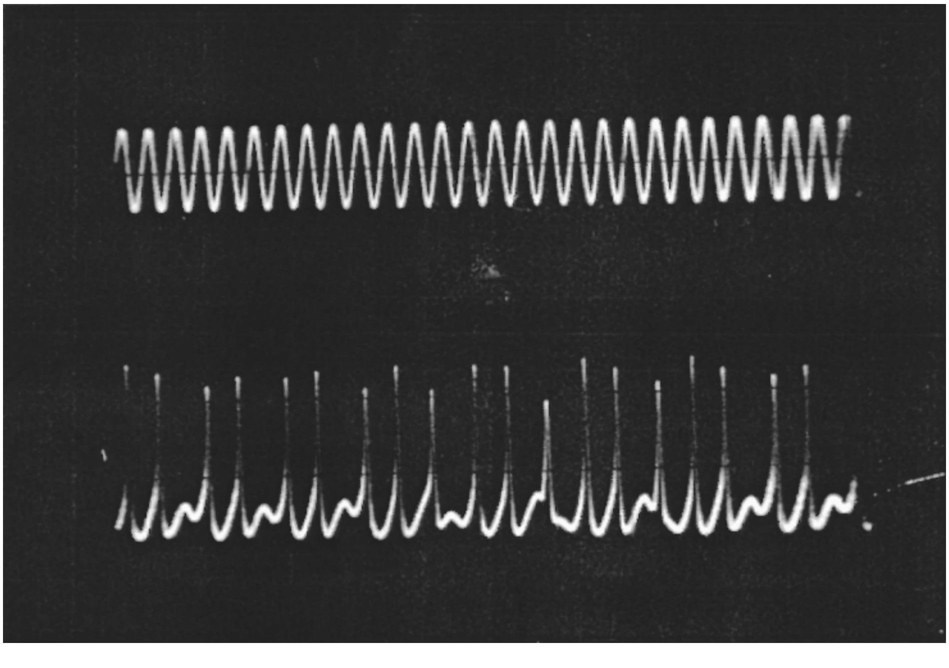

**Figure 1.** An example of chaotic response (below) of squid giant axon in a state of self-sustained oscillation to stimulation of a sinusoidal current (above).

time model of neural networks composed of neurons with their own chaotic dynamics (Aihara et al., 1990; Adachi and Aihara, 1997; Aihara, 2002). In fact, by adjusting the values of parameters, the model of chaotic neural networks can include many conventional discrete-time neuron models, such as the McCulloch-Pitts neurons with the Heaviside output function, analog neurons with the logistic output function used in backpropagation neural networks, and the Nagumo-Sato neurons with response characteristics of complete devil's staircases. Thus, with the model of chaotic neural networks, chaotic dynamics can be introduced into conventional discrete-time neural networks to explore possible functions and computational roles of spatiotemporal chaos in neural information processing by comparing the performance of the chaotic neural networks with that of the conventional neural networks in the common framework.

There is another approach to modeling chaos in neural systems. Rather than connecting chaotic neuronal elements, network dynamics can produce chaos by devising interactions through feedback connections among simpler neuronal elements, as follows: piecewise linear models (Lewis and Glass, 1992), balanced excitation and inhibition with sparsely connected strong synapses (van Vreeswijk and Sompolinsky, 1996), reduction of asymmetric connectivity storing cyclic memories by a pseudo-inverse method (Nara et al., 1995), coupled mesoscopic oscillators with different delayed feedback loops (Freeman, 2000), and two recurrent neural networks with excitatory and inhibitory feedback connections and stochastic renewal of dynamics representing synaptic noise (Kaneko and Tsuda, 2000; Tsuda, 2001).

## Possible Functions of Spatiotemporal Chaos in Neural Networks

Several aspects of useful computational dynamics with spatiotemporal chaos in neural systems are reviewed with the model of chaotic neural networks below. Since each constituent element of the chaotic neural network model has its own chaotic dynamics, the spatiotemporal dynamics of the whole network is fundamentally very rich, complicated, flexible, and dependent on the coupling of chaotic neuronal elements. The adjustment of chaotic dynamics in elemental neurons by constraining architecture, interactions among neurons, and other parameters in the model leads to functional harnessing of the spatiotemporal dynamics of the chaotic neural networks (Aihara et al., 1990; Rabinovich and Abarbanel, 1998; Kaneko and Tsuda, 2000).

### *Dynamical Association*

Associative memory is one of the most popular applications of neural networks (see Associative Networks; Computing with Attractors; Dynamics of Association and Recall; Statistical Mechanics of Neural Networks). As an example, we can consider the nonlinear dynamics of autoassociative memory networks composed of 100 chaotic neurons, where the synaptic weights are determined by the correlation matrix of four stored patterns: "cross," "triangle," "wave," and "star" (Adachi and Aihara, 1997).

Figure 2*A* shows spatiotemporal patterns generated by the associative dynamics of the chaotic neural network. In a recalling process in the conventional autoassociative memory network, the network state quickly converges from a perturbed stored pattern to the exact stored pattern, which is an asymptotically stable fixed point of the network dynamics. The network state of the chaotic neural network, on the other hand, displays itinerant behavior among stored patterns, as shown in Figure 2*A*, if the network parameters are appropriately adjusted so that the refractoriness is strong enough to escape from any fixed points except the totally quiescent state at which all neurons are resting. The pattern at $t = 1$ in Figure 2*A* is very close to the stored pattern of "wave." If the network were the conventional autoassociative memory, it would keep this pattern of "wave" forever after $t = 1$. However, the chaotic network continues recalling different stored patterns and their reversed patterns successively, intermittently, nonperiodically, and unpredictably; e.g., the patterns at $t = 23$ and $t = 80$ in Figure 2*A* are very close to the pattern "cross" and the reversed pattern of "triangle," respectively. It should be noted that this dynamical association process is different from cyclic memory, in which the order of recalled patterns is predictably periodic, as designed by synaptic connections.

Moreover, external inputs to neurons corresponding to a stored pattern can attract the spatiotemporally chaotic dynamics near the stored pattern for a while but not eternally, as shown in Figure 2*B*, where external inputs corresponding to the stored pattern "triangle" are applied to the chaotic neural network of Figure 2*A*. Actually, chaotic dynamics is effective for achieving a quick response to changing external inputs (van Vreeswijk and Sompolinsky, 1996; Rabinovich and Abarbanel, 1998).

The spatiotemporal dynamics of Figure 2*A* can be interpreted as either searching stored patterns or generating spatiotemporal patterns composed of static patterns memorized by synaptic weights. This dynamic may be related to a nonlinear phenomenon called *chaotic itinerancy*, widely observed in different nonlinear models of cortical neural networks, globally coupled maps, and optical turbulence (Kaneko and Tsuda, 2000; Tsuda, 2001). Recurrent neural networks composed of McCulloch-Pitts types of neurons display similar dynamics with chaotic association when reducing asymmetric connectivity storing cyclic memories (Nara et al., 1995).

Related to this kind of memory dynamics, Freeman and colleagues proposed, on the basis of their physiological experiments on the olfactory neural system, an intriguing hypothesis: Chaotic neural activities play functional roles in a global and unstructured basal state with the capability of rapid and unbiased access to learned patterns evoked by trained odors and a catchbasin state classifying and learning unknown patterns evoked by novel or unfamiliar odors (Freeman, 2000).

### *Dynamical Optimization*

The spatiotemporal searching dynamics demonstrated in Figure 2*A* also can be applied as a new kind of heuristic method to combinatorial optimization problems, especially the *NP*-hard problems that are quite important in many industrial and engineering applications. In the field of neural computation, gradient descent neurodynamics with a computational energy function has been applied to combinatorial optimization problems like the traveling salesman problems (TSP) (see Optimization, Neural). Although this dynamical method for combinatorial optimization is an interesting heuristic technique, its naive applications would usually suffer from the so-called local minimum problem.

Since the spatiotemporal dynamics of the chaotic neural networks can easily escape from local minimum states, the performance of the chaotic neural networks for *NP*-hard problems is expected to be better than that of the conventional neural networks with simple gradient descent dynamics. This method utilizes chaotic fluctuation rather than stochastic fluctuation for combinatorial optimization. We can theoretically guarantee the global searching capability of the chaotic neural networks under some sufficient conditions for fully developed chaotic dynamics (Aihara, 2002). However, it is speculated that efficient searching is achieved when the chaotic dynamics generates an appropriate strange attractor with fractal structure, which may be a zero measure with respect to the Lebesque measure of the whole state space but includes globally

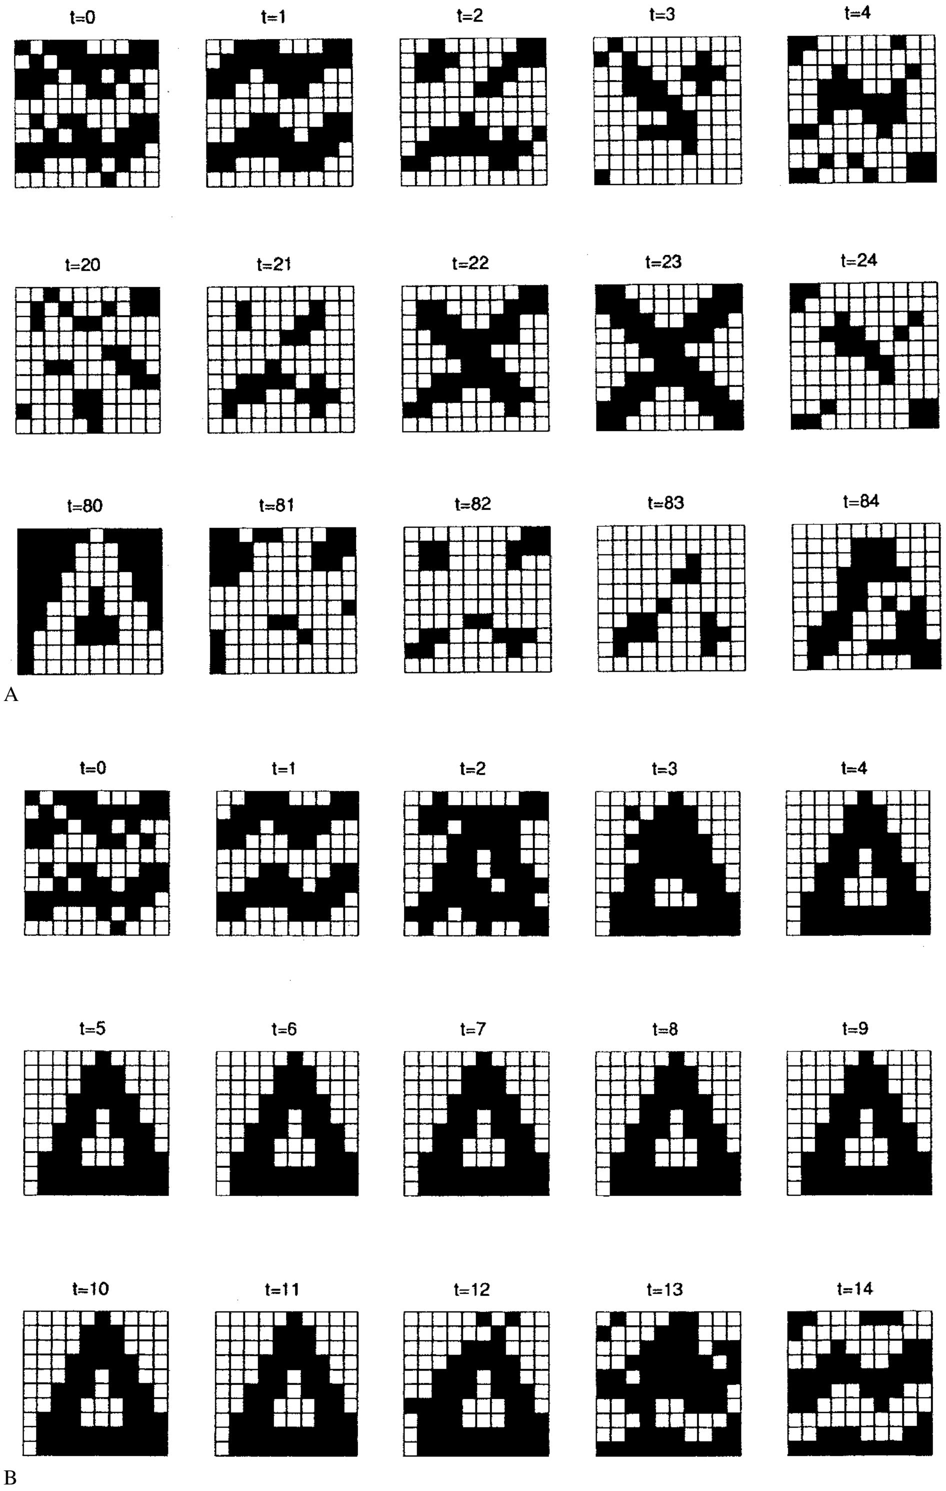

**Figure 2.** Associative dynamics of a chaotic neural network with four stored patterns. The network is composed of 100 chaotic neurons with refractoriness (Adachi and Aihara, 1997). *A*, Spatiotemporally chaotic patterns of the chaotic neural network. The output pattern of 100 constituent neurons is displayed in the form of a 10 × 10 matrix with black and white squares showing firing and quiescent neurons, respectively. *B*, Response of the chaotic neural network to the stimulation corresponding to the stored pattern "triangle."

optimal or near-optimal solutions. The optimization efficiency can be further improved by introducing chaotic simulated annealing with changing network bifurcation parameter values ranging from fully chaotic states to fixed points and by combining chaotic neurodynamics with effective heuristic methods like the 2-opt algorithm and the tabu search algorithm (Aihara, 2002).

### *Cantor Coding*

Tsuda and colleagues (Tsuda, 2001) proposed a chaos-driven contracting system, a simple example of which is a chaotic neural network with three neurons in which an unstable chaotic neuron drives a contracting system composed of a stable excitatory neuron and a stable inhibitory neuron. In this network, information of a symbolic sequence generated by the forcing chaotic neuron is encoded on a Cantor-like set in the state space of the contracting subsystem. Because the system can be extended to a more general architecture composed of a recurrent neural system with chaotic itinerant dynamics and a contracting neural network stimulated by the former network, similar phenomena are expected to be experimentally observed at CA3 and CA1 in the hippocampus and at the olfactory bulb and the prepyriform cortex in the olfactory neural system. These neural networks may ultimately be involved in the formation of episodic memory (Tsuda, 2001).

## Discussion

The chaotic neural networks and the possible computational dynamics with dynamical association, combinatorial optimization, and Cantor coding have been reviewed as simple examples of neural systems with chaotic dynamics. Although theoretical and experimental studies on chaos in neural systems further suggest other possible roles of chaotic neurodynamics in relation to higher functions of the brain, such as adaptation, perception, episodic memory, learning, awareness, intentionality, and thought (Freeman, 2000; Tsuda, 2001), it is still an important open question to experimentally prove or disprove the existence of these functions of chaos in real biological systems (Glass, 2001; see Chaos in Biological Systems). It is certain, however, that real nerve membranes have chaotic dynamics, while many artificial neuronal models are based upon oversimplified threshold dynamics. The chaotic dynamics in the level of single neurons may be the key to emergence of organized functions in biological neural networks (Rabinovich and Abarbanel, 1998). Thus, it is an important future problem to examine in detail dynamical cell assemblies and possible spatiotemporal coding (Fujii et al., 1996) in neural networks composed of chaotic neurons.

Neural systems with chaotic spatiotemporal dynamics, on the other hand, can be attractive models for analog neurocomputing (see also Analog Neural Nets: Computational Power; Neural Automata and Analog Computational Complexity; Spiking Neurons, Compution with) because chaotic dynamics can read out the complexity of a real number with time due to instability and nonlinearity. In fact, analog IC chips of chaotic neural networks have already been implemented as a new kind of analog computing circuits for practical applications of spatiotemporal chaos in the fields of engineering (Aihara, 2002).

# Cognitive Development

*Yuko Munakata*

## Introduction

Two classic questions in the study of cognitive development are:

1. *Where does our knowledge come from*? Questions about origins (whether of knowledge, life, the universe, etc.) form the basis for some of the most interesting, challenging, and hotly debated issues in science and popular culture. In regard to the origins of knowledge, the debate has taken the form of nature versus nurture, and more recently of specifying the interactions between them.
2. *How does change occur*? This question builds on the question of origins. A complete developmental account must specify not only the beginnings (of knowledge, life, the universe, etc.), but also the mechanisms that govern change in the system. The question of change is one of the most important yet relatively unanswered questions in the study of cognitive development. How do we progress, for example, from not speaking a word to communicating with short phrases to participating in lengthy, complex conversations?

Answering these two classic questions requires the ability to assess what is known at different points in development. For example, what do newborns, older infants, and toddlers know about the permanence of objects in the world? Specifying the time course of development of such knowledge could shed light on questions about the origins of this knowledge and how change occurs. Toward this end, researchers have developed a variety of clever techniques to assess knowledge in children of all ages, even preverbal infants. However, children sometimes provide conflicting impressions of what they know across this variety of techniques, raising another important question:

3. *Why does what children know depend so much on how they are tested*? That is, why is children's knowledge so task dependent? Why do children pass one measure of knowledge with flying colors, while simultaneously failing another measure meant to tap the same knowledge? For example, infants as young as 3.5 months seem to understand the permanence of objects, as assessed by their looking times at events with occluded objects (Baillargeon, 1995). However, infants fail to understand object permanence for many more months, as assessed by whether or not they search for toys that are presented and then hidden.

Resolving these discrepancies in what children seem to know is critical for understanding the origins of knowledge and how change occurs.

Connectionist models have provided a useful tool for exploring these three fundamental questions, as well as many other facets of cognitive development (McClelland and Plunkett, 1995; Elman et al., 1996). Such models provide a useful complement to behavioral studies in general (O'Reilly and Munakata, 2000), and particularly in the study of development. This article describes contributions from connectionist models in exploring the origins of knowledge, mechanisms of change, and the task-dependent nature of children's knowledge. These models span the domains of perception, memory, language, problem solving, and rule use.

## Origins of Knowledge

The debate about origins has played out in the domain of infants' perception of the world—whether they experience a "blooming, buzzing confusion," as William James claimed, or come equipped to make sense of objects moving around them. Young infants appear sensitive to the continuity of object motion, the fact that objects move only on connected paths, never jumping from one place to another without traveling a path in between. For example, infants as young as 2.5 months look longer at events in which objects appear to move discontinuously than at events in which the objects move continuously (Spelke et al., 1992). Such longer looking times suggest that infants find the discontinuous events unnatural, and so possess some understanding of object continuity. What are the origins of such knowledge?

An understanding of object continuity may be part of our innate core knowledge (Spelke et al., 1992). However, the label of "innate" leaves many questions unanswered about the origins of knowledge. For example, how do infants come to understand object continuity, and what are the mechanisms underlying such understanding?

These questions were explored in a connectionist model initially developed to explore imprinting behavior in chicks, and object recognition more generally (O'Reilly and Johnson, 2002). The model viewed a simplified environment in which objects moved continuously. Based on this experience, the model developed receptive field representations of objects that encoded continuous locations in space, thereby demonstrating a sensitivity to object continuity.

What were the origins of the model's sensitivity to object continuity? First, the network had recurrent excitatory connections and lateral inhibitory connections in the hidden layers that allowed active units to remain active; specifically, active units continued to send activation to themselves via the recurrent excitatory connections, and they prevented other competing units from becoming active via the lateral inhibitory connections. Thus, when the network viewed an object, certain hidden units became active, and they tended to stay active even as the object moved around in the input. As a result, the network represented the different input patterns associated with a moving object as the same object on the hidden layer. Second, the network learned according to a Hebbian learning rule, which led the model to associate this hidden unit pattern of activity with the object in different locations in the input. As a result, whenever the object appeared in any of these locations, the network came to activate the same hidden units, or the same object representation. In this way, with exposure to events in the world that conformed to the principle of continuity, the model developed receptive field representations of objects that encoded continuous locations in space, and so learned to "recognize" objects that moved continuously in its environment. Thus, the model provided a precise specification of the potential origins of knowledge about object continuity: a system with recurrent excitatory and lateral inhibitory connections and a Hebbian learning rule, and an environment with objects that move continuously.

One might describe this model in terms of an innate predisposition to understand the continuity of objects, given that the network was structured "from birth" with recurrent excitatory and lateral inhibitory connections and a Hebbian learning rule; all it needed was the typical experience of viewing objects moving continuously in its environment. However, again, it is not clear what benefits would be conferred by calling the developmental timecourse of the model innate. In contrast, the benefits of the model should be clear in providing an explicit, mechanistic account of the potential origins of sensitivity to object continuity.

## Mechanisms of Change

Most connectionist models, including the object continuity model, address some aspect of change. Networks change as activations are propagated through them, connection weights adjust during learning, and new forms emerge from the complex interactions of elements in the networks (as with the development of representations of object continuity). Here, we focus on models exploring two important issues regarding developmental changes: critical periods and stages.

### *Critical Periods*

Humans mature at a slower rate than any other species. Counterintuitively, this slow rate of development may provide the perfect biological environment (and a critical period) for mastering complex domains such as language. A connectionist model was developed to explore such critical periods in language learning (Elman, 1993). The model "heard" sentences of varying degrees of complexity, with the goal of predicting what word would come next at each point in a sentence. From this experience, the model learned to hold on to words it had heard recently in order to predict what might come next, allowing it to abstract the grammatical structure of the language. The model could thus correctly predict grammatically appropriate words within a sentence, even in complex sentences such as "Dogs see boys who cats who Mary feeds chase." The model displayed a critical period, in that "young" networks were able to master the language input, while "older" networks were unable to.

Why did this model display a critical period? The young and older networks differed only in their working memory spans, or how many words they could keep in mind. Although children of different ages differ in many more ways, this single manipulation in the model allowed the potential contribution of working memory to be isolated and evaluated. The young network could keep only three or four words in mind, because its working memory was cleared after every three or four words that were heard; this span was increased gradually as the network aged. In contrast, for the older network, no such clearing of working memory ever occurred, so it could keep more words in mind from the start of learning. Intuitively, one might have expected the older network to be more capable of learning. Instead, by being able to keep more in mind, the older network got bogged down in all of the information it was processing, and was unable to abstract the key kernels (of grammatical category, number, and verb argument type) for understanding the structure of its language. (Imagine trying to learn grammar by studying complex sentences like the "dogs" example above—there is quite a bit to get lost in!) In contrast, by being able to keep only a few words in mind, the young network was better able to focus on these key kernels. (Imagine trying to learn grammar by studying simple portions of complex sentences like the "dogs" example above, e.g., "Dogs see boys"—much less to get lost in.) After abstracting these key kernels, the young network was then able to build on this grammatical knowledge to process more complex sentences as its working memory span increased. Elman (1993) referred to this advantage of limited capacity as "the importance of starting small."

The model thus instantiated an explicit, mechanistic account for the potential causes of critical periods in language learning, leading to the conclusion of the importance of starting small. The conclusions from the simulations are bolstered by similar conclusions from the detailed analyses of behavioral results, and the conclusions from the behavioral results are bolstered by the working implementation in a connectionist model of the somewhat counterintuitive theory.

### *Stages*

Children appear to pass through qualitatively different stages in solving certain tasks. For example, in the balance-scale task, children view a scale with weights on each side at particular distances from the fulcrum, and they must decide which arm of the scale will fall when supports underneath the scale are released. Children initially answer these problems randomly, using no apparent rule about the physical properties of weight and distance to guide their decisions. They next attend only to the amount of weight on each side of the fulcrum (rule I), then include the distance of weights from the fulcrum if weights are equal on each side of the fulcrum (rule II), and eventually attend to both weight and distance information regardless of whether weights are equal on each side (rule III) (Siegler, 1976).

A connectionist model of the balance-scale task (McClelland, 1995) demonstrated how such stage-like progressions can result from small, successive adjustments to connection weights. The model received balance scale problems as patterns of activity corresponding to weight and distance information, and simulated children's performance of progressing from no-rule behavior to rule I, rule II, and rule III behavior.

Why did the model display stage-like behavior? Using error-driven learning, the network's initially random weights were slowly modified with each experience to reduce the discrepancies between the network's predictions about balance scale problems and the actual outcomes. For some time the network's answers were random, because the connections from input to hidden layer and from hidden layer to output layer were not yet meaningful. The network then began to develop representations of weight in its hidden layer. In one simulation, the earlier sensitivity to weight over distance arose because the network received greater exposure to problems where weight predicted the balance-scale outcome (reflecting the possibility that children have more experience with the effects of variations in weight than with the effects of variation in distance). In subsequent simulations, the earlier sensitivity to weight arose with equal exposure to the two cues, owing to the weight cue (a single piece of information) being more simple than the distance cue, which requires computing the relation between two pieces of information. As the hidden layer representations of weight became more fully formed, such that units were becoming more distinct in their activation patterns, units could be more readily credited for their contribution to the network's correct performance, or blamed for their contribution to the network's errors. The connections from the hidden units to the output units (and from the input units to the hidden units) could then be adjusted appropriately to improve the network's performance, producing a stage-like transition from random answers to rule I answers based on weight.

Sensitivity to the distance cue followed this same pattern of gradual development of hidden unit representations, facilitating credit and blame assignment and the adjustment of connections, leading to a stage-like transition to rules II and III. In this way, incremental weight adjustments in neural networks can result in small representational changes that then support relatively fast learning, producing stage-like behavior.

## Task-Dependent Behavior

Children's task-dependent behavior provides a challenge to stage theories, and to developmental theories more generally as discussed earlier. If children are in a given stage or have mastered a particular construct, why do they simultaneously pass and fail different measures of this knowledge? This section focuses on models that explore task-dependent behavior in two domains: memory for hidden objects (often studied under the rubric of a concept of object permanence) and perseveration (the repetition of behaviors that no longer make sense).

### *Object Permanence*

Infants show an incredible range of task-dependent behaviors in their memory for hidden objects. One of the most salient is their failure to search for hidden objects for months after demonstrating sensitivity to hidden objects in their looking times (specifically, looking longer at impossible than at possible events with objects that become occluded; Baillargeon, 1995). Competing interpretations of such task-dependent behaviors have fueled controversies surrounding the origins of knowledge and the mechanisms of change in this domain.

A connectionist model demonstrated how object permanence knowledge could develop without being prespecified, and how such knowledge could lead to success in one task but not another (Munakata et al., 1997). The model viewed a simplified environment in which objects conformed to the principle of object permanence (e.g., disappearing from view behind occluders and reappearing after the occluders were removed). Based on this experience, in the absence of any explicit signal that hidden objects continued to exist, the model became sensitive to the permanence of objects, continuing to represent objects even after they were hidden.

What were the origins of the model's knowledge of object permanence? As in the object recognition model described above, the object permanence model had recurrent excitatory connections that allowed active units to remain active. Like the language learning and balance scale models, the object permanence model also had a goal of predicting what would happen in its environment. Through error-driven learning, the network adjusted its weights if its predictions were incorrect, for example, if the network predicted that an occluded object would not reappear when the occluder was removed, and then the object did in fact reappear. So, when an object moved out of view, the network gradually learned to use its recurrent connections to maintain a representation of the object, allowing the network to accurately predict its environment (and the reappearance of such hidden objects).

Why was the model's knowledge of object permanence task dependent? The network's memory for hidden objects was graded in nature, gradually becoming more like the network's representations of visible objects. The network's perceptual prediction system could use weak memories of occluded objects to expect their reappearance, whereas the network's reaching system, with a delayed and slowed time course of development, could not use these weak memories of occluded objects to reach. This early inability to reach to occluded objects was not due simply to deficits in the reaching system, because this system was able to reach for visible objects (for which the network quickly developed strong representations). Thus, the strength of the graded representations was critical to the task-dependent behavior of the network. Moreover, the strengthening of the networks' memories alone was sufficient to allow the system to progress from initially reaching only for visible objects to then reaching for occluded objects as well. In this way, memory development may be critical to infants' increasing abilities to demonstrate sensitivity to hidden objects across a range of tasks.

Thus, with exposure to events that conformed to the principle of object permanence, the model provided an explicit, mechanistic account of the potential origins of our sensitivity to the permanence of objects, and of the task-dependent nature of infant knowledge in this domain.

### *Perseveration*

Task-dependent behaviors may be most compelling when infants and children *perseverate*, repeating prepotent or habitual behaviors when they no longer make sense. In these cases, participants pass and fail different measures of the same knowledge in a single testing paradigm, at the same moment or very close in time. For example, as soon as infants will search for a toy that is presented and then hidden, they search perseveratively, continuing to reach back to old hiding locations after watching as the toy is hidden in a new location (Diamond, 1985). However, even as infants reach perseveratively, they occasionally gaze at the correct hiding location. Similarly, after 3-year-olds correctly sort cards according to one set of rules (e.g., with blue cards going into one pile and red cards going into another pile), most perseverate in sorting by this rule even after the rules have changed (e.g., to sort the cards by their shape rather than their color) (Zelazo, Frye, and Rapus, 1996). However, the children can correctly answer questions about the new rule they should be using, such as where trucks should go in the shape game. Thus, even as infants and children perseverate with their previous responses, they sometimes seem to indicate through other measures that they have some awareness of the correct response.

Connectionist models have been used to explore the mechanisms that lead to perseveration, support improvements with development, and yield task-dependent behaviors (Munakata, Morton, and Stedron, in press). These models simulate all of these aspects of performance based on a competition between "active" and "latent" memory traces. In the connectionist framework, active traces take the form of sustained activations of network processing units, and latent traces take the form of changes to connection weights between units. Latent traces build as a network repeats a behavior (e.g., searching in one hiding location, or sorting according to one rule), biasing the network to repeat that behavior. These latent traces are thought to be subserved by posterior cortical areas, and to develop quite early in life. The ability to maintain active traces of currently relevant information (e.g., a new hiding location or rule) appears to depend on gradual developments in the prefrontal cortex. The strength of these active traces is manipulated in the models in terms of the strength of recurrent connections within a layer, which allow active units to maintain their activity. Networks perseverate when latent traces for previously relevant information are stronger than active memory traces for current information. Improvements in active memory abilities allow networks to overcome their prior biases when the task changes. Thus, perseveration may be understood in terms of neural specializations for different types of representations, which develop at different rates and compete with one another (see O'Reilly and Munakata, 2000, for further discussion of neural/computational trade-offs and their behavioral consequences).

Why do the models show task-dependent perseveration? As in the object permanence model, the strengthening of active representations is not an all-or-nothing process; these representations are graded in nature. The models can use weak active representations for certain tasks but not for others. For example, a network can use a weak active representation of a new card sorting rule to answer questions about the rule ("Where do trucks go in the shape game?"), because there is no competition from latent representations (e.g., to sort by color) in this task. No conflict needs to be resolved to answer this question, so weak representations suffice. In contrast, the network cannot use such weak representations to sort cards correctly. The inherent conflict in the sorting task (e.g., a card is both red and a truck) requires the active representation of the new rule to be strong enough to overcome the latent bias toward the old rule.

Similarly, a network can use weak memories for a toy's current hiding location for some tasks (gazing at the correct location) but not for others (reaching to the correct location). In this case, the gazing system updates more frequently than the reaching system (reflecting the general difference between these systems in infants, as well as in how often infants are allowed to use them in the typical toy-hiding task). Networks can thus gaze successfully with relatively weak memories, because they can update their gaze to the proper location frequently, thereby countering perseverative tendencies. In contrast, networks require stronger memories to reach to the correct location, because longer delays pass before they update their reaching, by which time they have become more susceptible to perseverative biases.

## Discussion

Connectionist models have thus addressed several key issues in the study of cognitive development—the origins of knowledge, the mechanisms of change, and the task-dependent nature of developing knowledge—across a variety of domains (see also LANGUAGE ACQUISITION; PAST TENSE LEARNING; and DEVELOPMENTAL DISORDERS). In each case, the models provided explicit instantiations and controlled tests of specific theories of development, and allowed the exploration of complex, emergent phenomena. As a result, these models have provided insight into how sophisticated object-processing mechanisms might develop in the first months of life, why we might have critical periods for learning language, how some problem-solving skills can progress in stages, and how we can simultaneously pass and fail different measures of memory and rule use.

Many challenges remain, however, for connectionist models to provide more complete accounts of cognitive development. Two important areas for advancement are the following:

1. *Models that shape their environments.* Most connectionist models are "fed" their inputs, activity pattern after activity pattern, regardless of what they output. For example, language learning models hear sentence after sentence, no matter how poorly the models do in their comprehension. Similarly, models see the same objects in their environments regardless of how they behave toward the objects. Quite in contrast, even very young children shape their environments based on how they behave. For example, infants who reach for objects receive different

sensory information about the objects than infants who simply gaze at the objects. Children who show more advanced language skills may shape the ways in which caregivers speak to them. Capturing these important aspects of development requires models that shape their environments, such that their behaviors influence their subsequent inputs (e.g., Schlesinger and Parisi, 2001).

2. *Models that are more all-purpose*. Most connectionist models are designed for and tested on a single task within a single domain, such as the balance-scale task or the task of searching for hidden objects. A single model sees only this single task during the course of its development. Again, quite in contrast, children face a multitude of tasks across a range of domains each day. Capturing this important aspect of processing requires models that take in a variety of types of information and determine how to appropriately process them to perform successfully across a number of tasks (Karmiloff-Smith, 1992).

These kinds of developments in modeling, together with further explorations of the origins of knowledge, mechanisms of change, and task-dependent behaviors, should help to advance our understanding of fundamental issues in cognitive development.

# Cognitive Maps

*Nestor A. Schmajuk and Horatiu Voicu*

## Introduction

According to Tolman (1932), animals acquire the *expectancy* that the performance of response R1 in a situation S1 will be followed by a change to situation S2 (S1-R1-S2 expectancy). Tolman hypothesized that a large number of local expectancies can be combined, through inferences, into a *cognitive map*. Tolman proposed that place learning, latent learning, detours, and shortcuts illustrate animals' capacity for reasoning by generating inferences. In place learning, animals learn to approach a given spatial location from multiple initial positions, independently of any specific set of responses. In latent learning, animals are exposed to a maze without being rewarded at the goal box (Figure 1). When a reward is later presented, animals demonstrate knowledge of the spatial arrangement of the maze, which remains "latent" until reward is introduced. Detour problems are those in which animals have to take an alternative, longer path to the goal. Shortcuts are those problems in which animals can take an alternative, shorter path to the goal.

When seeking reward in a maze, organisms compare the expectancies evoked by alternative paths. For Tolman, *vicarious trial-and-error behavior*, i.e., the active scanning of alternative pathways at choice points, reflects the animal's generation and comparison of different expectancies. At choice points, animals sample different stimuli before making a decision. For example, a rat often looks back and forth between alternative stimuli before approaching one or the other. According to Tolman's *stimulus-approach* view, organisms learn that a particular stimulus situation is appetitive, and therefore it is approached. It has been suggested that, in the presence of numerous intra- and extramaze cues, animals typically learn to approach a set of stimuli associated with reward and to avoid a set of stimuli associated with punishment. However, in a totally uniform environment, animals learn to make the correct responses that lead to the goal.

## Maze Learning

Deutsch (1960) presented a formal description of cognitive mapping that incorporates many of Tolman's cognitive concepts. Deutsch assumed that when an animal explores a given environment, it learns that stimuli follow one another in a given sequence. Internal representations of the stimuli are linked together in the order the stimuli are encountered by the animal. Deutsch suggested that a given drive activates its goal representation, which in turn activates the linked representations of stimuli connected to it. When the animal is placed in the maze, it searches for stimuli stimulated by the goal representation. When a stimulus activated by the goal

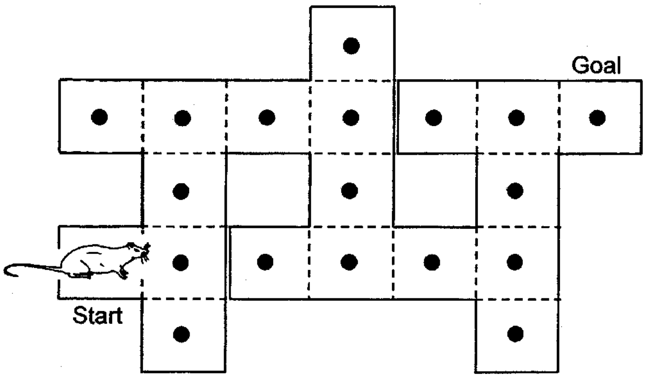

**Figure 1.** Latent learning. Schematic top view of a multiple T-maze. Places used in Figure 3 are represented by squares in broken lines, with the centers indicated by solid circles.

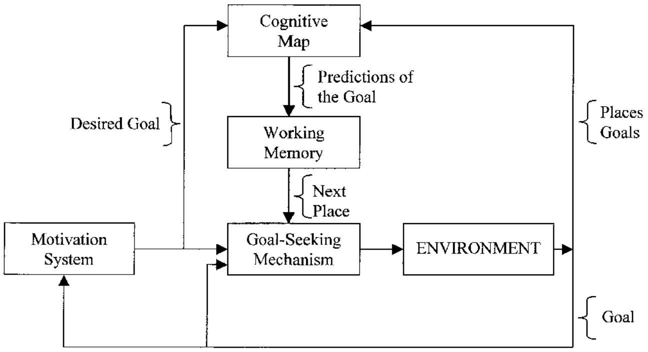

**Figure 2.** The model. Interactions between the motivation system, cognitive map, working memory, goal-seeking mechanism, and environment. (After Voicu and Schmajuk, 2001a.)

is perceived, the activation of lower stimuli in the chain is cut off, and behavior is controlled by the stimulus that is closer to the goal. Deutsch's theory can account for latent learning in the following terms. When animals are exposed to the maze without being rewarded at the goal box, they learn about the connections between different places in the maze. When a reward is subsequently presented, activation of the goal representation activates the representations of the stimuli connected to it.

Milner (1960) proposed a system capable of building a Tolmanian spatial map and of using it to control the animal's movements in a spatial environment. The model has nodes that are active only when a particular response ($R_i$) has been made in a particular location ($S_j$). The output of these nodes can be associated with nodes representing the location ($S_k$) that results from making response $R_i$ at location $S_j$. When the organism is placed in location $S_j$, random responses are generated. When response $R_i$ appears, the node with inputs $S_j$ and $R_i$ is active and, in turn, activates the node representing $S_k$. If $S_k$ is associated to an appetitive stimulus, it activates a mechanism that holds $R_i$ in the response generator, and location $S_k$ can be reached. Some views of hippocampal function (e.g., McNaughton, 1989) suggest that $S_j$-$R_i$-$S_k$ associations would be stored in the hippocampus (see Hippocampus: Spatial Models).

Lieblich and Arbib (1982) addressed the question of how animals build a cognitive model of the world. Lieblich and Arbib posited that spatial representations take the form of a directed graph in which nodes represent *recognizable situations* in the world. In Lieblich and Arbib's scheme, a node represents not only a place, but also the motivational state of the animal. Consequently, a place in the world might be represented by more than one node if the animal has been there under different motivational states. Lieblich and Arbib postulated that each node in the world graph is labeled with *learned* vectors, **R**, that reflect the drive-reduction properties for multiple motivations of the place represented by that node. Based on the value of **R**, the animal moves to the node most likely to reduce its present drive. More recently, Guazelli et al., (1998), following O'Keefe and Nadel's (1978) notions, integrated the world graph model, used for map-based navigation, with a "behavioral orientation" model, used for route navigation, in order to explain experimental data in normal and fornix-lesioned rats.

Hampson (1990) analyzed maze navigation in terms of a model that combines stimulus-response and stimulus-stimulus mechanisms into a system capable of assembling action sequences in order to reach a final goal.

Schmajuk and Thieme (1992) presented a real-time, biologically plausible neural network approach to purposive behavior and cognitive mapping. This biologically plausible theory includes (1) an action system, consisting of a goal-seeking mechanism with goals set by (2) a motivation system; (3) a cognitive system, in which a neural network implements a cognitive map; and (4) a working memory, where the readings of the cognitive map are temporarily stored (Figure 2).

The goal-seeking mechanism in the action system changes from exploratory behavior to approach behavior when either (1) the goal is found or (2) one place in the cognitive map generates a prediction of the goal that is stronger than the predictions generated by all other alternative places.

The cognitive map is a *topological map* that represents the adjacency, but not distances or directions, between places, as well as the associations between places and goals. Figure 3 shows a heteroassociative network (Kohonen, 1977) capable, through recurrent connections, of cognitive mapping. The network includes three types of inputs: current places, neighboring places, and goals. Cur-

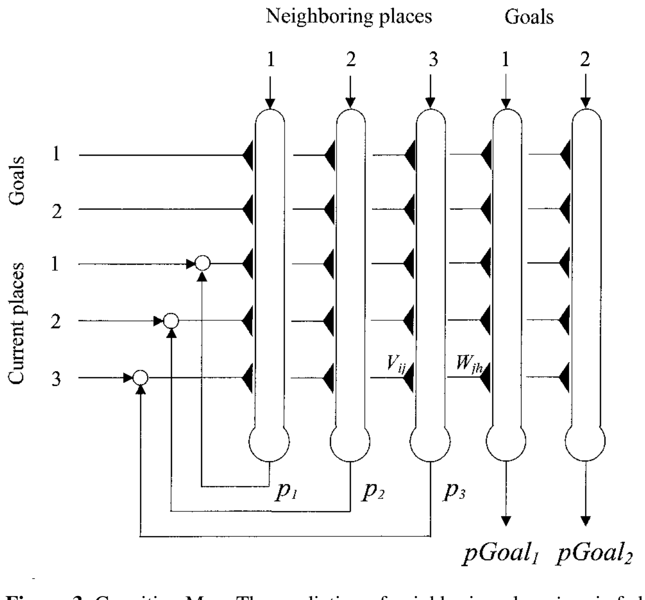

**Figure 3.** Cognitive Map. The prediction of neighboring place *j*, *p*; is fed back into the neuron representing place *j* as a current place. $V_{ij}$: association between place *i* and place *j*. $W_{hi}$: association between goal *h* and place *i* $W_{ih}$: association between place *i* and goal *h* $g_h$: activation of goal *h*. Arrows denote fixed excitatory connections; triangles denote variable excitatory connections. (After Voicu and Schmajuk, 2001a.)

rent places and neighboring places are defined by a system that determines the position of the animal in space. Goals represent a feature (e.g., food, unexamined places) that, under the appropriate motivation (e.g., hunger, exploration), the agent wants to approach.

Associations between place *i* and place *j*, $V_{i,j}$, are the elementary internal learned representations of the links in the external world. These associations are stored in modifiable synapses, indicated by triangles in Figure 3. Whereas a positive $V_{i,j}$ association means that place *j* can be accessed from place *i*, a positive $V_{j,i}$ association means that place *i* can be accessed from place *j*. In both cases, $V_{i,j} = V_{j,i} = 0$ mean that each place cannot be accessed from the other. At the beginning of the exploration, all adjacent places are assumed to be linked in the cognitive map (all $V_{i,j} = 1$). As the agent explores the environment, connections $V_{i,j}$ are modified in order to reflect the real environment. "Trodden" links between places are represented by stronger connections ($V_{i,j} = V_{j,i} > 1$) than unexplored links.

At the beginning of the exploration, each place is designated as "unexamined," $W_{j,\mathrm{GOAL}h} = W_{\mathrm{GOAL}h,j} = 1$. When place *j* can be accessed and occupied by the agent, it changes its status to "examined," $W_{j,\mathrm{GOAL}h} = W_{\mathrm{GOAL}h,j} = 0$, meaning that it is no longer a goal for exploration. When place *j*, adjacent to place *i* currently occupied by the agent, can be examined, place *j* also changes its status to examined, $W_{j,\mathrm{GOAL}h} = W_{\mathrm{GOAL}h,j} = 0$, even if it cannot be entered.

The cognitive map combines multiple associations $V_{i,j}$ to infer spatially remote locations. This is achieved by recurrently reinjecting the signal representing neighboring place *j* (as predicted by place *i* according to $V_{i,j}$) into the representation of current place *j*. Current place *j* now predicts neighboring place *k* according to $V_{j,k}$, and the signal representing neighboring place *k* is reinjected into the representation of current place *k*. At each reinjection, the signal representing a neighboring place is attenuated, for instance, in half. The process is halted when the representation of the remote position is eventually activated.

The network successfully describes how rats demonstrate latent learning, detour behavior, and place learning. In order to ascertain the power of the network in problem solving, Schmajuk and Thieme (1992) applied the network to the Tower of Hanoi task. Simulations show that the network takes a few trials to solve the problem in the minimum number of movements.

Schmajuk, Thieme, and Blair (1993) incorporated a route system to the network described by Schmajuk and Thieme (1992). Whereas the cognitive map stores associations between places and reward, the route system establishes associations between cues and reward. Both systems compete with each other to establish associations with the reward, with the cognitive system generally overshadowing the route system. In agreement with O'Keefe and Nadel (1978), after hippocampal lesions (see Hippocampus: Spatial Models), animals navigate through mazes by making use of the route system.

Recently, Voicu and Schmajuk (2001a, 2001b) introduced some modifications to the Schmajuk and Thieme (1992) model. First, whereas the early model assumed no a priori knowledge of the space to be explored, the modified model assumes a representation of the environment as a set of potentially connected and unexamined locations, each approximately the size of the footprint of the agent. Second, instead of random exploratory behavior, the model assumes that a curiosity drive guides the animal to examine all unvisited places. Third, whereas in the original model the decision of what place to move to next was based on a comparison of the predictions of the goal when each of the alternative places is briefly entered, in the new model this decision is based on a comparison of the activation of each of the alternative places when the goal is activated. This approach is similar to that described by Deutsch (1960) and subsequently used by Mataric (1991) and Reid and Staddon (1998). Fourth, the model differentiates between links that connect places but have not been traversed by the agent, and those that have. These links are part of what is referred to as "trodden path."

In addition to latent learning, detour behavior, and place learning, the new model (1) performs a thorough and efficient exploration of the environment, (2) describes shortcuts, and (3) generates novel predictions for a case in which animals have to circumvent an obstacle placed on their path to the goal and then either retake their usual route (detour) or advance directly to the goal (shortcut).

As mentioned above, in order to plan the shortest path between any two places, the model presented by Voicu and Schmajuk (2001a, 2001b) spreads activation between the representations of the goal and the current location of the animal. The resulting activities are stored in working memory. However, two problems might arise when navigating in a large environment. One, the capacity of working memory might be too small to store the activity of all intermediate places. Two, the attenuation suffered by the spreading activation is too large to reach the representation of the location of the animal. These potential problems call for the use of a hierarchical cognitive map (Voicu and Schmajuk, 2002).

In the hierarchical map, the environment is represented at multiple levels. At the highest level, the environment is divided in a number of regions equal to the size of working memory. The size of the working memory is such that the activation spreading through it can reach and activate the most remote spatial representations. At the lowest level, the environment is divided in parts equal in size to that of the footprint of the organism. Between the highest and the lowest level, each part of the previous level is divided in a number of parts equal to the size of the working memory. Path planning starts at the level that contains the points between which navigation is desired and ends at the lowest level, at which motion is produced.

According to the hierarchical cognitive model, and in agreement with experimental data, when information about the relationship between two places that belong to two different regions (e.g., Seattle and Montreal) is lacking, humans wrongly rely on the relation between the regions where those places are located (e.g., United States and Canada). Also in agreement with experimental results, the hierarchical cognitive model suggests that spatial memory is organized in a hierarchical fashion even when objects are uniformly distributed in space. Finally, experimental results suggest that hierarchical spatial representations support semantic priming, a result that the hierarchical model can explain in terms of one item activating the representation of a second one in the cognitive map, and therefore decreasing the response time to the second item.

## Discussion

In the last decades, Tolman's (1932) ideas about cognitive maps have been refined and given mechanistic embodiments. In recent models (e.g., Voicu and Schmajuk, 2001a), Tolman's vicarious trial-and-error behavior has been regarded as reflecting the animal's comparison, but not the generation, of different expectancies. Expectancies are generated by activating the representation of the location of the goal with the motivation system. That activation is subsequently spread over the cognitive map until the representation of the location of the agent becomes active. At choice points, animals make a decision after sampling the intensity of the activation elicited by the different alternative paths. Several models (Mataric, 1991; Reid and Staddon, 1998; Voicu and Schmajuk, 2001a) still use Tolman's stimulus-approach view and assume that animals approach the place with the strongest appetitive activation, thereby performing a gradient ascent toward the goal.

Interestingly, Tolman (1932, p. 177) suggested that the relations between initial and goal positions can be represented by a directed graph, and called this graph a means-end field. Current artificial intelligence theories describe problem solving as the process of finding a path from an initial to a desired state through a directed graph (see Competitive Queuing for Planning and Serial Performance).

In addition to storing the representation of the environment in terms of the contiguity between places (Schmajuk and Thieme, 1992), cognitive maps can store information about differences in height and in the type of terrain between adjacent places, contain a priori knowledge of the space to be explored (Reid and Staddon, 1998; Voicu and Schmajuk, 2001a), distinguish between roads taken and those not taken (Voicu and Schmajuk, 2002), and keep track of which places have been examined.

Schmajuk et al. (1993) used Kohonen's (1977) two-layer associative network to mechanistically implement the cognitive map. Networks with more than two layers can also be used to represent not only the contiguity between places, but also the relative position of those places.

Recently, Voicu and Schmajuk (2001b) introduced the idea of hierarchical cognitive maps in which the environment is represented at multiple levels. At each level, the environment is divided into a number of parts equal to the size of working memory. In contrast to their nonhierarchical counterparts, hierarchical maps can plan navigation in large environments, use a smaller number of connections in their networks, and have shorter decision times.

# Cognitive Modeling: Psychology and Connectionism

*Amanda J. C. Sharkey and Noel E. Sharkey*

## Introduction

Connectionism has had a major impact on psychology and cognitive modeling. In the next section we consider this influence, identifying four typical features of connectionist models of cognition:

1. They can be used both to model cognitive processes and to simulate the performance of tasks.
2. Data analogues can be derived from the models in such a way as to provide a good fit to data from cognitive psychology experiments.
3. Unlike traditional computational models, connectionist models are not explicitly programmed by the investigator.
4. They encourage the development of new accounts of empirical data.

Having identified these features, we point out that although the connectionist stance has some real benefits, it would be unwise to assume that it has been fully developed. There are aspects of it that still need to be understood and clarified. For instance, establishing equivalences between the performance of a net and the tasks it simulates involves a number of assumptions. At the same time, important aspects of the performance of a connectionist net are controlled by the researcher, by means of *extensional programming*. In particular, decisions are made about the selection and presentation of training data. This means that the achievement of a good fit to the psychological data depends both on the way in which analogues to the data are derived and on the results of extensional programming. Nonetheless, a major advantage of a connectionist approach to the modeling of psychological processes is that it has encouraged the development of new accounts of old data in a number of domains.

We subsequently consider the potential of connectionist computation for the development of a new theory of cognition. Rather than modeling the details of psychology experiments, the research efforts of a new breed of "cognitive connectionists" have been directed toward computational experiments. These experiments have demonstrated the ability of connectionist representations to provide a viable and different account of important characteristics of cognition (compositionality and systematicity), previously assumed to be the exclusive province of the classical symbolic tradition. Although connectionism has only an abstract relationship to neural processing, the promise here is that the use of brain-style computation will enable steps to be taken toward a unified account of how a mind emerges from a brain. Of course, it is not yet known whether connectionism will ultimately be able to account for all aspects of cognition. We discuss the likelihood that a more complete connectionist account of cognition will almost certainly involve the coordination of connectionist modules, and we point to the beginning of a debate over the extent to which such coordination requires a classical architecture or could be accomplished in a purely connectionist manner.

## Models of Cognition

In 1986, a two-volume edited work by McClelland and Rumelhart presented a number of connectionist models of different aspects of cognition that had been *trained* by exposure to samples of the required tasks. This work was indebted to earlier pioneering neural network research related to cognitive processing and memory (e.g., Anderson, 1972), but it was these two volumes that set the agenda for connectionist cognitive modelers and offered a methodology that has become the standard. Connectionist cognitive models are now legion. The domains that have been simulated include, in memory, retrieval and category formation; in language, phoneme recognition, word recognition, speech perception, acquired dyslexia, and language acquisition; and in vision, edge detection and object and shape recognition.

In this article we have chosen to discuss only supervised learning techniques, as these techniques have been most commonly used in connectionist cognitive modeling. In the simplest case of supervised learning, a net consists of a set of input units, a layer of hidden units, and a set of output units, each layer being connected to the next via modifiable weights. This is a feedforward net. When the net is trained on a set of input-output pairs, the weights are adjusted via a learning algorithm (e.g., backpropagation) until the required output is produced in response to each input in the training set. When tested on a set of previously unseen inputs, the net will, to a greater or lesser extent, display an ability to generalize, that is, to go beyond the data it was trained on, and to produce an appropriate response to some of the test inputs. The ability of the net to generalize depends on the similarity between the function extracted as a result of the original training and the function that underlies the test set. If the training set was sufficiently representative of the required function, generalization results are likely to be good. Where the inputs and outputs of such a net are given an interpretation relevant to the performance of a cognitive task, the net may be seen as a model of that task.

In addition to their basic architecture and mode of operation, it is also possible to identify four typical features of connectionist models of cognition that, in combination, account for much of the popularity of the approach they exemplify: (1) They can be used both to model mental processes and to *simulate* the actual behavior involved. (2) They can provide a "good fit" to the data from psychology experiments. (3) The model, and its fit to the data, is achieved without explicit programming, or "handwiring." (4) They often provide new accounts of the data. We discuss each of these features in turn.

The first two features, namely, the way in which connectionist nets can both provide a model of a cognitive process and simulate a related task, and their ability to provide a good fit to the empirical data, combine some of the characteristics of two earlier routes to modeling. One of these routes, taken by the cognitive psychology community, involved building models that could account for the results from psychology experiments with human subjects but did not incorporate simulations of experimental tasks. The second route, followed by the artificial intelligence (AI) community, was to build computer models that actually performed the task in ways that resembled human performance, without regard to detailed psychological evidence. The connectionist approach, as described here, provides the benefits both of simulating the performance of human tasks and, at the same time of fitting the data from psychological investigations.

As an example of the latter, consider Seidenberg and McClelland's (1989) model of word pronunciation. This model simulates a number of experimental behaviors, including pronunciation of novel items, differences in performance on lexical decision and naming tasks, and ease of pronunciation in relation to variables such as frequency of occurrence, orthographic redundancy, and orthographic-phonological regularity. At the same time, the model is generally accepted as providing a good fit to the experimental data. This is achieved by deriving an analogue to the data from the performance of the model. In the case of Seidenberg and McClelland's account of lexical decisions, the comparison with lexical decision data is accomplished by computing an "orthographic error score," based on the sum of squares of the differences between the feedback pattern computed by the network and the actual input to the orthographic units. Here a low error score is equated with a fast reaction time. Others have assumed different data analogues. For example, Plaut et al., (1996) present an attractor network that accounts for latency data in time to settle on a response.

The third typical feature of connectionist models of cognition is that the model and its fit to the data are achieved without explicit handwiring. This feature can be favorably contrasted to the symbolic programming methodology employed in AI, where the model must be programmed step by step, leaving room for ad hoc modifications and kludges.

The fourth feature, perhaps the most scientifically exciting, is the possibility of providing a novel explanation of the data. In their model of word pronunciation, Seidenberg and McClelland (1989) showed that their network provided an integrated (single mechanism) account of data on both regular and exception words; by contrast, the old cognitive modeling conventions had forced an explanation in terms of a dual route. A criticism of the Seidenberg-McClelland model was that it failed to provide an account of the reading of nonwords. However, a more recent formulation of the model (Plaut et al., 1996) shows that a single mechanism is able to provide an account of the basic patterns of word and nonword reading within a single mechanism. (See Christiansen, Conway, and Curtin, 2000, for a more recent example of a connectionist model that exhibits rule-like behavior from a single mechanism.)

On first consideration, the four features discussed above seem to provide support in favor of a connectionist approach to cognitive modeling, as opposed to the approaches taken in the two preceding routes to cognition, by AI and cognitive modelers. When the result has been the development of new, and simpler, accounts of the data, there are obvious benefits. The connectionist approach would also seem to be preferable to more symbolic approaches inasmuch as it makes it possible both to simulate the tasks and to provide a good fit to the data, and to do this without having to program these abilities in hand. However, we must tread warily here in claiming a clear distinction between the connectionist approach and those that preceded it.

Let us first reexamine the idea that connectionist network models are not explicitly programmed by hand. Although this statement is strictly true, a number of decisions that affect the subsequent performance of the model still have to be made by the researcher. The following factors, for example, both govern the creation of a model and are in the hands of the researcher: (1) the architecture of the net and its initial structure, (2) the learning technique, (3) the learning parameters (e.g., the learning rate), (4) the input and output representations, and (5) the training sample. The term *extensional programming* can be used to refer to the manipulation of these factors. By means of extensional programming, the clever experimenter can determine the ultimate form of a model and hence its performance in terms of any data set.

Control of the content and presentation of the training sample is an important aspect of extensional programming. Its potential influence on the performance of a connectionist model can be illustrated by considering some of the criticisms of McClelland and Rumelhart's past tense model (see PAST TENSE LEARNING). Their model is said to mirror several aspects of human learning of verb endings. However, Pinker and Prince (1988) pointed out that the experimenters had unrealistically tailored the environment to produce the required results and that the results were an artifact of the training data. More specifically, the results indicated a U-shaped curve in the rate of acquisition, as occurs with children, but, Pinker and Prince argued, this curve occurred only because the net was exposed to the verbs in an unrealistically structured order. These criticisms have largely been answered by further research, but the point remains. Selection of the input, and control of the way that it is presented to the net, affect what the net learns. A similar argument can be made about the selection of input representations. Plaut et al. (1996), in their model of normal and impaired word reading, explicitly discuss the role of their chosen input representation in achieving their results, claiming that is the change in input representation from the earlier Seidenberg and McClelland model that accounts for an improved ability to handle nonword data.

If the performance of a connectionist net is determined by its extensional programming, this means that there are a number of parameters that can be altered until a good data fit is achieved. Moreover, accepting that a good fit to the data has been achieved requires accepting a number of other assumptions about the way that the relevant tasks have been simulated, the consequent way that analogues to the data have been derived from the performance of the model, and so on. Thus, when a model is said to explain the empirical data from lexical decision tasks, the model does not actually perform a lexical decision task as humans do, outputing a yes when the input is a word and a no when it is not. An equivalence must be drawn between the task as it is performed by humans and the actual input-output relationships encoded by the net. In fact, the actual task in question is rarely performed by the model. What is performed is often something that approximates the task and is assumed to capture its essential characteristics. Thus, in a model of word pronunciation, the output of the model does not take the form of spoken words but rather a set of phonological features. Here the approximation is fairly straightforward, but in other cases the relationship is less obvious. Ratcliff (1990), for instance, equates the phenomenon of "recognition memory" with that of auto-association, assuming that the ability of a net to reproduce its inputs as outputs corresponds to the human ability to recognize inputs that have been seen before.

From the foregoing discussion it is apparent that some of the advantages of connectionist models of cognition are not entirely straightforward. Nonetheless, their potential for developing new accounts that go beyond the data is an important justification for their employment. Much of the excitement in the psychology community has been about their ability to handle apparently rule-governed phenomena without any explicit rules, and in particular to account for the processing of regular and exceptional material. For example, learning to produce the appropriate past tense form of verbs was always considered a rule-governed phenomenon until McClelland and Rumelhart (1986) showed that the behaviors could be trained in a model that did not contain any explicit rules. The different style of computation afforded by connectionism has also been the focus of much debate. The issue being debated is the extent to which connectionism is able to support the operations required of a theory of mind, namely, structure-sensitive operations. This debate is examined in the next section.

## An Emerging Theory of Cognition

The past two decades saw considerable discussion about whether or not the new connectionism actually constituted a paradigm shift. Whatever the eventual outcome of this discussion may be, it is clear that the adoption of connectionist modeling techniques has led to changes. One such change has been the emergence of a new breed of cognitive modelers who are concerned to explore the implications of connectionist computation for a new theory of cognition, with the ultimate aim of providing an account of the way in which a mind emerges from a nervous system. The methodology employed by these "cognitive connectionists" represents a move away from the detailed modeling of cognitive psychology experiments toward more abstract computational experimentation. This should broaden the scope of their investigations, for although there are benefits to models that provide a new explanation of a wide spectrum of data, the maintenance of a close relationship between model and data can limit investigations to previously identified questions from an older paradigm.

The promise of a new connectionist theory of cognition is that it will further our understanding of the relationship between brain and mind. However, this does not necessarily mean that such a theory will incorporate details of neural processing. It is important to make a clear distinction between the use of *brain-style* computation and neuropsychological modeling. Although connectionist models are sometimes described as being "neurally inspired," their relationship to neural processing is delicate and tenuous. In a model of cognitive processes, it is unlikely that the computation performed corresponds to what goes on at the neural level. Indeed, it has been suggested (Edelman, 1987) that it may take units on the order of several thousand neurons to encode stimulus categories of significance to animals. Clearly, when the inputs to a net are entities like noun phrases or disease symptoms or even the phonological representations of words, the inputs cannot be equated with neural inputs but must represent substantially preprocessed stimuli. In fact, there are few cases in which actual facts about the nervous system are used to constrain the architecture and design of a model. It is, of course, important to build computational models of real brain circuits in all of their glorious detail. But if one is concerned with cognition rather than with the details of neural processes, an appropriate research strategy is to use broader brush strokes, relying on computational abstractions.

In support of a movement away from the details of neurophysiology and away from psychology experiments, we can cite an example of progress from the history of connectionism itself. Arguably, it was two major simplifying assumptions made by McCulloch and Pitts that enabled them to develop their theoretical analyses without getting bogged down in the physical and chemical complexity of the nervous system. Their first simplification was based on the observation that neural communication is thresholded, and thus the spike activation potential is all or none: it either fires or does not fire. Thus, the neuron could be conceived of as a binary computing device. The second simplification was to view synapses as numerical weightings between simple binary computing elements. This meant that computation proceeded by summing the weighted inputs to an element and using the binary threshold as an output function (see Sharkey and Sharkey, 1994, for historical details). The position of the cognitive connectionist described here is therefore that we can best proceed by being constrained by simplifying but principled assumptions about neural computation and cognition.

Nonetheless, if the use of connectionist computation, as opposed to symbolic computation, is to lead to the development of a new theory of cognition, connectionist computation must first be shown to be capable, in principle, of supporting higher mental processes, and to do so in a novel manner; mere implementation of symbolic architectures will not do. The question of whether or not connectionism is capable of supporting a cognitive architecture has mainly been addressed in the context of discussions about the novelty and value of connectionist representation. This question is considered below. (See also Structured Connectionist Models; Connectionist and Symbolic Representations; Compositionality in Neural Systems.)

One of the properties of uniquely connectionist representations, as identified by N. E. Sharkey (1997), is that they are distributed and nonsymbolic. Proponents of the classical symbolic tradition have claimed that such representations are in principle incapable of supporting a cognitive architecture, because in order to account for the systematic nature of human thought, representations must be able to support structure-sensitive processes, and this requires compositional representations. The assumption is that there is only one kind of compositionality, namely, the concatenative compositionality of symbolic strings. This permits structure-sensitive operations, because in their mode of combination, the constituents of complex expressions are tokened whenever the complex expression is tokened. For example, in order to develop an expression from a sentence like "John kissed Mary," arbitrary symbols representing the constituents JOHN, KISSED, and MARY are combined in a contextually independent concatenation to produce the propositional representation KISS (JOHN, MARY). Whenever this latter complex expression is tokened, its constituents, KISS, MARY, and JOHN, are also tokened. This makes the manipulation of the representations by a mechanism sensitive to the syntactic structure resulting from concatenative compositionality relatively easy.

Distributed representations, on the other hand, do not exhibit this kind of compositionality. Instead, cognitive connectionists have identified an alternative form of compositionality, one that has been described as merely functional, nonconcatenative compositionality (see Compositionality in Neural Systems). Distributed representations combine tokens without those tokens appearing in the complex expression, since the tokens of the input constituents are destroyed in their combination. The point is that such representations can still be shown to be *functionally* compositional, because there exist general and reliable procedures for combining constituents into complex expressions and for decomposing those expressions back into the constituents. It is possible, for example, to encode simple syntactic trees in terms of connectionist distributed representations, and to decode them back into the same syntactic trees (Pollack, 1990). Thus the constituents of the tree have been combined into a form of representation that is nonconcatenative but that preserves the necessary information.

A considerable and growing body of research has shown that not only are distributed representations compositional, they can also enable *systematic* structure-sensitive operations. Chalmers (1990), for example, found that it was possible to use connectionist nets to transform distributed representations for active sentences into distributed representations for passive sentences. Thus, distributed representations allow at least a limited form of systematicity without emergence onto the symbol surface. Moreover, this is not just an example of old wine in new bottles, a mere implementation of the classical account. These uniquely connectionist representations operate in a different manner.

N. E. Sharkey (1997) describes seven major properties of uniquely connectionist representations. In addition to properties that overlap with those we identified earlier in this article, he identifies a further property of uniquely connectionist representations: namely, they are reusable, or portable, for other tasks. This property has been demonstrated in a number of cognitive tasks, such as Chalmers' (1990) active-passive transformations, and more recently in a control task. N. E. Sharkey (1997) reports the development of a disembodied arm control system in which the connectionist representations that had been developed as a result of training a net to output transformationally invariant position classes were reused as input to a net trained to direct a mobile robotic arm to pick up objects.

There is ongoing debate over the extent to which connectionism is capable of supporting a new style of cognitive architecture. The arguments in favor stress the capability of connectionist representations for both compositionality and systematicity, that the representations are resuable for other tasks, and that they accomplish these properties by different means than those of classical symbolic representations. Opponents stress the problems connectionists have in dealing with structured representations and expressing relationships between variables, and our ability to immediately follow a linguistically expressed rule (see Marcus, 2001). However, it should be noted that although it can be argued that connectionist representations can support structure-sensitive operations, or that connectionist nets can process regular and exception material within a single mechanism, it does not necessarily follow that the connectionists assume that the brain should be modeled as a unitary mechanism. There are a number of reasons for assuming that connectionist modeling of more complex cognitive functions will require some degree of modularization. For instance, there is the observed difficulty of training a net to perform two unrelated tasks at the same time, and concomitantly the advantages often observed in terms of performance when a task is modularized (A. J. C. Sharkey, 1999).

It seems likely that future connectionist research will have to attend to issues of modularity and the control and coordination of distinct connectionist modules. This research area is receiving increasing attention in the field of behavior-based robotics (see Reactive Robotic Systems; Biologically Inspired Robotics), where the challenge is not only to coordinate modules but also to provide an account of the way in which distinct modules, and the representations they employ, emerge in the first place (N. E. Sharkey, 1998). A related classical versus connectionist debate may also surface here, regarding the extent to which the coordination of modules requires a classical architecture (Hadley, 1999) or can be achieved without resource to a central executive (N. E. Sharkey, 1998).

## Discussion

This article began by outlining the main characteristics of connectionist models of cognition. Two of the main apparent advantages of connectionist models are (1) their ability to both model and simulate empirical data, and (2) their ability to do so without being explicitly programmed. These features segregate connectionist models from the earlier models of cognitive psychologists, who modeled the data without simulating the tasks involved, and from AI models, which are explicitly programmed and which simulate behavior without regard to the details of psychological evidence. On further reflection, however, the distinction between connectionist models and earlier approaches becomes less clear. Obtaining a good fit to the data relies on a number of assumptions and is not, as is sometimes supposed, achieved without experimental intervention. The researcher must make a number of decisions that determine the performance of the model. We introduced the term extensional programming to refer to these decisions, which include the selection of the training set and its manner of presentation. Nonetheless, even if there are some aspects of connectionist models that bear further consideration, it is still the case that the novel style of computation they embody often encourages the development of new accounts of previously investigated data.

Subsequently we considered the ability of connectionism to support a new theory of cognition. Cognitive connectionists, are more concerned to exploit the implications of connectionist computation than to provide detailed models of psychological data. An important issue for the cognitive connectionist is the notion of connectionist representation. It has been claimed that connectionist representations are in principle incapable of supporting an account of higher mental processes. To counter this claim, computational experiments have been conducted with the aim of demonstrating that connectionist representations have a complex internal structure, capable of fulfilling the requirements for a cognitive architecture.

Connectionist representations have been shown to be capable of much of the systematicity and compositionality required of them by their critics. They do not merely implement symbolic computation but operate in a novel manner. Whether it will be possible to provide a connectionist account of all aspects of cognition remains to be seen. An important issue to be addressed is that of modularity, in particular the extent to which the coordination of distinct modules implies a classical architecture or can be accomplished in a uniquely connectionist manner.

# Collective Behavior of Coupled Phase Oscillators

*Yoshiki Kuramoto*

## Introduction

Certain aspects of brain functions seem largely independent of the neurophysiological details of the individual neurons and their interconnections. The phase oscillator model for neural populations, like other neural network models, relies on this anticipation, still trying to recover the *phase information* that has been ignored by conventional models using all-or-none threshold elements. Here, phase information means the kind of information encoded in the form of specific temporal structures of the sequence of neuronal spikings that the real brain should make full use of. In this article, we present a brief survey of the collective behavior of coupled oscillators using the phase model and assuming all-to-all type interconnections. With these mathematical simplications, a number of definite results can be obtained. Because such a model could be too idealistic for practical purposes, we will not try to interpret the types of behavior obtained as relevent to specific brain activities.

Within the above restrictions on the model, the variety in collective behavior exhibited is still great. We will particularly be concerned in this article with the onset and persistence of *collective oscillation* in frequency-distributed systems; splitting of the population into a few subgroups, called *clustering*; and the more complex collective behavior called *slow switching*. It turns out that knowing the type of phase coupling between an interacting pair of oscillators is helpful for interpreting the resulting collective behavior. In the final section, a few remarks are provided on the limitations of the present model.

## Phase Model

By suitably defining the phase $\phi$ (mod $2\pi$) on the limit-cycle orbit of a given oscillator, its free motion can always be described by $\dot{\phi} = \omega$. When weak coupling is introduced between a pair of identical oscillators 1 and 2, each described by $\dot{\phi}_{1,2} = \omega$, phase reduction theory (Kuramoto, 1984) tells that these equations are modified as

$$\dot{\phi}_1 = \omega + \Gamma_{12}(\phi_1 - \phi_2) \tag{1}$$

combined with the similar equation for oscillator 2, where the coupling functions $\Gamma_{ij}(x)$ are $2\pi$-periodic. What is important here is that the coupling depends only on the phase difference. Whenever necessary, $\Gamma_{ij}(x)$ can be computed numerically from knowledge of the original dynamical system model for the coupled oscillators.

The above argument can easily be generalized to systems of slightly nonidentical oscillators by replacing $\omega$ with $\omega + \delta\omega_{1,2} \equiv \omega_{1,2}$. Thus, a general network of $N$ similar oscillators with pairwise coupling reduces to

$$\dot{\phi}_i = \omega_i + \sum_{j=1}^{N} \Gamma_{ij}(\phi_i - \phi_j) \tag{2}$$

This model, possibly with generalizations by including systematic and/or random forcing terms, provides a canonical model for oscillator networks.

Whether or not the weak coupling assumption is valid, the phase model has also been used as a convenient phenomenological model for the study of visual processing, motor control, and other life processes (Cohen, Holmes, and Rand, 1982; Ermentrout and Kopell, 1984; Sompolinsky et al., 1991).

## Types of Phase Coupling

Phase coupling functions can be classified into a few basic types, and they lead to qualitatively different dynamics of a coupled pair. Assuming that the coupling is symmetric, or $\Gamma_{12}(x) = \Gamma_{21}(x) \equiv \Gamma(x)$, we obtain the equation for the phase difference $\psi \equiv \phi_1 - \phi_2$ in the form

$$\dot{\psi} = \Delta\omega + \Gamma_a(\psi) \tag{3}$$

where $\Delta\omega = \omega_1 - \omega_2$ and $\Gamma_a(\psi)$ is twice the antisymmetric part of $\Gamma(\psi)$, i.e., $\Gamma_a = \Gamma(\psi) - \Gamma(-\psi)$. Note that $\Gamma_a(x)$ satisfies $\Gamma_a(0) = \Gamma_a(\pm\pi) = 0$. When the oscillators are identical ($\Delta\omega = 0$), there are three typical situations (Figure 1). For type A coupling, $\Gamma'_a(0) < 0$ and $\Gamma'_a(\pm\pi) > 0$, so that the phase-synchronized state $\psi = 0$ is stable, while the antiphase state $\psi = \pm\pi$ is unstable. This form of coupling is called *in-phase type*. For type B coupling, in contrast, we have $\Gamma'_a(0) > 0$ and $\Gamma_a(\pm\pi) < 0$, so that the coupling is called *antiphase type*. For type C coupling, both the in-phase and antiphase states are unstable, while the phase difference is locked at some intermediate value. We will call this *out-of-phase type* coupling. More complicated situations are possible where multiple values of $\psi$ become stable.

When the oscillators are nonidentical, each $\dot{\psi}$ versus $\psi$ curve in Figure 1 will be shifted upward or downward, so that the stable value of $\psi$ also changes. Clearly, outside a certain range of $\Delta\omega$, no fixed point can exist. Then the oscillators fail to synchronize, and the system as a whole exhibits quasi-periodic motion with two independent frequencies, their difference being given by the long-time average of $\dot{\psi}$. Numerical computation of $\Gamma_a$ for some neural oscillator models in a self-oscillatory regime assuming diffusive or pulsatile coupling suggests that any of these three types of coupling is possible in real neural systems. It is remarkable that type C coupling can be obtained for self-oscillatory Hodgkin-Huxley neurons with excitatory synaptic coupling (Hansel, Mato, and Meunier, 1993a).

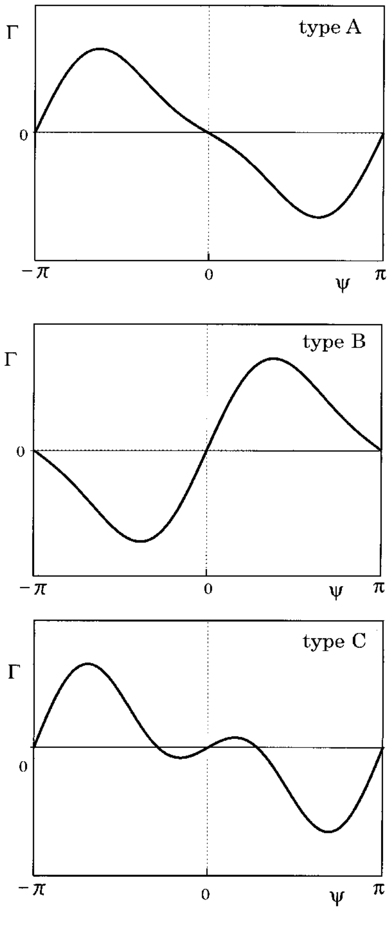

**Figure 1.** Three types of phase coupling functions.

Neural oscillators are often modeled with the so-called leaky integrate-and-fire (LIF) neurons. In order to see the connection of this model to the phase model (Kuramoto, 1990), let a LIF neuron be described with variable $u$ ($0 \le u \le 2\pi$), and identify the states $u = 0$ and $2\pi$ just as we did for the phase variable. The intrinsic dynamics of this neuron is such that $u$ is monotone increasing with $t$, so that when $u$ reaches the level $u = 2\pi$, it is immediately reset to the zero value. This instant is interpreted as the time of firing. Specifically, $u$ is supposed to obey the equation

$$\dot{u} = a - u \tag{4}$$

Obviously, the neuron repeats firing if $a > 2\pi$, while it is nonoscillatory but only excitable when $a < 2\pi$. As for coupling with another LIF neuron, the usual assumption is that $u$ changes by a small amount $\varepsilon$ each time $t_n (n = 1, 2, \ldots)$ the second neuron fires. The coupling is excitatory if $\varepsilon > 0$ and inhibitory otherwise. This dynamical rule is conveniently represented by the term $\varepsilon\Sigma_n\delta(t - t_n)$ added to the right-hand side of Equation 4.

In the self-oscillatory regime ($a > 2\pi$), the natural frequency is given by $\omega = 2\pi/|\ln(1 - 2\pi/a)|$. It can be shown that the network of self-oscillatory LIF neurons with weak coupling is equivalent to that of phase oscillators given by the form of Equation 2 with the coupling function $\Gamma(\psi) = \varepsilon\omega a^{-1}\exp(\psi/\omega)$ ($0 \le \psi < 2\pi$). Note that $\Gamma(\psi)$ has a discontinuity at $\psi = 0$. It is easy to check that for positive (negative) $\varepsilon$, the in-phase (antiphase) state gives a unique and strongly stable state.

Throughout the subsequent sections, the coupling will be assumed to be pairwise and symmetric, belonging to either A, B, or C type.

## Collective Oscillation

The collective behavior of coupled phase oscillators differs drastically for different coupling types. If the coupling is of the in-phase type and the oscillators are identical, then the whole assembly is in perfect phase synchrony, behaving as a single giant oscillator.

Many examples of collective oscillations in living and nonliving systems are known (Pikovsky, Rosenblum, and Kurths, 2001). With respect to sensory processing in the brain, in particular, collective synchronization may play a crucial role in the linking of sensory inputs across multiple receptive fields (Gray & Singer, 1998; Malsburg and Schneider, 1986). There are some studies on the last topic using the phase oscillator model (Sompolinsky et al., 1991).

Collective oscillations, if functionally relevant at all, should persist robustly against random perturbations from various sources, as would be unavoidable in the real world. How such robustness is guaranteed can theoretically be explained by using our phase model with all-to-all coupling. For a short history of this small branch of nonlinear science, see the review article by Strogatz (2000). The simplest model for this problem is given by

$$\dot{\phi}_i = \omega_i + \frac{1}{N}\sum_{j=1}^{N} \Gamma(\phi_i - \phi_j) \tag{5}$$

Here the randomness is assumed in the natural frequencies $\omega_i$ with distribution $g(\omega)$, which is unimodal and symmetric about $\omega = \Omega$. For the simplest coupling function $\Gamma(x) = -K \sin x$, and in the limit of the population size $N$ going to infinity, an exact solution with phase-transition-like behavior is available in a rather simple form. Macroscopic oscillation amplitude can be measured by the complex *order parameter* $w = N^{-1}\Sigma_{j=1}^{N} e^{i\phi_j}$. Analysis shows that the order parameter behaves like $w = \sigma \exp(i\Omega t)$, where $\sigma$ satisfies the transcendental equation

$$\sigma = K\sigma \int_{-\pi/2}^{\pi/2} dx g(\Omega + K\sigma \sin x) \cos x e^{ix} \equiv S(\sigma) \qquad (6)$$

$S(\sigma)$ is an S-shaped odd function saturating to 1 as $\sigma \to \infty$. Therefore, besides the trivial solution $\sigma = 0$, which always exists, a nontrivial solution appears when $K$ exceeds a critical value given by $K_c = 2/(\pi g(\Omega))$ at which $S'(0) = 1$. It is remarkable that the period $\Omega$ of the macroscopic oscillation becomes infinitely precise as $N \to \infty$.

There are also studies for more general coupling functions. A noticeable result of such studies is that the order parameter for $K$ slightly larger than $K_c$ behaves like $\sigma \propto (K - K_c)^{\beta}$ with the exponent $\beta = 1$ rather than the classical value ½, insofar as the coupling function is not completely free from the second harmonic component.

As the origin of randomness, the distribution in natural frequency may be replaced with external noise. When the noise is additive, white Gaussian, and drives the oscillators individually, the collective dynamics can also be studied analytically by means of a Fokker-Planck equation for the number density $\rho(\phi, t)$. Similar phase-transition-like behavior with $\beta = ½$ is then obtained. Such a stochastic population model with the extension of including external stimuli, and with particular emphasis on its phase-resetting characteristics, was extensively studied by Tass (1999) with a view to medical applications such as the analysis of magnetoencephalography/electroencephalography data and deep brain stimulation techniques used in Parkinsonian patients.

## Clustering and Complex Collective Behavior

We now consider the population dynamics of Equation 5 for the out-of-phase type coupling. The oscillators are assumed to be identical. Actually, owing to the desynchronizing nature of the coupling, the effects of randomness would be of secondary importance in causing complex collective behavior. Since perfect coherence is impossible, we want to find out what types of collective behavior can arise. The extreme opposite of perfect coherence is perfect *incoherence*, for which the phase distribution $\rho(\phi)$ is uniform. Such $\rho$ certainly exists as a particular solution of the problem. However, analysis shows that its stability is guaranteed only for a special form of the coupling function. Thus, what occurs generically seems to be something intermediate between perfect coherence and perfect incoherence. Numerical study shows that most commonly, the whole population splits into two-point clusters, each in perfect phase synchrony, their phase difference preserving a constant value. Such collective behavior is obtained for the coupling function

$$\Gamma(\psi) = -\sin \psi + a \sin 2\psi \qquad (7)$$

and illustrated in Figure 2 in comparison with the case of perfect coherence. The size proportion of the clusters, $p : 1 - p$, is not unique and depends on initial conditions; there is a certain range of $p$ in which such two-cluster states remain stable. On a macroscopic level, the transition from one-cluster state to two-cluster state may appear as *rhythm splitting*, such as is often reported in the literature on circadian oscillations.

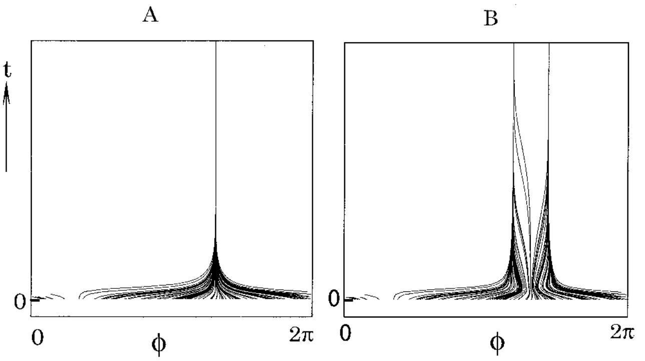

**Figure 2.** Formation of phase-synchronized clusters in a co-moving frame of reference for which $\phi$ remains constant for steady oscillation. A coupling function (Equation 7) with $\alpha = 0$ and random initial conditions are assumed. For $a = 0.4$ (*A*), the whole assembly converges to a single point cluster, while for $a = 0.7$ (*B*) it splits into two subpopulations, each in perfect phase synchrony.

The two clusters rigidly rotating in the phase space may become unstable for any $p$. When this happens, one or the other cluster may further split into multiple clusters, or otherwise a peculiar behavior called *slow switching* may occur (Hansel, Mato, and Meunier, 1993b). The latter phenomenon can be described as follows. For most periods, the system stays practically in a two-cluster state even if it is unstable. However, one of the clusters eventually becomes unable to maintain its internal phase synchrony, and starts to dissolve. This is followed by a short period of strong disorder. The entire system then relaxes to another two-cluster state, i.e., the state obtained by a constant phase shift of the original two-cluster state. Since the last state is also unstable, the same process repeats indefinitely, but with longer and longer time scales. The peculiar dynamics here is interpreted as resulting from the formation of an attracting heteroclinic loop connecting the first and second two-cluster states mentioned above. In the presence of weak randomness, in the form of either external noise or inhomogeneity, the switchings occur nearly periodically, with the period prolonged as the randomness is decreased.

## Discussion

A few remarks should be about the two simplifying assumptions we have worked with. They are first, the weak coupling assumption, which enabled the phase description, and second, the all-to-all coupling. The first assumption has two implications. First, it implies that the oscillators practically keep staying on their intrinsic limit-cycle orbit when perturbed by the other oscillators. This allows us to ignore all degrees of freedoms other than the phases. Second, the time scale associated with the coupling is so long (much longer than the period of oscillation) that the effect of coupling can be time-averaged over one cycle of oscillation. This results in the coupling function depending only on the phase difference, thus fascilitating the mathematical analysis greatly. Assuming the weakness in coupling in the first sense seems neurobiologically quite reasonable (Hoppensteadt and Izhikevich, 1997). However, the second condition seems more restrictive. For instance, whenever neural oscillators establish mutual synchronization only within a few interspike intervals, this condition must certainly be violated.

Regarding the connectivity of neural oscillators, all-to-all coupling is apparently an extreme idealization. Local coupling represents another idealization. Actual coupling must be something in between, but the studies on coupled oscillator networks with general nonlocal coupling are still few. A neurobiologically plausible form of coupling often employed is characterized by short-range excitation and long-range inhibition. For this specific coupling type, and using relaxation oscillators, Terman and Wang (1995) studied the collective dynamics of the network in an attempt to lay a physical foundation for the oscillatory correlation theory of feature binding.

# Collicular Visuomotor Transformations for Gaze Control

*J. A. M. Van Gisbergen and A. J. Van Opstal*

## Introduction

Neurophysiological studies on oculomotor control started in the early 1970s with descriptions of firing patterns at the motoneuron and the premotor level. Meanwhile, a wealth of information has become available on signal processing in the midbrain superior colliculus (SC) and at cortical levels. This article examines recent developments concerning the role of the SC in the control of gaze shifts (combined eye-head movements) and its possible involvement in the control of eye movements in 3D space (direction and depth). New experimental paradigms, putting fewer behavioral constraints on the eye and head motor systems, have led to novel views on the nature of collicular signals.

In classifying modes of oculomotor behavior, it appears useful to make a distinction between two behavioral states that alternate continuously in daily life. During attentive fixation the vestibulo-ocular reflex (VOR) and slow vergence maintain binocular foveal fixation to correct for body movements. When the task requires inspection of an eccentric stimulus, a complex synergy of coordinated movements comes into play. Such refixations typically involve a rapid combined eye-head movement (saccadic gaze shift) and often require binocular adjustment in depth (vergence). It is thought that the system responsible for rapid eye-head movements is actively suppressed during fixation, so that a gating signal (WHEN signal) is required which enables it to respond to the signals that specify the amplitude and the direction of movement (WHERE signals). There is evidence that large gaze shifts involve concurrent suppression of the VOR, which would otherwise counteract the system's effectiveness. As discussed later in this article, there is good reason to think that the SC is involved in this cyclic alternation between gaze holding and gaze shifting. This article will review related theoretical concepts, together with the underlying experimental data. For a broader orientation, see Scudder, Kaneko, and Fuchs (2002), and Wurtz (1996).

Fixation cells (FIX) in the rostral pole of the SC are active during attentive fixation and pause during large saccades (see Wurtz, 1996, for review). In the caudal zone, the pattern of activity is just the opposite. A group of saccade-related cells (SAC) becomes active prior and during the saccade and has low levels of activity during active fixation. A similar antagonistic pattern of activity, functionally reminiscent of the rostral-caudal distinction in the SC, characterizes omnipause neurons and saccadic burst cells in the brainstem. These cells pause and burst during saccades; it is thought that they are driven by FIX and SAC cells, respectively. The brainstem pause cells, and burst cells have mutual inhibition and it has recently been suggested that this is also the case for FIX and SAC cells in the SC (Munoz and Istvan, 1998). In the visual system, target position is topographically coded. At the level of burst cells and motoneurons, saccade size is coded temporally by the number of spikes in the burst or the instantaneous firing rate. This transition from spatial to temporal coding is a classical problem in the study of the saccadic system in which the SC is thought to play a key role. Early studies of SAC cells suggested that the SC contains a topographical map specifying desired saccade displacement. These recordings showed that each SAC neuron is recruited only for a limited range of saccade amplitudes and directions, denoted as its movement field. As one moves from the fixation zone to the caudal border, the movement field of local SAC neurons becomes larger and more eccentric. Since saccade direction is coded along the perpendicular dimension, the colliculus can be considered as a map of saccade amplitude and direction that is organized in polar coordinates. By virtue of its topographical organization, the SC has become a key area for experimental and modeling approaches to the question of how sensory signals can be transformed into goal-directed movements. It has become clear that the SC activity during saccades to auditory and somatosensory targets conforms to the same motor map, suggesting that considerable sensorimotor remapping must take place (for references and further explanation see DYNAMIC REMAPPING).

An early electrical stimulation study by Robinson showed for the first time that the SC motor map is highly nonhomogeneous:

relatively more space is devoted to the representation of small saccades. Based on these results, the collicular motor representation in the monkey has been modeled by a complex-logarithmic mapping function (Van Gisbergen, Van Opstal, and Tax, 1987). This description characterizes the relation between retinal target location and the site of maximum SAC cell activity (afferent mapping) as well as the inverse relation between the locus of movement cell activity and the resulting saccade vector (efferent mapping). In the model, the population activity resembles a Gaussian function centered on the point defined by the afferent mapping. This activity profile is translation-invariant so that the number of active cells is assumed constant, independent of saccade size. Such a topographical representation may generate goal-directed saccades if each cell has fixed connections with the horizontal and vertical burst cells downstream, allowing it to generate a small movement vector, proportional to its firing rate, into the direction of the retinal location to which it is connected by the afferent mapping.

Several recent developments have called for extensions of the model. For example, microstimulation in the SC (Van Opstal, Van Gisbergen, and Smit, 1990) has revealed that the eye displacement, encoded by a given site, can be systematically modified by the stimulation parameters. Furthermore, it now seems clear that the SC is involved with rapid gaze movements rather than being a purely saccadic eye-movement control center. Finally, there is increasing evidence that the SC is also involved in directing the eyes in depth. These latter two developments will now be discussed.

## Role of the Superior Colliculus in the Control of Gaze Shifts

That activity in the colliculus can generate gaze movements has become clear from electrical stimulation studies in a number of species. The possibility that the monkey SC may code desired gaze displacement has been investigated at the single unit level by Freedman and Sparks (1997). Their approach was to compare the activity of movement cells in trials in which either the gaze displacement vector, the eye displacement vector, or the head displacement vector was constant while the other two vectors varied widely. The conclusion from this work is that a gaze displacement signal is derived from the locus of activity in the SC motor map, which is subsequently decomposed into separate eye and head displacement signals downstream from the colliculus (see Figure 1). The work of Cullen and Guitton (1997) suggests that this separation is not yet evident at the level of premotor burst cells (see discussion later in this article).

Less is known about the extent to which the WHEN systems for eye and head are coupled. If omnipause cells would govern both subsystems, one would expect the onset latencies of eye and head movements to be strongly coupled. Although microstimulation in cat SC seems to support this notion, experiments in primates reveal a considerable degree of independence, arguing against a single shared WHEN system.

Struck by the similarities between eye and head contributions to natural gaze shifts in the cat, Guitton, Munoz, and Galiana (1990) have suggested the possibility that eye and head are driven by a common signal. However, experiments in humans where eye and head had nonaligned starting positions before the gaze movement started (Goossens and Van Opstal, 1997) revealed that their movements may have different directions, incompatible with a common input signal. This led them to propose a model in which eye and head are driven by signals expressed in oculocentric and craniocentric coordinates, respectively, which are nevertheless derived from a common collicular gaze displacement command. One feature of the model is that the driving signals for both the eyes and the head depend on absolute eye position (see Figure 1). The need for such an arrangement has also become apparent from electrical stimulation studies in the superior colliculus of the head-free monkey (Freedman, Stanford, and Sparks, 1996).

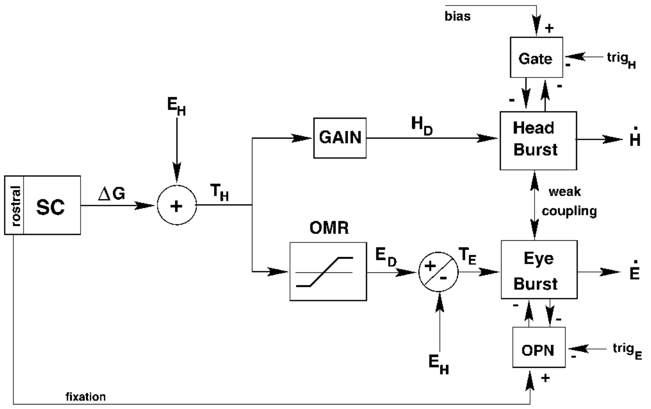

**Figure 1.** Primate gaze control model. As explained in the text, the collicular gaze displacement command, ΔG, cannot be used to drive eyes and head directly. The scheme proposes that it is first transformed into a desired craniocentric position, $T_H$, by adding current eye position, $E_H$. A scaled version of this signal ($H_D$, desired head position) controls the head movement generator and accounts for the finding that the head-movement gain is typically less than one. The craniocentric signal is also passed through a neural saturation element (OMR) to prevent the oculomotor system from running against the limits of its motor range. Dynamic eye motor error, $T_E$, which drives the oculomotor burst generator, is then obtained by subtracting current eye position from the clipped $T_H$ signal, $E_D$ (dynamic desired eye position). The model also proposes a weak excitatory coupling between the two motor systems (Galiana and Guitton, 1992; Goossens and Van Opstal, 1997). This coupling accounts for the differences in eye and head contributions to the gaze shift, as well as for the modulation of head movement trajectories by eye position. The gating mechanisms for the eye (OPN) and head burst generators (Gate) each have their own trigger and bias signals. Internal feedback loops that are assumed to control the eye and head burst generators to ensure that the eye reaches the target, as well as the role of the vestibular system, have been omitted for clarity (after Goossens and Van Opstal, 1997).

### *Activity of Burst Cells During Gaze Shifts*

Earlier discussions of the role to be assigned to the SC in models of the oculomotor system have generally taken for granted that the role of short-lead burst neurons (BN) was already well established. These cells were thought to carry a saccadic velocity signal. However, since the underlying evidence was based on studies in head-fixed animals, it cannot be excluded that the activity of these cells may in fact be related to gaze velocity. The main reason for considering this possibility is that the colliculus, their major source of input, is now thought to specify a desired gaze shift (see previous discussion).

Cullen and Guitton (1997) have made a thorough study of saccadic burst cells to find out whether their activity during head-free gaze shifts might be gaze rather than eye-related. To investigate this question, they fitted the discharge patterns of BNs during head-free gaze shifts, $B(t)$, with a descriptive model of the form: $B(t) = a + b.\dot{E} + c.\dot{H}$ where $a$ is a bias term, $\dot{E}$ represents instantaneous eye velocity, $\dot{H}$ is current head velocity, and $b$ and $c$ are coefficients. This formulation provides a framework for unambiguous definitions of gaze-related versus eye-related coding and yields numbers allowing each cell to be placed along the continuum between these two extremes.

If a cell is to code gaze velocity, it should not matter by which combination of eye and head velocity the gaze-velocity signal was created. In such an idealized cell, coefficients *b* and *c* would have identical values. In a pure eye velocity cell, coefficient *c* would be zero. Remarkably, the tacit assumption in the literature that burst cells are pure eye velocity cells, which seemed to make sense because these neurons have direct connections with oculomotoneurons, was not confirmed. Most cells had a head-velocity contribution in addition to the expected eye-velocity term. On the other hand, the cells were not straightforward gaze cells either because the weights are generally not equal ($c < b$) so that, in fact, their behavior is a compromise between eye related and gaze related.

## Control of Refixations in Direction and Depth

### *Delineation of the Problem*

Most refixations made in daily life involve both a change in direction and in depth. It has long been held that these movements are made by largely independent subsystems, the saccadic and the vergence system, which were conceived of as binocular controllers. The striking contrast between the quite slow movements in pure vergence and the rapidity of saccades tended to support the idea that these systems are quite different in nature. Early modeling studies have further emphasized the notion of distinct systems with unique properties. It was recognized early on that saccades are much too fast to allow the benefit of direct sensory feedback to guide the movement on a moment to moment basis. By contrast, it has often been proposed that pure vergence movements are slow enough to be under direct visual feedback. These distinctions, based on the extreme cases of pure vergence and pure saccades, become much less clear in the more common situation where both systems act together as occurs during refixations in 3D visual space. The finding that, in such cases, vergence shows a very clear velocity enhancement during the saccade has led to the proposal that perhaps saccades may be disconjugate (unequal in the two eyes). It should be noted that, for the portion of the vergence response that is executed as part of a fast movement, the role of direct sensory feedback must be extremely limited.

Since the saccadic and the vergence subsystems typically operate in joint fashion, we must ask how this coordination comes about. Some provision is necessary to ensure that the saccadic system and the vergence system will move to the same target when there are several alternatives. Chaturvedi and Van Gisbergen (1998) performed behavioral experiments in humans instructed to make binocular refixations to a green target in 3D space and to ignore a red distracter at another location. In short-latency responses, errors (to the red stimulus) and compromising responses (in between) were not uncommon but it appeared that the two systems always worked in unison, strongly suggesting that there must be a common central target selection system operating on 3D stimulus location information.

### *Possible Role of SC in Coding Refixations in 3D Space*

Recent evidence suggests that the SC, which receives depth information from parietal cortex, may be directly involved in saccade-vergence coordination. Chaturvedi and Van Gisbergen (1999) applied electrical stimulation in the caudal SC when the monkey was just preparing or executing the 3D refixation to a visual target. Electrical stimulation alone produced a saccade without an overt vergence component. Stimulation in midflight, just after the monkey had started his visually guided movement, caused a compromise saccade and a marked reduction of the fast vergence component. The vergence perturbation was not simply an epiphenomenon of a change in saccade duration and was comparable in strength to the saccadic disturbance. The vergence effect cannot be understood from classical models proposing that the SC specifies only the movement in the frontal plane, leaving the depth movement coding to some other area (see above). Instead, Chaturvedi and Van Gisbergen (1999) proposed that the population of cells at any SC locus shares the same direction movement vector, like in the old 2D-coding schemes, but suggest that there is also a depth movement component. The latter is different from cell to cell so that the entire depth dimension along the locally represented direction in space is covered (see Figure 2). With such an extended scheme it is understandable, in principle, why electrical stimulation in isolation may cause only a pure saccadic movement, without any overt sign of vergence. In this situation, the local cells with different depth tuning will be excited indiscriminately, thereby causing a zero vergence displacement command which can counteract the visually induced vergence signal. By contrast, the saccadic signal will still emerge during such local artificial intervention by virtue of the topographical organization of the motor map, which represents the desired horizontal and vertical components spatially on a much courser scale.

### *Coding of Eye Movements by Burst Cells*

At this point it is interesting to consider how fast eye movements in 3D are coded at the premotor level. It was thought until very recently that burst cells in the reticular formation coded saccades binocularly by providing a conjugate velocity signal. From a systematic study based on eye movements in 3D space, Zhou and King (1998) concluded that most cells code eye velocity for either one or the other eye, irrespective of the depth component involved. This means that the total population contains a 3D code, including both directional and depth components, and that the old idea that they

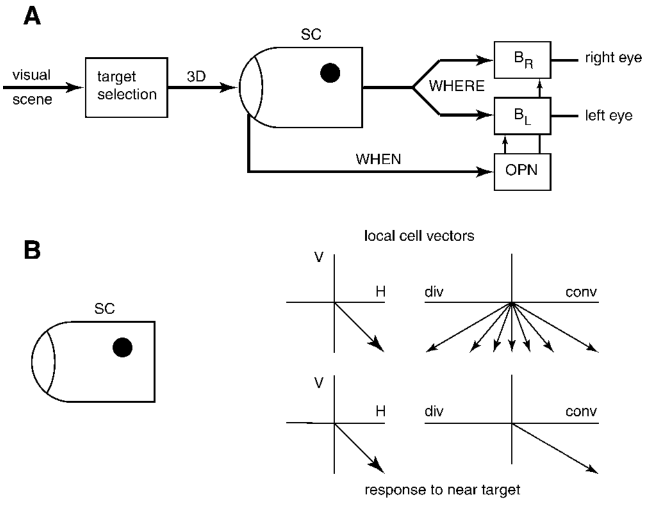

**Figure 2.** Possible role of SC in control of rapid eye movements in direction and depth. *A*, Based on evidence discussed in the text, the scheme proposes that the SC receives 3D information about the location of the selected target and emits a 3D WHERE signal to activate the populations of right eye and left eye burst cells in the brainstem (Zhou and King, 1998). The initiation system (WHEN) is embodied by the rostral zone in the SC and omnipause cells in the brainstem (OPN). The locus of the active zone in the SC determines the change in fixation in the frontal plane but has no topographic organization for depth coding. *B*, Proposal on how activity in the SC may code direction and depth. All the cells in the active zone code for an oblique downward movement but the cells differ in their depth coding directions as shown in the upper-right panel. For a near target in the locally represented direction of the visual field, the population will yield the direction vector shown at bottom left and the net convergence movement shown in the bottom-right panel.

code only conjugate saccades must be abandoned. It is tempting to suggest that the 3D coding at the level of the burst cells may be a further elaboration of the proposed 3D coding in the SC, which is known to be a major source of input signals for these neurons.

## Discussion

### *Decomposition of SC Signals for Eye and Head*

As explained in the previous section, it is now thought that the deep layers of the SC specify a desired gaze displacement, which typically involves movement of both the eyes and the head (Guitton et al., 1990; Freedman et al., 1996; Freedman and Sparks, 1997). However, accumulating evidence indicates that this signal cannot be used directly to drive eyes and head. First, the desired gaze shift may encode a movement well beyond the oculomotor range. For example, suppose a SC site that specifies a 40° rightward gaze displacement is active. When the eyes are looking 20° to the left, the entire movement could be covered by the oculomotor system alone. However, when the eyes start from a position 20° to the right, part of the gaze shift has to be made by the head so that the relative contributions of the eyes and the head to the total gaze shift will (in part) be determined by the initial position of the eyes in the orbit. Second, experiments have shown that the movement directions of eyes and head can be quite different when their initial starting positions are unaligned. Both motor systems appear to move in the direction of the spatial target position. Multiple regression of human data has shown that the direction of head movement is best described by the head motor-error vector (rather than by gaze error). In contrast, the eye-in-head displacement is best described in terms of an eye motor-error signal (Goossens and Van Opstal, 1997). Third, in primates the difference in movement onset of eyes and head varies considerably from trial to trial (see previous discussion). This variability is largely explained by the relative contributions of the two motor systems to the gaze shift: the larger the planned head movement, the earlier it starts (Freedman et al., 1996; Goossens and Van Opstal, 1997). These relative contributions are not fully determined by initial eye position, since stimulus modality is also an important factor: auditory gaze shifts tend to have larger (and thus earlier) head movements (Goossens and Van Opstal, 1997). Finally, the movement trajectories of the head are influenced by eye position, which suggests a subtle coupling between the two motor systems. The simplified scheme in Figure 1 incorporates these different aspects, and highlights the transformations that are required between the SC and the two motor systems.

### *Binocular Versus Monocular Control of Eye Movements*

The question of how the brain coordinates binocular eye movements has been debated already in the previous century, long before any neurophysiological evidence was available. One view, known as the principle of equal innervation, advocates that there are two binocular control systems that affect both eyes. The conjugate system moves both eyes equally and in the same direction. The disconjugate system in this scheme moves both eyes equally in opposite directions, to generate vergence movements. In this way, all binocular eye movements can be described mathematically as the linear sum of a conjugate and a disconjugate movement command, but it is not known whether this is also a valid description of how the real system operates.

The alternative idea is that each eye is controlled separately (monocular control systems). Quite unexpectedly, a recent study by Zhou and King (1998) has yielded evidence for the latter scheme at the level of burst cells. That the situation is not simple is indicated by the even more surprising finding by Zhou and King that motoneurons in the abducens nucleus often carry binocular signals. This is counterintuitive since, at first glance, it would seem hard to think of a more likely candidate for monocular eye movement coding than the oculomotorneuron level. The finding of monocular coding in premotor burst celld raises interesting questions for the organization at more central levels. If the SC indeed contains a 3D code for rapid eye movements, as discussed above, the question to be faced is how the functional projections of its cells may be organized. Sylvestre, Galiana, and Cullen (2002) have recently proposed a model featuring a shared vergence/saccade controller in the SC, which can yield monocular burst cells without requiring an exceedingly complex wiring diagram.

### *Is the SC an Open-Loop Controller?*

The two schemes in this chapter suggest that the SC provides a motor command to downstream platforms in open-loop fashion. There is general agreement that vision is much too slow to provide feedback during saccadic refixations. In other words, if ongoing platform movements are to affect current SC activity, the only possibility is to use internal (or local) feedback. Currently, there is no clear evidence for the idea that the SC has access to fast moment-to-moment local feedback about saccade execution. There are signs of a limited degree of local feedback but its precise role remains to be determined. For an extensive review on experimental and theoretical work in this vast and highly controversial field we refer to Scudder et al. (2002).

# Color Perception

*Robert Kentridge, Charles Heywood, and Jules Davidoff*

## Introduction

*Color* is the name we assign to the experience elicited by an attribute of a surface, namely, its spectral reflectance. Color sensations have a reliable, though complex, relationship to the spectral composition of light received by the eyes. The visual system tackles a series of computational problems in the course of processing wavelength. Variation in the wavelength of light is isolated from variation in its intensity. The spectral reflectance properties of surfaces are isolated from the effects of the spectral composition of light illuminating them (matching surfaces with the same reflectance properties in different parts of the visual scene or under different illuminants are the two problems of color constancy). Finally, the resulting continuous color space is partitioned into discrete color categories. In addition, it will become clear that wavelength signals can be used in the course of perceiving form or motion, independent of their role in the subjective experience of color.

## Wavelength-Dependent Differences Within the Visual System

Color percepts derive from light that varies in both wavelength and intensity. A single type of photoreceptor in the eye responds with differing efficiency to light over a wide range of wavelengths. Consequently, a visual system in which there is only a single type of photoreceptor inevitably confounds wavelength and intensity. A visual system containing photoreceptors that differ in their spectral response can, in principle, disambiguate wavelength and intensity by comparing the responses of different types of receptors.

### *Receptors*

Wavelength-selective processing can be traced from differentially wavelength-sensitive cone types in the retina to the lateral geniculate nucleus (LGN) and then on to striate cortex and extrastriate areas beyond it. There are three cone types in the human retina, with peak sensitivities at 560 nm, 530 nm, and 430 nm and referred to as L, M, and S (long-, medium-, and short-wavelength-sensitive) cones, respectively. In some people one or more of these cone types are missing; hence, color sensations that would normally be perceived as distinct are confused, and the individuals are "colorblind." The functions relating the sensitivities of these cone types to the wavelength of stimulating light can be inferred by comparing the wavelength sensitivities of color-blind and normal observers or by examining the effects of adaptation to light of one wavelength on sensitivity to light of other wavelengths. Figure 1 shows the relative absorption efficiencies of the three cone types and the typical pattern of behavioral sensitivity to intensity modulation.

The output of cones provides information about an object's state, for example, allowing ripe and unripe fruit to be discriminated. The peak sensitivities of photoreceptors appear exquisitely matched to maximize the discriminability of the foliage or fruits that form the diets of a number of species of primates (Sumner and Mollon, 2000). Studies of the genetic coding of cone pigments indicate that human trichromacy evolved from ancestral dichromacy through the division of a single long-wavelength-sensitive pigment into distinct L and M pigments (Bowmaker, 1998).

### *The Combination of Receptor Signals in the M, P, and K Channels*

Three anatomically distinct cell types in the retina combine cone signals in distinct ways (Dacey, 2000). In all cases, the response has a "center-surround" organization. A set of cones from one part of the visual field influences the cell in one way, while a set of cones from the surrounding area influences it in a different way. Parasol cells receive input from L and M, but not S, cones. Inputs from L and M cones are summed in both the center and surround fields of parasol cells (Figure 2*A*). Parasol cells cannot convey information about wavelength independent of intensity. They project to the magnocellular layer of the LGN, which in turn projects to layers 4C$\alpha$ and 4B of primary visual cortex (V1). This pathway, and its onward projections, is known as the M-channel. The M-channel contributes to the perception of luminance and motion but does not convey wavelength-coded signals.

Midget ganglion cells have color-opponent receptive fields. This center-surround organization sharpens the effective wavelength selectivity of the ganglion cell, helping to unconfound wavelength and intensity variation. Consider first a nonopponent cell, sensitive to medium wavelength light. This cell will produce the same re-

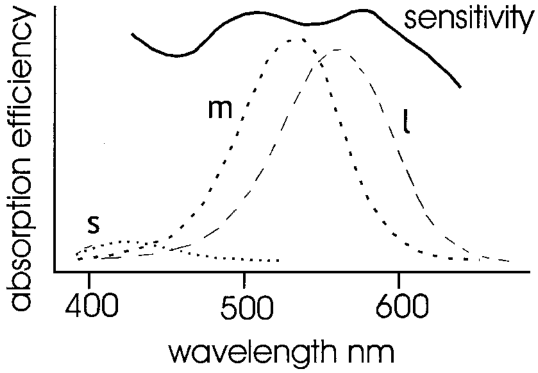

**Figure 1.** The relative absorption efficiencies of short-, medium-, and long-wavelength cone types, labeled s, m, and l, are shown as dotted, short-dashed, and long-dashed lines, respectively. The solid line shows sensitivity to increments in luminance for lights of different wavelengths. The sensitivity decreases falling between the peaks of the cone absorption spectra are known as Sloan-Crawford notches.

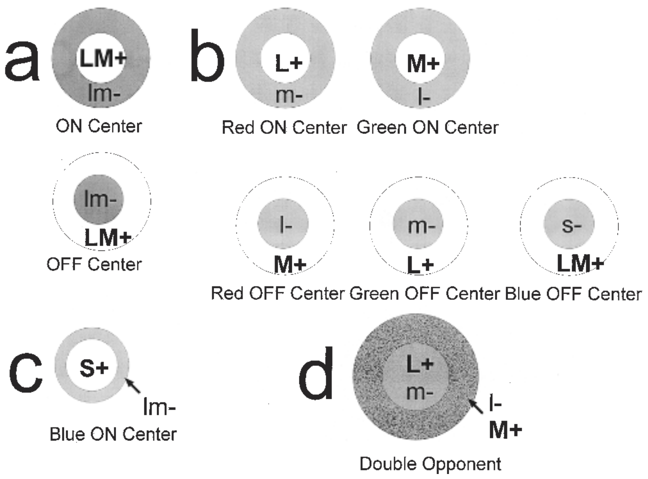

**Figure 2.** Schematic representations of receptive field organization of cells in (*A*) the M-channel, (*B*) the P-channel, and (*C*) the K-channel. (*D*) An example of receptive field organization of a cortical double-opponent cell.

sponse to a given intensity of medium wavelength light, or a stronger intensity of longer wavelength light. Although its peak sensitivity is to medium rather than longer wavelength light, because sensitivity only reduces gradually as wavelength deviates from the peak, the longer wavelength light still produces a response. Now consider the responses of an opponent cell excited by medium wavelength light in the center of its field and inhibited by long wavelength light in the surround to different intensities and wavelengths of light falling on its entire receptive field. Medium wavelength light produces excitation in the center and no inhibition in the surround; there is a net increase in the cell's firing rate. Higher intensities of medium wavelength light elicit stronger net responses. A slightly longer wavelength produces some excitation in the center field of the ganglion cell but also a small inhibitory response in the surround. These roughly balance, and so the firing rate of the cell is largely unaffected by the stimulus. The same situation applies to a high-intensity stimulus; again, central excitation is balanced by surround inhibition. This ganglion cell is therefore capable of conveying information solely about the intensity of medium wavelength light.

The vast majority of foveal midget ganglion cells are driven by L or by M cones in the center of their receptive field; these centers can be either excitatory or inhibitory. Away from the fovea, midget ganglion cells lose their spectral opponency, as more than one cone type drives both the center and surround. There appears to be little input from S cones to midget ganglion cells, just as there are very few S cones in the retina. About 2%–3% of parafoveal midget ganglion cells have S-OFF central receptive fields with an ON surround driven by both L and M inputs (Figure 2*B*). There are no S-ON center midget ganglion cells.

Small bistratified ganglion cells receive inputs from all three cone types; however, their central field always appears to be driven by an excitatory input from S cones, while their surround combines inhibitory L and M inputs. The bipolar cells that convey signals from cones to the central field receive inputs only from S cones and are driven by multiple cells, unlike the bipolar cells that drive the central fields of midget ganglion cells, which receive inputs from single cones. The result is that, although these cells do show clear spatial and spectral opponency, the size of the central field (100 $\mu$m standard deviation) is much larger than that found in midget ganglion cells (25 $\mu$m) (Figure 2*C*). The surround fields of small bistratified cells are smaller than those of midget ganglion cells (140 $\mu$m and 205 $\mu$m, respectively), so these cells show relatively weak spatial opponency. One additional consequence of the S-cone specificity of the small bistratified cells is that the S-ON center, LM-OFF surround organization extends into the peripheral visual field, whereas midget ganglion cells lose spectral opponency beyond the parafovea. There are no S cones in the central 0.3 degrees of the visual field, so foveal vision is effectively color-blind to color variation mediated by S cones.

Midget ganglion cells project to the parvocellular layer of the LGN, and thence to layer 4C$\beta$ of V1. This pathway, and its onward projections, is known as the P-channel. The P-channel conveys information about long and medium wavelengths and fine detail. It has been suggested that small bistratified ganglion cells conveying short wavelength information also contribute to the P-channel. However, it is now widely believed that small bistratified cells drive a distinct class of geniculate cells. The P-channel does contribute to motion perception; however, its contribution is weaker than that of the M-channel and nonveridical—the speed of perceived motion depends on the chromatic contrast of the stimulus.

Small bistratified ganglion cells form the start of the K-channel (Hendry and Reid, 2000). They project to koniocellular neurons in the LGN, distinguished from magno and parvo cells on the basis of their cell membrane chemistry. These cells mainly form layers intercalated between the parvo- and magnocellular layers, but some K-cells are also found in the parvocellular layer, with a smaller number being found in the magnocellular layer. K-cells project not only to layer 1 of V1, but also directly to V2. There is a particularly rich innervation of V2 by K-cells with foveal receptive fields. K-cells' receptive fields are large (at least as large as those of cells in the magnocellular layer) and often have irregular shapes. K-cells convey information contributing to color sensations, depending on contrasts of the output of S cones to combinations of M and L cone outputs; they may also contribute to motion perception.

The position summarized above remains controversial and has been challenged on a number of counts. In particular, it has been argued that the K-channel alone conveys chromatic signals (including L versus M information), while the P-channel is dedicated to fine spatial vision (Calkins and Sterling, 1999).

### *Primary Visual Cortex*

The M, P, and K pathways project to groups of cells within V1 that can be distinguished on the basis of cytochrome oxidase reactivity (Livingstone and Hubel, 1984). K and P, but not M, pathways innervate cytochrome oxidase–stained regions known as blobs. P and M, but not K, pathways innervate the remaining regions, known as interblobs. There is recent evidence that cells show different specificities for wavelength processing in V1 (Conway, 2001; Johnson, Hawken, and Shapley, 2001). The cells discussed earlier in this article had a "single-opponent" organization. They can convey information about the intensities of light of particular wavelengths while being relatively uninfluenced by other wavelengths. They cannot, however, convey information about wavelength contrast. This requires "double-opponent" cells in which a central receptive field excited by one wavelength and inhibited by another is surrounded by a field in which the same two wavelengths have the opposite actions (Figure 1*D*). Double-opponent organization allows a cell to convey a consistent response to the boundary between two surfaces, regardless of the light illuminating them. If the illuminant changes, for example lengthening in wavelength, then longer wavelength light will be reflected from both sides of the boundary. Consider a double-opponent cell whose central receptive field is excited by long wavelengths and inhibited by medium wavelengths and whose surrounding field is inhibited by long wavelengths and excited by medium wavelengths. Imagine that the cell's receptive fields fall on a boundary between a pair of surfaces, one of which is good and one poor at reflecting long wavelength light, so that the good reflector falls in the cell's central field. The net result will be excitation—that ratio of long to medium wavelength light is high in the central field and low in the surround. When the light illuminating both sides of the boundary lengthens in wavelength, the L/M ratios in both the excitatory center and the inhibitory surround will increase. The response of the cell is therefore largely unaffected by a change in illuminant. Obviously, such cells perform the preliminary computation necessary for color constancy. Of course, their responses only indicate spatially local changes in surface reflectance. To recover absolute reflectances throughout a scene, then, one also needs to estimate the response likely to be elicited by some fixed "anchoring" color in that scene and then to integrate local border contrasts from that anchoring point (see, e.g., Gilchrist et al., 1999, for similar arguments with respect to lightness perception). Until recently, evidence for the existence of double-opponent cells was controversial; however, recent findings indicate that such cells occur in V1 and, moreover, are sensitive to the orientation of chromatic (wavelength-dependent) borders as well as to the contrast of cone ratios across them.

### *Extrastriate Cortex*

The clinical condition of cerebral achromatopsia, in which patients lose the ability to perceive color not as a result of retinal abnormalities but rather as a consequence of brain damage, provides strong evidence that brain areas specialized for color perception exist beyond striate cortex. The identification of these areas is, however, wreathed in controversy. The damaged areas include extrastriate cortex in the vicinity of the fusiform and lingual gyri. Neuroimaging studies have also shown increases in cerebral blood flow (implying increased brain activity) in these areas when normal subjects observed colored scenes. Zeki et al. (1991) therefore suggested that there was a specific color center in human extrastriate cortex. Early studies in which the responses from single neurons in monkeys were recorded in response to visual stimuli suggested that the color center might correspond to cortical area V4. A number of problems arose with this interpretation. The selectivity of the response of neurons to particular characteristics of stimuli differs only in degree between brain areas. Some neurons in nearly all visual areas respond selectively to wavelength; the proportion in V4 is not comparatively large. In addition, damage to area V4 in monkeys did not cause deficits in discriminations based on wavelength, although deficits were induced by damage to areas anterior to V4 (Heywood and Cowey, 1998). These findings appeared consistent with neuroimaging studies in humans identifying a color-selective area anterior to V4, christened V8 (Hadjikhani et al., 1998). Whether V8 really corresponds to the anterior areas that, when damaged, caused deficits for wavelength discrimination in monkeys remains controversial.

## Wavelength Information Contributes to More Than Color Perception

The fact that our visual system can disambiguate wavelength and intensity makes it possible to ignore variations or sharp changes in intensity caused by shadows. One role of a wavelength-selective visual system is therefore segmentation of the visual scene on the basis of chromatic boundaries. Often chromatic boundaries will provide better cues for segmenting objects from their backgrounds than brightness boundaries—for example, in the dappled sunlight of a forest floor.

The residual abilities found in cerebral achromatopsia indicate that wavelength is exploited in more than one way. Although cerebral achromatopsics deny a phenomenal experience of color and cannot discriminate between stimuli differing only in wavelength, they can effortlessly perceive boundaries between areas differing only in wavelength (Heywood, Kentridge, and Cowey, 1998). Their ability to use wavelength information to perceive form or motion, but not to perceive color, suggests that these functions may have distinct anatomical bases. Destruction of the putative color center, be it V4 or V8, disrupts the perception and experience of color, but not other functional uses of wavelength.

## Discussion

Some of the earliest insights into the coding of color derived from work on color mixing. Following his discovery of the composition of white light, Newton developed the concept of the color circle, an arrangement of light sources around the periphery of a circle in which the mixture of any pair of diametrically opposite lights would produce white. Despite the color circle showing a continuum of light sources, Newton identified five primary colors (red, yellow, green, blue, and a violet-purple). However, attempts were soon made to discover how few colors were required in order to produce all other colors by mixing. Although there was some disagreement about which colors were primary, it was apparent to most investigators that three were sufficient. This culminated in the Young-Helmholtz trichromatic theory of color vision. Young believed that the primaries were red, green, and violet.

The fact that we require three primary colors in order to produce the full range of colored sensations reflects the fact that we have photoreceptors sensitive to three distinct wavelength distributions. The consequence is that any combination of lights that produces the same amount of activation in the three receptor types will produce the same response in the visual system and the same perception of color. There are, therefore, a large number of colors that are potential primaries.

Other features of color perception suggest an alternative to the trichromatic theory. In particular, there are limits to our abilities to see pairs of colors tinting one another. People perceive bluish reds and yellowish reds, but never greenish reds; they perceive reddish yellows and greenish yellows, but never bluish yellows. These opponent color pairings, red-green and blue-yellow, are also apparent in afterimages, color shadows, and color contrast. Observations such as these led Hering in 1905 to suggest a four-color opponent-process theory of color vision.

Both these theories assumed that the similarities between color sensations are completely determined by the outputs of the wavelength-dependent neurons in the visual system. For example, it is tempting to believe that opponent processes operating in V1 are the direct precursors of our space of colors. They have been taken as the sources of four primary colors (red, green, yellow, and blue) that are irreducible to other colors, and each contains one sensation that is pure (unique) in that it contains no trace of any other primary. However, the outputs of the cells in V1 would not produce these unique colors even if there were agreement as to what they might be (Saunders and van Brakel, 1997; Webster et al., 2000). Nor would the categories of color arise from variation in discrimination across the visible spectrum. The wavelengths at which there are minima in threshold do not correspond to the boundaries between primary colors. Controversially, it has been argued from cross-lingual evidence that color categories are determined by the speaker's color terms. The neurophysiology produces a given percept, but the assignment of that percept to a color category is a matter of agreement among observers.

# Command Neurons and Command Systems

*Jorg-Peter Ewert*

## Introduction

If a certain interneuron is stimulated electrically in the brain of a marine slug, the animal then displays a species-specific escape swimming behavior, although no predator is present. If a certain brain area of the optic tectum of a toad is stimulated in this manner, snapping behavior is triggered, although no prey is present. In both cases, a commanding trigger, which in the natural situation is associated with adequate predator or prey signals, activates an appropriate motor program. We address the notion "command" to a stimulus which elicits a rapid ballistic response. The transformation involves sensory pattern recognition and localization on the one side and motor pattern generation on the other; command functions provide the sensorimotor interface (Kupfermann and Weiss, 1978). This interface translates a specific pattern of sensory input mediated by sensory neurons (SN) into an appropriate spatiotemporal pattern of activity in premotor and motor neurons. The latter coordinate the corresponding action pattern, which, in various animal groups and depending on the task, may be rather stereotyped (fixed action pattern) or may leave room for variability (modal action pattern). This correspondence can be innate, modified innate, or acquired, strategy related. Commands are motivated. Once an action pattern is commanded, it tends to carry on to completion, although there may be cases in which a command is "countermanded." How does the sensorimotor interface operate?

Before we tackle this question in depth, a few comments on pattern generation are in order (see Motor Pattern Generation). In the present context, a motor pattern generator (MPG) is defined as an internuncial network that, in response to a commanding input, coordinates appropriate muscle contractions. The network is activated if and only if a specific (combination of) input occurs. An intrinsic pattern of neuronal connectivity in the network ensures the generation of a consistent spatiotemporal distribution of excitation and inhibition, often involving oscillatory circuits. The output of the network, mediated by premotor neurons, has privileged access to the requisite motor neuronal pools. Proprioceptive and internal feedback—or feedback from components of the motor network to the command neuron(s)—can play a role in the coordination and maintenance of a motor pattern (e.g., Jing and Gillette, 2000). Hence, command neurons can be involved to carry timing information for the MPG. Recurrent feedback from the motor system to the command and from the command to the sensory afferents may terminate the command and may also prevent sensory input during the animal's movement.

There are cases in which a short-term command *triggers* the corresponding MPG whose activity outlasts the command activity. In other cases, a sustained (tonic) command is necessary to drive the MPG. The efficacy of a triggering or a driving command depends on the requirements under which an action pattern is released: (1) locus of the stimulus, (2) presence of adequate stimulus features, (3) behavioral state (dominance), (4) motivation (variable on a relatively long time scale), attention, and arousal (variable in the short-term), (5) gating input, and (6) evaluation of the stimulus in connection with prior experience. The first two listed concern aspects of the releasing stimulus; the latter four refer to modulatory functions.

Sensorimotor interfaces with command functions occupy an important topic in neuroethology, the science of the neurobiological fundamentals of behavior (e.g., see Carew, 2000). Neuroethology contributes a valuable perspective to neuroscience of which the present article presents one component.

## The Command Neuron Concept

The question as to whether a sensorimotor command can be mediated by a command neuron (CN),

sign stimulus → SN → **CN** → MPG → behavior pattern

was and occasionally still is controversial (Kupfermann and Weiss, 1978; Eaton, Lee, and Foreman, 2001). After a definition by Kupfermann and Weiss (1978), a command neuron (CN) is an interneuron whose excitation is both necessary (n) and sufficient (s) to activate the corresponding MPG. Test criteria of this n&s condition include (1) the recording of the activity from the putative CN during the presentation of a stimulus signal in registration with the corresponding action pattern (link between stimulus and motor activity), (2) electrical stimulation of the putative CN with demonstration that this action pattern is executed (s-criterion), and (3) removal of the putative CN and demonstration that this action pattern is no longer elicited by the stimulus signal (n-criterion).

The best candidates for this approach are among the identified CNs of various invertebrates, such as the pair of lateral giant fibers in crayfish that, in response to mechanical stimulation, trigger the fast tail flip escape reaction. For the function of the lateral giant, the term "command" was first introduced by C.A.G. Wiersma and K. Ikeda (for a review, see Edwards, Heitler, and Krasne, 1999). Among vertebrates, there is the reticulospinal Mauthner cell of teleost fish, which, in response to certain acoustic-vibratory stimulation, commands the fast C-shaped body bend escape reaction, called "C-start" (Eaton et al., 2001). The C-start is triggered by a spike in one of the bilateral pair of Mauthner cells.

However, in such cases in which identified putative CNs activate corresponding MPGs, it was not trivial to evaluate the n&s condition. Eaton and co-workers performed a scholarly structured examination on the Mauthner cell (see Eaton et al., 2001). Surprisingly, it turned out that the n-criterion was not fulfilled clearly; after both Mauthner cells in the goldfish were lesioned, the C-start escape reaction could still be elicited by acoustic sign stimuli—however, at a longer latency. This suggests that appropriate auditory receptive "backup" systems, which are normally inhibited by Mauthner cell activation, commanded the C-start. Interestingly, also the s-criterion was not fulfilled unequivocally, because electrical stimulation of the Mauthner cell did not trigger the complete C-start. This suggests that for the full C-start pattern, the activity in other, parallel descending reticulospinal cells is required, too.

Is the CN concept restricted to very few cases, or is it even obsolete? Regarding unknown network interactions (serial, parallel, convergence, divergence, feedforward, and lateral inhibition), the n&s condition may be too rigorous in many cases. Depending on a sensorimotor function, we therefore envision a spectrum of possibilities by which command functions can be executed. The idea behind the revisited command concept (cf. Eaton et al., 2001) is furthermore fruitful both in the neurophysiological analysis of behavior (e.g., Ewert, 1997; Edwards et al., 1999) and in perceptual robotics (e.g., Lukashin, Amirikian, and Georgopolous, 1996; Reactive Robotic Systems).

Experiments to test the n&s condition of particular neurons for triggering behavioral acts are a historical fact that is part of the research record on these types of systems. However, this should not distract us from the complex results that emerge from the experiments done to test this paradigm or from the complex ways in which these cells really function.

## Command (Releasing) Systems

Plastic ballistic behavior elicited by distributed networks is triggered by populations of command-like interneurons that form a command system (CS) (Kupfermann and Weiss, 1978). Such a CS consists of collectively operating neurons, each of which is called a command element (CE) or command-like neuron. For just one CE of a CS, the n&s condition cannot be fulfilled. For example, if the CEs of a CS are connected to the MPG like a logical AND-gate, in this case a CE fulfills the n-criterion but not the s-criterion; if the CEs of a CS are connected to the MPG like a logical OR-gate, in that case a CE fulfills the s-criterion but not the n-criterion. However, when the CEs of a CS are treated as a unit, the CS will meet the n&s condition in both cases. We learn that the CS notion has a much broader applicability than the CN notion. In fact, the pair of identified bilateral cerebral interneurons of the type *cc5* in the marine snail *Aplysia* works conjointly as a two-neuron CS that fulfills the n&s condition for the bilateral pedal arterial-shortening component of defensive head withdrawal behavior (Xin, Weiss, and Kupfermann, 1996).

In Mauthner cell-initiated escape behavior, the current concept suggests that the C-start is elicited by a CS consisting of at least two groups of command-like reticulospinal neurons (CEs). One group, in which the Mauthner cell participates, controls the agonist muscular contraction; another group controls the antagonist contraction that, depending on the direction of the acoustic stimulus, precisely shapes the trajectory for certain C-start escape angles (Eaton et al., 2001). If we ask how the two parts of the CS control trajectory, it appears, for example, that the agonist and antagonist CEs can vary their respective output magnitudes and timing patterns to regulate the escape trajectory. This example introduces more sophisticated CSs and relates to the question whether a "backup" system really exists. Since it is difficult to explain how a backup system could evolve, it is a simpler interpretation to recognize the parallel nature of the CS. The role of the parallel output may be to produce variable trajectory angles. A consequence of its organization is that it is "robust" such that if one element (e.g., a Mauthner cell) does not participate, the behavior still can occur. But it could well be that an organism that is missing one Mauthner cell may not be able to accurately control its trajectory.

The concept of a command-releasing system (CRS) is suggested for functions requiring a more complex perception of the sensory input (Ewert, 1997). Different types of electrically uncoupled CEs (a population of each) cooperatively trigger an MPG. Each type of CE evaluates a certain aspect of the releasing stimulus signal, such as features or feature combinations and their location in space, respectively; we call this a *sensorimotor code*. The concept of coded commands stresses that firing of various types of efferent neurons (CEs) in a certain combination (CRS) characterizes an object in space and selects the appropriate goal-directed action pattern (MPG). In amphibians, such cells with different visual response properties project their axons from the optic tectum (T-type neurons) or thalamic/pretectal nuclei (TH-type neurons) to the bulbar/spinal motor systems via discrete tecto-bulbarspinal and pretecto-bulbar/spinal pathways (Figure 1). The hypothesis illustrated in Figure 1 suggests the following:

- The code **{T4, X, T5.2}** says: "an object is moving anywhere in the visual field [T4]" and "the object occurs at a certain position in the visual field x-y coordinates [X]" and "the object has prey features [T5.2]" → ***orient!***
- The code **{T1.3, T3, T5.2}** says: "an object is moving in the frontal binocular field of vision at a narrow distance [T1.3]" and "the small object is approaching [T3]" and "the object has prey features [T5.2]" → ***snap!***
- The code **{TH6, T6}** says: "a large object is moving in the dorsal visual field [T6]" and "the large object is approaching [TH6]" → ***duck!***

After the hypothesis, in such a multifunctional network, on one hand, the same goal can be reached by differently combined CRS whose CEs may be distributed in different brain structures; on the other hand, certain CEs can be shared by different CRSs for different goals. Evidence of such multifunctional properties, for example, is provided for *Aplysia* by Xin et al. (1996): The type *cc5* neuron contributes to different aspects of behavior, such as defensive head withdrawal, tentacular withdrawal, feeding, and locomotion. For some (aspects of) behaviors, the neuron probably acts as CE; for other aspects or components of behavior, however, the same interneuron may participate in a distributed circuit where it is neither necessary nor sufficient.

Also, Mauthner cells participate in behaviors other than escape, such as prey capture. The story of Mauthner cell function may be even more complex. In the electric fish *Gymnotus carapo*, auditory activation of Mauthner cell leads, by its connections to medullary pacemaker neurons of the electric organ, to an abrupt and pro-

**Neuronal properties**

T6 monocular dorsal large receptive field, sensitive to moving large objects

TH6 monocular wide receptive field, sensitive to approaching big objects

TH3*,T5.3* monocular receptive fields of 30-50° diameter, sensitive to moving large objects

TH4* receptive field encompassing the visual field of one or both eyes, sensitive to moving large objects

T5.4* monocular receptive field of about 35° diameter, sensitive to moving big compact objects

T5.1* monocular receptive fields of 20-30°, sensitive to moving objects of small or intermediate size

T3* nasal monocular receptive field of 20-30°, sensitive to approaching objects

T4* receptive field encompassing the visual field of one or both eyes, sensitivity like T5.1 or T5.2

X hypothetic tegmental neurons computing retinal topography and body segment orientation

T1.3* nasal binocular receptive field of 15-30°, responsive to objects moving at narrow distance

T5.2* monocular receptive field of 20-30°, sensitive to small objects with preference to objects elongated in the direction of their movement

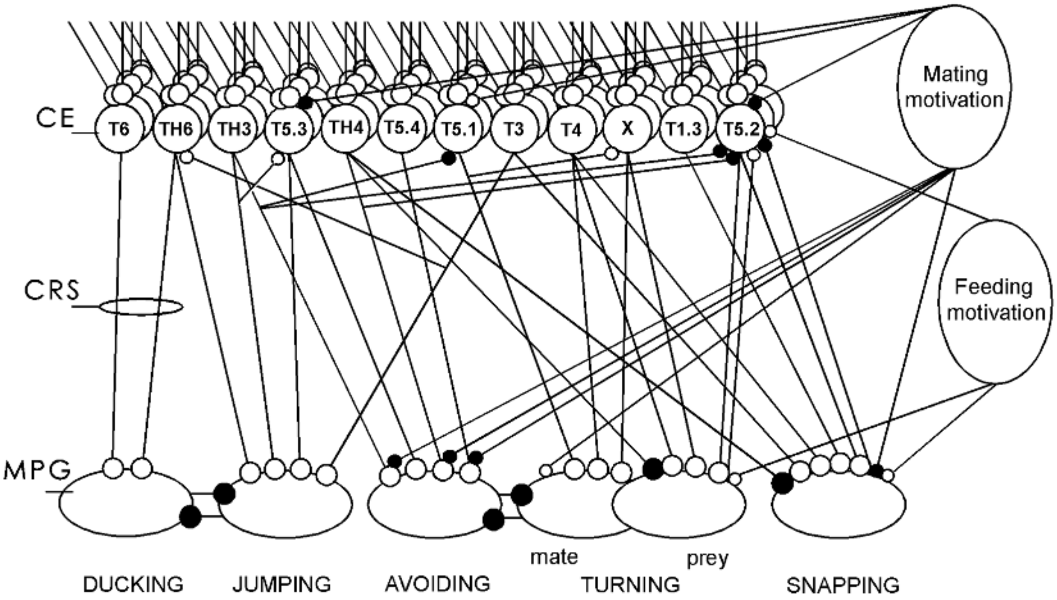

**Figure 1.** Concept of sensorimotor codes implemented by command-releasing systems (CRSs) in common toads. Different subsets of functionally identified types of visual thalamic/pretectal (TH) and tectal (T) neurons as command elements (CE) contribute to commanding and parameterizing motor patterns of feeding (prey orienting, snapping), escape (ducking, jumping, avoidance turning), and orienting by the male toad toward the female in the mating season. For example, *T5.1* neurons respond sensitively to prey objects, whereas *T5.2* neurons display prey-selective properties with respect to configurational visual cues; *T6, TH6, TH4*, and *T5.4* neurons respond best to various aspects of predator stimuli. Breeding motivation and hunger state deliver different modulatory influences. Each circle represents a set of neurons, each oval stands for a motor-pattern-generating circuit (MPG) with access to motor neuronal pools. The open dots refer to excitatory inluences, and the solid dots to inhibitory influences; the CE level obtains sensory inputs, for example, from retinal ganglion cells and interneurons. The asterisk indicates that the projective character of the neuron (command element) is evidenced by means of the antidromic stimulation/recording method. (Modified from Ewert, 1997.)

longed increase in the rate of discharges of the electric organ. This probably enhances the electrolocative sampling of the environment during Mauthner cell mediated escape or prey-catching behavior (Curti et al., 1999).

## Properties of Commands

With respect to requirements 1 through 6 listed in the introduction, the properties of a command can be manyfold. We select three aspects.

### *Localization*

Certain CEs of a CRS monitor the stimulus in space to select and direct the behavior in relation to the target. Visual space, the *x-y-z* position of an object, are translated into appropriate motor space. In mammals, the superior colliculus is involved in visual orientation of the eye, head, and trunk. Information about the position of these movable segments must be integrated in the topographic correspondence between sensory input and motor output. For example, the sensory map in the collicular superficial layers is transformed into a motor map in the deep layers, in which a vector from an initial eye position to a goal eye position is represented. Hypotheses concerning gaze, eye, and head displacement commands are discussed by Freedman and Sparks (1997).

Information on visual depth can be obtained in various ways, such as by binocular vision or motion parallax. Such information is necessary not only to select appropriate behavior, but also to estimate the real size of the target.

### *Feature Analysis*

Certain CEs of a CRS are involved in the feature analysis of the sensory signal. For example, the toad's visual system selects between prey and nonprey through an analysis of the moving object in terms of configurational features, namely, the dimensions of an object parallel versus perpendicular to its direction of movement. A bug or a millipede is thus not recognized explicitly; rather, they are implicit in the prey schema determined by an object-features-relating algorithm (Ewert, 1997). The discharge rate of toad's prey-selective *T5.2* neurons in response to a moving object is correlated with the probability that the configuration of this object fits the prey schema. These neurons, as CEs, obviously display predictive responses, since they show a strong premotor buildup of activity before the animal orients toward prey, but they are silent before or during a spontaneous head movement. In the response properties of *T5.2* neurons, certain kinds of interactions of distributed tectal (T) and thalamic/pretectal (TH) neuronal populations are expressed. This feature analyzing T/TH filter system is integrated in a macronetwork that allows various kinds of modulation (Figure 2), for example, with respect to response gating (involving basal/ganglionic nuclei) or to raising or lowering the classification threshold depending on motivation (involving preoptic/hypothalamic structures) or to generalization or specification by learning (involving the hippocampal ventral medial pallium).

### *Motivation and Attention*

A command cannot operate effectively if state-dependent inputs are not appropriate. If a toad is inattentive or not motivated to catch prey, the prey-selective *T5.2* neurons will continue to discharge, at a lower rate, in response to configurational visual prey features; however, they do not show the strong buildup of activity that in prey-responsive animals precedes and predicts grasping the prey with the tongue. Comparably, neurons of area 5 of the posterior parietal association cortex in monkeys discharge strongly before the animal performs a ballistic grasping movement with its arm toward a rewarding banana. In keeping with the proposal by Mountcastle and co-workers, these "arm projection neurons" function in a broad sense as a command system for the motivated exploration of extrapersonal space (for a complementary point of view, see GRASPING MOVEMENTS: VISUOMOTOR TRANSFORMATIONS). However, if the monkey was satiated, the banana did not elicit the predictive buildup of activity in these neurons required to elicit grasping. So whether or not the s-criterion is met depends on the behavioral state. This illustrates again one of the problems with rigidly designating neuronal function according to the n&s paradigm: Whether the cell is either n or s for a behavior depends on the conditions.

In crickets, the efficacy of the calling-song commanding interneuron, too, depends on the behavioral state (Hedwig, 2000). In silent animals that were previously singing, experimentally evoked commands by this interneuron triggered the song according to the s-criterion. In the resting state, however, experimentally evoked commands by the interneuron elicited an incomplete calling song, so the interneuron failed to meet the s-criterion.

## Behavioral Choice

Behavioral dominances exist, and these may depend, for example, on the season due to hormonal influences. In summertime, the toad's predator-avoiding behavior overrides prey-catching behavior if appropriate visual releasers are present simultaneously, whereas the male toad's mate-approaching behavior to an adequate stimulus is absent. In spring during the mating season, mate-approaching behavior dominates predator-avoiding behavior, whereas prey-catching behavior fails to occur. The behavioral choice may result from dual excitatory/inhibitory influences to the toad's tectal or thalamic/pretectal CEs and/or MPGs (cf. Figure 1).

The rat's colliculus superior (SC), too, in response to certain unexpected visual stimuli can initiate rapid ballistic opposite behaviors such as orienting/approaching versus freezing/avoiding. Each type of behavior is commanded by a different set of neurons located in the intermediate or deep SC layers, respectively, that project their axons in discrete phylogenetically old SC-bulbar/spinal pathways (homologous to the tecto-bulbar/spinal pathways in amphibians). Krout et al. (2001) provide anatomic evidence for the hypothesis that the decision in the SC to select one of these behaviors—approach versus avoidance—in an appropriate stimulus situation involves visual projections from SC to (1) thalamo-basal/ganglionic, (2) thalamo-amygdaloid, and (3) thalamocortical circuits. It is suggested that loop 1 is involved in behavioral choice via disinhibitory (gating) and inhibitory (selecting) pathways, and the connections with loop 2 add information related to emotional learning and memory, whereas the connections with loop 3 allow changes in strategy.

Studies in invertebrates show that there are several ways of interaction to explain the suppression of one of two mutually exclusive behaviors, each one organized by a network N1 and a network N2, respectively.

1. An influence of network N1 cancels the command in N2: for example, dominance of escape swimming over feeding in the snail *Pleurobranchaea*; the behavioral switch is caused by swim-induced inhibition of feeding command neurons, that is, activation of feeding interneurons that inhibit the feeding command neurons (Jing and Gillette, 2000).
2. An influence of network N1 suppresses both the command in N2 and the MPG in N2: for example, choice of the body shortening withdrawal behavior in favor of swimming in the leech; in response to mechanical stimuli, body shortening is commanded by a set of interneuronal parallel pathways that inhibit one of the swim command interneurons and an interneuron of the swim MPG (Shaw and Kristan, 1999).
3. An influence of network N1 inhibits the MPG in N2 but not the command in N2: for example, in stridulating crickets, wind-evoked signals that are silencing the calling song do not inhibit the ongoing activity of the interneuron that commands this song but do inhibit the song MPG. This allows immediate singing when the wind wanes (Hedwig, 2000).

## CRS and Schema Theory

A command-releasing system (CRS) can be regarded as the neurobiological correlate of Nico Tinbergen's concept of (innate) releasing mechanism (see Ewert, 1997), originally called by Konrad Lorenz "the (innate) releasing schema."

SCHEMA THEORY (q.v.) offers an interdisciplinary science that allows one to treat principles of neuroethology or neural engineering in the same language. In the language of schema theory, the sensorimotor code of a CRS embodies a *perceptual schema* that exists for only one purpose: to determine the conditions for the activation of a specific MPG embodying a *motor schema*. The CRS must also ensure that the resultant movement is directed in relation to the target. A schema and its instantiation usually are coextensive; that is, instantiation of a schema appears to be identifiable with appropriate activity in certain populations of neurons of the brain, whereby each schema may involve several cell types or brain regions, while a given cell type or brain region may be involved in several schemas. The motor schemas of directed appetitive behaviors and consummatory behavior need not occur in a fixed order; rather, each may proceed to completion, followed by perceptual

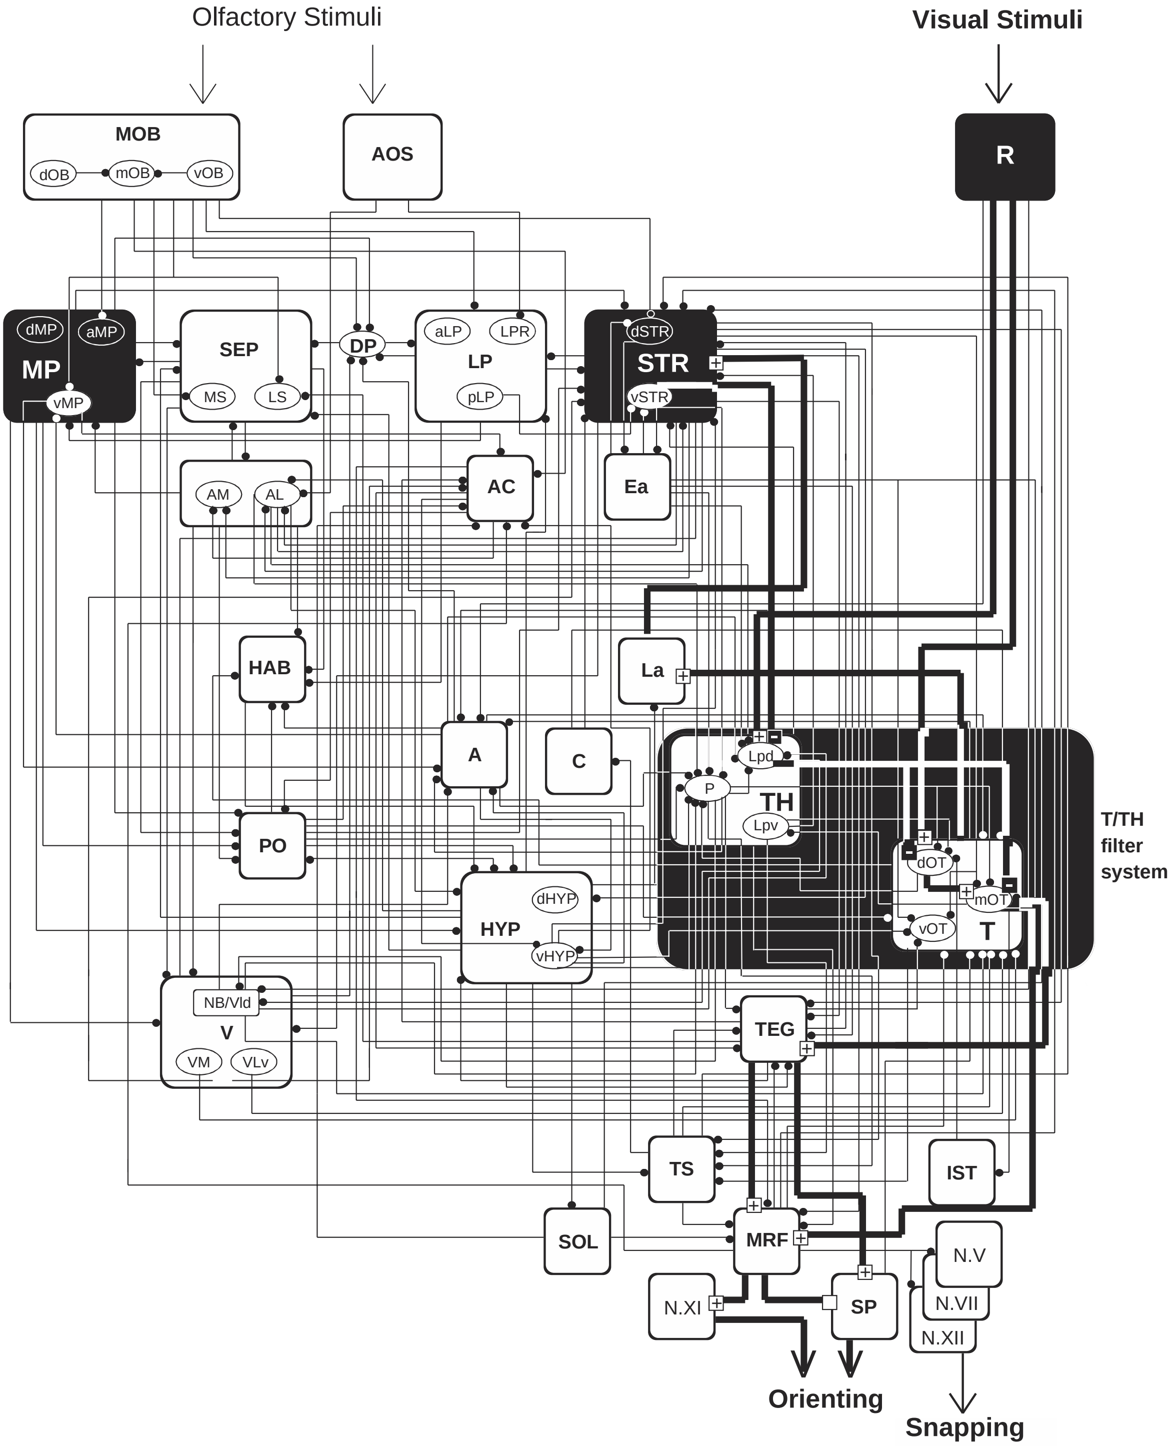

**Figure 2.** The visual configurational prey schema of common toads results from interactions between retina (R)-fed optic tectal (T) networks and retina-fed thalamic/pretectal (TH) networks. The former network evaluates the dimension of an object parallel to the direction of its movement; the latter evaluates its dimension perpendicular to the direction of movement. Pretectotectal inhibitory influences determine the prey-selective properties of tecto-bulbar/spinal projecting neurons of the type *T5.2* (cf. Figure 1). The T/TH filter system (see the black labeled large area) is integrated in a macronetwork, whose components may influence this system in different ways. For example, the basal ganglionic ventral striatum (vSTR) is involved in gating the orienting response toward prey (cf. thick labeled lines): retinal (R) output is fed both to T and TH (Lpd nucleus); vSTR obtaines T-information via the lateral anterior thalamic nucleus (La); a descending striato(vSTR)-pretecto (Lpd)-tectal (T) disinhibitory connection gates the tecto (T)/tegmento (TEG)-bulbar (MRF)/spinal (SP) processing stream. As a result, visual perception (prey recognition) is translated into action (prey-catching orienting). Suggested excitatory and inhibitory influences are indicated by plus and minus signs, respectively. Other, not labeled, loops involving the hippocampal ventral medial pallium (vMP) via anterior thalamic (A), preoptic (PO), and hypothalamic nuclei (HYP) modify the selectivity of the prey schema in the course of nonassociative or associative learning, such as by combining visual and olfactory cues. (For details, see Ewert et al., 2001.)

schemas that will determine which motor schema is to be executed next. Schemas may be linked by so-called *coordinated control programs*. Motor schemas, for example, can take the form of compound motor coordinations (such as a frog's programmed jump-snap-gulp sequence), which make up a set that will proceed to completion without intervening perceptual tests, for example, in such a manner that schema A proceeds to completion, and completion of schema A triggers the initiation of schema B, or that schema A passes a parameter X to schema B. It is also possible that two or more motor schemas are co-activated simultaneously and interact through competition and cooperation to yield a more complicated motor pattern.

## Perspectives

Operations between sensory analysis and motor response represented by sensorimotor codes (CRS) are of general importance. Of particular interest are the alternative ways in which different organisms solve similar problems. For example, it was shown that the same algorithm that underlies configurational prey selection is implemented by such different neuronal networks as those of a toad, which is a vertebrate, and a praying mantis, which is an insect (Prete, 1992). This biologically justifies the artificial neural network approach. Cervantes-Pérez (see Visuomotor Coordination in Frog and Toad) demonstrates that such an algorithm can be modeled by neural networks applying principles of parallel-distributed processing and convergence. Pavlásek (1997) uses artificial neuronal networks to investigate how the precise timing and structuring of neural commands controlling goal-directed movements can be realized in general. Lukashin et al. (1996) apply a computational paradigm that utilizes the actual impulse population activity of directionally tuned cells recorded from the motor cortex of monkey during the performance of a motor task as command signals to drive an artificial mechanical device: an artificial neuronal network recodes the brain signals into the motor schema of a simulated actuator, a method that is suitable for electronically driven prostheses such as a multijoint artificial limb. This is just one example of the applications of research on command functions in sensorimotor systems for perceptual and reactive robotics (cf. also Reaching Movements: Implications for Computational Models; Reactive Robotic Systems; and Robot Arm Control).

# Competitive Learning

*Nathan Intrator*

## Introduction

Competitive learning is described by a family of algorithms that use some sort of competition between lateral neurons during learning and normal activity. In a typical competitive network architecture, neurons in each layer are connected to the next layer, but, in addition, there are lateral connections between neurons in the same layer that cause the competition. Competitive learning includes a wide variety of algorithms performing different tasks, such as encoding, clustering, and classification.

The notion of a limited pool of individually adaptable tuned units is more than a functional abstraction useful for psychological modeling. The reality of a distributed representational substrate whose members compete for a share in the representation of the stimulus has been demonstrated in a variety of electrophysiological studies (Gilbert, 1994). These studies can be divided into two major groups. In the first group, competition among members of a pool of tuned units has been enhanced by the withdrawal of stimulation from some of the units. For instance, the induction of a retinal scotoma leads to invasion of the visual space of affected cells by the receptive fields of other, neighboring cells. An analogous effect, albeit on a much longer time scale, is observed in the somatosensory modality (Merzenich et al., 1988). In comparison, in the second group, the increased prominence of a subpopulation of functional units (whose emergence may in itself be a product of learning) is precipitated merely by the prevalence of the preferred stimuli of those units in the sensory repertoire of the system. For example, in the monkey, this phenomenon has been glimpsed in relation to face representation (Rolls et al., 1989), as well as the representation of general natural and artificial (Logothetis and Scheinberg, 1996) objects.

## Overview

In recent years, competitive learning has received considerable attention because of its demonstrated applicability and its biological plausibility. The idea of competition between neurons leads to sparse representations of data that are easy to decode and conserve energy. Current competitive learning algorithms can be distinguished by their learning rule (which is driven by their desired objective function) or by the form and role of the competition during learning. One form of competitive learning algorithms can be described as an application of a successful single neuron learning algorithm in a network with lateral connections between adjacent neurons. The lateral connections are needed so that each neuron can extract a different feature from the data. For example, if one has an algorithm for finding the principal component in a data set, i.e., the first eigenvector of the correlation matrix of the data, then a careful application of this learning rule in a lateral inhibition (competitive) network gives an algorithm that finds the first few principal components of the data (Sanger, 1989). This set of algorithms can be characterized by the fact that if the lateral connections are turned off, then neurons are likely to learn the most easily extracted feature in the data (based on the objective function), or the feature that corresponds to the closest local minimum of the objective function. For example, in a principal components network with no lateral inhibition, all neurons will converge to the first principal component of the data. In such algorithms, it is often sufficient to study the learning rule of a single neuron and deduce from it the performance of the network as a whole.

A second family of algorithms is characterized by the fact that turning off the lateral connections will result in a great loss of ability to extract useful features. Thus, the competition between neurons has an important role in improving, sharpening, or even forming the features extracted from the data by each single neuron. This is an important distinction that suggests that competitive learning may be useful in cases where other forms of learning may have difficulties. One such example is a network that searches for clusters. Clustering is the process of grouping together data points based on some measure of distance. When no inhibition exists between neurons, it is likely that neurons will converge to the mean of the data distribution. This follows from the fact that based on a Hebbian rule, neuronal weights (of radial basis neurons) tend to converge to the center of the distribution in order to maximize correlation of input activity with output activity. An algorithm that looks for tight clusters will probably find those that are occurring with highest probability, or those cluster centers that are closest to the initial weight values. When inhibition is turned on, the cluster centers will move to new locations and will become sharper and more distinct. There is evidence that inhibition plays a similar role in various brain functions such as the creation of orientation columns in visual cortex (Ramoa, Paradiso, and Freeman, 1988) or sharpening receptive fields in sensory cortex (Merzenich et al., 1988).

There are other points of view on competitive learning, in particular, competition over presynaptic versus postsynaptic resources (Willshaw et al., 1997). A more detailed review of these issues can be found in Intrator and Edelman (1997).

## Local Competition over Space

Frequently in a classification problem, there are regions in pattern space in which classification is easier, while there are other regions in which classification is not that simple and thus requires a larger (more complex) network. For example, there may be regions in which the different classes are linearly separable and other regions in which the boundary is highly nonlinear. Therefore, one of the key ideas in machine learning and statistical parameter estimation is recursive partitioning of the observation space in order to separate such regions. Motivation comes from the desire to study structure of high dimensional space by searching for homogeneous subregions that present a simpler structure than the original whole input space. Statistical theory suggests that the variance of the estimator, which directly influences generalization performance, is affected by the complexity of the estimator (polynomial degree, number of hidden units, etc.). Thus, performing the estimation with a simpler architecture is likely to improve generalization performance. However, if the network architecture is "too simple," in the sense that the architecture is not rich enough to allow a flexible enough function to fit the data, a large training error is unavoidable.

One solution to this trade-off is to recursively partition the data into several homogeneous regions so that a smaller network will suffice for each region. In this context we shall discuss in the next section the network of competing experts.

In a lateral competition network, a cluster center (the mean of a Gaussian distribution) is associated with a neuronal weight vector, and neurons compete between themselves to add each of the input patterns to their cluster. For a given pattern, the winner, in hard competition, is the neuron with highest probability for that pattern to belong to the Gaussian distribution represented by its center (see Winner-Take-All Networks). In soft competition, the cluster centers are organized in such a way that the distance of each data point from each of the cluster centers corresponds to the probability of this point under each of the Gaussian distribution (Jacobs et al., 1991).

If an input $x \in R^n$ is drawn with probability $\pi_i$ from one of $J$ independent Gaussians (for simplicity, assume that the Gaussians are radially symmetric), its a posteriori probability of belonging to the $j$th Gaussian is $\pi_j p_j(x)$, for

$$p_j(x) = \frac{1}{M\sigma_j} \exp\left( -\frac{\|x - \mu_j\|^2}{2\sigma_j^2} \right)$$

where $\sigma_j^2 I$ is the covariance matrix of Gaussian $j$, and $M$ is a normalizing constant. The partial likelihood that measures the probability of the data under the model of input $x_k$ in this model is $L(x_k) = \Sigma_j \pi_j p_j(x_k)$. The partial likelihood of a pattern set $\{x_k\}_{k=1}^K$ is

$$\mathscr{L} = \prod_k L(x_k)$$

assuming $K$ independent patterns. This could be turned into a likelihood if the marginal probabilities are taken into account to convert the partial likelihood into a probability function, but since the marginals do not participate in the optimization, there is no need to do that. Parameter estimation of such a model involves adjusting the centers $\{\mu_j\}$, the covariances $\{\sigma_j^2\}$, and the prior probabilities $\{\pi_j\}$ so as to maximize the likelihood of the model for a given training set. It is mathematically equivalent but more convenient to maximize the log likelihood, since the maximization is then on summation and not multiplication. In a radial basis function network realization of this model, there are $J$ radial basis hidden units and a linear output unit that gives the likelihood function under the conditions of the model.

Assuming for simplicity that $\sigma_j$ are equal, the hard competition approach for solving this problem would assume that each input can belong to only one cluster center. (Thus, the competition between neurons will lead to only one active neuron at a time), and, therefore, the above definition of $P(x)$ is replaced by

$$P(x) = \max_i \pi_i p_i(x)$$

The analytic solution for cluster centers (under assumptions about radial symmetry and $\sigma_i$ and $\pi_i$ being equal) is

$$\mu_i = \frac{\sum_{k \in C_i} x_k}{N_i}$$

where $C_i$ is the set of training patterns that were assigned to belong to the cluster center $i$ and $N_i$ is the number of these patterns. Note that this is not an explicit solution, since $C_i$ depend on all of the $\mu_k$s. A learning rule that converges to this solution is given by

$$\Delta\mu_{ij} = \eta(x_{ki} - \mu_{ij})p_i(x)$$

for the winning cluster $i$, and no change for the other clusters. This learning rule moves the closest cluster center in the direction of the data points that belong to that cluster, finally forming stable cluster boundaries and converging to the mean of the cluster. During this process, input patterns may "cross" from one cluster to another as a result of the movement of the cluster center. However, the process will converge to a stable solution simply because the mean squared distance of the patterns from their corresponding cluster centers goes down.

The soft competition paradigm assumes that each pattern can belong to any of the clusters. In this case, the solution that maximizes the likelihood of the model is given by

$$\mu_i = \frac{\sum_k p(i|x_k)x_k}{\sum_k p(i|x_k)}$$

where

$$p(i|x_k) = \frac{p_i(x_k)}{\sum_j p_j(x_k)}$$

A learning rule for the soft competition is similar to that for the hard competition. The difference is that each of the cluster centers is modified in the direction of the line connecting the cluster center and pattern $x_k$ in proportion to the probability that it belongs to that cluster. This follows from the formulation of the data as a mixture-of-Gaussians model. The soft competition approach is closely related to $k$-means clustering (Duda and Hart, 1973).

In practice, this algorithm does not perform well when the number of cluster centers is not known a priori or when the clusters are not radially symmetric. A lateral inhibition network in which each unit is locally pushing other units not to become selective to the region it is normally selective to can alleviate those problems. Kohonen's self-organizing map (SOM) is one of the earlier implementations of such networks (Kohonen, 1984). Its 2D lateral inhibition structure, which is also called learning vector quantization, implements clustering and has been shown to be useful in numerous applications, most recently in the WEBSOM project for text clustering.

The idea of having experts (entire modules), rather than units, compete globally over the whole space is a direct extension of the more local competitive learning approach. It leads to a competitive network and hierarchical mixture of experts (see MODULAR AND HIERARCHICAL LEARNING SYSTEMS).

## Competitive Learning and Resource Allocation

Competition over limited resources and the allocation of such resources are important characteristics of learning in biological systems. How do such systems manage and distribute their resources? It seems plausible to assume that a sophisticated system would choose an allocation strategy in response to the characteristics of the task. Consider, for instance, a situation that involves two consecutive learning tasks. In such a case, one may distinguish between two possibilities: (1) the second task involves the same data as the first one; (2) the second task involves new data (albeit presented in the same sensory modality).

We hypothesize the existence of a low-dimensional internal representation of the data, whose computation incurs a cost in terms of time and effort. It is then clear that in case 1, the system will be better off if it retains the same internal representation in both tasks. In comparison, in case 2, the existing representation may be modified, or a new one may be created. An intriguing glimpse into the approach taken by the brain in such a situation is provided by recent experimental results concerning the representation of extracorporal space in rat hippocampus (Wilson and McNaughton, 1993; see HIPPOCAMPUS: SPATIAL MODELS). In that study of place cells, Wilson and McNaughton used chronic multielectrode implantation techniques that allowed long-term recording of cell activities. They recorded more than a hundred cells from free-moving rats that had been trained so they were familiar with part of a simple maze. In these rats, certain hippocampal cells fired in relation to their place in the maze; when the rats were suddenly exposed to a new place, they underwent a short (about 5 minutes) phase of learning in which cells that were silent in the previous location were recruited to encode the new location. This process is consistent with a possible effective reduction in inhibition of cells that have not been recently active. Such a reduction in inhibition may enable them to modify their response patterns rapidly and to become coherently active in the new location.

## Discussion

There are various ways in which one can construct controller networks and they resemble various statistical approaches. One can construct either a wide shallow network, in which input patterns are split only once into one of several experts performing the task, or a deep tree with many splits, so that the regression or classification task is performed only by a bottom (terminating) node of the tree. This approach, known as the CART method, has gained considerable attention with the appearance of the classification and regression trees (Breiman et al., 1984). This method constructs a tree leading to different decisions in different regions of pattern space. A direct extension of competitive learning ideas motivated by the success of the above recursive partitioning methods is the hierarchy-of-experts approach (see MODULAR AND HIERARCHICAL LEARNING SYSTEMS).

There is no doubt about the importance of competition in the formation of neural and artificial networks. Experimental evidence from olfactory cortex suggests the performance of hierarchical clustering by a biological network (Lynch, 1986) and has led to the proposal of a model for hierarchical clustering as well. It uncovered the potential of recursive partitioning in complex pattern encoding and classification. Work by Merznick on motor cortex demonstrates that when inhibition is reduced (through amputation), a cortical region that has been responsive to input from one sensory region very quickly adapts to become sensitive to adjacent sensory regions. Competition between units and between collections of units is crucial for such a process. The exact nature of such competition, as well as the optimal architectures that exploit competition for self-organizing, have yet to be uncovered and are likely to benefit from recent advances in multiple cell recording.

# Competitive Queuing for Planning and Serial Performance

*Daniel Bullock and Bradley J. Rhodes*

## Introduction

In neural network studies of planning and serial performance, there is a long history of what Hartley and Houghton (1996) called *competitive queuing* (CQ) models (Figure 1). Such models follow naturally from two assumptions: (1) More than one plan representation can be simultaneously active in a planning layer; and (2) The most active plan representation is chosen, in a second neural layer, by a competition run to decide which plan to enact next. In CQ models, activation is the "common currency" used to compare alternative plans, and simple maximum-finding or winner-take-all (WTA) dynamics can be used as the choice mechanism in the choice layer. Once a plan wins the competition and is used to initiate a response, its representation is deleted from the field of competitors in the planning layer, and the competition is run again. This iteration allows the two-layer network to transform an initial activity distribution across plan representations, often called a *primacy gradient*, into a serial performance (Grossberg, 1978).

As a representation of serial order, the primacy gradient across plan representations in a CQ model is a fundamentally parallel representation. For this reason, CQ models provide a much different basis for control of serial behavior than what have come to be called recurrent neural networks (RNNs). An RNN, in this restrictive usage, is a network in which each output is fed back to the input (or other pre-output) stage as a way of helping to create a distinctive context for eliciting the correct next output. In such an RNN, the representation of the learned sequence is itself fundamentally serial, in the sense that the information that specifies the sequence only becomes available as the serial performance unfolds. In contrast, all the information needed to specify a forthcoming sequence is present in the current state of the planning level of a CQ system, although this current state may itself be dynamically evolving. Having such an explicit, parallel, activation-based representation of sequential plans becomes a substantial advantage for many purposes. For example, such representations can be learned and recalled via compressive and expansive coding operations, as noted later in this article.

Although CQ networks are a radically different basis for sequence control than RNNs, CQ networks also use neural signal recurrence, or internal feedback, for various purposes. The deletion signal sent to the planning layer once a plan is chosen for enactment is one example. Moreover, Grossberg (1978) showed how to implement both the planning layer and the choice layer of a CQ model as *recurrent competitive fields* (RCFs), which exhibit approximate normalization of the total activity level distributed across competing sites in a neural layer. These RCFs were interpreted as parts of a working memory system, in which activity distributions are maintained through significant intervals by recurrent self-excitation combined with recurrent inhibition of competitors. Yet simple changes of signal functions can transform a pattern-holding RCF into a WTA RCF, or even an RCF that quickly forgets initial activity differences. Beyond this ready tunability to realize both the pattern-holding and WTA properties of a CQ system, RCFs have two further properties that enhance their suitability as core models of the planning layers within biological CQ systems. If one plan representation is deleted (by zeroing its activity) from a planning layer RCF, then activity automatically redistributes among the remaining plan representations in a way that preserves the rank ordering of preexisting activation levels. This third property is crucial if iterated deletion is not to disrupt the planning layer's parallel representation of the serial order of subsequent plans.

A fourth property is another consequence of RCF normalization in the planning layer. Because total activity is conserved, *more* simultaneously active plans imply *less* activation per plan, including the plan scheduled to be performed first. If the initial activation level of this plan predicts the reaction time (RT) to perform the first planned action (as is the case if the choice layer is a WTA network with a high threshold for generating an output to the response execution system, and the latter system is set to perform as soon as it receives an input) then this variant of a CQ model makes a surprising prediction. The RT to *initiate* performance of a prepared sequence should increase with the number of plans in the prepared sequence. Such a "sequence length effect on RT" is true for humans performing lightly practiced sequences from working

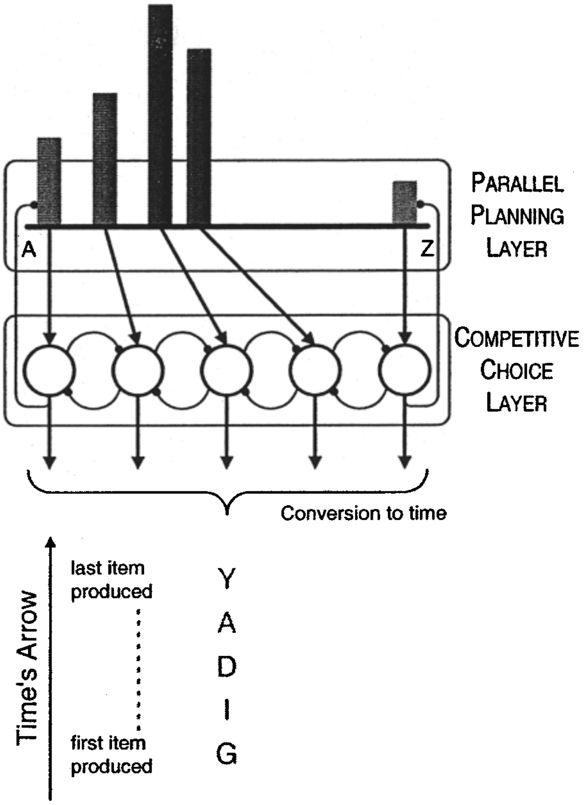

**Figure 1.** Initial state of a two-layer competitive queuing (CQ) system, prior to production of a five-letter sequence. The sequence that will emerge is shown in the lower part of the figure. Excitatory connections terminate with arrowheads, inhibitory connections with filled circles. The most active plan is selected for execution in the lower, competitive choice, layer by a winner-take-all dynamic whose outcome is wholly determined (in the absence of noise) by the activation gradient (representing the to-be-performed sequence) present in the parallel planning layer. Once a plan representation wins at the competitive layer, a large output signal is sent to initiate execution of the corresponding response (descending arrow) and to delete the plan's representation in the parallel activation layer (ascending path to parallel planning layer). This process iterates until all plans have been enacted and all planning layer activities deleted. The result is sequential plan execution that corresponds to the initial rank ordering (primacy gradient) of plan activation levels in the upper field of the CQ network. Although each competitive layer node would send an inhibitory connection to its correspondent in the parallel planning layer, only two such connections are shown here, to avoid clutter. In this example, which uses recurrent inhibition in the choice layer, each competitive layer node would inhibit all others, but only nearest-neighbor inhibition is actually depicted. (Adapted from Rhodes, 1999, with permission.)

memory (Sternberg et al., 1978; review in Rhodes, 1999). Simulations by Boardman and Bullock (1991) verified these RT properties for a two-layer CQ system coupled to a response generation network. They also showed that the model correctly predicted patterns of inter-item intervals observed in the Sternberg et al. RT task. Bradski et al. (1994, cited in Rhodes, 1999) developed a neural network that could serve as a perceptual preprocessor for a CQ model. In this network, a sequence of perceptual inputs induced an appropriate primacy gradient across plan representations in the planning layer of the CQ circuit.

## Applying the CQ Model to Immediate Serial Recall

In the Sternberg et al. (1978) task, subjects were told to repeat short prepared lists as fast as possible following an external signal. This qualified it as an RT task. A related list-recall task is the immediate serial recall (ISR) task, in which subjects also recall a short list from working memory, but without explicit instruction to initiate or perform recall as fast as possible. This non-RT sequence production task has also been modeled within the CQ framework. To the three core assumptions noted previously (primacy gradient, deletion on enactment, and iterated competitive choice of most-active remaining plan), Page and Norris (1998) added two auxiliary assumptions: that the choice is noisy, and that decay of activity in the planning layer occurs during input to the planning layer and during intervals spent performing items from the list. Error data favor both assumptions, and this extended model was able to address data on errors of serial recall. One kind of error, simple failure to recall, is most probable for list-final plans in long sequences. The extended model explains this as a consequence of their low initial activation level (due to being last in the primacy-gradient-coded sequence), which in turn makes them more susceptible to falling into inactivity due to the decay that can occur during enactment of the prepared sequence. Another feature of error data from ISR studies is that the vast majority of transposition errors (items are recalled, but in incorrect order) are simple exchanges with immediately adjacent items in the planned sequence. Given moderately noisy choice, this likewise follows from the gradient representation, because noise in the choice layer is less likely to illicitly promote a plan by two positions in the activity gradient than by one position.

## Brain Substrates of Competitive Queuing

Data that strikingly confirm one of the main physiological predictions of CQ models was recently reported in Chafee et al. (2001). Since the CQ model depends on a working memory to hold a gradient of activations across plan representations prior to and during performance, the model predicts that such a gradient will be observable in the part of the brain responsible for working memory, namely the prefrontal cortex (PFC). Chafee et al. observed three ensembles of prefrontal activities corresponding to three segments of a forthcoming line drawing that a monkey had been trained to produce. The relative strength of activation of the three cellular ensembles predicted the order of the forthcoming segments: the higher the premovement activation, the earlier in the sequence the corresponding segment was produced. Error data were also in accord with predictions of the CQ model.

Another property of some versions of the CQ model is the normalization of total activity in the planning layer. This property predicts that peak frontal cortical activities associated with plan representations will decline as the number of coactive plans increases. Data that confirm this prediction for plan representations' activities were recently reported by Cisek and Kalaska (2002). They found a class of cells in the rostral part of the dorsal premotor cortex (rPMd) that they called "potential response cells." Different subsets of such cells, representing different potential responses, were coactive during a delay period when there was uncertainty regarding which, if any, of one or two alternative responses should be performed. This delay period activity was much more vigorous in each plan representation (cell subset) when there was only one potential response to hold in working memory than when there were two potential responses to hold in working memory.

These data on rPMd and PFC are consistent with representations in a normalized working memory capable of storing a primacy gradient—the planning layer of a CQ system. What part of the brain serves as the choice layer for frontocortical plan representations? One idea that has grown in popularity in recent years is that the striatum, a subcortical structure that encompasses the caudate, putamen, and accumbens nuclei of the basal ganglia, may provide competitive arenas in which cortically represented plans vie for execution. According to the recent model of Brown, Bullock, and Grossberg (2000), the winning plan selectively activates a small subset of spiny projection neurons (SPNs) in the striatum, which receives a massive excitatory input from the cerebral cortex. Via a return pathway that traverses the pallidum and thalamus, this focal striatal activation enables selective activation of output cells in a cortical layer (layer Vb) that is below, and excited by, the layer in which the cortical planning cells are found. One point of current debate regards how the striatum runs its competition to choose the next plan to execute. This debate arises because the striatum contains both feedback inhibition, mediated by SPNs, and feedforward inhibition, mediated by inhibitory interneurons which, like the SPNs, are direct recipients of excitatory input from the cortex. The simulations reported in Brown et al. (2000) were based on recent physiological data indicating that the dominant factor in striatal choice making is feedforward inhibition, not recurrent inhibition. In a situation with many strongly activated competing plans, reliance on feedback inhibition to resolve the competition would require that many cells in the choice field would be transiently active. Therefore a high threshold downstream from the choice field would be necessary to prevent multiple premature response activations. With feedforward competition, none of the choice field's output cells—in the striatal case, the SPNs—need activate until the moment that the competition yields a winner.

## Plan Layer Loading by Rapid Parallel Recall from Procedural Long-Term Memory

One of the advantages of CQ models' explicit parallel representation of sequential plans—an advantage unavailable to RNNs as such—is that these distributed representations can be learned and recalled via compressive and expansive coding operations. In the Sternberg task and the ISR task mentioned previously, novel sequence information was provided to the performer. According to the CQ interpretation, performers hold a corresponding parallel representation for a few seconds in working memory (WM) before generating the sequence under the guidance of WM. However, Verwey (1996), among others, showed that a very high number of practice trials with short fixed sequences leads to *disappearance* of the sequence length effect on RT originally discovered by Sternberg et al. (1978). Is this result explicable in terms of a CQ model that uses activity normalization in the planning layer? Rhodes and Bullock (2002) have recently reported successful simulations of several sets of list learning and performance data, using a neural network in which the cerebellum, modeled as a substrate for procedural long-term memory (LTM), learns activation gradients over item nodes and rapidly recalls them into a normalized motor buffer (planning layer), which is a WM for action plans. The recall process is rapid because it entails *parallel loading of sequence chunks* into a WM from LTM. When the procedural LTM of a fixed sequence representation becomes strong enough (due to extensive practice), it causes preselection of the first list item within the CQ subsystem. Such preselection explains the disappearance of the sequence length effect on RT, which Verwey (1996) showed to be a reliable effect if subjects were given high levels of practice. This hybrid cerebellar-CQ model's assumption that the cerebellum can load parallel sequence representations into a frontocortical motor buffer is supported by recent neuroanatomical tracing studies, which have discovered pathways that run from the dentate nuclei of the cerebellum, via the thalamus, to several frontocortical zones, including premotor cortex and the PFC. More generally, the hybrid model illustrates how the CQ model, which focuses on WM dynamics that support sequential performance, can be interfaced with an LTM system that compressively learns and stores, and expansively recalls, oft-used sequences. Such a system is critical for functions that require frequent re-use of subsequences, such as musical performance or language production.

## CQ as a General Basis for Serial Behavior

For CQ to qualify as a core model for all sequence planning and control, it must be shown that it is extensible to a full range of human serial performance domains. Given the pervasive involvement of the brain substrate outlined previously, it is reasonable to look for CQ signatures far beyond the types of skill tasks considered thus far. The most highly developed example of human serial behavior, syntactic language production, is a critical test case for the thesis that CQ is general. Another instructive case is sequential control of attentional focus during information pickup from complex scenes.

### *Is CQ Extensible to Language Production?*

It might be thought that the CQ model cannot apply to syntactic language production, because sequencing errors in language production do not usually follow the "immediately adjacent items exchange" pattern found in ISR studies (which typically use non-grammatical item sequences). In most sequencing errors in language production, exchanges respect grammatical constraints, as when a sequencing error transforms the intended "flying saucers" into the spoonerism "sighing flossers." But note: the same example supports the CQ postulate that the initial segments of both words were already coactive in a planning field prior to production of either word. Moreover, it is plausible that the exchange error occurred because noise transiently rendered the plan for "fl" less active than the plan for "s" at the instant that "flying" should have been spoken. In fact, several neural network theorists have used CQ as a core of extended models that have offered explanations of many of the grammar-respecting patterns of sequencing-errors observed in language production (e.g., Dell, Burger, and Svec, 1997; Hartley and Houghton, 1996).

The most sustained treatment of CQ in language generation is that in Ward (1994). Far from simply explaining how the "emergent choice" that operates in CQ models is compatible with grammar-respecting sequencing errors in language production, Ward argues that *only* emergent choice offers a basis for overcoming more traditional language generators' failures to mimic the "flexible incremental generation" (FIG) exhibited in the real-time behavior of human speakers as they compose sentences "on the fly." Ward's FIG model combines CQ principles with principles inspired by *construction grammar* (e.g., Goldberg, 1995) to build a comprehensive connectionist model of grammatical sentence generation. The FIG algorithm is an iterated cycle: (1) Each node of an input conceptualization is a source of activation to "construction" nodes of various types, including words; (2) Activation is allowed to flow freely through the structured network of nodes; (3) When the network settles (or is forced to make an output) the most highly activated word representation is selected and enacted; (4) Any node or nodes of the input conceptualization that are expressed by the enacted word are inhibited, and activation levels are updated to represent the new current state; and (5) Steps 2–4 iterate until the conceptual content of the input has been expressed by the enacted word sequence. For the system to work well, the word plan that has the highest activation must be for a word that will be both syntactically and semantically correct if spoken as the next word in the utterance. This requirement is met, in part, by having the activation level of a word be determined by the product of its semantic and syntactic inputs, not by their sum.

Although much remains to test such models of CQ in the service of language production, initial simulation successes indicate that CQ may provide an ideal foundation for speech and language production models: one that is well grounded in neurobiology, and one that overcomes the inflexibility and other limitations inherent in more traditional, less parallel, theories.

### *Can CQ Be Considered an Attention Control Mechanism?*

To gather information from the visible world around us, we typically, and rapidly, move our attention sequentially from one part of the scene to another. Often such search is purposeful, as when we are attempting to find a particular item or object, such as a familiar face in a crowd. In other cases, the scan sequence can be driven by salient features present in the visible scene. Either way, there must exist some mechanism for determining where to focus attention first, where to move the focus next, and so on. As defined previously, CQ provides a very simple and elegant candidate mechanism. The combination of a "saliency map" with an "inhibition of return" mechanism forms the basic mechanism for controlling attention deployment in contemporary computational models of focal visual attention (e.g., Itti and Koch, 2001). The most salient location in the map has the highest activation and draws the focus of attention to that location, whereupon map activity at that location is inhibited. Consequently, some other location in the map becomes most active—i.e., most salient—and now attracts the attentional focus. This process is another example of CQ. That it applies to attention shifts is no surprise because of the close link between such shifts and saccadic eye movements, sequential control of which has been attributed to interactions between frontal cortex and the basal ganglia (e.g., Brown et al., 2000).

## Discussion

The fundamental scenario represented by the CQ model is almost palpable. We seem to be able to feel that two considered plans, or candidate words, begin with nearly equal potency, but that upon further deliberation, one waxes as the other wanes, and the waxing plan is first used to guide performance. Moreover, our capacity to simultaneously consider multiple plans in WM is limited to a small number. This limitation is predicted by the activity normalization property, which itself is needed to preserve the computational function of differences in activation levels. If forced to decide quickly, we feel that we choose the more vivid plan even if the rejected or deferred plan is also vivid and attractive. In the brain's parallel planning system, some common currency must be available for incrementing and decrementing the value of response alternatives, and in biological neural networks the use of excitation and inhibition to achieve these effects leaves activation level as the natural measure of relative priority. This, in combination with a maximum-finding network, creates a CQ system, which is probably an ancient invention in the evolution of animals. Recent computational studies, cited previously, have begun to explore how this ancient system may still serve as a viable core for the highest levels of planning and skilled sequencing exhibited by humans.

# Compositionality in Neural Systems

*Barbara Hammer*

## Introduction

In real life, people deal with composite structures: Written English language is built out of 26 characters (and a few additional symbols) that form syllables, words, sentences, articles, road maps, and finally the *Handbook of Brain Theory*. Spoken language consists of raw acoustic waves at a basic level; at a higher level, it can be decomposed into phonemes that form words, sentences, a poem or a speech. Visual data can be decomposed into pixels with various colors and intensities; alternatively, the raw image data may be represented by features like edges or texture, which are grouped to complex contours, objects, and, finally, a complete scene, such as the image of a grandmother sitting in a chair and knitting. Moreover, not only real-life data are processed as composite objects:

artificial data created by humans or virtual objects also have a composite structure. As examples, web sites consist of single pages with a head and body, links, tabulars, figures, enumerations, and so on. Computer programs decompose into procedures and functions, or objects and methods. Logical formulas and terms are recursive objects built out of symbols for constants, variables, and functions, logical connectives, and quantors.

In respect to neural systems, two questions arise:

1. Artificial neural networks are developed in order to model important aspects of the human brain and to explain how biological neural networks process information. A common characteristic of the way in which data are created, processed, and stored by humans is compositionality. *Which neural dynamics allow composite structures, grouping, and binding to emerge* in such a way that the single parts can be restored rapidly and, at the same time, the whole composite structure can be identified with a single object?

2. Artificial neural networks are a powerful and universal machine learning tool that is used in scientific and industrial applications for data contained in a finite dimensional vector space. Everyday data are composite. *How can we adapt standard neural techniques to composite structures* such that connectionistic methods can be used in everyday applications and combined with other compositional machine learning tools?

These two questions constitute extreme positions in a single problem spectrum: How is information processed in the brain? Since it is unlikely that models that are satisfactory with regard to both efficiency and biological plausibility will become available in the near future, the focus can be on one of two aspects: either one can develop practically applicable and efficiently trainable approaches or one can design biologically plausible and universal systems. Most existing approaches lie somewhere in between, partly because biological systems are indeed very effective, suggesting the universal principle of compositionality and dynamic binding, e.g., in the visual system (Bienenstock, 1996) (see DYNAMIC LINK ARCHITECTURE).

## Properties of Compositionality

What are the general properties of composite objects like the sentences “John loves Mary” or “Mary loves that John loves Mary”? The structures are composed of *basic primitives*—here, the words *John, Mary, loves*, and *that*. The primitives are instances of a certain *type*, e.g., a noun or verb. Composite expressions arise if the primitives are combined in specified *relations*. The sentence “John loves Mary” is an instance of a relation of the form subject–predicate–object, where subject and object can be instantiated with a specific noun, for example. Alternatively, these positions may be filled with composite objects, such as “John loves Mary” in the example “Mary loves that John loves Mary.” The complexity of recursively generated structures is usually not limited a priori. As an example, we could build the sentences “John loves that Mary loves that John loves Mary,” or “Mary loves that John loves that Mary loves that John loves Mary,” and so on. Hence, as pointed out in van Gelder (1990), the combination of primitives of certain types within constituency relations yields composite structures of *a priori unlimited complexity and an infinite number of possible combinations*.

The *semantics* of composite objects is determined by the semantics of the simple primitives and their relation in the structure. The primitives alone do not determine the semantics. The sentences “John loves Mary” and “Mary loves John,” for example, have identical constituents but different meanings. Moreover, the decomposition of complex objects into simpler parts and their interpretation may depend on the whole structure: the meaning of *her* in the sentence “Mary loves that John loves her” depends on the context of the part “John loves her.” Conversely, the same situation may be described with different composite objects, such as “Mary loves that John loves Mary” or “Mary loves that John loves her.” In other words, parts of a structure may be substituted by entirely different representations without affecting the semantics. Hence, the whole structure as well as the involved primitives and their relation should be available for referring the semantics.

Although an unlimited number of combinations of the primitives in constituency relations is possible in principle, commonly only a small number of all possible combinations are used in practice and make sense. Either basic syntactic rules or semantic limitations restrict the variety of possible compositions. “That John loves Mary loves Mary” does not make sense, for example, if the composite structure “that John loves Mary” is used as subject. Restrictions of possible combinations are often context dependent. For example, the sentence “John loves himself” would be preferred to “John loves John” unless the word “John” refers to two different persons.

Humans are capable of understanding and producing composite objects. Moreover, they can deal with new complex structures although they have never seen the specific combination of primitives before. As an example, having read the above sentences concerning John and Mary and the sentence “Mary loves Peter,” people would be capable of understanding the sentence “John loves that Mary loves Peter,” and they would possibly infer that this sentence is false. People can infer the meaning of partially new structures. They have knowledge about primitives and relations, and additional information such as rules for composition or experience with similar structures. Moreover, compositional structures play an important role if the capability of humans for analogy-based reasoning is investigated (see ANALOGY-BASED REASONING AND METAPHOR).

Appropriate artificial neural systems for use in processing compositional data should take these properties into account. Although they have to deal with an unrestricted amount of partially new and ambiguous data, they can use the sparseness and hierarchical structure of the data for efficient processing.

## Neural Systems and Compositionality

Popular neural methods perform pattern recognition, for which classical statistics provides a well-founded theory (see PATTERN RECOGNITION). Standard neural networks are adapted to real vectors contained in a finite dimensional Euclidean real-vector space. Concerning compositional structures, the question arises how to encode and process an arbitrary amount of information with this finite dimensional machinery.

Compared to their biological counterparts, artificial neural networks often neglect the fine temporal structure of spike trains (see OSCILLATORY AND BURSTING PROPERTIES OF NEURONS and ADAPTIVE SPIKE CODING): standard artificial networks process real values or binary values in a well-defined topological order. Real values correlate to the mean spiking frequence of the biological neurons; hence, the local temporal structure and respective correlation of spikes are not taken into account. Binary values might encode single spikes, although the topology allows processing on a discrete or fixed time scale only. Experiments provide evidence that the fine temporal structure may indeed carry important information for encoding complex scenes in biological networks (Engel et al., 1992). However, the precise way in which information is encoded in the respective parts of the brain is not yet understood. Moreover, some effects can possibly already be explained at the abstract level of rate coding (see RATE CODING AND SIGNAL PROCESSING). Hence it is worth considering the whole spectrum of neural architectures capable of dealing with compositionality. Our taxonomy for characterizing the various approaches is based on the connection structure of the neural architectures and on their fundamental dynamical behavior.

A key property of appropriate systems is their capability of processing a priori unlimited information. *Static solutions* with feedforward networks have the advantage that efficient training algorithms are readily available (see Backpropagation: General Principles). Unfortunately, either their capacity is limited or they need an a priori unlimited amount of neural resources.

Recurrent neural networks use the additional degree of freedom provided by a priori unlimited processing time in order to map the information appropriately. Recurrent networks may be *partially recurrent*, where the processing dynamics are determined by the respective data structure. The restriction to limited recursive data structures allows the immediate generalization of efficient standard learning tools (see Recurrent Networks: Learning Algorithms). Alternatively, the networks may be *fully recurrent*, in which case the dynamics are determined by the respective process. This allows more flexibility, but the processing time cannot be limited a priori, and alternative learning algorithms are necessary (see Temporal Sequences: Learning and Global Analysis). In particular, continuous-time fully recurrent neural networks can use the fine temporal structure for encoding complex information, such as in networks of spiking neurons (see Integrate-and-Fire Neurons and Networks). These approaches are biologically plausible and flexible. Unfortunately, no efficient learning algorithm comparable to standard backpropagation for feedforward networks has been established for networks of spiking neurons until today.

## *Static Approaches*

The *grandmother neuron doctrine* assumes that each simple or composite object is represented by the activity of a specific neuron for this object (see Localized Versus Distributed Representations). Neurons for complex objects are hierarchically connected to neurons representing their simple parts, and they only become active if all neurons for their parts become active. Putative "grandmother cells" have been found in the visual system of the macaque monkey, for example (see Sparse Coding in the Primate Cortex) but the data do not preclude the firing of such cells for a variety of patterns. Some invariance, for example with respect to the specific lighting, may be involved in the hierarchical computation, such that the neuron that encodes our grandmother fires independent of the specific context. Naturally, this approach requires additional neural resources for each new primitive, relation, or composite object, and therefore suffers from combinatorial limitations. Moreover, it is not obvious how entirely new combinations of well-known ingredients could be processed properly, i.e., in such a way that the possibility of analogies and transfer is taken into account. However, the hierarchical feedforward computation makes it possible to identify each neuron with a specific meaning and to use standard neural techniques.

Alternatively, composite objects may be represented in a *distributed manner* via the activation of a group of neurons for the single features (see Population Codes). This reduces the number of necessary neurons, but it is not obvious how invariance and not instantiated or new features are to be integrated. The necessary amount of resources depends on the respective task and cannot be uniformly limited. Moreover, the composition of two objects into a composite object is to be distinguished from the simple superposition of the activation of each; otherwise, the respective decomposition would become ambiguous.

Naturally, both encodings may be combined in *localized distributed representations* of objects that correspond to the firing of neurons at a certain area of the pool. This encoding is suggested by the presence of topology-preserving maps in biological systems where similar stimuli cause neural activities in similar neural regions (see Ocular Dominance and Orientation Columns).

Either localized or distributed encoding of composite objects in a vector space of fixed dimension has so far been the standard encoding for practical applications (see Localized Versus Distributed Representations). Hierarchical extraction of relevant features and finally of the respective class is a promising technique that has been successfully applied in various applications, such as the recognition of visual objects or text processing (Riesenhuber and Poggio, 1999; Mel and Fiser, 2000). Given the limits with respect to the number of recognized objects, static approaches suffer from a priori limitations and can only explain parts of biological information processing.

## *Partially Recurrent Systems*

*Discrete time partially recurrent neural networks* are widely used in time series prediction, speech recognition, and the processing of sequences of real vectors in general (Kremer, 2001) (see Constituency and Recursion in Language; Identification and Control). They deal with sequences of real vectors as opposed to simple real vectors and hence are capable of processing very simple composite objects with a priori unlimited informational content. Their dynamics directly mirror the recursive structure of the data: a standard feedforward network encodes in its internal activations the context of the computation, i.e., the first part of a sequence, and recursively maps one entry of the sequence after another to new contexts, depending on its internal state. Since the dynamic is fixed according to the data structure, standard gradient descent techniques can be used for supervised learning of mappings with sequences as inputs or outputs (see Recurrent Networks: Learning Algorithms).

The a priori unlimited information in the data structure changes the learning theoretical properties compared to standard feedforward networks: On the one hand, the power of recurrent networks can be demonstrated by relating them to classical symbolic computing mechanisms, such as Turing machines (Hammer, 2002) (see Neural Automata and Analog Computational Complexity). On the other hand, valid generalization can no longer be guaranteed for training set sizes that are both independent of the underlying input distribution and independent of the specific output of the training algorithm (Hammer, 2002) (see PAC Learning and Neural Networks; Vapnik-Chervonenkis Dimension of Neural Networks).

One can think of the recursive dynamics of simple recurrent networks as a recursive coding of sequences to distributed representations in a finite dimensional vector space. This idea can immediately be generalized to more complex composite objects, provided they have a recursive structure: trees consist of a label and a fixed number of subtrees. Hence, a network that is to encode trees instead of simple sequences can recursively map the root's label and the already computed codes for the subtrees to a code for the entire tree. It can also decode a distributed representation of a tree by computing the root's label and codes for the subtrees, which can be recursively processed further (Frasconi, Gori, and Sperduti, 1997; Hammer, 2002). This mechanism can be found in various Structured Connectionist Models (q.v.). Note that terms and formulas have a natural representation as tree structures: the single symbols are contained in the respective nodes, and the subformulas or subterms respectively correspond to subtrees. Thus, networks capable of encoding or decoding tree structures constitute a universal mechanism that enables the use of neural techniques in symbolic domains.

Concrete implementations of this basic idea differ in how the respective networks are trained. With the dynamics being determined by the data structure, gradient descent techniques can be used for supervised learning of general mappings, with trees as input or output. Recursive networks are trained directly for the specific learning problem (Frasconi et al., 1997; Hammer, 2002). The recursive autoassociative memory trains only encoding and decoding, such that their composition yields the identity on the data, leading to universal encoding (Frasconi et al., 1997; Sperduti, 1994). Holographic reduced representation uses a fixed transition function that is not trained at all (Plate, 1995). These approaches have been successfully applied in such different areas as chemistry, theorem proving, and language processing (Frasconi et al., 1997; Hammer, 2002). Learning is quite similar to the training of simple recurrent networks as far as practical algorithms as well as theoretical properties like approximation and generalization capability are concerned (Hammer, 2002).

This approach, however, is limited to recursive compositions with a well-defined recursive structure; cyclic structures cannot be processed in this way. Moreover, gaining access to single parts of recursive structures may be time-consuming and subject to noise, depending on the level of recurrence. There exist fundamental mathematical limitations to the possibility of coding infinite tree structures in a finite dimensional vector space: encoding has to be nested or fractal, which means that the Euclidean metric is no longer appropriate for the resulting distributed representations (Hammer, 2002). Thus, various neural methods that are based on the Euclidean metric cannot be used for further processing. Reliable decoding is a difficult task with a lower-bounded complexity (Hammer, 2002) (see Vapnik-Chervonenkis Dimension of Neural Networks). Therefore, neural networks with the above dynamics are not appropriate for efficiently decoding a large amount of distributed data.

### *Fully Recurrent Systems*

*Fully recurrent neural systems* are networks where the neuron's activations evolve in time in a continuous or discrete manner. Commonly, the dynamics can be described by nonlinear difference equations in discrete time or differential equations in continuous time. The main difference from partially recurrent networks is that the processing dynamics and consequently the required computation time are not directly determined by the data structures. Time and complexity of computation and representation of information are a priori unlimited. The systems may use the temporal structure of the neuron's activations for storing important information in specific spatiotemporal activation patterns such as synfire chains, i.e., successive spiking of specified neurons in precise time intervals (see Synfire Chains). As proposed by Bienenstock (1996), for example, the synchronous oscillation of different neurons or assemblies may indicate that they represent objects that are bound together (see Synchronization, Binding and Expectancy and Adaptive Spike Coding). This type of binding could easily be further processed with coincidence detectors. Alternatively, information may be stored in simple localized or distributed patterns of the neuron's activities, as in the static and partially recurrent approaches. Various systems obey a gradient dynamics as an example and converge to a fixed point that contains the important information (see Temporal Sequences: Learning and Global Analysis).

Concrete implementations differ considerably in their complexity and intention. Several approaches merely demonstrate that important effects such as *oscillation, synchronization*, and *coincidence detection* can be found in experiments on biological neural activities and can be simulated in an artificial, though biologically plausible, environment (see Chaos in Neural Systems; Collective Behavior of Coupled Oscillators, and Cortical Population Dynamics and Psychophysics). Particularly in the context of networks of spiking neurons, methods that allow a mathematical investigation of complex systems have been developed over the last years (see Integrate-and-Fire Neurons and Networks). First steps in possible training mechanisms use the principles of self-organization and Hebbian learning (see Post-Hebbian Learning Algorithms). Binding via the temporal structure and synchronous oscillation is a biologically plausible mechanism that is supported by experimental results (Engel et al., 1992). It is not yet obvious how complex recursive and hierarchical structures can be represented in this way, since methods such as iterated period doubling or a superposition of the oscillation, for example, are restricted by the computation accuracy of neurons. Moreover, efficient learning algorithms for practical applications are not yet available.

Other approaches *develop practical tools for concrete tasks* that involve binding mechanisms, such as feature grouping or edge detection in images (see Visual Scene Segmentation). Grouping may be encoded in synchronously oscillating neurons or in the localized activation of specific neurons in a limiting state that minimizes an energy function, such as in the competitive layer model (Wersing, Steil, and Ritter, 2001). Most approaches are based on appropriate excitation of similar neurons and an inhibition of cells with dissimilar activation. Again, only limited possibilities of automatic learning of the connections are available so far.

Finally, recurrent systems for *complex analogical reasoning and symbolic processing* have been proposed (see Structured Connectionist Models). Popular approaches are LISA, SHRUTI, and INFERNET, which have in common that binding is realized via synchronous oscillation of neurons or pools of neurons (Hummel and Holyoak, 1997; Sougné, 1999; Shastri, 1999). Structures are represented through localized or distributed cell activations. Rules correspond to specific neural connections that allow human-like analogical reasoning and are mostly hand encoded. They are capable of simulating various effects and limitations of human-like reasoning. However, like most fully recurrent approaches, the systems suffer from the lack of universal and efficient training algorithms.

## Discussion

Compositionality as a common principle of information processing should find its counterpart in artificial neural systems. Solutions may either enhance static feedforward systems and represent the objects by static activation patterns, or may rely on recursive and adaptive encoding mechanisms in partially recurrent networks, or may use complex dynamics and the fine temporal structure of the neuron's activation for reliable representation. Of course, it is possible to transfer more practical tools and theoretical guarantees from classical network techniques to these systems if they are similar to classical systems. It should be pointed out that it is still disputed whether artificial neural networks are capable of adequately handling compositional data, and if so, which type of network is the most suitable one. Remarkable results have been obtained with simple recurrent networks, although some researchers argue that more complicated dynamics or dynamics similar to classical symbolic processing mechanisms are necessary for successful modeling within the context of compositionality (see Connectionist and Symbolic Representations and Elman (1998) and references therein for a discussion of this subject).

Important directions for future research include the exploration of real neural codes in biological systems. Of particular interest is whether effects such as synchronous activation indeed contain information that is necessary for the representation of relations. Oscillations could constitute a byproduct of information processing that merely enables efficient adaptation in biological systems.

Restrictions on compositionality are another avenue of exploration. In practice, only a small subset of all possible combinations of primitives and relations occurs. Mathematical analysis of structure-processing systems implies usually a worst-case analysis and might indicate, for example, that static approaches are not appropriate for this field. However, neural mechanisms that are not capable of representing arbitrary composite objects in principle might be well suited for restricted, though important, domains.

# Computing with Attractors

*John Hertz*

## Introduction

This article describes how to compute with networks with feedback that exhibit complex dynamical behavior. In order to compute with any machine, we need to know how data are to be fed into it and how the result of a computation is to be read out. These questions are trivial for layered feedforward networks, but not for networks with feedback. A natural proposal is to wait until the network has “settled down” and then read the answer off a suitably chosen set of units. The state a dynamical system settles into is called an *attractor*, so this paradigm is called computing with attractors.

The term “settling down” is not meant to restrict this picture to cases in which the dynamical state of the network stops changing. This is one kind of attractor, but it is also possible to settle down into periodic or even chaotic patterns of activity, as described below.

It is possible in principle to perform computations based on the transient approach to the attractor, in addition to or instead of on the basis of the attractor alone. However, we will not consider this alternative in this article.

Computing with attractors is appealing because it does not require the person reading the result to observe the entire evolution of the network. Neither need she know when the computation was started or how long it took. All that is required is the identification of the attractor that a given initial condition evolves toward (and a way of recognizing that the network has reached the attractor). Therefore, this survey will begin with a brief description of the kinds of attractors one can meet: fixed points, limit cycles, and strange attractors. We will illustrate the paradigm with a simple example, the Hopfield model for associative memory. We then indicate briefly both how the connections necessary to embed desired patterns can be learned and how the paradigm can be extended to time-dependent attractors. Finally, we examine the possible relevance of attractor computation to the functioning of the brain.

## Networks, Attractors, and Stability

We will focus our attention on networks described by systems of differential equations like

$$\tau_i \frac{du_i}{dt} + u_i(t) = \sum_{j \neq i} w_{ij} g[u_j(t)] + h_i(t) \tag{1}$$

Here $u_i(t)$ is the net input to unit $i$ at time $t$ and $g(\quad)$ is a sigmoidal activation function ($g' > 0$), so that $V_i = g(u_i)$ is the activation of unit $i$. The connection weight to unit $i$ from unit $j$ is denoted $w_{ij}$, $h_i(t)$ is an external input, and $\tau_i$ is a relaxation time.

We can also consider discrete-time systems governed by

$$V_i(t + 1) = g\left[\sum_j w_{ij} V_j(t) + h_i(t)\right] \tag{2}$$

Here it is understood that all units are updated simultaneously.

These models are deterministic. Noisy networks can be analyzed by the methods of statistical mechanics and are treated extensively elsewhere in this *Handbook* (see, e.g., Statistical Mechanics of Neural Networks and Statistical Mechanics of Generalization).

Viewing such a network as a computer, data can be read into it in two ways. One is as the $h_i(t)$ on a subset of the units, which we can call input units. The $h_i(t)$ values might be held fixed or varied in time, depending on the problem. This way of loading data is, of course, just carried over directly from the conventional input-output paradigm as we normally apply it to feedforward networks. Alternatively, we can load the data by setting the values of the initial activations $V_i(0)$. For layered feedforward networks this procedure is equivalent to the previous one, but for recurrent nets it is fundamentally different. We can also use both these input mechanisms simultaneously. The first is appropriate when we want to have the output vary with the input (e.g., continuous mapping), while we use the second when we want an output to be insensitive to small changes in the input (e.g., error correction). As the second one is intrinsic to recurrent networks, we will focus most of our attention on it.

The program of such a computer is its connection weights $w_{ij}$. Some of them may be zero, but the questions we address here are rather trivial unless there is some feedback, i.e., unless our networks are *recurrent*. We will not restrict our attention to symmetric connections; $w_{ij}$ need not equal $w_{ji}$.

Finding the correct weights to implement a particular computation is a highly complex problem. However, for recurrent networks, we must first understand something about the attractors that represent the results of computations, so we now turn our attention to this problem.

To describe the dynamics of our networks, we make use of a picture in which the activation of each unit in the network is associated with a direction in a multidimensional space, called the *configuration space*. Every point in this space represents a possible state of the network, called the *state vector*, and the motion of this vector represents its evolution in time. For all recurrent networks of interest, there are just three possibilities for the asymptotic state:

1. The state vector comes to rest, i.e., the unit activations stop changing. This is the simplest case to analyze and is called a *fixed point*. Different results of a computation (owing to different input data) are characterized by settling into different fixed points. The region of initial states that settles into a single fixed point is called its *basin of attraction*. Most of the examples of recurrent networks in the literature, such as the Hopfield model and many related ones, compute with fixed points.
2. The state vector settles into a periodic motion, called a *limit cycle*.
3. The state vector moves chaotically, in the sense that two copies of the system that initially have nearly identical states will grow more and more dissimilar as they evolve: the two state vectors diverge from each other. However, the way they diverge is restricted. At any time the two state vectors are actually growing closer together in many directions in the configuration space; the divergence occurs only in some (typically a few) directions. A Poincaré map showing, e.g., the states of some of the units every time the state vector passes through some hyperplane in configuration space will be a fractal object with a dimensionality greater than zero (Schuster, 1989). This kind of attractor is called *strange* (see CHAOS IN BIOLOGICAL SYSTEMS and CHAOS IN NEURAL SYSTEMS).

Which kind of attractor we obtain will depend on the connections in the network and, possibly, the input data. Suitable learning algorithms make it possible to design the desired type. In simple applications, fixed points are naturally easiest to deal with. However, it may sometimes be advantageous to exploit the richer dynamical possibilities available in non-fixed-point attractors. For example, limit cycles allow the timing of the network's response to be controlled.

For all three kinds of attractors, the computation performed is a mapping from an initial condition to a particular attractor. It is evident that the dynamics partitions the configuration space into basins of attraction around the attractors. All initial conditions within a given basin map to the same attractor; that is, they are classified in the same way by the computation.

There are conditions under which the attractors will always be fixed points. For nets described by the continuous dynamics of Equation 1, a sufficient (but not necessary) condition is that the connection weights be symmetric: $w_{ij} = w_{ji}$.

General results about the stability of recurrent nets were proved by Cohen and Grossberg (1983). They showed that for static external input $h_i$, if the connection matrix $w_{ij}$ is symmetric, the attractors of Equation 1 are always fixed points, even if the activation function is allowed to differ from unit to unit, the $u_i(t)$ on the left-hand side is replaced by a general monotonic function $b_i(u_i)$, and $\tau_i$ is a (positive) function of $u_i$.

The proof illustrates the basic mathematical strategy for proving stability. Suppose we can find some quantity, a nontrivial function of the state variables $u_i$, which always decreases under the dynamics described in Equation 1 except for special values of $u_i$ at which it does not change. These values are fixed points. For values of $u_i$ near such a point, the system will evolve either toward it (an attractor) or away from it (a repellor). For almost all starting states, the dynamics will end at one of the attractor fixed points. Furthermore, these are the only attractors. If there were a limit cycle, for example, our function would decrease everywhere on a closed curve, which is impossible. Thus, whether such a quantity exists for a given network is very important. A function with this property is called a *Lyapunov function*.

There is indeed such a function for the Cohen-Grossberg extension of the dynamics described in Equation 1:

$$L(\mathbf{u}) = \sum_i \int^{u_i} [b_i(u) - h_i]g_i'(u)du - \tfrac{1}{2} \sum_{ij} w_{ij} g_i(u_i) g_j(u_j) \quad (3)$$

We can show directly that it is a Lyapunov function by computing its time derivative. Making use of the equations of motion and the symmetry of $w_{ij}$, we find

$$\dot{L} = -\sum_i g_i'(u_i)\tau_i(u_i)\dot{u}_i^2 \leq 0 \quad (4)$$

Thus $L$ is always decreasing, except at the fixed points $\dot{u}_i = 0$.

When a Lyapunov function exists, we may think about the dynamics in terms of sliding downhill on a surface in configuration space, the height of which is given by $L(\mathbf{u})$. The motion is not simple gradient descent, since $\dot{u}_i$ is not exactly proportional to $-\partial L/\partial u_i$ (there is an extra factor $g_i'(u_i)\tau_i(u_i)$). Nevertheless, the motion is always downhill, and the bottoms of the valleys correspond to the fixed points.

If we know the form of the Lyapunov function for a particular kind of network, this picture gives us a clue about how to program desired fixed-point attractors: we try to choose the connection weights $w_{ij}$ and biases $h_i$ so that $L$ has minima at these points in configuration space.

To gain a little more insight, we restrict ourselves to the case $b_i(u) = u$ and an activation function $g(u) = \tanh(\beta u)$. Using the activation variables $V_i = g(u_i)$ instead of $u_i$, we find that we can write $L$ in the form

$$L(\mathbf{V}) = \frac{1}{\beta} \sum_i \int^{V_i} dy \tanh^{-1} y - \sum_i h_i V_i - \tfrac{1}{2} \sum_{ij} w_{ij} V_i V_j \quad (5)$$

For large gain $\beta$, the first term is small. It is natural to think of the other two simply as a "potential energy" that the system tries to minimize. The $w_{ij}$ and $h_i$ should thus be chosen so that their sum has minima at or near the desired fixed points. The main effect of the first term is just to prevent the activations from reaching 1 or $-1$, since its derivatives diverge there.

Sometimes it is simple to construct a potential energy with the desired minima, at least approximately. In other problems, this strategy may be inadequate, and we have to resort to iterative learning algorithms to determine the network parameters.

Limit cycles and strange attractors are harder to handle mathematically. Often, however, it is possible to proceed in some kind of analogy with the fixed-point case.

## Associative Memory

The most celebrated application of computing with fixed points is ASSOCIATIVE NETWORKS (q.v.). Here we follow the treatment due to Hopfield (1984) (see also Hertz, Krogh, and Palmer, 1991, chaps. 2 and 3). There is a set of patterns to be stored somehow by the computer. Given as input a pattern that is a corrupted version of one of these, the result of the computation should be the corresponding uncorrupted one.

The strategy for solving this problem is to try to guess a form for the potential energy part of Equation 5 that will have minima at the configurations corresponding to the patterns to be stored. We take patterns $\xi_i^\mu = \pm 1$. The subscript $i$ labels the $N$ elements of the pattern (e.g., pixel values), and the superscript $\mu$ labels the $p$ different patterns in the set. The patterns are assumed random and independent for both different $i$ and different $\mu$. (This assumption is artificial for most potential applications, but studying this simple case affords us some insight into how the network works, and we will see how to relax it in the next section.) If we wanted to store just one such pattern $\xi_i$, a natural choice is just to take the potential energy function proportional to $-(\Sigma_i \xi_i V_i)^2$. The quantity $\Sigma_i \xi_i V_i$ measures the similarity between the pattern and the state of the network. It achieves its maximal value at $+N$, and therefore $-(\Sigma_i \xi_i V_i)^2$ is minimal if and only if every $V_i$ coincides with $\xi_i$. For more than one pattern we try one such term for each pattern, yielding a total potential energy

$$H = -\frac{1}{2N} \sum_{\mu=1}^{p} \left( \sum_i \xi_i^\mu \, V_i \right)^2 \tag{6}$$

Multiplying out the square of the sum, we can identify the connection weights in Equation 5 as

$$w_{ij} = \frac{1}{N} \sum_\mu \xi_i^\mu \xi_j^\mu \tag{7}$$

The form of this equation suggests a Hebbian interpretation (see Hebbian Synaptic Plasticity). For each pattern, there is a contribution to the connection weight proportional to the product of sending ($\xi_j^\mu$) and receiving ($\xi_i^\mu$) unit activities when the network is in the state $V_i = \xi_i^\mu$. This is just the form of synaptic strength proposed by Hebb (1949) as the basis of animal memory, so this is sometimes called a Hebbian storage prescription. This matrix is symmetric and has positive definite eigenvalues, so our earlier results guarantee that the attractors of our network dynamics are fixed points for both continuous and discrete-time dynamics.

The hope is that this will produce a fixed point of the network dynamics at or near each $\xi_i^\mu$. (Because our $H$ is purely quadratic in the $V_i$, we also expect fixed points near $-\xi_i^\mu$.) We can see how well this works by examining the stationary points of the Lyapunov function described by Equation 5, which are

$$V_i = \tanh \left( \beta \sum_j w_{ij} V_j \right) \tag{8}$$

We would first like to know whether there are solutions of Equation 8 that vary across the units like the individual patterns $\xi_i^\mu$.

The quality of retrieval of a particular stored pattern $\xi_i^\mu$ is measured by the quantity $m_\mu = N^{-1} \Sigma_i \xi_i^\mu V_i$. Using Equation 8, with the weight formula of Equation 7, we obtain

$$m_\mu = \frac{1}{N} \sum_i \xi_i^\mu \tanh \left( \beta \sum_\nu \xi_i^\nu m_\nu \right) \tag{9}$$

The kind of solution we are looking for should describe a state of the network that is correlated with only one of the stored patterns, i.e., just one of the $m_\mu \neq 0$. With this restriction, Equation 9 reduces to

$$m = \tanh (\beta m) \tag{10}$$

where $m$ is the value of the one non-zero $m_\mu$. This equation has nontrivial solutions whenever $\beta > 1$. Next we have to inquire whether these solutions are truly attractors, i.e., whether they are stable. At this point the story gets mathematically involved, so we simply survey the results (Kühn, Bös, and van Hemmen, 1991). Everything here is derived in the limit of a large network, i.e., $N \to \infty$; thus, the tools of statistical mechanics can be brought to bear.

The story is quite simple when $p$ (the number of stored patterns) is a negligible fraction of $N$, the number of units in the network. Then the nontrivial solutions are globally stable, while the solution $m = 0$ is unstable, whenever $\beta > 1$.

If the gain is high enough, there are other attractors in addition to the ones we have tried to program into the network with the choice of Equation 7. In the simplest of these, the state of the network is equally correlated with three of the $\xi_i^\mu$, say, $\xi_i^{\mu_1}$, $\xi_i^{\mu_2}$, and $\xi_i^{\mu_3}$. These other attractors are thus mixtures of three of our desired attractors. Such solutions exist whenever $\beta > 1$, but they are locally stable only when $\beta > 2.17$. Turning the gain up higher still, combinations of greater numbers of the desired memories also become stable. Thus, by keeping the gain between 1 and 2.17, we can limit the attractor set to the desired states.

When $p$ is of the same order as $N$, the analysis is more involved. The root of the problem is that the different terms in the weight formula in Equation 7 interfere with each other, even for independent random patterns. (The overlap between two patterns is of order $N^{-1/2}$, but as there are of order $N$ such overlaps, the net effect is of order 1.) This cross-talk has three important effects. First, it induces small mismatches, which grow with increasing $\alpha = p/N$, between the original patterns $\xi_i^\mu$ and the attractors. Second, and more dramatically, it destroys the pattern-correlated attractors completely above a critical value of $\alpha$, $\alpha_c$. This critical value depends on the gain $\beta$, and in the limit $\beta \to \infty$, $\alpha_c$ approaches 0.14. Finally, one finds that whenever the gain exceeds $\beta_s = (1 + 2\sqrt{\alpha})^{-1} \leq 1$ there are infinitely many fixed points, all completely uncorrelated with the patterns $\xi_i^\mu$.

Nevertheless, as long as we are not trying to store too many patterns ($\alpha < \alpha_c$), there will be attractors that are strongly correlated with the patterns. The unwanted other attractors can no longer be completely eliminated by suitable tuning of the gain, but as they are uncorrelated with the patterns, they do not have much effect on the retrieval of a pattern, starting from an initial configuration not too far from the attractor.

Thus, attractor computation works in this system over a wide range of model parameters. It can be shown to be robust with respect to many other variations as well. These include dilution (random removal of connections), asymmetry (making some of the $w_{ij} \neq w_{ji}$), and quantization or clipping of the weight values.

Obviously, both this network and the kind of computation it performs are very simple. It is not directly applicable to problems like scene analysis, where several objects, as well as relationships between them, have to be identified and characterized. It is possible to construct more complex networks, with modular and hierarchical structure, to perform such computations, but space does not permit us to treat them here.

A number of other problems, in particular in optimization theory, have been treated using the same strategy of choosing the connections so that the potential energy has minima in the appropriate places (see Optimization, Neural). The features we have noted in the associative memory problem appear to be universal. It is possible to obtain the desired attractors (at least approximately), but other, undesired attractors are generally also created. These can be controlled in some degree by suitable adjustment of the gain or other parameters.

## Learning

The weight formula in Equation 7 was only an educated guess. It is possible to obtain better weights that reduce the cross-talk and increase $\alpha_c$ by employing systematic learning algorithms.

One of the simplest of these is *Boltzmann learning* (see Simulated Annealing and Boltzmann Machines and Hertz et al., 1991, chap. 7). Originally, Boltzmann learning was formulated for stochastic binary units. Here we use a formulation for continuous-valued deterministic units. Suppose, as above, that we want to make an attractor of the configuration in which the unit activations are proportional to pattern $\xi_i^\mu$. Now if we start the network in the configuration $V_i = \xi_i^\mu$, it will settle into some fixed point $V_i^\mu$. The algorithm is to change the weights according to

$$\Delta w_{ij} = \eta(\xi_i^\mu \xi_j^\mu - V_i^\mu V_j^\mu) \qquad (11)$$

The first term is a Hebb-like learning term, like Equation 7, and the second term ensures that learning stops when the fixed point $V_i^\mu$ coincides with $\xi_i^\mu$. This is then performed for every pattern and repeated until the attractors converge to the desired locations. It is evident from Equation 11 that the resulting connections will be symmetric if the initial ones are. Boltzmann learning can also be used when there are hidden units. In that case, when $i$ or $j$ is a hidden unit, the patterns $\xi_i^\mu$ or $\xi_j^\mu$ are simply replaced by the stationary values those units take when the nonhidden units are clamped at the pattern values.

In the stochastic Boltzmann machine algorithm, the degree of stochasticity is controlled by a "temperature" parameter $T$. It corresponds in our deterministic network of continuous-valued units to the degree of softness in the sigmoidal activation function $g(u)$. (For $g(u) = \tanh \beta u$, the parameter $\beta$ can be identified with $1/T$.) For both kinds of networks, convergence to the fixed point $V_i^\mu$ is aided by starting at high $T$ and gradually lowering it. This procedure goes by the name *simulated annealing*.

The other simple learning rule that can be used to learn particular attractors is the delta rule. When there are no hidden units, its weight updating rule is

$$\Delta w_{ij} = \eta(\xi_i^\mu - V_i^\mu)\xi_j^\mu \qquad (12)$$

As in Equation 11, the role of the second or "unlearning" term in the parentheses is to turn learning off when the desired fixed points are achieved. With hidden units, the delta rule becomes what is known as *backpropagation* (see Perceptrons, Adalines, and Backpropagation). There is insufficient space here to go into the mathematical description of backpropagation in recurrent networks (but see Recurrent Networks: Learning Algorithms). We only remark that it is describable as propagating weight adjustments through the original network with all the directions of the connections reversed (see Hertz et al., 1991, chap. 7).

## Nonstationary Attractors

So far, we have worked with networks with first-order dynamics (1 or 2) and a symmetric weight matrix. If we relax either of these conditions, non-fixed-point attractors are possible.

It is possible to extend the Hopfield model described above to store pattern sequences, by including suitable delays into the discrete-time dynamics (2). This problem is treated in detail in Temporal Sequences: Learning and Global Analysis (q.v.). It can be mapped onto the one with static patterns, and much of the analysis for that model can be carried over to the dynamic case. Recent experimental investigations (Markram et al., 1997; Bi and Poo, 1998) have found synaptic changes that depend in sign on the relative timing of pre- and postsynaptic spikes. Such synaptic dynamics could provide a physiological substrate for sequence learning.

In a purely computational context, iterative learning algorithms can also be brought to bear to stabilize specific desired limit cycles. In particular, the recurrent backpropagation algorithm mentioned above for learning fixed points can be extended rather straightforwardly to learning arbitrary time-dependent patterns (see Hertz et al., 1991, chap. 7).

If networks can learn arbitrary periodic attractors, the obvious next question is whether they can learn strange attractors. The answer to this is also affirmative. The initial work on this problem was done by Lapedes and Farber (1987), who succeeded in teaching a network a strange attractor generated by a nonlinear differential-delay equation known as the Mackey-Glass equation, which was originally introduced in a model of blood production.

## Discussion: Attractors in the Brain?

Both local (see Motor Pattern Generation) and macroscopic neural activity (as in epilepsy; see EEG and MEG Analysis) can be described in terms of non-fixed-point attractors. However, the most interesting questions about attractors in the brain have to do with their functional roles in processes such as perception, recognition, and memory. For example, are particular attractors associated with the recognition of particular objects? Can the settling of the brain's activity into such an attractor be identified with the recognition process?

It has also been suggested (Skarda and Freeman, 1987) that a strange attractor in which the system hops irregularly between two or more regions of configuration space can provide a model for understanding why the brain does not get trapped forever in a fixed-point or limit-cycle attractor.

There is progress toward more biologically realistic modeling of the neural structures that could carry out the kinds of computations we have been discussing (see Cortical Hebbian Modules).

Some interesting evidence in favor of attractor computation comes from modeling by Griniasty, Tsodyks, and Amit (1993) of some experiments in which monkeys learn to identify a set of visual patterns. During training, the patterns are presented in a particular order. After learning, the patterns are presented in random order and multicellular recordings are made in a small region of anterior ventral temporal cortex during the period between stimuli. The spatial pattern of the mean firing rates across the electrode array is found to be stimulus specific. The interesting finding is that although the stimuli are not correlated with each other, the resulting firing patterns are. Strong correlations are found only between pairs of activity patterns evoked by stimuli that were close together in the training sequence.

In the theoretical analysis, the firing rate patterns are identified with attractors of the cortical dynamics. They suppose there are pre- and postsynaptic delays in the learning of the patterns, which leads to new terms proportional to $N^{-1}\Sigma_\mu \xi_i^\mu \xi_j^{\mu\pm1}$ added to the weight formula of Equation 7. This has the consequence that the attractor corresponding to a particular pattern is correlated with those of nearby patterns in the sequence. The form of this correlation can be calculated and is quite similar to that observed in Miyashita's experiments. This result lends credence to both the idea of attractor computation and the Hebbian learning picture.

Another phenomenon in which attractor networks appear to play an important role is working memory. The basic experimental finding is the following. Macaque monkeys perform a match-to-sample task: in each trial the animal sees a sequence of visual patterns, and it must press a bar when the one shown first is repeated. It thus has to keep a memory of the first stimulus during the intervening ones in the sequence. Some neurons in prefrontal (PF) cortex that are selectively sensitive to the first (sample) pattern exhibit continuing activity, above background level, in the entire delay period up to the re-presentation of that pattern, despite the intervening stimuli. Some neurons in inferior temporal (IT) cortex, which provides input to PF, exhibit similarly persistent "delay activity," but this activity is terminated by the presentation of different, intervening stimuli. Thus, these areas seem to be involved in the temporary storage of memories for visual patterns.

Associative memory networks incorporating important features of cortical circuitry and firing dynamics and exhibiting delay activity for learned attractors were developed by Amit and Brunel (1997). Their approach was developed further and applied to the phenomenology described above by Renart, Parga, and Rolls (2000) and Renart et al. (2001), who modeled IT and PF cortices as a pair of coupled associative memory modules. For appropriate coupling between the modules, the initial stimulus leads to an attractor state, associated with the first pattern, that persists in the PF module, even after the stimulus is changed and the state of the IT module is pushed into another attractor by the new (different) stimulus.

Related work by Compte et al. (2000), focusing on PF cortex alone, models experiments on an oculomotor delayed-response task in which a monkey has to remember the location of a visual cue during a delay period of a few seconds before it makes a behavioral response. Although the details of the two groups' models differ, both reproduce the phenomenology of the experiments quite well, lending support to an interpretation in terms of attractor computation.

It is thus evident that the attractor hypothesis at least provides a useful framework within which to address a number of problems in cortical computation, both theoretically and experimentally. It is too soon to know how widely it will be applicable, but it plays a key role in the current interplay of theory and experiment, as we try to build a coherent mathematical framework for cognitive neuroscience.

# Concept Learning

*Thomas J. Palmeri and David C. Noelle*

## Introduction

Concepts are mental representations of kinds of objects, events, or ideas. We have concepts because they allow us to see something as a kind of thing rather than just as a unique individual. Concepts allow generalization from past experiences: By treating something as a kind—as an instantiation of some concept—as a member of some category—we can use what we have learned from other examples of that kind. Concepts permit inferences: Deciding predator from prey, edible from inedible, friend from enemy involves concepts. Concepts facilitate communication: Describing something as a kind of thing may obviate the need to provide details of the thing itself. Concepts permit different levels of abstraction: We know the difference between objects and ideas, animals and plants, dogs and cats, and terriers and collies. Concepts bring cognitive economy: What we learn about animals generally can be applied to specific animals without needless replication of that knowledge throughout our conceptual hierarchy. Concepts are fundamental building blocks of human knowledge (see Margolis and Laurence, 1999).

The focus of this article is on learning mental representations of new concepts from experience. We will also address how we use mental representations of concepts to make categorization decisions and other kinds of judgments.

## Overview of Concept Learning Models

One goal of model development is to test specific hypotheses regarding the kinds of representations created during learning and the kinds of processes used to act upon those representations to make decisions. In order to develop a formal model of concept learning, a modeler must specify what perceptual information is provided by the sensory system, how that information is represented, how that information is compared with what has been learned about a concept, how this previously learned knowledge is represented in memory, and how decisions are made based on comparing perceptual information with stored conceptual representations (see PATTERN RECOGNITION).

A tacit assumption of many models of concept learning is that the perceptual system extracts information from the environment, passing a perceptual representation on to a conceptual stage of processing, which in turn generates an action. In the parlance of neural networks, the perceptual system provides the inputs to the network, the association weights and activation functions encode the conceptual representations, and decision processes use the outputs to generate a response. Most concept learning models characterize the perceptual system as a dimensionality reduction device (see OBJECT RECOGNITION and OBJECT STRUCTURE, VISUAL PROCESSING). For example, in the case of vision, the input on the retina is an extremely high-dimensional representation, with every photoreceptor effectively encoding an independent dimension of sensation. The perceptual system creates a relatively low-dimensional representation by recoding the retinal input in terms of a smaller number of features or dimensions. These vectors of features or dimensions serve as the inputs to the concept learning network.

The distinction between features and dimensions is fully discussed elsewhere (e.g., Tversky, 1977). The members of a category—the extension of a concept—may be seen as clusters of perceptual vectors in a psychological space. An important type of concept learning entails associating regions in that space with particular category labels.

A *featural representation* in a neural network essentially consists of a vector of input nodes encoding the presence or absence of primitive elements. Similar stimuli share many common features. Dissimilar stimuli correspond to uncorrelated vectors. Often in simulation modeling, feature representations have no direct relationship to the actual stimuli of an experiment, but are instead designed to capture the statistical relationships among stimuli.

A *dimensional representation* is not discrete, but represents information in terms of values along continuously varying psychological dimensions. Similar stimuli have similar values along the dimensions, occupying adjacent locations in psychological space. Often in simulation modeling, dimensional representations may be derived from physical properties of actual stimuli or may be derived from similarity ratings (or other measures of psychological proximity) made by subjects using techniques such as multidimensional scaling (although feature representations can be derived as well).

The core of this article reviews models of how concepts are learned and represented in neural networks. One important distinction between models is whether concepts have LOCALIZED VERSUS DISTRIBUTED REPRESENTATIONS (q.v.). Another is whether conceptual knowledge relies on abstractions, such as rules or prototypes, or relies on specific exemplar knowledge. Most models focus on supervised learning, where trial-by-trial feedback is supplied, but some models address unsupervised learning. Most models focus on how concepts are learned within a category learning paradigm, whereby subjects learn to produce the correct label for each stimulus, but some models address how subjects can learn to infer properties other than the category label. Most models focus on learning from induction over examples, but some address learning from instruction or from explanation as well.

## Concept Learning Models

### *Rule Models*

Early philosophers conjectured that all concepts were decomposable into necessary and sufficient conditions for membership (e.g., Plato in Margolis and Laurence [1999]). A "triangle" is a closed form with three sides, a "bachelor" is an unmarried adult male, and so forth. Conceptual rules are like carefully worded definitions provided to a student. Indeed, a strength of this hypothesis is the apparent alignment of mental representations with self-reports of conceptual knowledge. Generally, to be considered a rule, a concise definition is required—if arbitrarily complex rules are allowed, the rule hypothesis becomes vacuous, because virtually any representation can be characterized by complex rules. Therefore, rule representations typically include just a small set of dimensions—sometimes only a single dimension. Although this may seem overly restrictive, humans frequently exhibit reliance on individual dimensions during concept learning (Nosofsky, Palmeri, and McKinley, 1994).

Simple neural network units may be connected to compute logical functions (see NEURAL AUTOMATA AND ANALOG COMPUTATIONAL COMPLEXITY). A rule involving a threshold along a single dimension is the simplest example, and serves as the basis for rules in some concept learning models (e.g., Ashby et al., 1998; Erickson and Kruschke, 1998). Assuming a dimensional input representation, a single-dimension rule simply involves a learned weighted connection $w_{ij}$ from input node $a_i$ to output unit $o_j$ with learned bias $\theta_j$

$$o_j = \frac{1}{[1 + \exp(-w_{ij}a_i - \theta_j)]} \tag{1}$$

The sigmoidal activation of this unit is proportional to the likelihood of category membership. A network of this kind essentially implements a linear decision boundary in psychological space, with the boundary orthogonal to one of the psychological dimensions, and with the position of the boundary specified by the learned bias $\theta_j$ (see Figure 1*A*).

### *Prototype Models*

Although people often report conceptual knowledge in terms of rules, there are reasons to question rules as the universal basis for conceptual knowledge. Many common concepts are difficult to de-

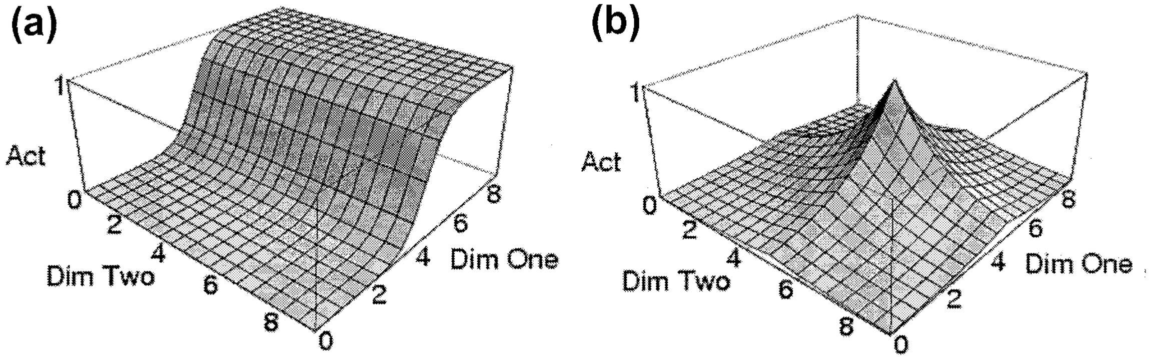

**Figure 1.** Examples of activation (Act) as a function of location in a two-dimensional psychological space (Dim One × Dim Two) for (a), the logistic sigmoidal function in Equations 1–3 and for (b), the radial-basis function in Equation 4.

fine using rules—Wittgenstein suggested the example of "games" as appearing to defy definition (see Margolis and Laurence, 1999). Instead, concepts seem to possess "family resemblances," with instances bearing many similarities but no characteristics common to all members. Human performance often belies the existence of rules in that some items appear to be "better" members than others in terms of typicality ratings, speed of processing, and inductive power.

Such findings led to an alternative view of conceptual knowledge based on abstract prototypes (see Rosch and also Lakoff in Margolis and Laurence, 1999). A prototype need never be directly experienced, but can be formed by averaging across observed instances. In psychological space, the prototype is the centroid of a cloud of instances. New items are classified according to their relative similarity to learned prototypes, with typicality effects emerging from this process. Learning just two prototypes effectively partitions psychological space into two regions separated by a linear boundary, but this boundary is a fuzzy (probabilistic) one and is unconstrained in terms of its orientation within psychological space.

A simple two-layer prototype model assumes an input layer of features (or dimensions) with learned associations to category output nodes. Each output unit $o_j$ corresponds to a single concept prototype, and the weights $w_{ij}$ from inputs $a_i$ to each $o_j$ reflects the strength of association of particular stimulus features with that concept:

$$o_j = \frac{1}{\left[1 + \exp\left(-\sum_i w_{ij}a_i - \theta_j\right)\right]} \tag{2}$$

The probability $P(j)$ of categorizing a stimulus as a member of category $j$ can simply be given by the relative activation of node $j$ compared to all other nodes. Other more dynamic mechanisms, such as lateral inhibition, can also introduce competition between concepts in Winner-Take-All Networks (q.v.).

This simple network learns to associate input stimuli with their corresponding categories. A related approach is to train Associative Networks (q.v.) to reproduce the features of each training instance as well as the correct category label (e.g., McClelland and Rumelhart, 1985). This pattern completion approach permits the network to not only categorize stimuli, but also to infer other missing features as well. More powerful pattern completion arises when Computing with Attractors (q.v.) such as in the Brain State in a Box model (see Associative Networks). Recurrent connections between all category label units and all feature units permit the network to encode soft constraints guiding how activation settles over time. In addition to their pattern completion properties, learned basins of attraction in such networks can instantiate nonlinear decision boundaries between categories, potentially creating a kind of prototype model that incorporates information about both the mean and the variability of a distribution of category exemplars.

### Exemplar Models

Simple concept learning networks of the sort just described can learn category structures (a) and (b) depicted in Figure 2—linearly separable categories—but cannot learn category structure (c)—nonlinearly separable categories. This is the classic XOR problem that stymied early developments in neural networks (see Perceptrons, Adalines, and Backpropagation). In contrast, multilayered networks with an input layer, a hidden layer, and an output layer can learn these category structures. Activation of hidden and output nodes is determined by a nonlinear sigmoid function like that shown in Equation 2. Learning takes place via gradient descent on error, with knowledge fully distributed throughout the network connections (see Backpropagation: General Principles). These "backpropagation networks" are powerful learning devices and, with sufficient hidden nodes, they can acquire concepts of nearly unlimited complexity.

Psychological models of concept learning attempt to model human behavior, with all its errors and apparent inefficiencies. Although backpropagation networks are powerful machine learning devices, they make relatively poor models of human concept learning. For one, backpropagation networks are insensitive to the psychological dimensional structure within the categories. From a statistical standpoint, structure (a) and structure (b) in Figure 2 have equivalent complexity, so backpropagation networks learn both types equally quickly. But people find structure (a) far easier to learn than structure (b) because structure (a) permits attending to a single dimension. Backpropagation networks generally learn linearly separable categories, such as structure (b), far more quickly than nonlinearly separable categories, such as structure (c). By contrast, people find structure (c) easier to learn. More generally, people are not constrained by linear separability, and often exhibit more rapid learning of nonlinearly separable than linearly separable categories. Finally, backpropagation networks suffer from catastrophic forgetting in which new concept learning overwrites previous concept learning. There have been many modifications to simple backpropagation networks to combat this problem. Common to many approaches is the use of semilocalized representations instead of fully distributed representations (see Localized Versus Distributed Representations).

Exemplar-based models assume local representations (see Smith and Medin in Margolis and Laurence, 1999). In contrast to rule and prototype models, concepts are represented extensionally, in terms of specific category instances. A number of variations of exemplar models have been proposed, and a vast set of empirical phenomena is consistent with them (Nosofsky and Kruschke, 1992). Perhaps the best-known neural network exemplar model is ALCOVE (Kruschke, 1992), which is largely derived from the gen-

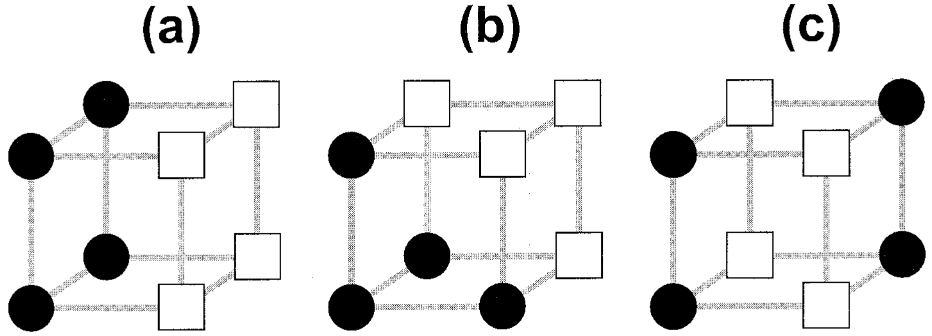

**Figure 2.** Depictions of three category structures. Individual stimuli are composed of three binary-valued dimensions. The dimensional values of a stimulus are specified by its location in the three-dimensional psychological space. For each structure, black circles represent stimuli in one category and white squares represent stimuli in another category.

eralized context model of categorization (Nosofsky, 1986), but incorporates error-driven learning.

ALCOVE is a three-layered feedforward network in which activation passes from a dimensional input layer, with each dimension scaled by a learned selective attention weight, to an exemplar-based hidden layer, to a category output layer via learned association weights. In contrast to backpropagation networks (compare Figures 1(a) and 1(b)), activation $h_j$ of hidden exemplar node $j$ is based on its similarity to the input stimulus

$$h_j = \exp\left[-c\left(\sum_i \alpha_i |e_{ji} - a_i|^r\right)^{1/r}\right] \tag{3}$$

where $a_i$ is the value of the input stimulus along dimension $i$, $e_{ji}$ is the value of exemplar $j$ along dimension $i$, $\alpha_i$ is the learned attention to dimension $i$, $c$ is a similarity scaling parameter, and $r$ determines the psychological distance metric (see also Radial Basis Function Networks). When optimally allocated, selective attention weights emphasize differences along diagnostic dimensions and deemphasize differences along nondiagnostic dimensions (Nosofsky, 1986).

ALCOVE also learns to associate exemplars with category outputs. Activation of category output node $k$ is given by

$$o_k = \sum_j w_{kj} h_j \tag{4}$$

where $w_{kj}$ is the learned association weight between exemplar $j$ and output node $k$. The probability of categorizing the input stimulus as a member of category $K$ is given by

$$P(K) = \frac{\exp(\varphi o_K)}{\sum_k \exp(\varphi o_k)} \tag{5}$$

where $\varphi$ is a response mapping parameter. Attention weights ($\alpha_i$) and association weights ($w_{kj}$) are learned by gradient descent on error.

Although exemplar models like ALCOVE have accounted for a wide variety of fundamental categorization phenomena (Nosofsky and Kruschke, 1992), until recently they have ignored the time-course of making a categorization decision. One avenue of recent theoretical development has addressed the time-course of the accumulation of perceptual evidence used to categorize a stimulus (Lamberts, 2000), modeling how perceptual processes make some information available sooner than others. Another avenue of development has examined the time-course of making categorization decisions. Nosofsky and Palmeri (1997) proposed a stochastic exemplar-retrieval model with a competitive decision process to account for both categorization response probabilities and response times. Although this theoretical development was formalized using mathematical modeling tools, such as a random walk decision process, the dynamics of these stochastic, competitive categorization models could be implemented in various neural network architectures as well.

### Mixed Models

Exemplar models have been shown to account for a variety of results, including some that were originally thought to unequivocally indicate rules or prototypes as concept representations. Yet, there seems to be some emerging evidence that people do use abstractions, particularly abstract rules, as concept representations. Clearly, people can be instructed to use rules before they have experienced any examples (Palmeri, 1997; Noelle, Cottrell, and McKinley, 2002). Also, it appears that people may approach the task of learning categories by testing simple categorization rules (e.g., Nosofsky et al., 1994), although people may eventually shift to using exemplars with experience (Johansen and Palmeri, in press). One important focus of current research is developing and testing formal models with mixed representations. At one extreme are models that posit functionally independent rule-based and exemplar-based systems that race to completion (e.g., Palmeri, 1997); exemplar-based representations gain strength with repeated exemplar experience and eventually win the race. Alternatively, rule and exemplar representations may be functionally independent, but the outputs of these systems may compete based on strength of evidence rather than completion time (e.g., Ashby et al., 1998). Erickson and Kruschke (1998) proposed a neural network model (ATRIUM) with separate rule and exemplar representations that compete, with the model learning whether rule-based or exemplar-based information should be used to categorize a particular instance. Finally, other architectures have proposed combinations of rules, exemplars, and perhaps other representations within a single representational medium.

### Neuroscientific Models

Neurobiological findings have begun to constrain concept learning models by ruling out mechanisms that resist reasonable neural implementation. Some recent models have included hypotheses concerning how conceptual knowledge is instantiated in the brain.

COVIS is one example of a model grounded in neurophysiology (Ashby et al., 1998). COVIS is a mixed representational model, incorporating implicit decision boundaries and explicit unidimensional rules. The implicit learning system, assumed to reside within the striatum, encodes a category decision boundary (although other representations—such as exemplar-like coarse-coded topological maps of psychological space with regions associated with category labels—also fits within this general framework). Verbal rule processing is assumed to exist in the prefrontal cortex, with the selection of rule-attended dimensions handled by a reinforcement learning process in the anterior cingulate, mediated by projections from the basal ganglia. Given a stimulus, the implicit and rule-based systems compete to provide a category response. This model has been applied to concept learning deficits seen in the very old and the very young, in patients with Parkinson's disease and Huntington's disease, in clinically depressed patients, in individuals with focal brain lesions, and in nonhuman animals.

Other neurally oriented concept learning models have focused on the role of prefrontal cortex in representing and actively maintaining rule-based information during categorization (Noelle et al., 2002; O'Reilly et al., 2002). A distinguishing feature of these models is the use of signals that encode changes in expected future reward (see Reinforcement Learning)—emanating from the basal ganglia dopamine system (see Dopamine, Roles of)—to determine when a useful rule representation has been found and should be gated into a prefrontal working memory system. Like COVIS, these dopamine-gating models incorporate a mixed representation, integrating rules with a kind of procedural knowledge. Unlike COVIS, these models focus on procedural knowledge embedded in multilayer networks, presumably located within the cortex, rather than on a special implicit learning system within the striatum. Rule representations, stored as patterns of activity in a prefrontal attractor network (see Computing with Attractors), do not directly compete with these procedural systems, but rather modulate them through the injection of activity. Models of this kind have provided explanations for frontal lesion data, suggested a coarse topological organization for prefrontal cortex, captured patterns of performance on dynamic classification tasks, explained interference effects in instructed category learning, and illuminated learning deficits in schizophrenia.

## Discussion

In this article, we limited our discussion to the kinds of representations and processes that subserve a particular aspect of concept learning, namely learning to categorize. Recent work has investigated other topics, as well, including how people learn to infer properties other than the category label and how learning about categories may influence perceptual processing in a top-down manner (e.g., Schyns, Goldstone, and Thibaut, 1998).

An important focus of current research was outlined in this article: Do people use different kinds of concept representations, how are those representations learned, and is the dominance of particular representations modulated by experience or other task demands? In order to help answer these questions, and in order to develop neurally plausible models of concept learning, some researchers are beginning to incorporate the constraints imposed by various neuroscientific sources of evidence, including studies of patients with focal brain damage, functional imaging and evoked potential studies, and single unit recordings in animals.

# Conditioning

*Nestor A. Schmajuk*

## Introduction

During conditioning, animals modify their behavior as a consequence of their experience of the contingencies between environmental events. This article delineates several formal theories and neural network models that have been proposed to describe classical and operant conditioning. Other important theories, omitted here owing to space limitations, are described by Schmajuk (1997).

## Classical Conditioning

During classical conditioning, animals change their behavior as a result of the contingencies between the conditioned stimulus (CS) and the unconditioned stimulus (US). Contingencies may vary from very simple to extremely complex ones. For example, in Pavlov's famous experiment, dogs were exposed to the sound of a bell, the CS, followed by food, the US. At the beginning of training, animals only generated unconditioned responses (UR), salivation, when the US was presented. With an increasing number of CS-US pairings, CS presentations elicited a conditioned response (CR). In general, a CR is analogous to the UR (dogs salivate in response to the bell), CR onset precedes the US onset (salivation precedes food presentation), and the peak CR amplitude tends to be located around the time of the occurrence of the US. When acquisition is followed by presentations of CS alone, the CR extinguishes.

Different CS-US interstimulus intervals (ISI) may be employed. Conditioning is negligible with short ISIs, increases dramatically at an optimal ISI that depends on the response being conditioned, and gradually decreases with increasing ISIs.

Second-order conditioning consists of a first phase in which $CS_1$ is paired with the US. In a second phase, $CS_1$ and $CS_2$ are paired together in the absence of the US. Finally, when $CS_2$ is presented alone, it generates a CR. Sensory preconditioning consists of a first phase in which two CSs, $CS_1$ and $CS_2$, are paired together in the absence of the US. In a second phase, $CS_1$ is paired with the US. Finally, when $CS_2$ is presented alone, it generates a CR.

In latent inhibition, pre-exposure to CS retards the acquisition of CS-US associations. Latent inhibition is characterized by a large number of properties. In blocking, an animal is first conditioned to $CS_1$, and this training is followed by conditioning to a compound consisting of $CS_1$ and a second stimulus, $CS_2$. This procedure results in a weaker conditioning to $CS_2$ than would be attained if paired separately with the US. In overshadowing, an animal is conditioned to a compound consisting of $CS_1$ and $CS_2$. This procedure results in weaker conditioning to each CS than it would achieve if it was independently trained.

In conditioned inhibition, $CS_2$ acquires inhibitory conditioning following $CS_1$ reinforced trials interspersed with $CS_1$-$CS_2$ nonreinforced trials. In contrast to excitatory conditioning, presentations of $CS_2$ alone do not extinguish inhibitory conditioning.

In compound conditioning, two or more stimuli are presented together in the presence of the US. In a feature-positive discrimination, animals receive reinforced simultaneous compound presentations ($CS_1$ overlapping with $CS_2$) alternated with nonreinforced presentations of $CS_2$. Animals learn to respond to $CS_1$ but not to $CS_2$. In an occasion-setting paradigm, animals receive reinforced serial compound presentations ($CS_1$ preceding $CS_2$) alternated with nonreinforced presentations of $CS_2$. Animals learn to respond to the $CS_1$-$CS_2$ compound but not to $CS_1$ or $CS_2$. In negative patterning, presentations of a reinforced component ($CS_1$ or $CS_2$) are intermixed with nonreinforced compound ($CS_1$-$CS_2$) presentations. Negative patterning is attained if the response to the compound is smaller than the sum of the responses to the components. In positive patterning, reinforced compound ($CS_1$-$CS_2$) presentations are intermixed with nonreinforced component ($CS_1$ or $CS_2$) presentations. Positive patterning is attained if the response to the compound is larger than the sum of the responses to the components.

### *Associations, Predictions, and Connections*

Modern learning theories assume that the association between events $CS_i$ and $CS_k$, $V_{i,k}$, represents the *prediction* that $CS_i$ will be followed by $CS_k$. Neural network or connectionist theories frequently assume that the association between $CS_i$ and $CS_k$ is represented by the efficacy of the synapses, $V_{i,k}$, that connect a presynaptic neural population excited by $CS_i$ with a postsynaptic neural population that is excited by $CS_k$ (event $k$ might be another CS or the US). When $CS_k$ is the US, this second population controls the generation of the CR. At the beginning of training, synaptic strength $V_{i,\mathrm{US}}$ is small, and therefore, $CS_i$ is incapable of exciting the second neural population and generating a CR. As training progresses, synaptic strengths gradually increase, and $CS_i$ comes to generate a CR.

Although some models of conditioning describe changes in $V_{i,k}$ on a trial-to-trial basis, real-time networks describe the unbroken, continuous temporal dynamics of $V_{i,k}$. In general, real-time neural networks assume that $CS_i$ gives rise to a trace, $\tau_i(t)[d(\tau_i)/dt = K_1(CS_i - \tau_i)]$, in the central nervous system that increases over time to a maximum and then gradually decays to zero. The increment in $V_{i,k}$ is a function of the intensity of the $CS_i$ trace at the time the US is presented.

Changes in synaptic strength $V_{i,k}$ might be described by $\Delta V_{i,k} = f(CS_i)f(CS_k)$, where $f(CS_i)$ represents the presynaptic activity and $f(CS_k)$ the postsynaptic activity. Different $f(CS_i)$ and $f(CS_k)$ functions have been proposed. Learning rules for $V_{i,k}$ either assume variations in the effectiveness of $CS_i$, $f(CS_i)$, the US, $f(CS_k)$, or both. The following sections describe how different types of models deal with the many experimental results presented before.

### *Variations in the Effectiveness of the CS: Attentional Models*

Attentional theories assume that the formation of $CS_i$-US associations depend on the magnitude of an internal representation of $CS_i$, $f(CS_i)$. In neural network terms, attention may be interpreted as the modulation of the CS representation that activates the presynaptic neuronal population involved in associative learning. When focused on a particular CS, selective attention enhances the internal representation of that specific CS.

Mackintosh's (1975) attentional theory suggests that $CS_i$ associability, $f(CS_i)$, increases when $CS_i$ is the best predictor of (the CS most strongly associated with) the US and decreases otherwise. Mackintosh's model describes latent inhibition, overshadowing, and blocking. In contrast to Mackintosh's (1975) view, Pearce and Hall (1980) suggested that $f(CS_i)$ increases when $CS_i$ is a poor predictor of the US, $f(CS_i) = |US - \Sigma_j V_{j,\mathrm{US}} CS_j|$, where $\Sigma_j V_{j,\mathrm{US}} CS_j$ represents the aggregate prediction of the US computed on all CSs present at a given moment. In addition to latent inhibition, blocking, and overshadowing, the Pearce and Hall model correctly predicts that latent inhibition might be obtained after training with a weak US. According to Grossberg's (1975) neural attentional theory, pairing of $CS_i$ with a US causes both an association of $f(CS_i)$ with the US and an association of the US with $f(CS_i)$. Sensory representations $f(CS_i)$ compete among themselves for a limited-capacity short-term memory activation that is reflected in $CS_i$-US associations.

### *Variations in the Effectiveness of the US: Simple and Generalized Delta Rules*

A popular rule, proposed independently in psychological (Rescorla and Wagner, 1972) and neural network (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION for the Widrow-Hoff rule) domains, has been termed the delta rule. The delta rule describes changes in the synaptic connections between the two neural populations by way of minimizing the squared value of the difference between the output of the population controlling the CR generation and the US. According to the "simple" delta rule, $CS_i$-US associations are changed until $f(\mathrm{US}) = \mathrm{US} - \Sigma_j V_{j,\mathrm{US}} CS_j$ is zero. In neural network terms, $f$(US) can be construed as the modulation of the US signal that activates the postsynaptic neural population involved in associative learning. Rescorla and Wagner showed that the model describes acquisition, extinction, conditioned inhibition, blocking, and overshadowing.

Sutton and Barto (1981) presented a temporally refined version of the Rescorla-Wagner model. In the model, the effectiveness of $CS_i$ is given by the temporal trace $\tau_i = f(CS_i(t)) = Af(CS_i(t)) + BCS_i(t)$, which does not change over trials. The effectiveness of the US changes over trials according to $f(\mathrm{US}(t)) = (y(t) - y'(t))$, where the output of the model is $y(t) = f[\Sigma_j V_{j,\mathrm{US}} f(CS_j) + f(\mathrm{US})]$, $f$(US) is the temporal trace of the US, and $y'(t) = Cy'(t) - (1 - C)y(t)$. Computer simulations show that the model correctly describes acquisition, extinction, conditioned inhibition, blocking, overshadowing, primacy effects, and second-order conditioning. In 1990 the authors proposed a new rendering of the Sutton and Barto (1981) model, designated the temporal difference model, in which $f(\mathrm{US}) = (\mathrm{US} + \gamma y'(t + 1) - y'(t))$. The temporal difference model correctly describes ISI effects, serial-compound conditioning, no extinction of conditioned inhibition, second-order conditioning, and primacy effects.

Kehoe (1988) presented a network that incorporates a hidden-unit layer trained according to a delta rule. In addition to the paradigms described by the Rescorla-Wagner model, the network describes stimulus configuration, learning to learn, savings effects, and positive and negative patterning.

Schmajuk and DiCarlo (1992) introduced a model that, by employing a generalized delta rule (also known as backpropagation; see PERCEPTRONS, ADALINES, AND BACKPROPAGATION) to train a layer of hidden units that configure simple CSs, is able to solve negative and positive patterning. Interestingly, this biologically plausible, real-time rendition of backpropagation differs from the original version in that the error signal that is used to train hidden units, instead of including the derivative of the activation function of the hidden units, simply contains their activation function. Figure 1 shows real-time simulations on trials 1, 4, 8, 12, 16, and 20 in a delay-conditioning paradigm with a 200-ms CS, a 50-ms US, and a 150-ms ISI. As CR amplitude increases over trials, output weights $VS_i$ and $VN_j$ and hidden weights $VH_{ij}$ may increase or decrease.

The network provides correct descriptions of acquisition of delay and trace conditioning, extinction, acquisition-extinction series, blocking, overshadowing, discrimination acquisition and reversal, compound conditioning, feature-positive discrimination, conditioned inhibition, negative patterning, positive patterning, and generalization.

Gluck and Myers (1993) presented a network that also trains a hidden layer through a backpropagation procedure. The authors assume three three-layer networks that work in parallel. The output and hidden layers of one of the networks are trained to associate CS inputs with those same CS inputs and the US. The output layers

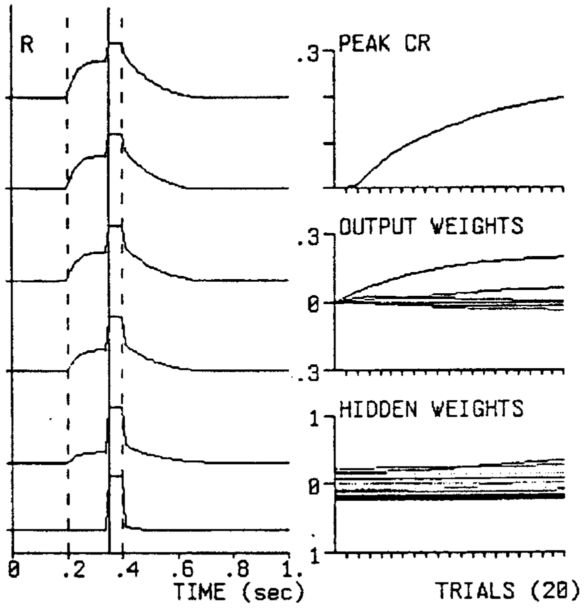

**Figure 1.** Acquisition of classical conditioning. *Left*, Real-time simulated conditioned and unconditioned response on trials 1, 4, 8, 12, 16, and 20. Vertical dashed lines indicate CS onset and offset. Vertical solid line indicates US onset. Trial 1 is represented at the bottom of the panel. *Right*, Peak CR: Peak CR as a function of trials. Output weights: Average *VS*s and *VN*s as a function of trials. Hidden weights: Average *VH*s as a function of trials. (After Schmajuk and DiCarlo, 1992.)

of the other two networks are also trained by the US, but their hidden units are trained by the hidden units of the first network.

### *Variations in the Effectiveness of Both the CS and the US*

To account for a wider range of classical conditioning paradigms, some theories have combined variations in the effectiveness of both the CS and the US. For example, Wagner (1978) suggested that $CS_i$-US associations are determined by (1) $f(\mathrm{US}) = (\mathrm{US} - \Sigma_j V_{j,\mathrm{US}}\mathrm{CS}_j)$ as in the Rescorla-Wagner model, and (2) $f(\mathrm{CS}_i) = (\mathrm{CS}_i - V_{i,\mathrm{CX}}\mathrm{CX})$, where CX represents the context and $V_{i\mathrm{CX}}$ the strength of the CX-$\mathrm{CS}_i$ association.

Schmajuk, Lam, and Gray (1996) introduced a theory that assumes that $f(\mathrm{CS}_i)$ is modulated by the association of the internal representation of $\mathrm{CS}_i$ with the total environmental novelty, $z_i$. Total environmental novelty is given by $\Sigma_j|\bar{\lambda} - \bar{B}_j|$, that is, the sum of the absolute values of the differences of the average predicted and the average observed event *j*. Schmajuk et al. (1996) showed that the model correctly describes most of the properties of latent inhibition.

Buhusi and Schmajuk (1996) showed that when combined with the Schmajuk and DiCarlo (1992) model (see Figure 2), the Schmajuk et al. (1996) approach can describe a wide variety of classical conditioning data; see the figure caption for details.

### *Multiple Representations of the CS: Timing*

The fact that the peak CR amplitude tends to be located around the time of the occurrence of the US suggests that animals learn about the temporal relationship between the CS and the US. Grossberg and Schmajuk (1989) proposed a neural network (called the spectral timing model) that is capable of learning the temporal relationships between the CS and the US. The model consists of three layers of neural elements. A step function, activated by the CS presentation, excites the first layer that contains many elements, each one having a different reaction time. The output of each element in the first layer is a sigmoid function that activates a second layer of habituating transmitter gates. In turn, the output of each transmitter gate activates a $f(\mathrm{CS}_i)$ element. Those $f(\mathrm{CS}_i)$ elements active at the time of the US presentation become associated with the US in proportion to their activity. All $f(\mathrm{CS}_i)$ elements activate their corresponding $V_{i,\mathrm{US}}$ weights and are added to generate the CR. During testing, the CR shows a peak at the time when the $f(\mathrm{CS}_i)$ elements that have been active simultaneously with the US are active again. The model is able to describe ISI curves with single and multiple USs and a Weber's law for temporal generalization. Grossberg and Schmajuk (1989) showed that the model can explain the effects of increasing CS and US intensity, an inverted U in learning as a function of ISI, multiple timing peaks, effect of increasing US duration, and the effect of drugs on timed motor behavior.

Church and Broadbent (1991) presented a connectionist version of Church's scalar timing theory. The model consists of the following components: (1) a pacemaker that emits pulses, (2) a switch that is opened at the onset of the event to be timed and closed at its offset, (3) a counter that accumulates pulses, (4) a reference memory that accumulates pulses of reinforced times and a working memory that stores the total number of pulses accumulated in a particular trial, and (5) a comparator that compares the values stored in both memories. Values stored in working memory are compared to values stored in reference memory, and if they are similar, a response is produced. Notice that the number of stored pulses increases with the measured time. The model is able to describe timing with single but not with multiple USs and describes a Weber's law for temporal generalization.

## Operant Conditioning

During operant (or instrumental) conditioning, animals change their behavior as a result of a triple contingency between its responses (R), discriminative stimuli ($S_D$), and the reinforcer (US). Animals are exposed to the US in a relatively close temporal relationship with the $S_D$ and R. As they experience the $S_D$-R-US contingency, animals emit R when $S_D$ is presented.

Four classes of $S_D$-R-US contingencies are possible: (1) positive reinforcement, in which R is followed by the presence of an appetitive US; (2) punishment, in which R is followed by the presence of an aversive US; (3) omission, in which R is followed by the absence of an appetitive US; and (4) negative reinforcement (escape and avoidance), in which R is followed by the absence of an aversive US. As in reinforcement learning (see REINFORCEMENT LEARNING), during operant conditioning, animals learn by trial and error from feedback that evaluates their behavior but does not indicate the correct behavior.

### *Positive Reinforcement*

Operant conditioning can be obtained with free operant procedures, in which the operant response may occur repeatedly. Free operant paradigms are usually run in a Skinner box. In such a box, rats learn to press a bar (R) or pigeons learn to peck a key (R) to obtain food (US) from a dispenser when a light ($S_D$) is lit.

Dragoi and Staddon (1999) introduced a model that describes the major properties of free operant conditioning. According to their theory, (1) responses and stimuli become associated with re-

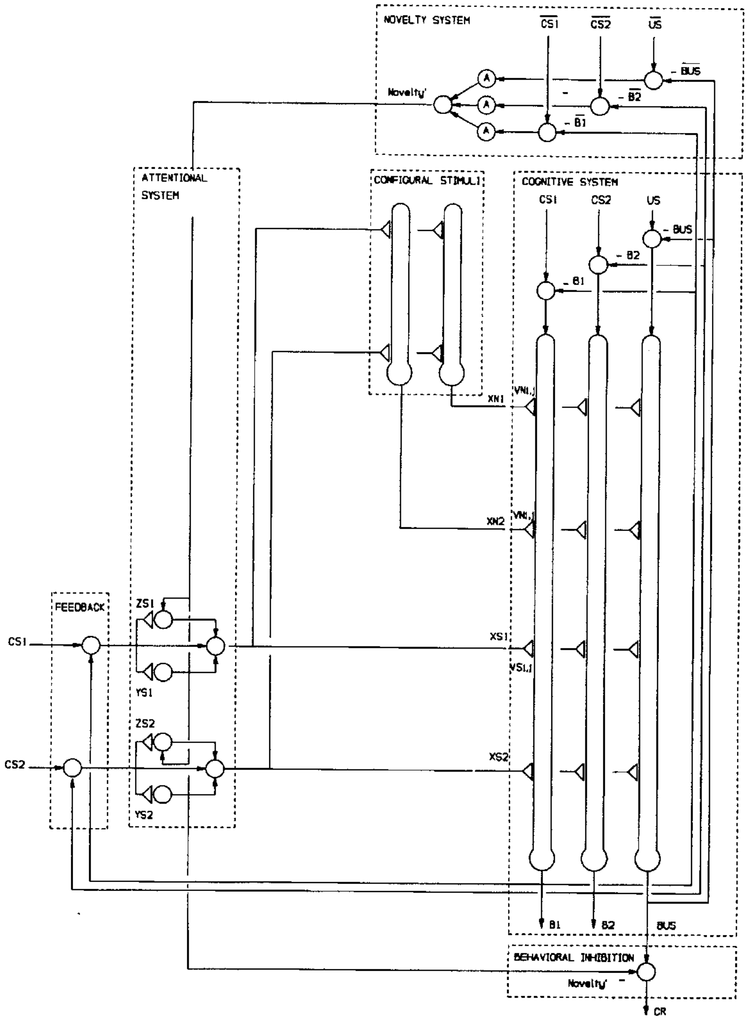

**Figure 2.** Diagram of a network that incorporates (a) an attentional system and (b) a configural system. In the attentional system, the internal representations of $CS_i$ are modulated by the total environmental novelty, Novelty', computed in the novelty system. In the configural system, the internal representations of simple stimuli $XS_i$ become *configured* with the internal representations of other CSs in hidden units that represent configural stimuli $CN_j$. In the associative system, both $CS_i$ and $CN_i$ become associated with the ohter CSs and the US. The attentional system permits the description of latent inhibition, and the configural system permits the description of occasion setting. $CS_i$: conditioned stimulus; $ZS_i$, $YS_i$: attentional associations; $XS_i$: $CS_i$ internal representation; $CN_j$: configural representation; $VS_{ik}$: $XS_i$-$CS_k$ association; $VS_{iUS}$: $XS_i$-US association; $VN_{ik}$: $CN_i$-$CS_k$ associations; US: unconditioned stimulus; $B_k$: $CS_k$ aggregate prediction; $B_{US}$: US aggregate prediction; $\overline{CS}_k$: $CS_k$ average observed value; $\overline{B}_k$: $CS_k$ average predicted value; CR: conditioned response. Arrows represent fixed synapses. Solid circles represent variable synapses. (After Buhusi and Schmajuk, 1996).

inforcement, (2) response-reinforcement and stimulus-reinforcement associations are combined to generate learning expectancy, and (3) the operant response is controlled by the interaction between expected and experienced events. The model describes qualitative features of operant behavior such as discrimination learning, response selection, contingency effects, effects of reinforcement delay, matching in choice experiments, development of preference, contrast effects, resistance to extinction, spontaneous recovery, regression, serial-reversal learning, and overtraining reversal effect.

## *Negative Reinforcement*

Operant conditioning can also be obtained with discrete trial procedures, in which the operant response occurs only once on a given trial. For instance, discrete-trial avoidance paradigms are usually run in a two-way shuttle box. The shuttle box is a chamber with two compartments separated by a barrier with a door. Each compartment has a metal grid floor that can deliver a shock (US). Lights above the chambers provide warning signals (WS) for the US. The experiment starts with both compartments being illuminated. At time zero, the light above the compartment where the animal is located turns off (WS), and the door separating both compartments opens. If the animal has not crossed to the opposite side after a given time (that may vary between 2 and 40 s), the shock US is applied. If the animal has crossed to the opposite side before that time, it avoids the US, and the separating door closes behind it. After a constant or an average intertrial interval that varies from 15 s to 4 minutes, the whole sequence restarts.

Schmajuk, Urry, and Zanutto (1998) presented a real-time two-process theory of avoidance that combines elements of classical and operant conditioning. The network incorporates two processes: classical and operant conditioning. Whereas the classical conditioning process controls US-US, WS-US, and R-US associations, the operant conditioning process controls US-$R_{\text{escape}}$ and WS-$R_{\text{avoidance}}$ associations. Whereas classical conditioning is regulated by a delta rule, $f(\text{US}) = \text{US} - \Sigma_j V_{j,\text{US}} X_j$, where $X$ represents WS, R, or the US, operant conditioning is regulated by a novel algorithm that mirrors the classical conditioning algorithm, $f(\text{US}) = -(\text{US} - \Sigma_j V_{j,\text{US}} X_j)$. Schmajuk et al. (1998) applied the network to the description of escape and avoidance behavior in a shuttle box, running wheel, leg flexion, or lever-pressing paradigms as Sidman avoidance. Schmajuk et al. (1998) demonstrated through computer simulations that the model describes most of the features that characterize avoidance behavior.

## Discussion

Theories and neural networks of conditioning can be evaluated at different levels. At the behavioral level, simulated behavioral results are compared with experimental data. At the computational level, simulated activity of the neural elements of the model are compared with the activity of single-neuron or neural population activity. At the anatomical level, interconnections among neural elements in the model are compared with neuroanatomical data. Finally, model and animal performances can be compared after brain lesions, induction and blockade of long-term potentiation, or administration of different psychopharmacological drugs.

Examples of these good matches include the Schmajuk et al. (1996) model, which describes a very large number of conditioning paradigms, many of the behavioral properties of latent inhibition, the activity of dopamine neurons in the nucleus accumbens as coding for the variable novelty, the effect of lesions of the hippocampus and different regions on the accumbens on latent inhibition, the effect of administration of amphetamine and haloperidol also on latent inhibition. Another interesting case is the Sutton and Barto (1990) model, which, when combined with some of the principles used in the Grossberg and Schmajuk (1998) model, describes the activity of dopamine neurons of the ventral tegmental area and substantia nigra in terms of the prediction errors for rewards (Schultz, Dayan, and Montague, 1997).

Good models are characterized by (1) a large percentage of simulation results that match experimental results and (2) a relatively small number of equation parameters. As Schmajuk (1997) explains, the ratio between (1) and (2) gives a measure of the overall quality of a model.

# Connectionist and Symbolic Representations

*David S. Touretzky*

## Introduction

In symbolic representations, the heart of mathematics and most models of cognition, symbols are meaningless entities to which arbitrary significances may be assigned (Newell, 1980; Harnad, 1990). Composing ordered tuples from symbols and other tuples allows us to create an infinitude of complex structures from a finite set of tokens and combination rules. Inference in the symbolic framework is founded on structural comparison and rule-governed manipulation of these objects.

Many aspects of language and cognition appear rule-like but, on closer inspection, are not so amenable to axiomatization. A famous example is the production of past tense forms of English verbs (Rumelhart and McClelland, 1986; see Past Tense Learning). Regular verbs add /t/ or /d/ or /ed/ to derive their past tense phonetic form, depending on the final sound of the stem, e.g., “flipped” versus “fibbed” versus “fitted.” People generate regular past tenses of novel forms, such as “bork” to “borked,” as if they were “applying the rule.” But multiple classes of irregular verbs follow different conventions, e.g., sing/sang, bring/brought, or leave/left. People sometimes apply these patterns to novel forms, as in “bling”/“blang,” or misapply them to stems that follow a different irregular convention (“bring” to “brang” instead of “brought”). There are stages in child language acquisition where the regular suffix is not only misapplied, as in “bring” to “bringed,” but sometimes combined with the output of an exception pattern, producing forms such as “broughted.” The interactions of regular and exception forms, and the developmental phenomena associated with past tense acquisition, are difficult to formalize. Thus, it seems unlikely that children are constructing explicit past tense *rules* in their heads.

The aim of the formal symbolic approach to understanding is to give a precise account of a domain in the language of that domain, e.g., a theory of grammar expressed in terms of morphemes, words, and phrases, or a theory of vision formulated in terms of pixels, regions, boundaries, etc. Axioms (rules) determine the structures that may be composed and the inferences that may be drawn from them. The approach has had great success in formalizing mathematics, but the hope that language, perception, or other aspects of cognition might succumb to similar treatment has faded.

It is important to note here that rule-based systems are not limited to deductively sound, consistent inferences. Artificial intelligence makes extensive use of nondeductive reasoning methods. For example, case-based reasoning tries to match a problem description against a library of cases for which the solution is already known. Match scores are determined heuristically, in some instances simply by counting the number of shared features. The cases retrieved provide only a best guess at an answer, but this may be sufficient.

The search for sound deductive rules for cognitive domains having long been abandoned, the debate between symbolists and connectionists is over how much of the formalist enterprise should be retained. Symbolists have moved to more complex formalizations of cognitive processes, using heuristic and unsound inference rules. (No one claims humans are sound reasoners. Heuristics have proved very useful, and suitably constrained inference systems might never suffer the consequences of their unsoundness.) Connectionists explore a radical alternative: that cognitive processes are mere epiphenomena of a completely different type of underlying system, whose operations can never be adequately formalized in symbolic language (Smolensky, 1988; see PHILOSOPHICAL ISSUES IN BRAIN THEORY AND CONNECTIONISM).

That connectionist models are implemented on digital computers does not make them symbolic models. The past tense model can be described in terms of nodes and links and activation values, but there is no isomorphism between this description and one phrased in the domain language, i.e., in terms of verb stems and affixes. The relationships between elements at the two levels can only be hinted at. This is what makes the model nonsymbolic.

In summary, connectionism replaces classical discrete, set-theoretic semantics with continuous, statistical, vector-based semantics. In the following sections we examine representation and processing issues from a connectionist perspective.

## Feature Vector Representations

If arbitrary symbols are replaced by feature vectors, the similarity of two concepts can be measured by their dot product. This is an attractive alternative to defining explicit axioms for determining, say, whether *chair* should be more similar to *table* than to *couch.* Similar concepts will naturally have similar vector representations, which facilitates generalization in neural networks.

Early models in this vein used hand-constructed feature vectors, often with familiar semantic features such as "human," "animate," "solid," etc. But other types of representations were also used. Rumelhart and McClelland's past tense model represented present tense verb forms with a triplet encoding. The phonemic sequence /stop/ would be encoded in triplet form as $_{\#}s_{t}$, $_{s}t_{o}$, $_{t}o_{p}$, and $_{o}p_{\#}$. The encoding used in Rumelhart and McClellands's model was actually a finer-grained representation that used triplets of phonetic features instead of whole phonemes. Words were encoded as 460-element vectors, with each element corresponding to a possible triplet. A network trained on some past tense forms could thus generalize correctly to novel forms.

The advent of backpropagation learning led to the creation of feature vectors by the networks themselves. Hinton's (1990, pp. 47–76) family tree model learned relationships about three generations of people, such as "Victoria is the mother of Colin," "Victoria is the wife of James," and "Penelope is the mother of Victoria." The network took as input a pair such as "Victoria" and "mother," and was trained to activate the output unit for "Colin." A separate unit was used to represent each individual or relationship, but these units projected to small hidden layers that in turn projected to the central hidden layer. After training on 104 tuples defined over 24 persons and 12 relationships, feature vector representations developed in the dedicated person and relationship hidden layers that reflected the similarity structure of the domain. For example, one unit came to be strongly inhibited when coding for people in the third generation. The unit was weakly active for people in the middle generation; and strongly active for grandparents, i.e., persons in the first generation.

Connectionist representations have been termed subsymbolic (Smolensky, 1988) because they capture graded, messy, but statistically important aspects of a domain. This idea has also been explored in Latent Semantic Analysis (Foltz, 1996), which derives feature vector representations for words in a large text corpus. First a matrix of occurrence information for each word in each of many contexts is constructed. A context can be a document, a paragraph, or even a sentence. The matrix is then reduced to a lower-dimensional form by singular value decomposition (SVD), similar to Principal Components Analysis. The result is a set of 100–300 dimensional feature vectors, one per word, which are useful for many kinds of text matching and retrieval applications. These features capture information about linguistic relations but do not look anything like the semantic features normally used in linguistic analysis. Once again, dot product can be used to compute similarity.

A problem with fixed feature vector representations is that what should count as similar is often context dependent. Another problem is that while feature vectors are a natural way to represent individual concepts, they are not so convenient for representing relationships among concepts; the latter may have to be generated on the fly during reasoning rather than constructed gradually through gradient descent learning.

## Composite Structure

Symbolic models create trees of increasing size to encode structures with more components, but this route is not open to connectionist networks, which use fixed-length vectors (see COMPOSITIONALITY IN NEURAL SYSTEMS). Several solutions have been proposed. Encoder/decoder networks created using backpropagation can map composite objects into points in a vector space. Simple recurrent networks (SRNs; see Elman in Touretzky, 1991) represent sequences this way, and Recurrent Auto-Associative Memories (RAAMs; see Pollack in Hinton, 1990) use a similar approach to represent trees. The problem with this method is that the inductive bias of backpropagation learning does nothing to enforce systematicity in these representations, so novel inputs will not be treated correctly unless the model has been trained on a substantial fraction of the set of all possible structures to be encoded.

An alternative approach employs simple combinatorial operations on vectors to perform composition and extraction operations, thereby enforcing systematicity (see SYSTEMATICITY OF GENERALIZATIONS IN CONNECTIONIST NETWORKS). Plate's (2000) holographic reduced representation is the most promising example. Holographic reduced representations encode frame-like objects where each role and each filler is a vector of several thousand bits. Roles are paired with fillers using a circular convolution operator, which produces a vector result. Multiple role/filler pairings are then combined by vector addition and normalization. *John kissed Mary* might be encoded as $\mathit{agent} \otimes \mathit{john} + \mathit{patient} \otimes \mathit{mary} + \mathit{action} \otimes \mathit{kissed}$. The vectors encoding composite objects can themselves serve as roles or fillers, providing a limited form of structural recursion. But the primitive vectors, e.g., for *john* and *mary*, must be nearly orthogonal to prevent interference between overly similar patterns, which precludes the use of a meaningful feature vector representation. On the other hand, dot product can still be used to do matching and retrieval, and even to measure analogical similarity (Eliasmith and Thagard, 2001).

## Nonlinear Mapping

Certain types of representation support certain types of processing better than others. Most of the inference in connectionist networks takes place via nonlinear mapping of vectors, implemented by one or more weight matrices. Properly constructed, such matrices can simulate the effects of discrete inference rules, combine rules with exceptions, express graded inferences, exploit statistical structure in the domain, and incorporate information from multiple evidence sources. Most important, these mappings can be constructed automatically using learning procedures.

A single layer of weights was sufficient to allow the Rumelhart and McClelland past tense model to capture both the regular past tense rules and various classes of exceptions. More powerful mappings can be achieved with additional layers of weights, and by allowing a network to feed back on itself. In SRNs (Elman in Touretzky, 1991), the hidden layer activity at time $t$ is fed back as an additional input to the network at time $t + 1$ (see CONSTITUENCY AND RECURSION IN LANGUAGE). SRNs process information sequentially and can learn finite-state grammars. But Servan-Schreiber, Cleeremans, and McClelland (in Touretzky, 1991) showed that these networks do more than that: they learn and exploit the statistical structure of the training data. Servan-Schreiber et al. suggest that statistical differences between main and embedded clauses might help a language learner track long-range dependencies generated by recursive grammatical constructs.

The problems with the nonlinear mapping approach are that it requires lots of training data to adequately cover a small domain, and the "rules" are often learned imperfectly, so the network does not always generalize correctly. On the other hand, it provides a way to study complex phenomena without having to formulate rules explicitly. Plaut (1999) showed that lesioning a network that mapped orthographic to phonetic representations (and that also had attractor dynamics) could reproduce many interesting effects observed in word reading and acquired dyslexias (see LESIONED NETWORKS AS MODELS OF NEUROPSYCHOLOGICAL DEFICITS). Some of these effects, such as characteristic mixtures of error types, have proved difficult to explain with symbolic models.

Rohde's connectionist sentence comprehension and production model (CSCP) shows that nonlinear maps can challenge symbolic language models in nontrivial domains (Rohde, 2002). CSCP is a collection of SRNs that learns a substantial fragment of English grammar, including many types of embedded and relative clauses. The model has a 300-word vocabulary and contains both parsing and sentence production components. It required 2 months on a fast workstation to train. Although its performance is not perfect, its coverage is impressive.

## Parallel Constraint Satisfaction

Rule-based systems have trouble determining the best interpretation of an ambiguous stimulus because of the difficulty of formulating explicit rules that weigh multiple sources of evidence in a flexible manner. Connectionist networks approach this as a constraint satisfaction problem. Evidence sources impose weak constraints on the stimulus interpretation, and the activity of the network evolves to reflect the collective effect of all these influences.

One of the simplest constraint satisfaction architectures is the interactive activation network, in which constraints are expressed as weighted excitatory or inhibitory links between nodes standing for concepts. Semantically related units have mutually excitatory connections, while units that code for alternative hypotheses inhibit each other. Consider the treatment of *The astronomer married the star* in Waltz and Pollack's (1985) interactive parsing model. There are two word-meaning nodes for *star*, one being "heavenly body" and the other "movie star." There is an excitatory link from astronomer to the heavenly body node because the two are semantically related. Hence, the model predicts that this meaning of star will be primed by "astronomer," and will initially be favored over "movie star." But when *married* is encountered, it imposes a constraint that the subject and object must be human. This ultimately leads to suppression of activity in the heavenly body node, causing movie star to become active.

Neural net constraint satisfaction systems, unlike their symbolic counterparts, are attractor networks (see COMPUTING WITH ATTRACTORS). We can draw on dynamical systems theory to understand their behavior. Most of these networks use "localist" or symbolic rather than "distributed" or vector representations (see LOCALIZED VERSUS DISTRIBUTED REPRESENTATIONS), but their inference mechanism is still nonaxiomatic.

More sophisticated constraint satisfaction can be done with Boltzmann machines, which employ hidden units to express nonlinear interactions among constraints, and simulated annealing search to find the best interpretation of the input. An example of spreading activation and simulated annealing using localist representations is Hofstadter and Mitchell's analogy-making program, CopyCat (Mitchell, 1993). One of the few annealing reasoners developed to date that employs feature vector representations is microKLONE (Derthick in Hinton, 1990), which translated a frame-based semantic network language into a complex structure of nodes and links expressing semantic constraints among slot fillers. microKLONE was able to use these constraints not only to fill in missing information, but also to produce plausible inferences in counterfactual situations.

## Discussion

Connectionist representations promise a continuous, statistical, vector-based alternative to rule-based reasoning over discrete symbol structures. Although too abstract to map directly onto neural circuitry, the new conceptual framework has strongly influenced theorizing about the brain.

As yet we have only glimmerings of how connectionist models might surpass the abilities of symbolic reasoners. One suggestion of how they might do this is Hinton's (1990, pp. 47–76) notion of a "reduced description," in which the encoding of a concept like "room" contains abbreviated but directly accessible information about affiliated concepts such as "window," "door," "doorknob," and "keyhole." A reasoner could thus immediately recognize how a room could have a keyhole, rather than having to follow a chain of pointers to reach that concept via "door" and "doorknob." But we have not yet seen a successful implementation of reduced descriptions, much less a mechanism to automatically tailor such descriptions to the requirements of a domain.

The elements discussed in this article—feature vector representations, composite structure, nonlinear maps, and parallel constraint satisfaction—do not yet work well together. Multiple conceptual breakthroughs are likely required before they can be incorporated into a unified connectionist theory of symbol processsing.

# Consciousness, Neural Models of

*John G. Taylor*

## Introduction

The construction of neural theories of consciousness faces the difficulty that, by its very nature, consciousness is subtle, and its defining characteristics are still poorly discerned. This leads to uncertainty about what properties create consciousness in the brain and even regarding the location of the sites of consciousness creation, the so-called neural correlates of consciousness (NCC). In order to prevent the NCC from wandering all over the brain, whether in the primary sensory or unimodal associative cortices (Pollen, referred to in Taylor, 2001), or now in the prefrontal cortex (Crick and Koch, 1998), care must be taken in assessing evidence in support of various possible sites of the NCC. New experimental results from brain imaging, as well as further insights into single cell activity and the effects of brain deficits, are now leading to a clearer picture of the NCC (Taylor, 1999, 2001a). This is an important advance, since concentration can now be turned to the nature of the neural representations crucially involved in consciousness. Neural network ideas and explicit models are helping to pin down what these representations consist of and how they function. Thus, progress is slowly being made to understand scientifically this most mysterious of human phenomena: the race for consciousness has started in earnest (Taylor, 1999).

Yet consciousness is not easy to define precisely. In order to make initial progress without spending time in logic chopping, let us follow the article on consciousness in the previous edition of the *Handbook* (Velmans, 1995). The definition given there is initially appropriate for the present purposes:

> Consciousness is synonymous with awareness or conscious awareness (sometimes phenomenal awareness). The contents of consciousness encompass all that we are conscious of, aware of or experience.

This distinguishes consciousness from other mental activity; there is much in the mind of which the possessor is not conscious, so that consciousness is a special faculty of the mind. The nature of its function has been vigorously debated (Velmans, 1995), although with no justification of either extreme: consciousness has no purpose, but is solely an epiphenomenon, or alternatively it is the ultimate control system of the mind. Comments supporting the latter view will be given later in this article, as well as further discussion of the validity of the above definition.

If consciousness is difficult to define and its function is hard to discern, at least some features involved with its creation are more generally agreed upon. Characteristics needed for consciousness are as follows:

1. *Temporal duration*. Neural activity is needed to be present for at least 200 ms for awareness to arise. This is supported by the data of Libet and colleagues (1964) and by the duration of activity in buffer working memory sites, suggested by a number of workers as being the sites of creation of consciousness (Taylor, 1999).
2. *Attentional focus*. It is widely supposed that consciousness can only arise of an object at the focus of attention; there is experimental support for this position (Mack and Rock in Wright, 1997). The resulting amplification of the attended input allows it to attain consciousness and also be laid down in long-term memory, for later conscious access.
3. *Binding*. The binding of features, analyzed in separate areas of cortex, to allow recognition and experience of objects, has long been regarded as crucial for the explanation of consciousness. Such binding has been proposed to occur by several means, especially by simultaneous activations, such as by coupled oscillatory modules (Crick and Koch, 1990) or by attentive competitive/amplificatory processing (Triesman in Wright, 1997). There is evidence for both of these being involved in cortical processing.
4. *Bodily inputs*. The availability of such inputs is needed to give a perspective to inputs, following detailed investigations by psychologists (Bermudez, Marcel, and Eilan, 1995).
5. *Salience*. Coded in the limbic system, salience is needed to give a suitable level of importance to a given input, and can arise, for example, from the cingulate cortex, as involving motivational activation, or from other limbic sites.
6. *Past experience*. This gives content to conscious experience, by reactivating previous relevant experience (Taylor, 1999); such memories are especially involved in defining the self.
7. *Inner perspective*: Besides having awareness of an input, we each possess an inner perspective, without which we cannot experience the mental world as belonging to us. The inner perspective is thus that of ownership of our awareness. Without it we would be zombies, having content but no sense of “what it is like to be me” (Nagel, 1974).

Only by a concerted attack on the underlying brain structures involved in the creation of consciousness, and their detailed modelling, can real progress be made. Recent advances on the three counts—the “where,” the “what,” and the “how” of consciousness—will be described in this article. Several recent experimental results from brain imaging, single-cell data, and brain deficits will be described in the next section. These help in determining a site for the NCC. From these data, the inferior parietal lobes are concluded to be the most appropriate region for the site of consciousness (Taylor, 2001a). In the following section the notion of the central representation will be developed; it contains the crucial contents for consciousness. A general model of attention control, the CODAM model, which incorporates the central representation and is appropriate for simulating the associated emergence of consciousness, is then presented in the next section. Relations to other models are described briefly in the penultimate section, and a short conclusion and discussion of open questions finishes the review.

## Experimental Data

The data to be considered are of a variety of sorts: from single cells, lesion effects on behavior, and from brain imaging (especially that using PET and fMRI). The single-cell data involves information on the presence or absence of significant activity observed in an animal under anesthesia. This has little effect on the level of early sensory cortical responses, for example, in V1 and MT or in inferotemporal cortex. We will later consider the important effects of attention on such activity, although this does not change the overall story. There is considerable effect of anesthesia on parietal lobe single-cell responses, which led to great difficulty in measuring from such cells before the advent of the ability to record from awake, behaving monkeys. Thus, occipital and temporal cortices are not sufficient for consciousness, while parietal may be.

As a start to considering lesion effects, we note the singular lack of loss of consciousness due to frontal deficits brought about either by disease or injury, as numerous reports show. For example, there is the famous case of Phineas Gage (described in Taylor, 1999), who had a tamping iron blown through his frontal lobes with considerable loss of frontal cortex but without successive loss of consciousness as he was carried to the local doctor. There is also the case of the young man who was born bereft of most of his frontal lobes (mentioned in Taylor, 2001), but yet, apart from great social problems, lived a normal conscious existence.

One area of brain lesions of particular relevance to the NCC is that of neglect (which can be either of visual inputs or control of actions). Patients usually suffer a loss of the right parietal lobe, and subsequently lose awareness of input from their left hemifield. This loss, for example, is observed in the inability to cross out lines on the left of their field of view. It is now agreed that neglect arises specifically from damage to the inferior parietal lobe (Milner, 1997).

Much is also being discovered by brain imaging about the siting in cortex of buffer working memories. Those for spatial vision are in the right, those for language and temporal estimation in the left, inferior parietal lobes. Extinction, involving loss of awareness of the right-hand object of two similar objects, one on the left, one on the right, is sited separately in the superior parietal lobe (Milner, 1997).

Recent fMRI data indicates that the experience of the motion aftereffect (MAE) most occurs strongly in BA 40 (the supramarginal gyrus), in the inferior parietal lobe. The experimental paradigm to observe this uses motion adaptation to a set of horizontal bars moving vertically downward for 30 s, and then stopping. Subjects exposed to such a display usually experience the MAE for 9 or so s after cessation of the movement of the bars.

Whole-head fMRI measurements during this paradigm (Taylor et al., 2000) showed a network of connected areas, as in Figure 1. This network has a posterior group, involving especially the motion area MT, which was found to be responsive to all forms of motion as well as the MAE. On the other hand, there is a set of anterior modules, shown in Figure 1, which are particularly active both during the MAE period and just after the cessation of oscillatory movement of the bars both up and down (after which there is no MAE experience reported). Finally, there are inferior parietal regions, which demonstrate activity almost solely in response to the MAE period.

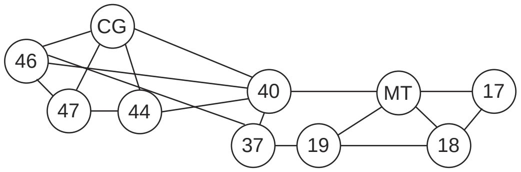

**Figure 1.** The network of areas active in the brain during the MAE experiment (Schmitz et al., 1998, referred to in Taylor, 2001). The lines joining the various modules denote those for which the correlation coefficient is at least 0.4. MT denotes the middle temporal area, and the other areas are numbered according to Brodmann's numeration.

All of the inputs required to support the features described in the first section are available, it would seem almost uniquely, for the inferior parietal lobe. Thus, the buffer working memory sites for space and time (and language) have been noted previously as being there, as is a competition for consciousness associated with these sites (Taylor, 1999). Bodily inputs are also available there, as noted from effects of manipulation of the body in neglect, as well as from known neuroanatomy (connections with the vestibular apparatus and the cerebellum are well known). The limbic system is also well connected to the inferior parietal lobe and so is episodic memory.

We conclude that the inferior parietal lobe (IPL) is suitably connected and structured to satisfy all of the criteria A–F in the first section. We will discuss its relevance to criterion G when we consider the CODAM model of a Heution control.

## The Central Representation

Evidence from neglect studies and brain imaging on healthy subjects has been presented in this article to implicate the IPL as playing a crucial role in controlling attention and creating awareness. Attention can occur in a range of possible frames of reference: neglect can be observed tied to an object, or to a trunk-centered frame of reference or a variety of other reference frames (Milner, 1997). This implies that the IPL is composed of a set of modules carrying information from the environment as well as modulation by possible body input. Thus, the IPL is eminently suited to carry what is termed the "Central Representation," defined as: "The combined set of multi-modal activations involved in fusing sensory activity, body positions, salience and intentionality for future planning; it involves a competitive process between the various working memory modules it contains to single out one to be conscious and be used for report to other working memory sites for further planning or action" (Taylor, 2001a).

There are several important features of the central representation (CR) that need discussion, in relation to the criteria in the introduction to the article:

1. The CR must have access to sensory input, such as in vision, coded at a high level. Thus, it must have good access to temporal lobe representations, so as to use the categorization built there to guide action.
2. It also must have access to the bodily input needed to guide actions in terms of the intentionality coded in the superior parietal lobe. Such intentionality is coded for various sorts of actions: of the limbs, eyes, head, or fingers. This intentionality must be furnished with the parameters of the objects on which the actions must be taken; thus, cerebellar and vestibular input must also be accessible to the central representation, as it is in the parietal lobes. A neural model of this intentionality has been presented in Fagg and Arbib (1998).

3. Salience of the inputs in the sensory field is an important attribute for the guidance of actions; that arises from limbic input already activated to provide saliencies of inputs from the orbitofrontal cortex by way of the cingulate. This is compounded by activations in the posterior cingulate gyrus, encoded as parts of episodic memory.
4. Several modules in the CR are involved in the IPL; the total activity must undergo an overall competition, possibly aided by thalamonucleus reticularis processing. A simulation of such a model has been given earlier (described in Taylor, 1999). The existence of such competition is supported by attention deficits observed in subjects with pulvinar lesions.
5. Siting the emergence of awareness in the IPL, as the result of the competition ongoing there, is supported by simulation of the data of Libet and colleagues (1964). The original experiment involved the creation of sensory experience (that of a gentle touch on the back of the patient's hand) by direct stimulation of cortex in patients being operated on for movement problems. The simulation (described in Taylor, 1999) used a simplified model of the corticothalamo-nucleus reticularis circuit, and led to the observed dependence of the delay of awareness on the strength of the threshold current for experiencing the touch on the back of the patient's hand.
6. Such a competition has also been suggested (described in Taylor, 1999) as occurring to explain experimental results of subliminal effects on lexical decision response times obtained by Marcel (1980). The experiment involved measurement of the reaction times of subjects to deciding if the first or third of three letter strings were words or not. Subliminal exposure to priming words occurred for the second letter string under one condition, with the presentation of polysemous words such as "palm," on which the lexical decision had to be made to the third word. The prior exposure caused the decision to be speeded up or delayed in characteristic ways according to the semantic relations of the three words to each other; the simulation was able to explain these results by means of a competition assumed to occur on the phonological store, aided and abetted by activations from a semantic memory store.

In conclusion, we site the CR in the IPL as the site for attention and short-term memory processing, with confluence there of information on salience, episodic memory, high level coding of inputs, and information on body state.

## An Attention Control Model (CODAM) of the Emergence of Awareness

Attention, the respectable face of consciousness for neuroscience, has received surprisingly short shrift recently from those directly attacking the problem of consciousness. This is in spite of the phenomenon of inattentional blindness, that there is no perception without attention, as noted by Mack and Rock (in Wright, 1997), and the many claims by those working on attention that there is no consciousness of an unattended input. There is now improved understanding of attention arrived at by brain imaging using a range of psychophysical paradigms and ever more careful single-cell experiments. A control view of attention is now accepted, in which signals from outside early cortex modulate inputs so as to allow selection of a desired target input from a set of distracters. We will now develop this view, describing how the Central Representation supports the creation of consciousness by means of a suitable control model.

In such a control model, there are the "plant" components of primary and secondary sensory and motor cortices containing input activations being attended to, an inverse controller in parietal/frontal as source of the attention signal, and a rules module containing the desired state into which attended input should be transformed (there being a prefrontal top-down rules module, and a bottom-up component in superior colliculus). Further components of a so-called forward model (or observer) can also be tentatively identified. This resides as buffer sites in inferior parietal and updating areas in prefrontal, as well as parts involved in monitoring effectiveness of response under the guidance of the rules modules, sited in cingulate cortex. This model (shown in Figure 2) has been simulated for a variety of paradigms (Taylor and Rogers, 2001), being an engineering control formalization of many neural models of attention.

To bring consciousness to the foreground inside the control model of attention, we turn to recent developments in phenomenology to guide us: there are two components of consciousness: "consciousness of" and the pre-reflective self. The pre-reflective self is experienced as the ownership of one's conscious experience and as the basis of all awareness; without it there would be content but no owner of that content.

To incorporate this important component in the attention control model, a very conjectural step was made in Taylor (2000): it was proposed that an observer is present that contains a buffered copy of the controller signal (more properly called a *corollary discharge,* since it is coded in the same manner as attended sensory activation on its buffer). This copy is used to achieve more rapid updating of the movement control signal. Such a copy will not be bound in any attention-based manner to the content of consciousness, since that can only be present on feedback from the plant. The corollary discharge signal will therefore not have any content. It can, however, be identified with the experience of "ownership," that of the about-to-appear amplified input that is being attended to. Such a signal can grant immunity to error through misidentification of the first-

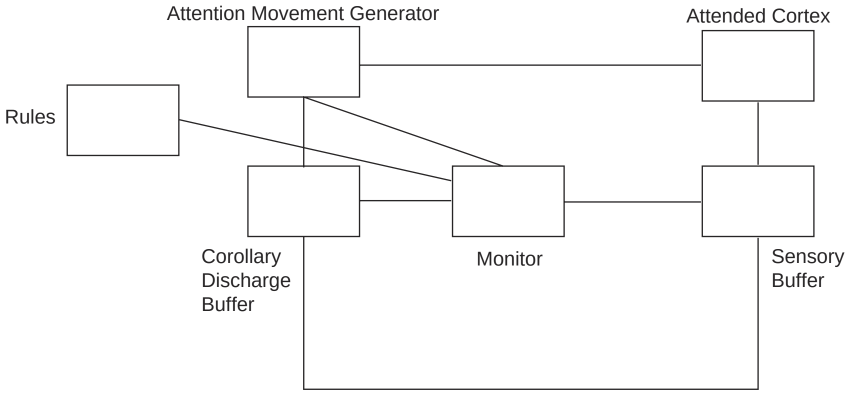

**Figure 2.** A simple attention movement control model (shown in bold lines), composed of attended cortex (containing activity representing an attended input), an attention movement generator, a rules module (for either top-down or bottom-up control of attention), and a monitor (based on the error between the required attention state and that occurring as determined by a sensory buffer). The additional module and connections (in dotted lines) completes the CODAM model. It involves a buffer to hold the corollary discharge of attention movement. This corollary discharge signal is employed to speed up movement of attention as well as prevent incorrect updating of the sensory buffer until attention has been moved to the correct place (as assessed by the corollary discharge buffer acting as an observer or attention state estimator).

person pronoun. This would follow if the corollary discharge acts only to let onto the buffer what it has been told to by the inverse attention controller. As such, it inhibits all other possible entrants to contentful consciousness. This occurs for the brief period before the attentionally amplified input from sensory cortex arrives. The corollary discharge is then supposed to be inhibited in its turn. Such complex processing is supported by the siting of much of the attention control structures nearby in the parietal lobe, singled out recently as crucial for consciousness to arise. A simple model for such usage of the corollary discharge is shown in Figure 2, involving an additional observe component (shown in dotted lines), beyond the control model used in Taylor and Rogers (2001).

Following many experimental results, we site the attention controller in superior parietal lobe, the prefrontal cortex or superior colliculus, the attended plant in sensory cortices, working memory buffers in inferior parietal lobe, the monitor in the cingulate, and the goals module in the prefrontal cortex.

This approach results in the corollary discharge of attention movement (CODAM) model of consciousness (Taylor, 2000, 2001b):

> Experience of the pre-reflective self is identified with the corollary discharge of the attention movement control signal residing briefly in its buffer until the arrival of the associated attended input activation at its own buffer.

The CODAM model achieves the required unpacking of the Central Representation: its essential constituents are (1) that of a signal of ownership in the corollary discharge buffer (with no content), (2) contents of external inputs represented by activity subsequently stored on the attended input buffer. There is a strict temporal order of activation, with the former briefly activated first, followed by the attended input buffer. More extended duration of the corollary discharge signal is suggested as the source of the meditatory states of samadhi or nirvana: this is attention observing itself (Taylor, 2002). The presence of the pre-reflective self implies that the definition of consciousness given in the introductory section is incomplete; it needs extension by addition of the sentence “Those contents include awareness of consciousness itself, as occurs in the pre-reflective self.”

The above model is only presented at the “arrows and boxes” level. Detailed neural implementations of various components are possible:

1. *Temporal duration*: achieved by the neural field recurrence—the bubble model, in which bubbles are temporally extended but spatially localised regions of neural activity with a certain degree of independence from inputs (Taylor, 1999).
2. *Attention focus*: numerous neural models of attention processing in terms of object recognition have been created, such as the feedback amplification system of Mozer and Sitton (referred to in Taylor and Rogers, 2002), and see references therein). A general control framework encompassing such models has been suggested (Taylor, 2000, 2001b). A specific simulation, using competitive processing on the IMC is given in Taylor and Rogers (2001). Global competition across the CR is achieved by the NRT (with simulation described in Taylor, 1999).
3. *Binding*: achieved by attention processing in the models noted above, to which synchronized activity can be added.
4. *Bodily inputs*: the effect of these on attention processing in the parietal lobe has been modeled by modulations using various neural methods.
5. *Salience*: amygdala encoding salience of inputs has been used in models of frontal set shifting (discussed in Taylor, 1999).
6. *Episodic memory*: various hippocampal models have been created, although the manner in which episodic memory is built in cortex is still unclear (see discussion in Taylor, 1999).

There are numerous important questions to be answered before the CODAM model can be accepted as a source of inner experience:

Would it pass the Turing test if it were included in a full neural simulation?

How does the control aspect of attention, regarded as the highest control system in the brain, achieve learning of effective motor responses so as to achieve automaticity?

How is language (and thought) built from this overall framework?

It is hoped that answers to these questions will be forthcoming by subsequent work.

## Other Neural Models of Consciousness

Numerous models have been presented in the past to explain consciousness; only neural models will be considered here, and those only briefly.

1. Gray’s Hippocampal Predictor model (see Gray et al. in Freeman and Taylor, 1997). This suggests that the hippocampus enables predictions to be made of future experiences, so creating consciousness. Various amnesic subjects, without hippocampus, however, still respond in a conscious manner in conversation, in spite of severe long-term memory deficits.
2. Aleksander’s MAGNUS (see Browne et al. in Freeman and Taylor, 1997). This is based on a set of attractors, built by learning in a recurrent net in RAM-based hardware. Activation of an attractor is claimed to be the “artificial consciousness” of the system of the related input. This model has the defect that it involves no “internal experience” associated with attractor activity; it is a useful, if broad, model of the contents of consciousness.
3. Shallice’s SAS (see reference in Taylor, 1999). This assumes total control of neural activity by the frontal “supervisory attention system.” However, evidence against the NCC being sited in the frontal lobes was given in the section on experimental data. Better consistency with the CODAM model of the previous section can be achieved by extending the supervisory attention system to include parietal sites.
4. Baar’s Global Workspace (see Newman et al. in Freeman and Taylor, 1997). This regards consciousness as the gaining of access to a “global workspace” (GW), considered as being on layer 1 of cortex. The GW is an incompletely defined concept, especially since it also does not necessarily have any internal experience. It can be related to the CODAM model by regarding access to the GW as the important process for determining the pre-reflective self. The CODAM model indicates how this access is controlled by suitable buffer activity, as well as determining the temporal nature of activity on ensuing access, when content enters consciousness.
5. Crick and Koch’s 40 Hz (1990). That gamma-band oscillations are important for binding and segmenting is now well established (both experimentally in the brain and by computation). However, since such oscillations are observed in anesthetized animals, such activity cannot be regarded as sufficient for consciousness.
6. Pollen’s Early model (see reference in Taylor, 2001). This supposes consciousness arises from feedback and relaxation to a fixed point of an attractor dynamics. Yet there is such reentrance at many levels in the brain, such as between LGN and V1. The activity in LGN is not in consciousness, so indicating that the existence of such feedback is not sufficient for consciousness to be created.
7. Zeki’s “local homunculus” (see references in Taylor, 2001a). This proposes that micro-consciousnesses arise in numerous

early cortical areas. However not only does this proliferation of homunculi add to the difficulties of consciousness but is also contradicted by the results presented in the section on experimental data.

8. Edeleman's Reentrant Theory (see reference in Taylor, 1999). This is based on the special use of reentrant circuits, and so suffers from the difficulties of item 6 of this list.
9. Roll's Higher Order Theory (HOT; expanded in Roll's article in Freeman and Taylor, 1997). This uses language to enable higher order thoughts of lower order experienced inputs. The original HOT theory faces the difficulty that it rules out non-reflective consciousness in animals other than humans. Moreover the perspectival nature of experience cannot be incorporated into the HOT model in any obvious manner.
10. Harth's Inner Sketchpad Model (see Harth in Freeman and Taylor, 1997). This is based on the use of the reentry of a global scalar quantity, the degree of overlap between the input and activation, to achieve hill-climbing or attractor relaxation; it has the same defect as that of item 6 of this list, being involved in much dynamical processing in the brain but not just that specifically producing consciousness.
11. The Competitive Relational Mind model (Taylor, 1999). That a competitive process occurs in and between working memory sites for the emergence of consciousness is now becoming clear, but is still insufficient for the production of any perspectival account of awareness at the level of the pre-reflective self (Taylor, 2001b). Further circuitry is needed to build on this approach, as described in the section on the CODAM model.

In spite of the defects pointed out in the above models, they all involve important components in overall brain processing. The CODAM model introduced earlier is to be regarded as an extra component that benefits from the various computational features emphasised in the models of the previous section.

## Discussion

Our main conclusions are:

1. The IPL is the essential site in the brain for consciousness.
2. The central representation, based there, gives conscious content (through activity in attended sites bound to the central representation by various mechanisms).
3. A simple control model of the movement of attention, supported by experimental data, can be extended to a mechanism for the creation of consciousness through the CODAM model. This led to a computational understanding of the minimal or pre-reflective self.

The broad range of the review touched on many areas, all of which require considerable further work. If the basic CODAM principles are correct—as is so far supported by a range of material (Taylor, 2001b)—it provides a first viable neural approach to understanding human consciousness. It could even lead to the creation of a viable blueprint for machine consciousness. The greatest challenge facing the computational neuroscience community is to create simulations that can properly test the ideas presented here. At the same time, the challenge to neuroscience is to develop experimental proof or disproof of the CODAM model.

# Constituency and Recursion in Language

*Morten H. Christiansen and Nick Chater*

## Introduction

Upon reflection, most people would agree that the words in a sentence are not merely arranged like beads on a string. Rather, the words group together to form coherent building blocks within a sentence. Consider the sentence, *The girl liked a boy.* Intuitively, the chunks *the girl* and *liked a boy* constitute the basic components of this sentence (compared to a simple listing of the individual words or alternative groupings, such as *the girl liked* and *a boy*). Linguistically, these chunks comprise the two major *constituents* of a sentence: a subject noun phrase (NP), *the girl*, and a verb phrase (VP), *liked a boy.* Such *phrasal* constituents may contain two types of syntactic elements: other phrasal constituents (e.g., the NP *a boy* in the above VP) or *lexical* constituents (e.g., the determiner *the* and the noun *girl* in the NP *the girl*). Both types of constituent are typically defined *distributionally* using the so-called replacement test: If a novel word or phrase has the same distribution as a word or phrase of a known constituent type—that is if the former can be *replaced* by the latter—then they are the same type of constituent. Thus, the lexical constituents *the* and *a* both belong to the lexical category of determiners because they occur in similar contexts and therefore can replace each other (e.g., *A girl liked the boy*). Likewise, *the girl* and *a boy* belong to the same phrasal category, NP, because they can be swapped around, as in *A boy liked the girl* (note, however, that there may be semantic constraints on constituent replacements. For example, replacing the animate subject NP *the girl* with the inanimate NP *the chair* yields the semantically anomalous sentence, *The chair liked a boy*).

In linguistics, grammar rules and/or principles determine how constituents can be put together to form sentences. For instance, we can use the following phrase structure rules to describe the relationship between the constituents in the example sentences above:

$$\begin{aligned} \mathrm{S} &\rightarrow \mathrm{NP\ VP} \\ \mathrm{NP} &\rightarrow \mathrm{(det)\ N} \\ \mathrm{VP} &\rightarrow \mathrm{V\ (NP)} \end{aligned}$$

Using these rules we obtain the following relationships between the lexical and phrasal constituents:

$$[_{\mathrm{S}}[_{\mathrm{NP}}[_{\mathrm{det}}\text{ The }][_{\mathrm{N}}\text{ girl }]][_{\mathrm{VP}}[_{\mathrm{V}}\text{ liked }][_{\mathrm{NP}}\ [_{\mathrm{det}}\text{ a }][_{\mathrm{N}}\text{ boy }]]]]$$

To capture the full generativity of human language, *recursion* needs to be introduced into the grammar. We can incorporate recursion into the above rule set by introducing a new rule that adds a potential prepositional phrase (PP) to the NP:

$$\begin{aligned} \mathrm{NP} &\rightarrow \mathrm{(det)N(PP)} \\ \mathrm{PP} &\rightarrow \mathrm{prep\ NP} \end{aligned}$$

These rules are recursive because the expansion of the right-hand sides of each can involve a call to the other. For example, the complex NP *the flowers in the vase* has the simple NP *the vase* recursively embedded within it. This process can be applied arbitrarily often, creating, for instance, the complex NP with three embedded NPs:

$$\begin{aligned} [_{\mathrm{NP}}\text{ the flowers } &[_{\mathrm{PP}}\text{ in }[_{\mathrm{NP}}\text{ the vase} \\ &[_{\mathrm{PP}}\text{ on }[_{\mathrm{NP}}\text{ the table} \\ &[_{\mathrm{PP}}\text{ by }[_{\mathrm{NP}}\text{ the window}]]]]]]] \end{aligned}$$

Recursive rules can thus generate constructions of arbitrary complexity.

Constituency and recursion are some of the most fundamental concepts in linguistics. As we saw above, both are defined in terms of relations between symbols. Symbolic models of language processing therefore incorporate these properties by fiat. In this article, we discuss how constituency and recursion may fit into a connectionist framework and the possible implications for linguistics and psycholinguistics.

## Constituency

Connectionist models of language processing can address constituency in three increasingly radical ways. First, some connectionist models are *implementations* of symbolic language processing models in "neural" hardware. Many early connectionist models of syntax used this approach; an example is Fanty's (1986) network implementation of a context-free grammar. This kind of model contains explicit representations of the constituent structure of a sentence in just the same way as a nonconnectionist implementation of the same model would. Connectionist implementations of this kind may be important; they have the potential to provide feasibility proofs that traditional symbolic models of language processing are compatible with a "brain-style" computational architecture. But these models add nothing new with respect to the treatment of constituency.

The remaining two classes of connectionist models *learn* to process constituent structure, rather than having this ability hardwired. One approach is to have a network learn from input "tagged" with information about constituent structure. For example, Kim, Srinivas, and Trueswell (2002) train a network to map a combination of orthographic and co-occurrence-based "semantic" information about a word onto a structured representation encoding the minimal syntactic environment for that word. With an input vocabulary consisting of 20,000 words, this model has an impressive coverage and can account for certain results from the psycholinguistic literature concerning ambiguity resolution in sentence processing. But because constituent structure has been "compiled" into the output representations that the network was trained to produce, this kind of model does not offer any fresh insight into how linguistic constituency might operate, based on connectionist principles.

The third class of connectionist models addresses the more ambitious problem of learning the constituent structure of a language from untagged linguistic input. Such models have the potential to develop a new or unexpected notion of constituency, and hence may have substantial implications for theories of constituency in linguistics and psycholinguistics.

To understand how the more radical connectionist models address constituency, we need to frame the problem more generally. We can divide the problem of finding constituent structure in linguistic input into two interrelated parts: segmenting the sentence into chunks that correspond, to some extent, to linguistic constituents, and categorizing these units appropriately. The first problem is an aspect of the general problem of *segmenting* speech into appropriate units (e.g., phonemes, words) and more generally is an aspect of perceptual grouping. The second problem is an aspect of the general problem of classifying linguistic units—for instance, recognizing different classes of phonemes or establishing the parts of speech of individual lexical items. The segmentation and classification problems need not be solved sequentially. Indeed, there may be mutual influence between the decision to segment a particular chunk of language and the decision that it can be classified in a particular way. Nonetheless, it is useful to keep the two aspects of the analysis of constituency conceptually separate.

It is also important to stress the difference between the problem of assigning constituent structure to novel sentences where the language is known and the problem of acquiring the constituent structure of an unknown language. Statistical symbolic parsers are able to make some inroads into the first problem (Charniak, 1993). For highly stylized language input, and given a prestored grammar, they can apply grammatical knowledge to establish one or more possible constituent structures for novel sentences. But symbolic methods are much less advanced in acquiring the constituent structure of language, because this requires solving the hard problem of learning a grammar from a set of sentences generated by that grammar. It is therefore in relation to the acquisition of constituency that connectionist methods, with their well-developed learning methods, have attracted the most interest.

We begin by considering models that focus on the problem of classifying, rather than segmenting, the linguistic input. One connectionist model (Finch and Chater, 1993) learns the part of speech of individual words by clustering words together on the basis of the immediate linguistic contexts in which they occur. The rationale is based on the replacement test mentioned earlier: if two words are observed to occur in highly similar immediate contexts in a corpus, they probably belong to the same syntactic category. Finch and Chater used a single-layer network with Hebbian learning to store co-occurrences between "target" words and their near neighbors. This allowed each target word to be associated with a vector representing the contexts in which it typically occurred. A competitive learning network classified these vectors, thus grouping together words with similar syntactic categories. This method is able to operate over unrestricted natural language, in contrast to most symbolic and connectionist models. From a linguistic perspective, the model slices lexical categories too finely, producing, for example, many word classes that correspond to nouns or verbs. On the other hand, the words within a class tend to be semantically related, which is useful from a cognitive perspective. The same method can be extended to classify sequences of words as NPs, VPs, etc. An initial classification of words is used to recode the input as a sequence of lexical constituents. Then, short sequences of lexical constituents are classified by their context, as before. The resulting groups of "phrases" (e.g., determiner-adjective-noun) are readily interpretable as NPs, and so on, but again, these groupings are too linguistically restrictive (i.e., only a small number of NPs are included in any particular cluster). Moreover, this phrasal level classification has not yet been implemented in a connectionist network.

A different attack on the problem of constituency involves training simple recurrent networks (SRNs) on linguistic input (Elman, 1990). An SRN involves a crucial modification to a feedforward network: the current set of hidden unit values is "copied back" to a set of additional input units, and paired with the *next* input to the network. The current hidden unit values can thus directly affect the next hidden unit values, providing the network with a memory for past inputs. This enables it to tackle sentence processing, where the input is revealed gradually over time rather than being presented at once.

Segmentation into constituents can be achieved in two ways by an SRN trained to *predict* the next input. One way is based on the assumption that predictability is higher within a constituent than across constituent boundaries, and hence that high prediction error indicates a boundary. This method has been advocated as potentially applicable at a range of linguistic levels (Elman, 1990), but in practice it has been successfully applied only on corpora of unrestricted natural language input in finding word boundaries (Cairns et al., 1997). Even here, the prediction strategy is a very partial cue to segmentation. If the network is provided with information about naturally occurring pauses between utterances (or parts of utterances), an alternative method is to assume that constituent boundaries occur where the network has an unusually high expectation of an *utterance boundary*. The rationale is that pauses tend to occur at constituent boundaries, and hence the prediction of a possible utterance boundary suggests that a constituent boundary may have occurred. This approach seems highly applicable to segmenting sentences into phrases, but it, too, has primarily been used for finding word boundaries in real corpora of language, when combined with other cues (Christiansen, Allen, and Seidenberg, 1998).

So far we have considered how SRNs might find constituents. But how well do they classify constituents? At the word level, cluster analysis of hidden unit activations shows that, to some extent, the hidden unit patterns associated with different word classes group naturally into syntactic categories, for SRNs trained on simple artificial grammars (Elman, 1990). These results are important because they show that even though the SRN may not learn to classify constituents explicitly, it is nevertheless able to *use* this information to process constituents appropriately.

Another way of assessing how SRNs have learned constituency is to see if they can generalize to predicting novel sentences of a language. The logic is that to predict successfully, the SRN must exploit linguistic regularities that are defined across constituents, and hence develop a notion of constituency to do so. However, Hadley (1994) points out that this type of evidence is not compelling if the novel sentences are extremely similar to the network's training sentences. He suggests that, to show substantial evidence for generalization across constituents, the network should be able to handle novel sentences in which words appears in sentence locations where they have not previously occurred (see Systemacity of Generalizations in Connectionist Networks). For example, a novel sentence might involve a particular noun in object position, where it has previously occurred only in subject position. To generalize effectively, the network must presumably develop some abstract category of nouns. Christiansen and Chater (1994) demonstrated that an SRN can show this kind of generalization.

Despite this demonstration, though, connectionist models do not mirror classical constituency precisely. That is, they do not derive rigid classes of words and phrases that are interchangeable across contexts. Rather, they divide words and phrases into clusters without precisely defined boundaries, and they treat words and phrases differently, depending on the linguistic contexts in which they occur. This *context-sensitive* constituency can be viewed either as the undoing of connectionist approaches to language or as their radical contribution.

The potential problem with context-sensitive constituency is the productivity of language. To take Chomsky's famous example, how do we know that the statement *colorless green ideas sleep furiously* is syntactically correct, except by reference to a context-*in*sensitive representation of the relevant word classes? This seems necessary, because each word occurs in a context in which it has rarely been encountered before. But Allen and Seidenberg (1999) argue that this problem may not be fatal for context-sensitive notions of constituency. They trained a network to mutually associate two input sequences, a sequence of word forms and a corresponding sequence of word meanings. The network was able to learn a small artificial language successfully: it was able to regenerate the word forms from the meanings, and vice versa. Allen and Seidenberg then tested whether the network could recreate a sequence of word forms presented to it, by passing information from form to meaning and back. Ungrammatical sentences were recreated less accurately than grammatical sentences, and the network was thus able to distinguish grammatical from ungrammatical sentences. Importantly, this was true for sentences in which words appeared in novel combinations, as specified by Hadley's criterion and as exemplified by Chomsky's famous sentence. Thus, the context sensitivity of connectionist constituency may not rule out the possibility of highly creative and novel use of language, because abstract relations may be encoded at a semantic level as well as at the level of word forms.

If the apparent linguistic limitations of context-sensitive constituency can be overcome, then the potential psychological contribution of this notion is enormous. First, context sensitivity seems to be the norm throughout human classification. Second, much data on sentence processing seem most naturally to be explained by assuming that constituents are represented in a fuzzy and context-bound manner. The resulting opportunities for connectionist modeling of language processing are extremely promising. Thus, connectionist research may provide a more psychologically adequate notion of constituency than is currently available in linguistics.

## Recursion

As with constituency, connectionist models have dealt with recursion in three increasingly radical ways. The least radical approach is to hardwire recursion into the network (e.g., as in Fanty's (1986) implementation of phrase structure rules) or to add an external symbolic ("first-in-last-out") stack to the model (e.g., as in Kwasny and Faisal's (1990) deterministic connectionist parser). In both cases, recursive generativity is achieved entirely through standard symbolic means, and although this is a perfectly reasonable approach to recursion, it adds nothing new to symbolic accounts of natural language recursion. The more radical connectionist approaches to recursion aim for networks to *learn* to deal with recursive structure. One approach is to construct a modular system of networks, each of which is trained to acquire different aspects of syntactic processing. For example, Miikkulainen's (1996) system consists of three different networks: one trained to map words onto case-role assignments, another trained to function as a stack, and a third trained to segment the input into constituent-like units. Although the model displays complex recursive abilities, the basis for these abilities and their generalization to novel sentence structures derive from the configuration of the stack network combined with the modular architecture of the system, rather than being discovered by the model. The most radical connectionist approaches to recursion attempt to learn recursive abilities with minimal prior knowledge built into the system. In this type of model, the network is most often required to discover both the constituent structure of the input and how these constituents can be recursively assembled into sentences. As with the similar approach to constituency described in the previous section, such models may provide new insights into the notion of recursion in human language processing.

Before discussing these modeling efforts, we need to assess to what extent recursion is observed in human language behavior. It is useful to distinguish *simple* and *complex* recursion. Simple recursion consists in recursively adding new material to the left (e.g., the adjective phrases (AP) in *the gray cat* → *the fat gray cat* → *the ugly fat gray cat*) or the right (e.g., the PPs in *the flowers in the vase* → *the flowers in the vase on the table* → *the flowers in the vase on the table by the window*) of existing phrase material. In complex recursion, new material is added in more complicated ways, such as through center-embedding of sentences (*The chef admired the musicians* → *The chef who the waiter appreciated admired the musicians*). Psycholinguistic evidence shows that people find simple recursion relatively easy to process, whereas complex recursion is almost impossible to process with more than one level of recursion. For instance, the following sentence with two levels of simple (right-branching) recursion, *The busboy offended the waiter who appreciated the chef who admired the musicians*, is much easier to comprehend than the comparable sentence with two levels of complex recursion, *The chef who the waiter who the busboy offended appreciated admired the musicians*. Because recursion is built into the symbolic models, there are no *intrinsic* limitations on how many levels of recursion can be processed. Instead, such models must invoke *extrinsic* constraints to accommodate the human performance asymmetry on simple and complex constructions. The radical connectionist approach models human performance directly without the need for extrinsic performance constraints.

The SRN model developed by Elman (1991) was perhaps the first connectionist attempt to simulate human behavior on recursive constructions. This network was trained on sentences generated by a small context-free grammar incorporating center-embedding and a single kind of right-branching recursive structure. In related work, Christiansen and Chater (1994) trained SRNs on a recursive artificial language incorporating four kinds of right-branching structures, a left-branching structure, and center-embedding. The behavior of these networks was qualitatively comparable with human performance in that the SRN predictions for right-branching structures were more accurate than on sentences of the same length involving center-embedding, and performance degraded appropriately as the depth of center-embedding increased. Weckerly and Elman (1992) further corroborated these results, suggesting that semantic bias (incorporated via co-occurrence restrictions on the verbs) can facilitate network performance in center-embedded constructions, similar to the semantic facilitation effects found in human processing. Using abstract artificial languages, Christiansen and Chater (1999) showed that the SRN's general pattern of performance is relatively invariant across network size and training corpus, and concluded that the human-like pattern of performance derived from intrinsic constraints inherent to the SRN architecture.

Connectionist models of recursive syntax typically use "toy" fragments of grammar and small vocabularies. Aside from raising concerns over scaling-up, this makes it difficult to provide detailed fits with empirical data. Nonetheless, some attempts have recently been made to fit existing data and derive new empirical predictions from the models. For example, the Christiansen and Chater (1999) SRN model fits grammaticality rating data from several behavioral experiments, including an account of the relative processing difficulty associated with the processing of center-embeddings (with the following relationship between nouns and verbs: $N_1N_2N_3V_3V_2V_1$) versus cross-dependencies (with the following relationship between nouns and verbs: $N_1N_2N_3V_1V_2V_3$). Human data have shown that sentences with two center-embeddings (in German) are significantly harder to process than comparable sentences with two cross-dependencies (in Dutch). The simulation results demonstrated that the SRNs exhibited the same kind of qualitative processing difficulties as humans on these two types of complex recursive constructions.

Just as the radical connectionist approach to constituency deviates from classical constituency, the above approach to recursion deviates from the classical notion of recursion. The radical models of recursion do not acquire "true" recursion because they are unable to process infinitely complex recursive constructions. However, the classical notion of recursion may be ill-suited for capturing human recursive abilities. Indeed, the psycholinguistic data suggest that people's performance may be better construed as being only quasi-recursive. The semantic facilitation of recursive processing, mentioned earlier, further suggests that human recursive performance may be partially context sensitive. For example, the semantically biased sentence, *The bees that the hive that the farmer built housed stung the children*, is easier to comprehend than the neutral sentence, *The chef that the waiter that the busboy offended appreciated admired the musicians*, even though both sentences contain two center-embeddings. This dovetails with the context-sensitive notion of constituency and suggests that context sensitivity may be a more pervasive feature of language processing than is typically assumed by symbolic approaches.

## Discussion

This article has outlined several ways in which constituency and recursion may be accommodated within a connectionist framework, ranging from direct implementation of symbolic systems to the acquisition of constituency and recursion from untagged input. We have focused on the radical approach, because this approach has the greatest potential to affect psycholinguistics and linguistic theory. However, much of this research is still preliminary. More work is needed to decide whether the promising but limited initial results can eventually be scaled up to deal with the complexities of real language input, or whether a radical connectionist approach is beset by fundamental limitations. Another challenge is to find ways—theoretically and practically—to interface models that have been proposed at different levels of linguistic analyses, such as models of morphology with models of sentence processing.

Nevertheless, the connectionist models described in this article have already influenced the study of language processing. First, connectionism has helped promote a general change toward replacing "box-and-arrow" diagrams with explicit computational models. Second, connectionism has reinvigorated the interest in computational models of learning, including learning properties, such as recursion and constituent structure, that were previously assumed to be innate. Finally, connectionism has helped increase interest in the statistical aspects of language learning and processing.

Connectionism has thus already had a considerable impact on the psychology of language. But the final extent of this influence depends on the degree to which practical connectionist models can be developed and extended to deal with complex aspects of language processing in a psychologically realistic way. If realistic connectionist models of language processing can be provided, then the possibility of a radical rethinking not just of the nature of language processing, but of the structure of language itself, may be required.

# Contour and Surface Perception

*Heiko Neumann and Ennio Mingolla*

## Introduction

Accumulating evidence from psychophysics and neurophysiology indicates that the computation of visual object representations is organized into parallel interacting subsystems, or streams, that consist of mechanisms following complementary processing strategies. *Boundary formation* proceeds by spatially linking oriented contrast measures along smooth contour patterns, whereas *perceptual surface* attributes, such as lightness or texture, are derived from local ratio measures of image contrast of regions taken along contours. Mechanisms of both subsystems mutually interact to resolve initial ambiguities and to generate coherent representations of surface layout.

Even when viewing single-gray-level images, people can discern important characteristics of visual scenes, including brightness, reflectance, surface orientation, texture, transparency, and relative depth. It has been proposed that these inferences are based on neural mechanisms that compute distinct and spatially registered representations of such characteristics or features, so-called *intrinsic images*. This approach has been formalized on the basis of statistical inference theory, in which the a posteriori likelihood of estimating several scene characteristics given the available image is optimized. Common to these approaches is the requirement that representations of intrinsic scene characteristics are constrained in order to guarantee the consistency of the set of solutions, which often involve smoothness assumptions for correlated feature estimates. These consistency constraints are typically based on the laws of physical image generation, such as Lambertian surface reflectance properties, and thus the overall process comprises an ideal observer seeking an optimal solution to the problem of inferring physical scene properties from images.

After briefly summarizing fundamental approaches to the computation of intrinsic scene characteristics, we consider an alternative literature of neural models of boundary and surface computation.

## Intrinsic Images and the Neural Processing of Surface Layout

Barrow and Tenenbaum (1978) proposed a framework for machine vision based on computation of view-centered families of representations of local estimates of intrinsic scene characteristics, such as illumination, surface reflectance, and orientation. The resulting images are spatially registered with the single achromatic luminance image in which all the attributes are encoded pointwise. In order to regularize the inverse problem of computing several attributes from image data, several constraints, or assumptions, need to be incorporated into the recovery mechanisms. For example, in order to achieve the continuity of homogeneous surface attributes, each intrinsic image incorporates lateral smoothing of values in a discrete grid unless an edge breaks the local continuity. Discontinuities need to be in registration with intensity edges, and the recovered values for attributes need to fulfill the image irradiance equation at each grid point. This approach has been formalized in terms of coupled Markov random field (MRF) models in which the a posteriori probability for scene interpretation given an image, $p(scene|image) \propto \exp(-E/T)$ ($E$ is an energy function that sums the image and prior constraints, $T$ is a temperature term), can be maximized utilizing a stochastic sampling scheme (simulated annealing; see SIMULATED ANNEALING AND BOLTZMANN MACHINES). The MRF formulation allows us to incorporate a line pro-

cess (representing discontinuities) in the form of additional associated energy terms that can break the smoothness within an intrinsic attribute representation at locations where the tension of the recovered surface exceeds certain limits. These interactions correspond to the bidirectional coupling of boundary and surface computation depicted in Figure 1. More recent developments of the MRF approach take into account the computation of perceptual surface attributes, such as transparency (Kersten, 1991).

These approaches share the same basic computational principles: representations of smooth surface characteristics are generated by interpolating sparse data from initial estimates, and an edge map is extracted to depict the discontinuities in one or several attributes. In order to generate mutually consistent maps of intrinsic image characteristics, or attributes, the energy function used in the MRF model must utilize the prior probabilities of image characteristics, which in turn are derived from physical imaging models, e.g., for reflectance or transparency. In that sense the estimation process defines an ideal observer that utilizes knowledge about image formation by trying to invert the optical image generation process. Perceptual findings, however, indicate that, for example, an attribute such as lightness (the perceived surface reflectance) depends on surface size and that the judgment of surface orientation is unreliable over variations in surface curvature or lighting conditions. These observations cannot uniquely be accounted for by the intrinsic image approach, since size effects impose constraints not considered by such local processes as are employed in implementing an inverse optics solution.

In addition, line processes representing physical discontinuities in a surface property are modeled as separate MRFs. In order to be computationally tractable their prior probability structure is formulated over a small local pixel neighborhood only. Empirical observations again suggest that contour processes act over long spatial distances in order to reliably integrate contour fragments to form surface boundaries under variable imaging conditions. In all, these observations motivate the investigation of the neural mechanisms underlying the computation of perceptual boundaries and the subsequent assignment of surface attributes.

## Elements of Spatial Long-Range Integration in Boundary Finding

Formal approaches to the Gestalt concept of *good continuation* have garnered increasing attention since Field, Hayes, and Hess (1993) popularized the notion of an "association field," an elongated spatial zone aligned with oriented contour segments denoting facilitatory perceptual interactions with other segments. This geometry of spatial integration is summarized in the "bipole" icon of Figure 2, a figure-eight-shaped zone that was introduced as a "cooperative cell" unit in a neural network model for grouping by Grossberg and Mingolla (1985). The strength of spatial integration in the presently considered models is always some function of the distances and relative alignments of oriented units, such as contrast edges. Imagine that a contrast pattern occurs along the orientations denoted by the long axes of the dark and light ellipses at locations **x** and **x**′. The influence of the edge at the light ellipse on the representation of the contour strength in the region of the dark ellipse is calculated using the following fundamental quantities: (1) the distance, **r**, between the centers of the two ellipses; (2) the angle, $\vartheta$, between the ray passing through the centers of the two ellipses and the principal axis of the dark ellipse; and (3) the difference in orientation, $\varphi$, of the principal axes of the two ellipses.

The bipole shape expresses the region of relatively high coupling strength for the influence of contour segments remote from the central ellipse on a unit whose positional and orientational preferences are denoted by the ellipse at the center. Its shape and connectivity pattern is justified by recent investigations in psychophysics, physiology, and anatomy. For example, the co-occurrence of edge segments in natural scenes have been shown to have a bipole distribution, and cortical cells of similar orientation selectivity in tree shrew are preferentially connected along the axis of their visuotopic alignment to cells of compatible orientational preference (see Neumann and Mingollia, 2001, for details). Thus, the bipole icon for grouping of contour segments, originally suggested on intuitive grounds, is validated by a growing body of empirical data.

The bipole concept can be embedded in a framework in which the pattern of connectivity among relatively tightly coupled neural units is described formally by a *spatial weighting*, or kernel, function, coding the strength of connections between units in a spatial array. Items that are closely spaced are more likely to be grouped than candidates that are located far apart. The underlying neighborhood function often selectively facilitates a sector of a spatial surround to define an anisotropic coupling that is compatible with the feature domain. Elementary features along dimensions such as (tangential) orientation, motion direction, and disparity provide the

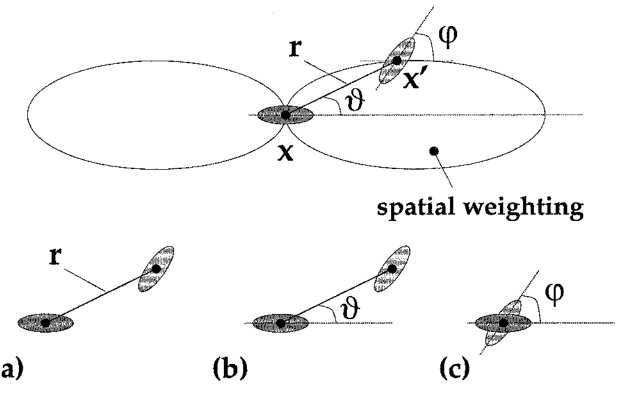

**Figure 2.** *Top*, The "bipole icon" for modeling feature integration in spatial grouping. The quantity to be assessed is the "contribution" of activation in an oriented unit, denoted by the light ellipse, to the activation at the center unit, denoted by the dark ellipse. *Bottom*, The figure-eight shape of a bipole expresses relations among three fundamental quantities: (a) the distance, **r**, between spatial locations, (b) the angle, $\vartheta$, between the virtual line and the target orientation, and (c) the difference in orientation, $\varphi$, of the two ellipses.

dimensions of the visual representation space. The feature *relatability* (or *compatibility*) between stimulus items is defined along these dimensions. Herein, the most likely appearance of meaningful structure is encoded to represent "what feature goes with what." In the following treatment we will focus on grouping mechanisms for static form processing and therefore consider only *orientation* as the relevant feature dimension.

The result of integration of items defines the *support* of a localized feature measurement at a given spatial location based on the configuration of other items. Based on the bipole structure of left and right subfields (Figure 2), the support of a target item can be defined as a function

$$\text{support}_{xy,feature} = \{\text{left-input}_{xy,feature}\} \circ \{\text{right-input}_{xy,feature}\} \qquad (1)$$

where $\circ$ denotes some operation to define the *combination of subfields*. Subscripts *xy* denote spatial locations in a two-dimensional (2D) retinotopic map, and *feature* identifies the feature dimension involved in the grouping process—in our case, *orientation*. The *activation* of the corresponding target cell results as a function $f(\cdot)$ of the support. The formal description of the mechanisms underlying the computation of activations "left-input" and "right-input," respectively, necessitates the detailed specification of the interaction of activities in grouping.

In most models the connectivity pattern of the relatable features is prespecified, or *programmed*, referring to some measure of geometric entities. These are designed to encode static efficacies between *n*-tuples, e.g., pairs, of feature measurements at given locations optimizing a given functionality. To date, few approaches have investigated the possible *self-organization* of such lateral interactions in a neural architecture. Note that the spatial weighting function and the feature relatability define the components of the net *coupling strength*. This function specifies a metric for the similarity measure in the $\langle xy, feature\rangle$-space and thus defines the distance function of *feature cooperation* for the clustering of a visual pattern in accordance with a relatability measure that underlies the visual interpolation in spatial grouping for object recognition (Kellman and Shipley, 1991). *Input activations* at the different sites are necessary to gather any support. Here, two different types of interactions can be distinguished: (1) a convergent feedforward mechanism is defined when the *bottom-up* input is integrated at the target location, whereas (2) a mechanism of (nonlinear) *lateral* interaction is defined when activity is horizontally integrated within a neural layer.

Taken together, the activation of, say, "left-input" derived from the feature integration process using the bipole mechanism is computed by

$$\text{left-input}_{\mathbf{x}\theta} = \sum_{\mathbf{x}'\phi} \{\text{act}_{\mathbf{x}'\phi} \cdot \text{relate}_{\mathbf{xx}'\theta\phi} \cdot \text{weight}^{L}_{\mathbf{xx}'\theta}\} \qquad (2)$$

where "weight" denotes the spatial weighting kernel, "relate" the feature relatability, and "act" the input activations. The "right-input" activity is computed similarly. Here, $\mathbf{x} = (x, y)$ and $\theta$ correspond to the location and orientation of the target feature, respectively. Other parameters refer to the specific location $\langle \mathbf{x}', \phi\rangle$ in the space-orientation neighborhood (see Figure 2).

## Grouping Models and Their Components

The initial processing stages of these models consist of some form of filtering the input luminance image. A (possibly nonlinear) center-surround mechanism (resembling segregated ON and OFF contrast channels at the retina and LGN) computes contrast ratios throughout the image. These outputs drive oriented simple and complex cells, which are often modeled as localized spatial frequency filters, such as Gabor or wavelet kernels. Their output of different orientation fields defines the interface representation for subsequent grouping processes. We focus on those models that (1) have their roots in the explanation of empirical data and (2) were most influential for subsequent scientific developments. A comprehensive treatment can be found in Neumann and Mingolla (2001).

The Boundary Contour System (BCS) has been developed as part of a unified modeling framework called FACADE (Form-And-Color-And-DEpth). As described by Ross, Gossberg, and Mingolla (2000), the BCS consists of a series of boundary detection, competition, and cooperation stages. The general layout of basic processing stages is presented in Figure 3 (left). Long-range boundary cooperation of this scheme (stage 3) accomplishes the grouping of consistent boundaries and the completion of interrupted boundaries. Spatial weighting and relatability, as elements of the support function, in this model are defined as $\text{weight}^{L/R}_{\mathbf{xx}'\theta} = [\pm\Gamma^{rad}_{\mathbf{xx}'} \cdot \Gamma^{ang}_{\mathbf{xx}'\theta}]^+$ (for a scheme separable in polar coordinates; $[\cdot]^+$ denoting half-wave rectification) and $\text{relate}_{\mathbf{xx}'\theta\phi} = \cos^q(2\tan^{-1}((y' - y)/(x' - x)) - (\theta + \phi))$ (for a co-circularity constraint; $q$ controlling the angular width of the lobes). The support and activation function is computed employing bipole cells that fire only if both lobes of their integration fields are sufficiently activated. The left/

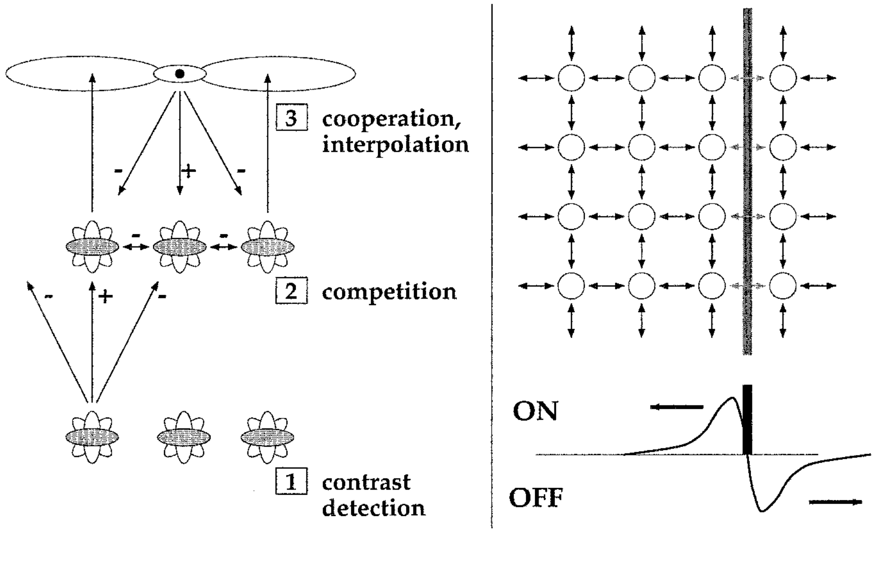

**Figure 3.** Details of the mechanisms involved in boundary and surface computations. *Left*, The three major stages for *boundary computation* involve contrast detection and competition between responses in space and orientation domain. Resulting responses are integrated over longer distances utilizing oriented bipoles, which lead to on-center/off-surround feedback interaction. *Right*, Lateral interaction for *surface computation* between sites of a regular grid. Local contrast signals measured near boundaries are laterally propagated to fill in regions void of activities. The lateral interaction is controlled by an inhibitory mechanism to reduce or switch off lateral couplings by high boundary activation, as indicated by the light shaded arrows. See text for details.

right subfield combination thus realizes a multiplicative, or AND gate, combination of input terms. The cooperative-competitive (CC) feedback loop between stages 1 and 3 (Figure 3, left) acts to complete and enhance spatially and orientationally consistent boundary groupings while inhibiting inconsistent ones, thereby also suppressing noise. This mechanism of long-range completion is also capable of signaling boundaries over gaps in the image, that is, over regions void of any contrast signals, and thus can generate illusory contours for images in which humans perceive them.

Relaxation labeling schemes have been developed as optimization procedures to find consistent interpretations for measurement problems with uncertainty. The computational goal seeks to achieve a consistent labeling assigning graded activations, or probabilities, to a limited set of labels for nodes in a graph representation. For contour integration, the labeling problem can be formulated as one of finding the most likely set of orientations for discrete grid locations corresponding to the graph nodes (a "no-line" label is taken into account to represent the nonresponsiveness of cells at locations that are not boundary elements). Parent and Zucker (1989) determine unambiguous orientation estimates along contours by evaluating consistency constraints based on a measure of compatibility between pairs of orientations. Initial responses are generated by oriented filters (Figure 3, left, stage 1) that were normalized in order to allow filter activations treated as probabilities for assigning orientation labels (stage 2). The individual strengths for orientation measures at a given image location are iteratively updated through the support that is gathered from relatable activities in a spatial neighborhood. Spatial weighting and relatability are defined as $\text{weight}^{L/R}_{\mathbf{xx}'\theta} = P^{length,L/R}_{\mathbf{xx}'\theta} \cdot d(\mathbf{x}, \mathbf{x}')$, where $P$ denotes a predicate to compensate for path length differences on discrete grids and $d(\cdot)$ compensates for differences in interpixel distances, and $\text{relate}_{\mathbf{xx}'\theta\phi} = c_{\mathbf{xx}'\theta\phi} \cdot K^{k}_{\mathbf{xx}'\theta\phi} \cdot C^{kk'}_{\mathbf{xx}'\theta\phi}$. Here the co-circularity measure $c$ is augmented by two binary predicates to exclude any candidates of incompatible local contour curvature. Input activations in the orientation field are thinned by nonmaximum suppression in order to generate localized representations of contours. The support and activation function is computed by integrating responses from the subfields of the spatial weighting functions (stage 3). Activities are iteratively updated by a nonlinear recurrent competitive/cooperative mechanism.

Contrary to the previous approaches, Heitger et al. (1998) proposed a feedforward scheme of successive filtering for contour grouping that selectively integrates activities from oriented single end-stopped (ES) filters, which respond to, e.g., line ends and corners. The result of such grouping is combined with the representation of oriented contrast responses to generate a final contour map. The core mechanism of grouping again utilizes spatial weighting functions (bipoles) virtually equivalent to those of the BCS (Figure 3, left, stage 3). Two grouping rules are distinguished for corners (para grouping) and line ends (ortho grouping). The responses of ortho and para grouping are linearly interpolated. Different curvature classes are distinguished, similar to the relaxation scheme (see above), by partitioning the bipoles into subfields such that only some of them in the left lobe can cooperate with their counterparts in the right lobe. Left/right lobes are combined in a multiplicative fashion via an AND-gating mechanism, similar to the BCS approach. This makes the grouping scheme selective to complete activations between localized ES features. The elongated bipole lobes are also capable of signaling boundaries over gaps, and thus generate illusory contours. This model does not incorporate any feedback mechanism and must, therefore, employ some stages of postprocessing in order to sharpen the final boundary response.

Based on the previous "core models," other approaches have been developed that elaborate aspects of the general framework. For example, random walks of particles in a discrete lattice of the sampled space-orientation domain have been investigated to determine the paths of spatially relatable items at a given location ($x$, $y$, $\theta$) and another point ($i$, $j$, $\phi$). Particles were initiated at sparse keypoint locations corresponding to localized responses of ES cells. The probability densities in the stochastic completion field represent the strengths—and therefore likelihood—of smooth paths connecting pairs of key points. Another study investigated how V1 horizontal long-range integration could functionally account for the enhancement of texture region boundaries and pop-out effects in visual search. Here, the spatial integration field is subdivided into spatially nonoverlapping parts of excitatory and inhibitory contribution. An elongated bipole integrates activities of cells oriented such that they form smooth interpolations with the target cell at the bipole center. Activities of like orientation from a sector orthogonal to the target cell orientation generate the inhibitory signal. In a similar spirit, a scheme of excitatory long-range integration has been used that consists of two spatial regions: one coaxial bipole with cocircular relatability and one sector that extends orthogonally from the target cell's orientation axis and integrates units oriented parallel to that of the cell. The latter component contributes to a facilitation of simple symmetric shape axes. Each cell inhibits itself based on a threshold of the average input from its immediate neighbors, so that only salient arrangements produce a net output.

Contrast integration for boundary grouping addresses the particularly important question about what the core principles are that underlie the establishing of spatial integration and grouping. Yet there still is an ongoing debate about the role of feedforward and feedback mechanisms involved in spatial grouping and the dominance of their individual contributions in visual processing. Aspects of *temporal coding* principles based on oscillator mechanisms or spiking neurons may play another important role in grouping tasks. Several neurophysiological studies indicate that distributed representations of related scene fragments are linked by temporally correlated, or synchronized, neural activation. The temporal coding hypothesis studied in isolation appears, however, to be incomplete. The temporal establishment of grouping addresses the signaling of binding, but not the "how" or "what" of its computation. The mechanisms of oriented long-range interactions for integration provide the underlying basis for grouping to establish perceptual items related to surface boundaries.

## Complementary Mechanisms of Surface Perception

The computation of perceptual surface qualities complements the formation of their boundaries. Image regions that are sufficiently homogeneous in luminance or statistical distribution of contrasts can give rise to the impression of color, texture, brightness, or lightness, also known as achromatic color. How is the generation of smooth representations of surface qualities accomplished? Paradiso and Nakayama (1991) provided compelling psychophysical evidence for a long-hypothesized neural process that propagates local estimates of lightness from boundaries into region interiors. Further psychophysical as well as physiological investigations of temporal properties of brightness and texture filling-in revealed further details of the neural machinery underlying the integration of perceptual surface properties.

Computational models for the generation of perceptual surface quantities generally pursue one of three basic strategies: (1) filtering and rule-based symbolic interpretation, (2) spatial integration via inverse filtering and labeling, or (3) filling-in. In the first scheme, (nonlinear) combinations of filter responses and subsequent rule-based decision operations lead to the final prediction of lightness. The latter two approaches both begin with local luminance ratios estimated along boundaries. Computation of surface qualities proceeds by propagating local estimates into region interiors in order to generate a spatially contiguous representation of homogeneous properties (Figure 3, right). In the spatial integration approach, the lateral propagation is the consequence of an iterative process to invert previous spatial derivative operations labeling region interiors with estimates of quantities derived at region boundaries. Filling-in approaches spread activity in a neural map such that at locations coding region interiors, activation is generated by a spatial diffusion process integrating estimates of local contrasts from remote boundaries.

*Spatial filtering* approaches utilize initial stages of either isotropic or oriented filters, or both, over multiple bandpass channels of spatial frequency. The filter outputs are scaled nonlinearly by a gain-control mechanism and thresholded, individually interpreted by a set of rules, and finally combined over several scales. In two dimensions this strategy leads to results that depend on the direction of the sequential application of interpretation rules. Authors pursue a simple averaging of results from forward and backward scanning over different orientations (McArthur and Moulden, 1999). Approaches in this category follow a tradition that the input luminance distribution is processed through a sequence of filtering steps during the early stages of the visual system. It is assumed that specific features in the responses directly contribute to observable brightness effects by implicitly propagating local qualities into region interiors as a consequence of applying some interpretation rules.

*Spatial integration models* attempt to recover object lightness of a surface by utilizing the sequence of processing stages *Filtering/Differentiation* → *Boundaries/Thresholding* → *Integration*. Differentiation and subsequent thresholding operations are intended to detect salient changes in the luminance signal, which in turn trigger the integration from local luminance ratios. Luminance ratios provide the basis to infer surface-related properties that are invariant against gradual illumination changes, thus discounting the illuminant. Furthermore, lightness can be influenced by luminances at regions remote from each other. The Retinex algorithm by Land and McCann (1971) accounts for these observations by integrating contrasts along several pathways of different lengths. The logarithms of luminance ratios at thresholded contrast locations are summed such that, as a net effect, ratios measured between the target region and distant regions are integrated and averaged. A center-surround interaction accounts for this process in an approximate form. Alternative formulations of lightness integration numerically invert the differentiated 2D luminance image. Under certain boundary conditions a unique solution exists that can be computed by numerical techniques (Hurlbert, 1986). Changes in reflectance properties occur locally, thus comprising a high spatial frequency pattern, while inhomogeneous illumination constitutes a phenomenon at low spatial frequencies. Suppression of influences in low spatial frequencies could be achieved by homomorphic filtering in which low-frequency components are reduced or even suppressed and higher frequencies are amplified. Following this idea, approximate approaches for lightness computation utilize multiple spatial frequency channels of center-surround mechanisms based on divisive, or shunting, interactions of different scales.

As a second computational strategy of spatial integration models, *filling-in* approaches proceed by taking local ratios along boundaries and subsequently propagate these measures into the void spaces of bounded regions. Generating a representation of surface quality utilizes the processing stages *Filtering* → *Boundaries* → *Filling-in*. The algorithm proposed by Grossberg and Todorović (1988) was the first implementation in two dimensions of the complementary operations of the combined BCS and Feature Contour System (FCS) model of brightness perception that was able to explain a wide variety of phenomena, such as simultaneous contrast and the Craik-O'Brien-Cornsweet illusion. The model was later demonstrated to also account for the temporal properties of brightness filling-in (Paradiso and Nakayama, 1991). Filling-in of local contrast ratios taken along extended figural boundaries is laterally propagated in a diffusion process. Such a diffusion is controlled by a gradual permeability function $\Upsilon$ utilizing a boundary signal such as the one generated by mechanisms of long-range integration (compare Figure 2 and Figure 3, right). This renders filling-in a spatially inhomogeneous diffusion process that generates a maximum likelihood (regularized) solution of a brightness surface given the sparse contrast estimates at the boundaries, where $\Upsilon$ is monotonically decreasing to split apart regions of homogeneous surface properties. In the case that the function $\Upsilon$ is solely controlled by an auxiliary boundary signal, the function solves a simple gradient descent of finding a dense activity distribution representing surface brightness. In general, $\Upsilon$ could also depend on gradients of the filling-in signal itself, such that boundary *and* surface computation become mutually interdependent (dotted arrow in Figure 1) and the overall system becomes nonlinear.

Ross and Pessoa (2000) describe an important extension of previous models by suggesting a context-sensitive weighting of contrast measures prior to a final integration stage. Emphasis is put on a computational mechanism that tags boundaries from contrast detection and grouping to (partially) segment an image into different context domains. The segmentation is triggered by the presence of T-junctions, which are used as seed points to propagate the tagging signal along the roof of the Ts and the adjoining smooth boundary segments, thus generating a map of context boundaries. These boundaries are subsequently used to suppress initial contrast measures along the corresponding contours via a gating mechanism. As a result, the contribution of contrast measures that could lead to erroneous lightness estimates over segmentation boundaries is reduced or even suppressed. This computational mechanism is capable of producing region lightness estimates that account for several effects that have been previously shown to be unexplainable by simple local mechanisms of contrast integration, e.g., White's effect, the Benary cross, and Adelson's folded-card stimuli.

Although not described here, the FACADE model, with which the Ross and Pessoa model has certain parallels, proposes related explanations of the just-mentioned and related lightness effects (Grossberg, 1994). FACADE has also been developed to account for the perception of such phenomena as amodal surface completion, whereby occluded portions of objects are sensed as being present in specific locations behind foreground objects, and more generally the separation of surface regions seen as figures from backgrounds. The development of this and other models (Heitger et al., 1998) that attempt to account for more complex aspects of surface perception than are captured in planar arrays indicates that an exciting new phase of inquiry into surface perception is under way.

## Stochastic Formulation of Boundary/Surface Computations

In the tradition of intrinsic image architectures, some approaches formulate the above-outlined boundary and surface computations in a Bayesian framework. For example, Lee (1995) utilized a variant of a nonlinear diffusion mechanism that incorporated piecewise smoothness of filling-in domains that were separated by contour segments denoting breaks in the smooth surface signal. Statistical signals from initial responses of oriented Gabor filters of different frequency selectivity served as filling-in signals. These inputs were subsequently diffused in the space-frequency domain incorporating a spatial modulation by the boundary signal. Mutual interaction between boundary and surface processes were modeled as MRF processes in which Bayesian priors propagated bidirectionally and interacted through local connections in each area. Since this approach focuses on texture region segregation, an explicit modeling of the optical image generation process, as in classical intrinsic image approaches, is not necessary here. This renders the model a Bayesian interpretation of above-mentioned neural processes for surface/boundary extraction.

## Discussion

We have seen that the key stages of a common framework of computational models for generating perceptual surface representations utilize separate subsystems for boundary and surface computation. Depending on the modeling framework, different processes of mutual interaction are defined to achieve the goal of generating a coherent representation of object surfaces and their attributes. Modeling the *neural* processes of a perceptual surface layout has focused on the processes of contour completion based on long-range integration based on some variation of the structure of the bipole kernel and a number of additional computational principles in evaluating related activities in feature space. The bipole kernel itself graphically visualizes the oriented fan-like connectivity between sites in a space-orientation feature space.

In comparison with processes of boundary finding, the situation with respect to surface quality perception is considerably less developed, most especially with respect to attributes such as texture perception, which we have not reviewed. All models presented are based on some mechanism to laterally propagate activities to interpolate and smooth sparse estimates. Improved empirical techniques juxtaposed with hypotheses developed by computational modelers offer the hope that coming years will see a convergence in this area, as has already occured in the field of contour completion.

# Convolutional Networks for Images, Speech, and Time Series

*Yann LeCun and Yoshua Bengio*

## Introduction

The ability of multilayer backpropagation networks to learn complex, high-dimensional, nonlinear mappings from large collections of examples makes them obvious candidates for image recognition or speech recognition tasks (see Pattern Recognition). In the traditional model of pattern recognition, a hand-designed feature extractor gathers relevant information from the input and eliminates irrelevant variabilities. A trainable classifier then categorizes the resulting feature vectors (or strings of symbols) into classes. In this scheme, standard, fully connected multilayer networks can be used as classifiers. A potentially more interesting scheme is to eliminate the feature extractor, feeding the network "raw" inputs (e.g., normalized images) and relying on learning algorithms to turn the first few layers into an appropriate feature extractor. Although this can be done with an ordinary fully connected feedforward network with some success for tasks such as character recognition, there are problems.

Firstly, typical images, or spectral representations of spoken words, are large, often with several hundred variables. A fully connected first layer with, say a few hundred hidden units would already contain tens of thousands of weights. Overfitting problems may occur if training data are scarce. In addition, the memory requirement for that many weights may rule out certain hardware implementations. But the main deficiency of unstructured nets for image or speech applications is that they have no built-in invariance with respect to translations or local distortions of the inputs. Before being sent to the fixed-size input layer of a neural net, character images, spoken word spectra, or other two-dimensional (2D) or one-dimensional (1D) signals must be approximately size normalized and centered in the input field. Unfortunately, no such preprocessing can be perfect: handwriting is often normalized at the word level, which can cause size, slant, and position variations for individual characters; and words can be spoken at varying speed, pitch, and intonation. This causes variations in the position of distinctive features in input objects. In principle, a fully connected network of sufficient size could learn to produce outputs that are invariant with respect to such variations. However, learning such a task would probably result in multiple units with identical weight patterns positioned at various locations in the input. Learning these weight configurations requires a very large number of training instances to cover the space of possible variations. Conversely, in convolutional networks, shift invariance is automatically obtained by forcing the replication of weight configurations across space.

Secondly, a deficiency of fully connected architectures is that the topology of the input is entirely ignored. The input variables can be presented in any (fixed) order without affecting the outcome of the training. But images, or spectral representations of speech, have a strong 2D local structure, and time series have a strong 1D structure: variables (or pixels) that are spatially or temporally nearby are highly correlated. Local correlations are the reasons for the well-known advantages of extracting and combining *local* features before recognizing spatial or temporal objects. Convolutional networks force the extraction of local features by restricting the receptive fields of hidden units to be local.

## Convolutional Networks

Convolutional networks combine three architectural ideas to ensure some degree of shift and distortion invariance: local receptive fields, shared weights (or weight replication), and, sometimes, spatial or temporal subsampling. A typical convolutional network for recognizing characters is shown in Figure 1 (from LeCun et al., 1990). The input plane receives images of characters that are approximately size normalized and centered. Each unit of a layer receives inputs from a set of units located in a small neighborhood in the previous layer. The idea of connecting units to local receptive fields on the input goes back to the perceptron in the early 1960s, and was almost simultaneous with Hubel and Wiesel's discovery of locally sensitive, orientation-selective neurons in the cat's visual system. Local connections have been reused many times in neural models of visual learning (see Mozer, 1991; see also NEOCOGNITRON: A MODEL FOR VISUAL PATTERN RECOGNITION). With local receptive fields, neurons can extract elementary visual features such as oriented edges, end points, or corners (or similar features in speech spectrograms). These features are then combined by the higher layers. As stated earlier, distortions or shifts of the input can cause the position of salient features to vary. In addition, elementary feature detectors that are useful on one part of the image are likely to be useful across the entire image. This knowledge can be applied by forcing a set of units whose receptive fields are located at different places on the image to have identical weight vectors (Rumelhart, Hinton, and Williams, 1986). The outputs of such a set of neurons constitute a *feature map.* At each position, different types of units in different feature maps compute different types of features. A sequential implementation of this, for each feature map, would be to scan the input image with a single neuron that has a local receptive field and to store the states of this neuron at corresponding locations in the feature map. This operation is equivalent to a convolution with a small-size kernel, followed by a squashing function. The process can be performed in parallel by implementing the feature map as a plane of neurons that *share* a single weight vector. Units in a feature map are constrained to perform the same operation on different parts of the image. A convolutional layer is usually composed of several feature maps (with different weight vectors), so that multiple features can be extracted at each location. The first hidden layer in Figure 1 has four feature maps with 5 × 5 receptive fields. Shifting the input of a convolutional layer will shift the output but leave it unchanged otherwise. Once a feature has been detected, its exact location becomes less important, as long as its approximate position relative to other features is preserved. Therefore, each convolutional layer is followed by an additional layer that performs a local averaging and a subsampling, reducing the resolution of the feature map, and reducing the sensitivity of the output to shifts and distortions. The second hidden layer in Figure 1 performs 2 × 2 averaging and subsampling, followed by a trainable coefficient, a trainable bias, and a sigmoid. The trainable coefficient and bias control the effect of the squashing nonlinearity (for example, if the coefficient is small, then the neuron operates in a quasi-linear mode). Successive layers of convolutions and subsampling are typically alternated, resulting in a *bi-pyramid* at each layer, the number of feature maps is increased as the spatial resolution is decreased. Each unit in the third hidden layer in Figure 1 may have input connections from several feature maps in the previous layer. The convolution/subsampling combination, inspired by Hubel and Wiesel's notions of "simple" and "complex" cells, was implemented in the neocognitron model, although no globally supervised learning procedure such as backpropagation was available then.

Since all the weights are learned with backpropagation, convolutional networks can be seen as synthesizing their own feature extractor. The weight-sharing technique has the interesting side effect of reducing the number of free parameters, thereby reducing the "capacity" of the machine and improving its generalization ability (see LeCun, 1989, on weight sharing, and LEARNING AND GENERALIZATION: THEORETICAL BOUNDS for an explanation of capacity and generalization). The network in Figure 1 contains about 100,000 connections, but only about 2,600 free parameters because

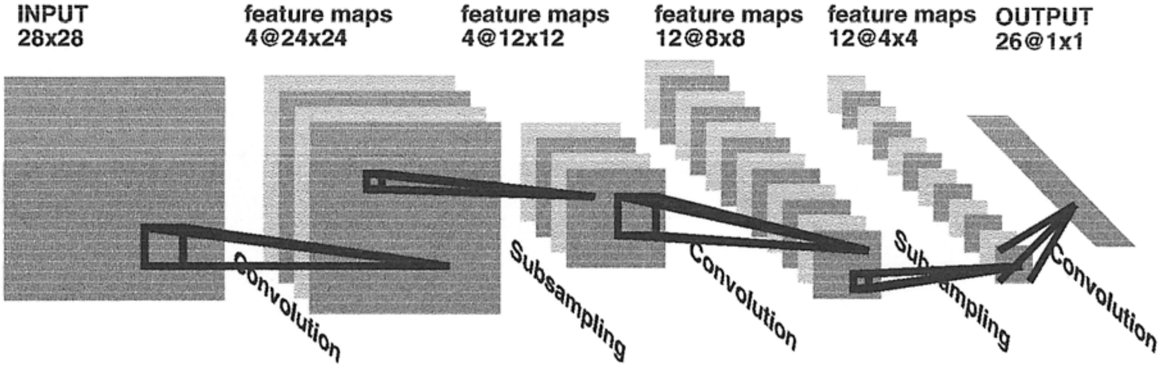

**Figure 1.** Convolutional neural network for image processing, e.g., handwriting recognition.

of the weight sharing. Such networks compare favorably with other methods on handwritten character recognition tasks (Bottou et al., 1994; see also PATTERN RECOGNITION), and they have been deployed in commercial applications (LeCun et al., 1998).

Fixed-size convolutional networks that share weights along a single temporal dimension are known as time-delay neural networks (TDNNs). TDNNs have been used in phoneme recognition (without subsampling) (Lang and Hinton, 1988; Waibel et al., 1989), spoken word recognition (with subsampling) (Bottou et al., 1990), and on-line handwriting recognition (Guyon et al., 1991).

## Variable-Size Convolutional Networks: SDNNs

While characters or short spoken words can be size normalized and fed to a fixed-size network, more complex objects such as written or spoken words and sentences have inherently variable size. One way of handling such a composite object is to segment it heuristically into simpler objects that can be recognized individually (e.g., characters, phonemes). However, reliable segmentation heuristics do not exist for speech or cursive handwriting. A brute force solution is to scan (or replicate) a recognizer at all possible locations across the input. While this can be prohibitively expensive in general, convolutional networks can be scanned or replicated very efficiently over large, variable-size input fields. Consider one instance of a convolutional net and its alter ego at a nearby location. Because of the convolutional nature of the networks, units in the two nets that look at identical locations on the input have identical outputs; therefore their output does not need to be computed twice. In effect, replicating a convolutional network can be done simply by increasing the size of the field over which the convolutions are performed and replicating the output layer, effectively making it a convolutional layer (see Figure 2). An output whose receptive field is centered on an elementary object will produce the class of this object, while an in-between output may be empty or may contain garbage. The outputs can be interpreted as evidence for the categories of objects centered at different positions of the input field. A postprocessor is therefore required to pull out consistent interpretations of the output. Hidden Markov models (HMMs) or other graph-based methods are often used for that purpose (see LeCun et al., 1998; see also HIDDEN MARKOV MODELS, SPEECH RECOGNITION TECHNOLOGY, and PATTERN RECOGNITION). The replicated network and the HMM can be trained simultaneously by backpropagating gradients through the HMM. Globally trained, variable-size TDNN/HMM hybrids have been used for speech recognition (see PATTERN RECOGNITION for a list of references) and on-line handwriting recognition (Schenkel et al., 1993). Two-dimensional replicated convolutional networks, called *space displacement neural networks* (SDNNs), have been used in combination with HMMs or other elastic matching methods for handwritten word recognition (Keeler, Rumelhart, and Leow, 1991; Bengio, LeCun, and Henderson, 1994). Another interesting application of SDNNs is in object spotting (Wolf and Platt, 1994).

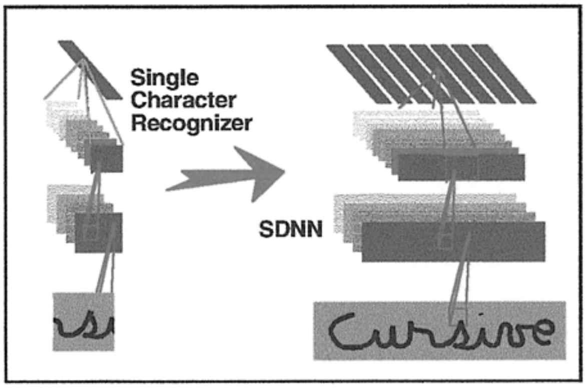

**Figure 2.** Variable-size replicated convolutional network called a space-displacement neural network (SDNN).

An important advantage of convolutional neural networks is the ease with which they can be implemented in hardware. Specialized analog/digital chips have been designed and used in character recognition and in image preprocessing applications (Boser et al., 1991). Speeds of more than 1,000 characters per second were obtained with a network with around 100,000 connections (shown in Figure 1).

The idea of subsampling can be turned around to construct networks that are similar to TDNNs but can generate sequences from labels. These networks are called reverse TDNNs because they can be viewed as upside-down TDNNs: temporal resolution increases from the input to the output, through alternated oversampling and convolution layers (Simard and LeCun, 1992).

## Discussion

Convolutional neural networks are a good example of an idea inspired by biology that resulted in competitive engineering solutions that compare favorably with other methods (Bottou et al., 1994; LeCun et al., 1998). Although applying convolutional nets to image recognition removes the need for a separate hand-crafted feature extractor, normalizing the images for size and orientation (if only approximately) is still required. Shared weights and subsampling bring invariance with respect to small geometric transformations or distortions, but fully invariant recognition is still beyond reach. Radically new architectural ideas, possibly suggested by biology, will be required for a fully neural image or speech recognition system.

# Cooperative Phenomena

*Hermann P. J. Haken*

## Introduction

Most objects of scientific study in physics, chemistry, biology, neuroscience, and many other fields are composed of many individual parts that interact with each other. By their interaction, the individual parts may produce cooperative phenomena that are connected with the emergence of new qualities that are not present at the level of the individual subsystems. For instance, the human brain consists of a network of some 100 billion neurons that, through their cooperation, bring about pattern recognition, associative memory, decision making, steering of locomotion, speech, emotions, and so on. Physical systems may serve as model systems or as testing grounds for the development of new concepts and mathematical tools. One important class comprises systems in thermal equilibrium that may undergo a phase transition when the temperature changes. A typical example is water freezing to ice. At the microscopic level, where we are concerned with the motion of individual molecules, molecules above freezing temperature exhibit disordered movement. Below freezing temperature, also called the *critical temperature*, water molecules take their positions in the highly ordered ice crystal. Incidentally, at the macroscopic level, the properties of ice are different from those of water, as is quite evident in the mechanical properties of the two substances. Another example is afforded by ferromagnets. Ferromagnets are composed of many individual elementary magnets that change their orientation randomly but interact to align with each other below a critical temperature, the *Curie temperature*, and may thus produce a macroscopic magnetization typical for ferromagnets. While in metals at a somewhat elevated temperature the electrons move entirely independently of each other, in superconducting metals below a critical temperature the electrons form pairs. At the macroscopic level, the electrical resistance drops to zero, and the metals become superconducting. In both of these cases the macroscopic properties of the system change dramatically when the temperature of the system is changed from the outside and passes through a critical value. Theories that address these phase transitions were originally developed by Landau (cf. Landau and Lifshitz, 1959) and later by K. G. Wilson (1971) and others.

In contrast to biological systems, whose functioning is maintained by a continuous flux of energy or matter through them, the physical systems just described are truly dead. There are, however, physical systems whose spatial, temporal, or spatiotemporal structures are produced and maintained by a continuous influx of energy and/or matter and which may show phase-transition-like phenomena. Thus, they seem suited to act as model systems for biological systems (including the brain), and they may also guide the development of new types of neural nets. Typical examples are provided by lasers, fluids, plasmas, and semiconductors.

Let us consider a solid state laser (Haken, 1983). In a solid matrix, laser-active atoms are embedded that are excited ("pumped") by, for example, light from other lamps. When the excitation level is low, the individual atoms emit their light independently of each other so that microscopically chaotic—i.e., irregular—light waves emerge. If the pump power exceeds a critical value, the properties of the light change dramatically. It is now composed of a single, almost infinitely long wave track that shows only minor fluctuations in phase and amplitude. In the laser, the emission acts of the electrons of the individual atoms have become correlated to produce the collective phenomenon of coherent light. This ordering phenomenon is brought about by the system itself, not by an outside agent interfering with the system, and for this reason this ordering phenomenon is called *self-organization*. The basic mechanism for the emergence of a single coherent light wave is as follows: When a light wave has been emitted from an excited atom, it may hit another excited atom and force that atom to enhance the impinging light wave by the process of stimulated emission (as formulated by Einstein). When a number of atoms are excited, an avalanche of that light wave is generated. Again and again such avalanches are generated, and thus start to compete with each other. The one that has the largest growth rate wins the competition and establishes the laser light wave. Because the energy supply to the system is limited, the light wave eventually saturates. The light wave so established forces the individual electrons of the atoms into its rhythm (synchrony) and thus forces them to support it. In the terminology of synergetics (Haken, 1983), the light wave acts as the *order parameter*. This is a variable that describes the macroscopic order of the system and gives orders to the individual parts of it. In the laser, the order parameter *enslaves* the electrons of the atoms.

When the pump power to the laser is further increased, new effects may appear. For instance, several coherent waves may be produced simultaneously and may lead to specific spatiotemporal intensity distributions; ultrashort regular light pulses may occur; or light may show deterministic chaos. Thus, a single, rather unspecific input variable—namely, the pump power—controls the self-organization of the system, resulting in the production of entirely new temporal or spatiotemporal structures. This input variable is called the *control parameter*. Note the difference between the concepts of order parameter and control parameter: a *control parameter* is a quantity that is imposed on the system from the outside, whereas an *order parameter* is established by the system itself via self-organization.

A variety of similar phenomena related to the formation of spatiotemporal patterns can be observed in fluid layers heated from below or from above, in fluids between two vertical, coaxial, rotating cylinders, and in semiconductors that are driven away from thermal equilibrium. Additional examples of pattern formation can be found in specific chemical reactions. All of these structure-forming processes in nonequilibrium systems are studied in the interdisciplinary field of synergetics, which affords a unified approach to such processes.

## Outline of the Mathematical Approach

In order to make visible the profound analogies between the formation of patterns by quite different systems, and to prepare the ground for establishing an important analogy between pattern formation and pattern recognition, we have to adopt a rather abstract level of formulation (Haken, 1983). To describe a system at the microscopic level, we introduce the state vector

$$\mathbf{q} = (q_1, q_2, \ldots, q_n) \tag{1}$$

In the example of a laser, the individual components $q_j$ may stand for the time-dependent field amplitudes used in a decomposition of the electric field strength of the laser light into so-called modes. The modes are typically standing or running sinusoidal waves that fit in between the mirrors of the laser. Further components $q_j$ may stand for the dipole moments of the individual atoms and for the inversion (i.e., degree of excitation) of the atoms. In fluids, $q_j$ denotes the density, the components of the velocity field, and the temperature field. In semiconductors, $q_j$ stands for the densities of electrons, holes, impurity centers, and the electric field. In these cases, the components are both space and time dependent. In models of chemical reactions, $q_j$ may stand for the concentration of a chemical of kind $j$. In general, the state vector develops in the course of time; this time evolution is described by evolution equations of the form

$$\dot{\mathbf{q}} = \mathbf{N}(\mathbf{q}, \nabla, \alpha) + \mathbf{F}(t), \tag{2}$$

where $\alpha$ represents one or several control parameters. The left-hand side is the temporal derivative of the state vector $\mathbf{q}$, which is determined by the right-hand side of this equation. $\mathbf{N}$ is a nonlinear function of the state vector. The state vector may be subjected to spatial differential operations $\nabla = (\partial/\partial x, \partial/\partial y, \partial/\partial z)$. Finally, $\mathbf{F}$ represents stochastic forces that stem from internal or external fluctuations. In chemical reactions the typical reaction-diffusion equations are of the form

$$\dot{\mathbf{q}} = \mathbf{N}(\mathbf{q}, \alpha) + \mathbf{F}(t) + D\Delta\mathbf{q} \tag{3}$$

where $D$ is a diffusion matrix and $\Delta\text{-}\nabla^2$ is the Laplace operator.

Equation 2 in this general form covers an enormous range of phenomena, and at first glance it appears impossible to devise a general method of solution. From the experimental point of view, however, we are often confronted with situations like the following. Below a certain pump power threshold, a laser acts as a lamp without the emission of coherent light. When we slowly increase the pump power, suddenly the laser forms coherent laser light. In other words, the former state has become unstable and has been replaced by a new state. This suggests the following strategy: We assume that, for a given control parameter value $\alpha_0$, a solution $\mathbf{q}_0$ of Equation 2 (with $\mathbf{F} \equiv 0$) is known. The general procedure allows us to treat all kinds of $\mathbf{q}_0$ as such a reference state; $\mathbf{q}_0$ may be time-independent (representing a fixed point), time-periodic (representing a limit cycle), time-quasi-periodic (forming a torus), or time-chaotic (forming a chaotic attractor). Common features and differences with respect to bifurcation theory, an important branch of dynamic systems theory, are worth mentioning. Dynamic systems theory also considers bifurcation from a fixed point and from time-periodic solutions; however, it neglects the very important impact of fluctuations as well as dynamical behavior (i.e., relaxation processes), whereas in synergetics these phase-transition effects are included, as is the bifurcation from quasi-periodic and chaotic reference states $\mathbf{q}_0$. Here we explicitly consider the case of a fixed-point $\mathbf{q}_0$. To check the stability of the state $\mathbf{q}_0$ when we change the control parameter, we make the hypothesis that, for $\alpha$ close to $\alpha_0$, the state $\mathbf{q}_\alpha$ can be written as

$$\mathbf{q}_\alpha = \mathbf{q}_0 + \mathbf{w}(\mathbf{x}, t) \tag{4}$$

where $\mathbf{w}$ is assumed to be a small quantity. We may thus insert Equation 4 into Equation 2. In the resulting equation for $\mathbf{w}$ (still with $\mathbf{F} \equiv 0$), we keep only the linear terms and obtain

$$\dot{\mathbf{w}} = L(\mathbf{q}_0)\mathbf{w} \tag{5}$$

where $L$ is a linear operator. It can be shown quite generally in all the previously mentioned cases of $\mathbf{q}_0$ that the solutions $\mathbf{w}$ can be written in the form

$$\mathbf{w}(\mathbf{x}, t) = \begin{cases} e^{\lambda t}\mathbf{v}_u(\mathbf{x}, t), & Re\lambda \geq 0 \\ e^{\lambda t}\mathbf{v}_S(\mathbf{x}, t), & Re\lambda < 0 \end{cases} \tag{6}$$

where we distinguish between the two sets of modes: *unstable modes*, with $Re\lambda \geq 0$, and *stable modes*, with $Re\lambda < 0$ ($Re$ = real part of). Here, $\mathbf{v}$ depends on $t$ in a way that is weaker than an exponential growth or decay. The $\lambda$'s are the eigenvalues of Equation 5. Any linear combination of Equation 6 is, of course, again a solution of Equation 5. In what follows, it, however, will be crucial to treat the solutions in Equation 6 individually and to distinguish between those eigenvalues $\lambda$ whose real part is positive or zero and those whose real part is negative. It is our goal to solve the nonlinear stochastic Equation 2 exactly, i.e., not only in a linear approximation. To this end, we expand the unknown function $\mathbf{q}$ into a superposition of the individual eigenfunctions $\mathbf{v}$ of the linear operator $L$ in Equation 5:

$$\mathbf{q}(\mathbf{x}, t) = \mathbf{q}_0 + \sum_u \xi_u(t)\mathbf{v}_u(\mathbf{x}) + \sum_s \xi_s(t)\mathbf{v}_s(\mathbf{x}) \tag{7}$$

In the mathematical sense, this is a complete superposition representing $\mathbf{q}$ as a function of $x$. The amplitudes $\xi_u$ and $\xi_s$ are still unknown functions of time. To obtain equations for $\xi_u$, $\xi_s$, we insert the expansion of Equation 7 into Equation 2. On the right-hand side of Equation 2 we expand the nonlinear function $\mathbf{N}$ that has become a function of $\xi_u$ and $\xi_s$ into a power series of $\xi_u$ and $\xi_s$. The terms *linear* in $\xi_u$ or $\xi_s$ read $\xi_u L(\mathbf{q}_0)\mathbf{v}_u$ or $\xi_s L(\mathbf{q}_0)\mathbf{v}_s$, respectively. Because of Equation 5, in the case of a fixed point $\mathbf{q}_0$, we may replace, for instance, $L\mathbf{v}_u$ by $\lambda_u\mathbf{v}_u$.

Keeping these and all higher-order terms and projecting both sides of Equation 2 on the modes $\mathbf{v}$, we obtain the following two sets of equations:

$$\dot{\xi}_u = \lambda_u\xi_u + \hat{N}_u(\xi_u, \xi_s) + \hat{F}_u(t) \tag{8}$$

and

$$\dot{\xi}_s = \lambda_s \xi_S + \hat{N}_s(\xi_u, \xi_s) + \hat{F}_u(t) \tag{9}$$

The first term on the right-hand side of Equations 8 and 9, respectively, stems from the linear part of $N$, where use was made of the fact that $\mathbf{v}_u$ and $\mathbf{v}_s$ are eigenfunctions of the linear operator $L$ in Equation 5 with the eigenvalues $\lambda$ that occur on the right-hand side of Equation 6. These equations are entirely equivalent to the former Equation 2. However, provided the inequality

$$|Re\lambda_s| \gg |Re\lambda_u| \tag{10}$$

holds, the *slaving principle* of synergetics (Haken, 1983) can be applied. According to this principle, the mode amplitudes $\xi_s$ are uniquely determined (enslaved) by $\xi_u$. The possibility of expressing $\xi_s$ by $\xi_u$ can be made plausible in the following fashion: Let us assume that according to Equation 10, the mode amplitudes $\xi_s$ relax much faster than the mode amplitudes $\xi_u$. Consider Equation 9 with slowly varying $\xi_u$ that act as driving forces on $\xi_s$. When we neglect transients, $\xi_s$ being driven by $\xi_u$ changes much more slowly than it normally would because of the first term on the right-hand side in Equation 10. In other words, this means that $\dot{\xi}_s$ can be neglected against $\lambda_s\xi_s$, or that $\dot{\xi}_s = 0$. This turns Equation 9 into an algebraic equation that can be solved for $\xi_s$, expressing $\xi_s$ by $\xi_u$. This approximation is called *adiabatic approximation*. The slaving principle ensures that this procedure is a first step toward a systematic procedure by which $\xi_s$ can be expressed uniquely and exactly by $\xi_u$ and $\hat{F}_s$:

$$\xi_s(t) = f_s(\xi_u(t), t) \tag{11}$$

The explicit dependence of $f_s$ on $t$ stems from the time dependence of the fluctuating forces, but not of that of the amplitudes $\xi_u$. In most cases of practical interest, $f_s$ can be approximated by a low-order polynomial in $\xi_u$.

In practically all cases that have been treated in the literature, the systems are of very high dimension—i.e., they contain very many variables—but the number of unstable mode amplitudes $\xi_u$ is very small. The amplitudes $\xi_u$ are called *order parameters*, whereas the variables $\xi_s$ can be called *enslaved variables*. The order parameter concept allows an enormous reduction in the degrees of freedom. Think of a single-mode laser in which we have one mode and, say, $10^{16}$ degrees of freedom stemming from the dipole moments and inversions of the individual laser atoms. The order parameter in the single-mode laser is identical with the lasing mode, i.e., a single degree of freedom. Once we have expressed the enslaved modes by means of the order parameters $\xi_u$ via Equation 11, we may insert Equation 11 into Equation 8 and thus find equations for the order parameters alone:

$$\dot{\xi}_u = \lambda_u \xi_u + \hat{N}_u(\xi_u, f_s(\xi_u, t)) + \hat{F}_u(t) \tag{12}$$

In a number of cases, these equations can be put into *universality classes* describing the similar behavior of otherwise quite different systems. The term *universality classes* is chosen in analogy to universality classes in the theory of phase transitions of systems in or close to thermal equilibrium, such as superconductors or ferromagnets, although the classes treated here are of a more general character. In the present context, the term means that Equation 12 can be put into specific general forms (see below). For instance, a single-mode laser, the formation of a roll pattern in a fluid, or the formation of a stripe pattern in chemical reactions obey the same basic order parameter equation. Such universality classes can be established because of the following facts:

- When we are dealing with a *soft transition* of a system, its order parameters are small, close to the instability point. In analogy to conventional phase transition theory, we call a transition a soft transition if the order parameters change smoothly with the control parameter. This allows us to expand $\hat{N}_u$ into a power series with respect to the order parameters, where we may keep only a few, leading terms.
- Furthermore, we may exploit symmetries. For instance, given a term $\beta\xi_u^2$, if there is an inversion symmetry of the system, it follows that $\beta = 0$. Symmetries lead also in a number of cases to relationships between coefficients.
- Finally, we may invoke so-called normal form theory to simplify the nonlinear functions on the right-hand side of Equation 13.

## Some Examples for the Formation of Patterns

We illustrate the procedure just described with a few typical examples encountered in concrete, important cases. In the case of a *single real or complex order parameter*, a typical order parameter equation reads:

$$\dot{\xi}_u = \lambda\xi_u - \beta|\xi_u|^2\xi_u + F(t) \tag{13}$$

where $\lambda$ plays the role of a control parameter. The state vector reads

$$\mathbf{q}(\mathbf{x}, t) = \mathbf{q}_0 + \xi_u(t)\mathbf{v}_u(\mathbf{x}) + \sum_s \xi_s(t)\mathbf{v}_s(\mathbf{x}) \tag{14}$$

where the sum over the enslaved modes, $s$, is in general small, so that the evolving pattern is determined by the second term on the right-hand side, which is called the mode skeleton because it represents the basic features of the evolving pattern. If the system is originally spatially homogeneous, $\mathbf{q}_0$ does not depend on the space coordinate, and $\mathbf{v}_u(\mathbf{x})$ as a solution of Equations 5 and 6 is basically a sine function. If $\lambda$ is real, a spatial stripe pattern is formed (stripes in chemical reactions, rolls in fluids, current filaments in semiconductors, etc.). If $\lambda$ is complex, a coherent (and spatially modulated) wave emerges (single-mode laser). The stochastic force $F$ leads to amplitude fluctuations and phase diffusion.

In the case of *two order parameters*, the mode skeleton is determined by

$$\mathbf{q}(\mathbf{x}, t) = \mathbf{q}_0 + \xi_1(t)\mathbf{v}_1(\mathbf{x}) + \xi_2(t)\mathbf{v}_2(\mathbf{x}) \tag{15}$$

Depending on the order parameter Equation 12, modes $\mathbf{v}_u$ may either coexist or compete, with the result that only one remains. In the case of competition, either $\xi_1$ or $\xi_2$ vanishes, and a stripe pattern appears. In the case of coexistence, both are nonvanishing, so that the total pattern becomes a superposition of the patterns $\mathbf{v}_1$ and $\mathbf{v}_2$ (square pattern).

A further example for pattern formation in physics is provided by the computer simulation shown in Figure 1, where a liquid in a circular vessel is heated from below. Depending on a prescribed initial state, different stripe patterns may evolve, where in one stripe the fluid is up- and downwelling. In such a case the fluid has the property of an associative memory; i.e., an incomplete set of data (one stripe) is supplemented automatically by the system to a full stripe pattern.

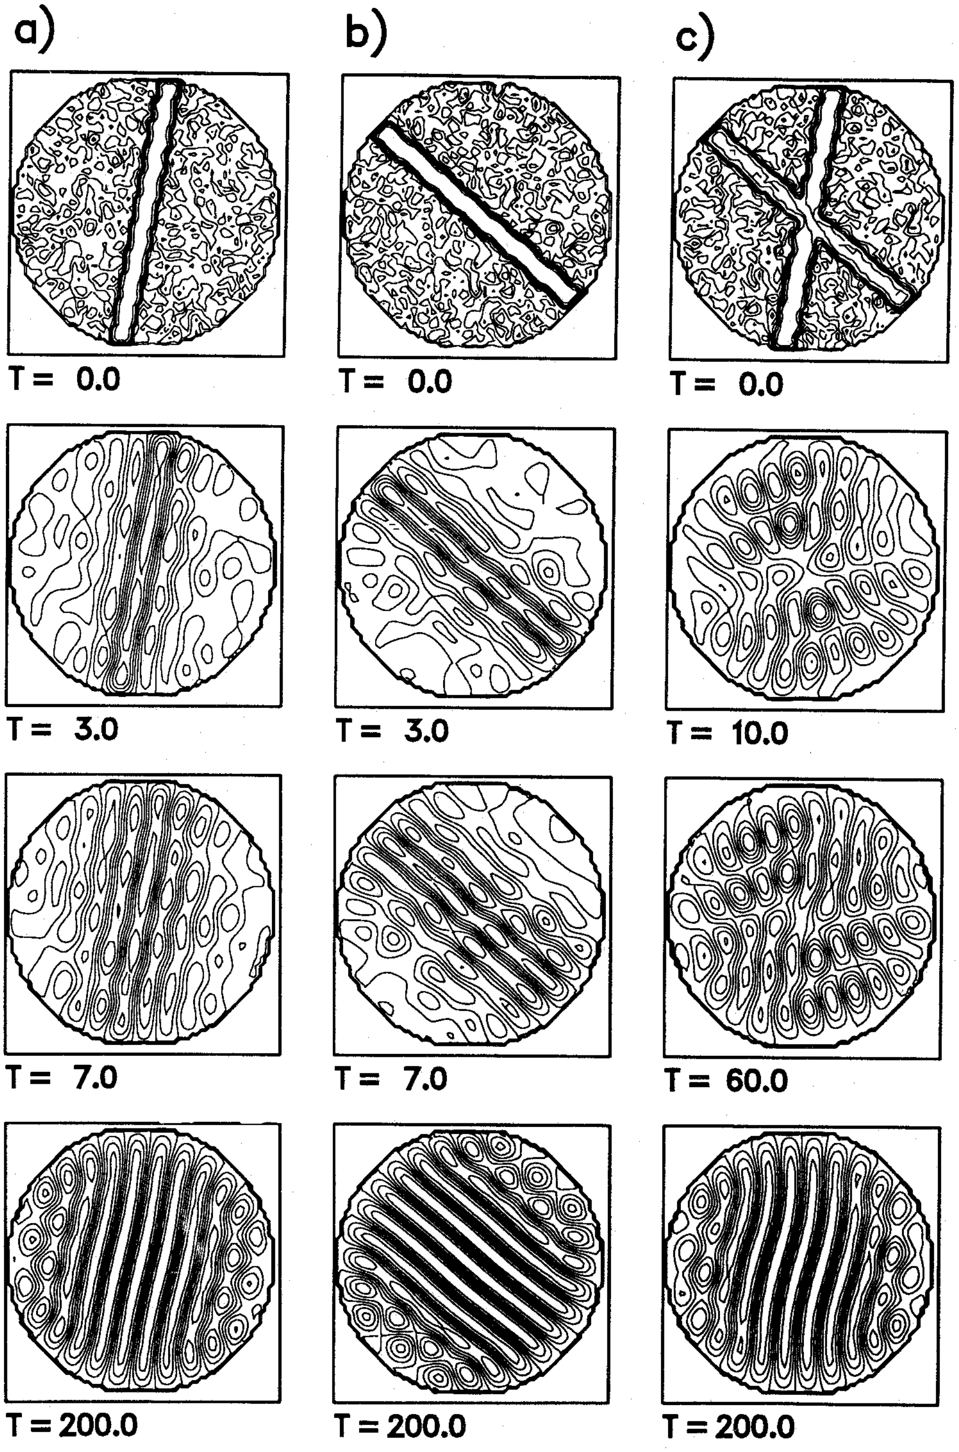

**Figure 1.** Computer simulation of a fluid heated from below in which initially one upwelling stripe is given. *Left column*, Completion of the single stripe to a full stripe pattern in the course of time. *Middle column*, The same as before, but with a different orientation of the initial stripe. *Right column*, Two initially given upwelling stripes, where one stripe is somewhat stronger than the other one. In the course of time, the originally stronger stripe wins the competition and determines the whole stripe pattern.

## Phenomenological and Macroscopic Approaches

In many complex systems, such as biological systems, the basic microscopic evolutions in Equation 2 are not or not fully known. Nevertheless, in this case also we may capitalize on the results shown earlier under the assumption that a nonequilibrium phase transition happens. This is the case if the macroscopic behavior of the system studied changes qualitatively. In such a case, we may phenomenologically postulate order parameter equations. We may also analyze spatiotemporal patterns by invoking the decomposition formulated in Equation 7 and simple forms of the order parameter equations and using experimental data on evolving or changing spatiotemporal patterns.

## Cooperative Phenomena in Neuroscience I

### *Pattern Recognition*

Cooperative phenomena according with the models and interpretations discussed to this point abound in neuroscience. In all of these cases the brain is understood as a self-organizing (synergetic) system. It is possible that important aspects of brain function can be described in terms of order parameters and enslavement.

We have just seen that synergetic systems may act as an associative memory (Kohonen, 1987). This allows us to devise an algorithm (or model) for pattern recognition based on an analogy between pattern formation and pattern recognition (Haken, 1991). In both cases, an incomplete set of data (fluid: a single stripe; pattern recognition: part of a pattern) is completed to a full set of data (fluid: complete stripe pattern; pattern recognition: complete pattern) by means of order parameters and the slaving principle. The algorithm can be formulated as follows: We consider a set of prototype patterns stored in our system. These patterns are represented by vectors $\mathbf{v}^{(k)}$ of a high-dimensional space, where one component $v_i^{(k)}$ corresponds to the gray value or color value of a specific pixel, $i$, of a pattern labeled by an index $k$. In the same way we encode a starting or test vector $\mathbf{q}$ (a pattern to be recognized).

By means of these vectors $\mathbf{v}_i^{(k)}$ we construct a dynamics for the test vector $\mathbf{q}$ in the following sense: The test vector $\mathbf{q}$ becomes a time-dependent quantity undergoing a gradient dynamics in a potential field, which may be visualized as a mountainous landscape. This potential field possesses those and only those minima that correspond to the stored prototype pattern vectors $\mathbf{v}^{(k)}$. Note that this approach avoids the well-known difficulty of a number of neural networks, in particular of the Hopfield type (Hopfield, 1982), in which the system can be trapped in spurious minima that do not correspond to any stored patterns (compare the concept of the Boltzmann machine). Here the dynamical system leads to an identification of prototype patterns without the need to introduce simulating annealing, i.e., a statistical pushing of the test vector $\mathbf{q}$ (see SIMULATED ANNEALING AND BOLTZMANN MACHINES).

In Figure 2, the associative property of the dynamical system is shown using three different initial conditions: part of a face, the name of a pattern, and a pattern that is disturbed by noise. In every case there is complete restoration of the original prototype. The dynamics of a "synergetic computer" can be interpreted or realized by means of a parallel network in which each component $q_j$ of $\mathbf{q}$ represents the activity of a model neuron $j$. By means of the hypothesis

$$\mathbf{q}(t) = \sum_{k'=1}^{M} \xi_{k'}(t)\mathbf{v}^{(k')} + \mathbf{w}(t) \qquad (16)$$

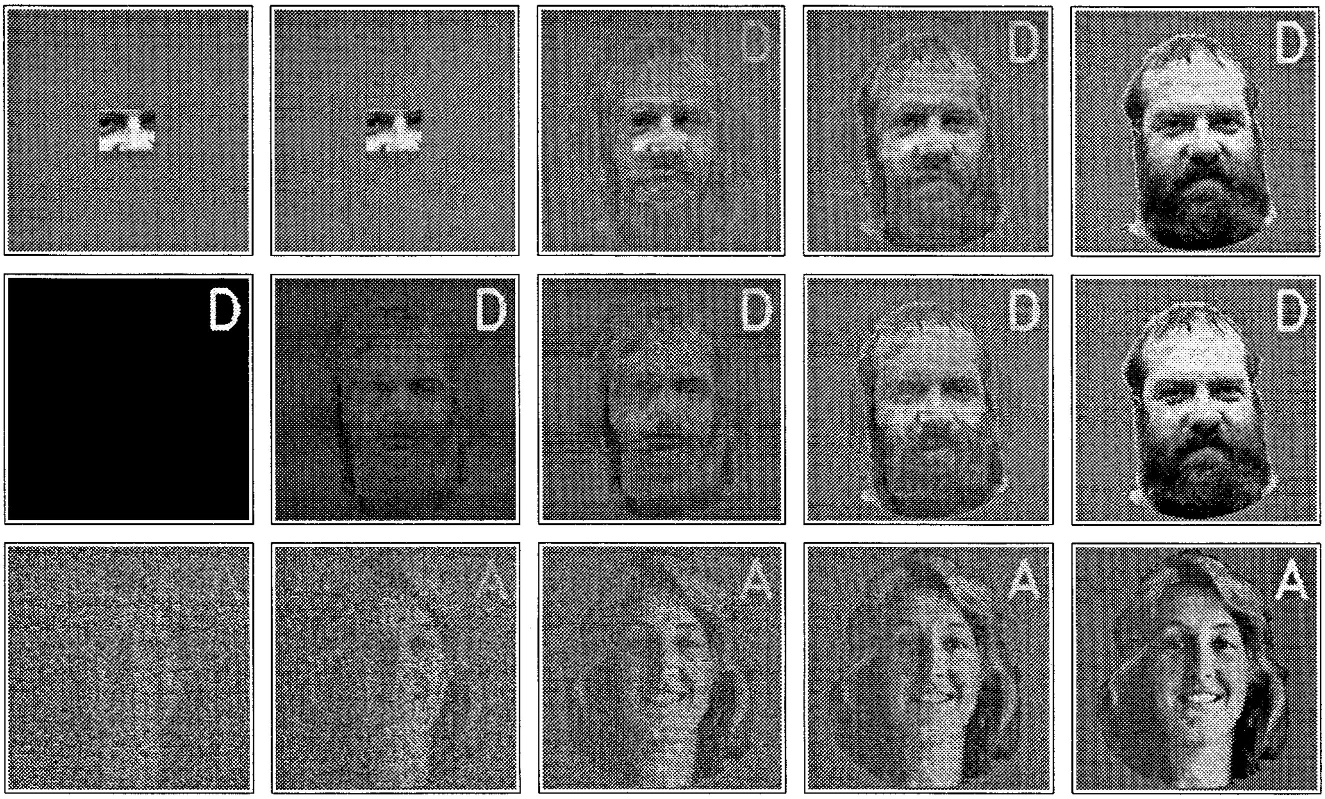

**Figure 2.** *Upper row*, Restoration of a full face from part of it. *Middle row*, Restoration of a full face from the single letter coding for the name. *Bottom row*, Restoration of a face from an originally noisy face.

where **w** is a residual vector, the dynamics of **q** can be transformed into the order-parameter equations

$$\dot{\xi}_k = \lambda_k \xi_k - B \sum_{k' \neq k}^{M} \xi_{k'}^2 \xi_k - C \sum_{k'=1}^{M} \xi_{k'}^2 \xi_k \qquad (17)$$

The attention parameters $\lambda_k$ play the role of control parameters and serve to amplify each order parameter, while the second term serves for a discrimination and the last term for a saturation of the order parameters. In this way, an individual order parameter $\xi_k$ is attached to each perceived pattern. The formalism allows one to treat time-dependent attention parameters and the properties of the perception of ambiguous patterns (Haken, 1991, 1996). The formalism can be extended to model stereovision (cf. Haken, 1996).

Thus far we have described a formal model (algorithm) that can be implemented on a serial computer or realized by some parallel devices. But we can go a step farther. The "enslaved" parts are the neurons with their activities, while the order parameters are interpreted as the percepts. In this "synergetics" approach, a connection between the microscopic level, described by the individual parts of a system, and the macroscopic level, described by order parameters, is established. This separation is made possible by a separation of time scales for the reaction of the parts and of the order parameters. Whereas in the brain, the typical time constants of neurons are on the order of milliseconds, those of the brain's macroscopic performance, such as recognition and speech, are on the order of hundreds of milliseconds. At the microscopic level we may mention in particular the neural network model by McCulloch and Pitts (1943), who modeled the individual neurons as two-state elements. A fruitful subsequent step was recognition of the analogy between the McCulloch-Pitts network and spin glasses, which allowed Hopfield (1982) to introduce an energy function for that network, and which gave rise to an avalanche of studies, in particular by theoretical physicists.

## Cooperative Phenomena in Neuroscience II

### *EEG, MEG, Movement Coordination, Hallucinations*

An important and very comprehensive model of brain action in terms of neurons (spike rates of action potentials) was established by Wilson and Cowan (1972), who solved their equations numerically. The spatiotemporal patterns found by the authors (for instance, to model hallucinations) can be, at least qualitatively, rederived in the terms set out in this article. Further evidence for the occurrence of adequate order parameters in brain activities is as follows:

1. The identification of low-dimensional chaos (describable by order parameters) by Babloyantz (1985).
2. The identification of low-dimensional attractors in the olfactory bulb by Freeman (1975).
3. The analysis of petit mal epilepsy, describable by Shilnikov chaos (Friedrich and Uhl, 1992).
4. The MEG analysis of sensorimotor coordination by Kelso (Kelso, Fuchs, and Haken, 1992; see also Haken, 1996). In this work, MEG changes (in both frequency and time domains) in response to auditory and visual stimuli are revealed.
5. The analysis of movement coordination by Haken, Kelso, and Bunz (1985); see also Haken, 1996.

Because in some EEG and MEG measurements, multi-electrode or squid derivations were possible, the spatiotemporal patterns could be determined and, in particular, the basic modes in the sense of a mode decomposition could be identified. In a number of experiments, a surprisingly low number of dominating modes and thus order parameters could be found.

In conclusion, the strategy of searching for order parameters describing brain functions has found some justification, but considerable work remains to be done. Important work about connecting levels of description of cortical and behavioral dynamics in a systematic way has been done by Kelso's group (Kelso, Fuchs, and Jirsa, 1999).

# Cortical Hebbian Modules

*Daniel J. Amit*

## Introduction

Before describing model networks of cortical Hebbian modules, we will briefly review some experimental findings. Primates are trained to perform a delay match-to-sample (DMS) task or a delay eye-movement (DEM) task in which a relatively large set of stimuli is presented. The behaving monkey must remember sufficient information about the sample (eliciting) stimulus in order to decide on its behavioral response following the presentation of a second (test) stimulus. The test stimulus is, with equal likelihood, identical to or different from the first stimulus in the DMS task, and a "go" signal in the DEM task. Using single-unit extracellular recordings, neurophysiologists have observed elevated spike rates during the delay period, after the eliciting (sample) stimulus was removed. These elevated spike rates are reproducible and occur in areas such as inferotemporal cortex (IT) and prefrontal cortex, which have been suggested to be part of a working memory system (Fuster, 1995; Goldman-Rakic, 1987). Neurons in rather compact columns have been observed to exhibit stimulus-selective elevated rates that can persist for as long as 30 s, a very long time on the scale of neural time constants. The rates observed are in the range of about 10–20 spikes/s, against a background of spontaneous activity of a few per second. The subset of neurons that sustain elevated rates in the absence of a stimulus is selective of the preceding, first, or sample stimulus. The distribution of rates during the delay among the neurons of the cortical module, or the *delay activity distribution* (DAD), could therefore act as a neural representation and an active memory of the identity of the eliciting stimulus, the representation or memory being transmitted for processing later, when the stimulus is no longer present (Amit, 1995).

The DADs appear to be concentrated in localized columns in associative cortex. The estimate is that this column is about 1 mm$^2$ in cross-section parallel to the cortical surface. The delay activities corresponding to all the stimuli (as many as 100 in some studies) are constrained to this small module: it contains some $10^5$ cells, and 1%–2% of the cells participate in the DAD of a given stimulus (Brunel, 1996); i.e., 1,000–2,000 cells would propagate elevated rates.

The absence of the external stimulus during delay activity leads to the conclusion that the selective activity distributions must be an expression of autonomous local dynamics in the column, whose substrate either forms during the training process or is innate. Some exegesis is needed here. First, the selective delay activity may, of course, be a result of a structure in the afferents arriving at the column under observation. In other words, the particular column may be a mere readout board. However, the absence of the stimulus implies that the structured activity must be maintained somewhere in the brain, and an autonomous mechanism for sustaining a DAD must exist and be formed by learning in the alternative location. We will assume that it is sustained where it is observed. There is some experimental evidence to support such a position.

A second point concerns the assertion that the local structure underlying the delay dynamics could be formed by learning. This statement is supported by the fact that when new stimuli are added to the set after the appearance of DADs, no delay activity is observed for the new stimuli. The alternative situation may describe prefrontal cortex, where DADs appear to be built-in (Goldman-Rakic, 1987).

These observations raise two preliminary issues concerning possible models to account for the computational aspects: (1) the necessary neural elements and synaptic structures that can reproduce the observed neuronal spike dynamics, and (2) the synaptic dynamics that can give rise, in the process of training, to a synaptic structure in the local module that is capable of sustaining selective DADs. We will concentrate on the first issue and limit ourselves to a few comments about the second.

A successful treatment of the first issue would conclude with a network of neural elements of a given internal dynamics and synaptic matrices that would lead to neurons emitting spikes in spontaneous activity, at low rates, in a very stable way, and, when stimulated by prelearned stimuli, would maintain selective DADs for a large set of eliciting stimuli. For each stimulus, a small fraction of the cells in the module would have elevated rates, and the rest of the cells would maintain spontaneous activity. The spike activities, both spontaneous and structured, would be rather noisy. In other words, there would be large variability in interspike intervals (Softky and Koch, 1992).

At this point we arrive at the second issue: the effect of neuronal activities on synaptic efficacies, which is at the basis of learning. This issue can be broken down into two major parts for further discussion. One part has to do with the feedforward synaptic dynamics, leading to the formation of the module by afferents from preceding cortical areas, the same module for an entire set of different stimuli. The other part has to do with the formation of collateral synapses within the module. The synaptic matrices, which should sustain the various structured activity distributions, must be generated in the process of training via the neuronal activities. If neuronal activities are expressed in terms of spikes, synaptic efficacies must be sensitive to pre- and postsynaptic spikes, in order to affect Hebbian learning, that is, to be potentiated when presynaptic and postsynaptic neurons are simultaneously active and to be depressed when the activities of the two are anticorrelated. There is a tension between the need to learn at least something from every stimulus, so as to accumulate memory, and the need for synaptic stability on long time scales (hours, days, years). Some synapses must change for every stimulus, but the learning process must be immune to spontaneous activity; synapses should not change too easily. Moreover, since neuronal spike dynamics is governed by the emerging synapses, the learning process (synaptic acquisition) may deviate while learning goes on. All of these considerations impose rather severe constraints on both neuronal and synaptic dynamics, over and above the constraints implied by the collective network dynamics (see, e.g., Fusi et al., 2000).

## Minimal Elements for a Spiking Network

As a minimal model we take neurons to be of the form described in Equation 1, that is, simple point RC integrators of their afferent currents that emit a spike when the integrated level of depolarization $V$ reaches a threshold $\theta$, followed by an absolute refractory period $\tau_0$ and a resetting of the depolarization to $H$—an integrate-and-fire (IF) device (see Integrate-and-Fire Neurons and Networks). Formally, the dynamics of the depolarization is given by

$$\tau \dot{V} = -V + \sum_{i=1}^{C} J_i \tau \sum_{k} \delta(t_i^k - t) \qquad (1)$$

where $\tau$ is the integrator's time constant (RC of the equivalent circuit). Effectively, the depolarization $V(t)$ is a sum of unit contributions, each with amplitude $J_i$, over the interval $\tau$. This simplified form presupposes that the dynamics of the synaptic conductances is much faster than that of the depolarization (for extensions,

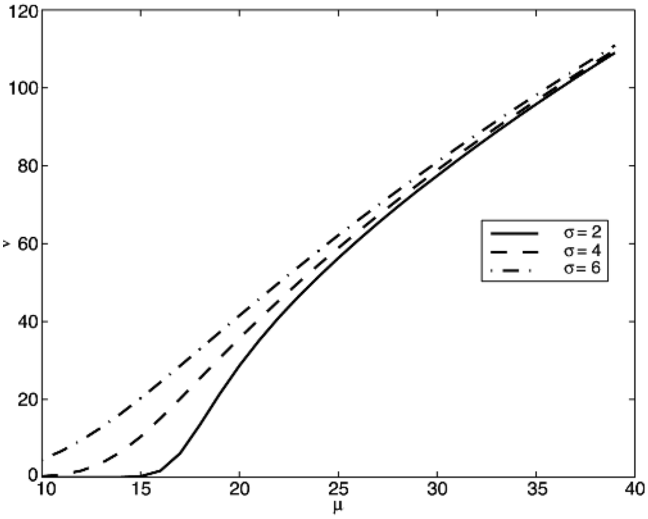

**Figure 1.** Gain function of integrate-and-fire neuron: rate versus mean afferent current ($\mu$), for several values of the noise $\sigma$, for afferent Gaussian current.

see Brunel and Sergi, 1998). In that case the synaptic efficacies $J_i$ are equivalent to the depolarization provoked by a single afferent spike.

The output spike rate of such a neuron is the inverse of the mean time between two consecutive events in which the depolarization reaches threshold. It is the mean first passage time across the threshold. If the neuron is depolarized by a current of Gaussian distribution, uncorrelated at different times, the output rate can be calculated explicitly (Tuckwell, 1988) by the following:

$$\nu_{\text{out}} = \left(\tau_0 + \tau \int_{(H-\mu)/\sigma}^{(\theta-\mu)/\sigma} du\sqrt{\pi}\,\exp(u^2)[1 + \text{erf}(u)]\right)^{-1} \equiv \Phi(\mu,\,\sigma) \tag{2}$$

where $\tau_0$ is the absolute refractory period, $\mu$ is the mean of the Gaussian afferents depolarizing the cell per $\tau$, and $\sigma$ is the corresponding standard deviation (SD).

Note that the response function of this neuron depends not only on the constant part of the afferent current but also on its variance $\sigma$, and is an extension of common mean-field results (see, e.g., Amit and Brunel, 1997a). The rate versus the average part of the current ($\mu$) is represented in Figure 1 for several levels of the noise ($\sigma$). For low noise, it is zero below a threshold and is convex throughout; with increasing noise a concave region appears, allowing for more than one stable rate. It is the concave part that makes possible the coexistence of spontaneous and selective, elevated spike rate distributions (see, e.g., Fusi and Mattia, 1999; Brunel, 2000).

The assumption of an afferent current of Gaussian distribution is quite useful in cortical conditions. If neurons emit spikes at low rates and receive them via a large number of independent channels (synapses), the total current will be a sum of Poisson processes and hence a Gaussian process. The various assumptions can be verified in microscopic simulations.

## The Network

Such minimal elements are put together in a 4:1 ratio of excitatory to inhibitory neuron populations and in large numbers (if not quite as large as the $10^5$ of anatomy), in a module that represents a cortical column. A putative assumption for the connectivity pattern would be total randomness, implying that (1) every neuron in the module can synapse on any other neuron; (2) the set of neurons in the local module synapsing on any given cell is chosen at random, constrained only by a mean connectivity given by anatomy (about 10%); (3) synaptic efficacies (excitatory and inhibitory) are random, centered on some plausible mean for each population of synapses; and (4) spike transmission delays are randomly distributed among the synapses (with an average of a couple of milliseconds).

In addition to collateral connections, neurons receive afferents from outside the module (Figure 2). Those afferents may represent a general arousal level or a selective stimulus. The fraction of such synapses is estimated by Braitenberg and Schüz (1991) to be roughly equal to the collateral one. In the absence of structured stimulation, these afferents will be considered uncorrelated, nonselective, and of a fixed spike rate. Stimulation will consist of attributing to the external afferents of a given subset of neurons in the module a higher rate. This leads to higher response rates in that subset of neurons and corresponds to the "visual response" of neurons observed experimentally.

Estimates of $J$ range from 0.05 to 0.5 mV. If one uses an average of 0.2 mV for the excitatory efficacy and a threshold of 20 mV, some 100 simultaneous excitatory synaptic events are required to bring the postsynaptic neuron to threshold.

The above description of neural elements and connectivity of the network can be studied in simulations once the numerical parameters are set. Spike activity in the simulation can be recorded under different conditions, much as would be done in a neurophysiological experiment. One can also record spikes from single or multiple neurons and observe spike rasters, peristimulus histograms (see Figure 4), and cross-correlations of spike emission times prior to learning, in spontaneous activity states. Then, one can impose a synaptic matrix, presumed to have been formed by learning, and observe the same quantities inside and outside of the subset of selective neurons. These are quantities that can also be sampled by electrodes in the cortex of performing animals.

## Extended Mean-Field Theory

When the network is in asynchronous activity states, i.e., when neural spike emissions of different neurons are essentially inde-

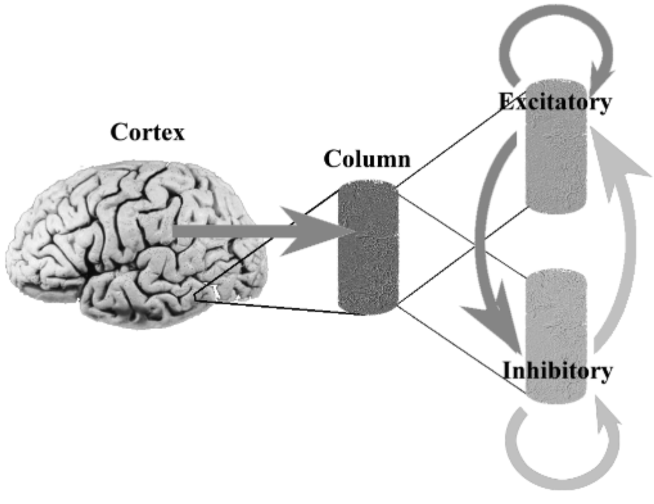

**Figure 2.** Connectivity scheme. The local network, embedded in the cortex and represented as a column, is divided in two populations of neurons, the excitatory population and the inhibitory population. Neurons in the local network receive collateral connections from excitatory and inhibitory neurons in the same module, as well as from excitatory neurons elsewhere in the cortex.

pendent, there are compact, analytical tools to study a wide variety of properties of large subpopulations of neurons—the collective, computational properties of the network. In other words, if the dynamics of the network leads to large subpopulations within each of which neurons act in a statistically similar way, then the dynamics of the very large network can be described at a level of computational complexity equal to the number of populations that are expected to express different statistical properties. This may appear as a severe restriction. However, one should keep in mind that observable neural phenomena must involve large numbers of neurons acting in essentially the same fashion; otherwise the probability of an electrode detecting a neuron representative of a behavioral correlate would be too low. Similarly, macroscopic probes, as in FMRI or EEG, would not have a large enough signal representing a specific phenomenon. What makes the theory particularly simple is that each neuron (in cortex) receives a very high number of afferents.

The assembly of neurons can be divided into subsets according to neuron types (e.g., excitatory, inhibitory), different sets of afferent synapses (e.g., potentiated or depressed by learning a given stimulus, or not), currently driven by a stimulus or not (e.g., receiving selective external currents), and so on. The network is divided into $P$ subpopulations $\Pi_\delta$, $\delta = 1, \ldots, P$. Each neuron in population $\delta$ is assumed to have the same time constant $\tau_\delta$, the same rate $\nu_\delta$, the same mean number of afferents from population $\gamma$—$C_{\delta\gamma}$, and the same mean afferent synaptic efficacy $\langle J_\delta \rangle_\gamma$. The mean afferent current to a neuron in population $\delta$ can be written as:

$$\mu_\delta = \tau_\delta \sum_\gamma C_{\delta\gamma} \langle J_\delta \rangle_\gamma \nu_\gamma(t) + \langle I_{\text{ext},\delta} \rangle \tag{3}$$

where the sum is over all populations $\gamma$. $I_{\text{ext},\delta}$ is the afferent current from outside the module. Here, for simplicity, we assume the rate to be constant for all neurons inside a population (for extensions, see Amit and Brunel, 1997a).

Spike trains are assumed to be Poissonian, so the variance of the input to a neuron in population $\delta$ is given as:

$$\sigma_\delta^2 = \tau_\delta \sum_\gamma C_{\delta\gamma} (\text{Var}(J_\delta)_\gamma + \langle J_\delta \rangle_\gamma^2) \nu_\gamma(t) + \sigma_{\text{ext}}^2) \tag{4}$$

Writing $\text{Var}(J_\delta) = \Delta \langle J_\delta \rangle^2$ ($\Delta$ independent of $\gamma$) we obtain:

$$\sigma_\delta^2 = (1 + \Delta) \tau_\delta \sum_\gamma C_{\delta\gamma} \langle J \rangle_\gamma^2 \nu_\gamma(t) + \sigma_{\text{ext}}^2 \tag{5}$$

The afferent currents are converted to output rates via the response function, Equation 2:

$$\nu_{\text{out},\delta} = \Phi(\mu_\delta, \sigma_\delta) \tag{6}$$

For a specified network, $\mu_\delta$ and $\sigma_\delta$ are functions of the set of rates in the different populations. Hence, if we impose the condition that rates on the left-hand side of Equation 6 be equal to the input rates forming the currents, Equations 6 become a set of self-consistent equations, whose number is equal to the number of populations, for the same number of unknowns: the set of stationary rates in the network. A solution of this set of equations provides a set of rates for the populations selected, and an accompanying study of their stability will determine which of the solutions is an attractor—a DAD. The fact that the feedback depends not only on the mean of the current but also on its variance is where mean-field theory is extended.

The importance of mean-field theory goes well beyond its analytic, compact treatment of the behavior of the spiking network. The theory also allows us to identify the *collective variables* characterizing the dynamics of the system, such variables as can be observed experimentally and by other components of a multimodular brain.

## Dynamic Mean-Field Theory

In addition to the self-consistent equations given in the preceding sections, a very effective tool for testing the stability of the different stationary states is the dynamic extension of mean-field theory. From the depolarization dynamics of Equation 1 one obtains evolution equations for $\mu[V]$ and $\sigma^2[V]$, which are the asymptotic mean and variance of the depolarization in absence of a threshold (Tuckwell, 1988; Amit and Brunel, 1977b):

$$\begin{aligned} \tau_\delta \frac{d\mu_\delta[V(t)]}{dt} &= -\mu_\delta[V(t)] + \tau_\delta \sum_\gamma A_{\delta,\gamma} \nu_\gamma + \mu_{\delta,\text{ext}} \\ \tau_\delta \frac{d\sigma_\delta^2[V(t)]}{dt} &= -2\sigma_\delta^2[V(t)] + \tau_\delta \sum_\gamma B_{\delta,\gamma} \nu_\gamma + \sigma_{\delta,\text{ext}}^2 \end{aligned} \tag{7}$$

where $A_{\delta,\gamma}$ and $B_{\delta,\gamma}$ are the coefficients of the rates, as in the sums in Equations 3 and 5. But $\mu_\delta$ and $\delta_\delta^2$, required for the response function that determines the output rate of the neuron, are the means and variances of the afferent currents.

The connection between ($\mu_\delta[V]$, $\sigma_\delta^2[V]$), computed in the dynamic equations, and ($\mu_\delta$, $\sigma_\delta^2$) is made in the following manner. In a stationary state, when the left-hand sides of Equations 7 vanish, we have:

$$\begin{aligned} \mu_\delta[V(t)] &= \mu_\delta = \tau_\delta \sum_\gamma A_{\delta,\gamma} A \nu_\delta + \mu_{\delta,\text{ext}} \\ 2\sigma_\delta^2[V(t)] &= \sigma_\delta^2 = \tau_\delta \sum_\gamma A_{\delta,\gamma} B \nu_\delta + \sigma_{\delta,\text{ext}}^2 \end{aligned} \tag{8}$$

When the temporal variation of the input currents (and hence of the rates) is slow, Equations 8 can also be used away from the stationary state, and we can substitute $\mu_\delta[V(t)]$ and $2\sigma_\delta^2[V(t)]$ for $\mu_\delta$ and $\sigma_\delta^2$, respectively, in Equation 2 and obtain a relation between $\nu_\delta(t)$ and ($\mu_\delta[V(t)]$, $2\sigma_\delta[V(t)]$). Substituting this relation in Equations 7 gives us a closed set of dynamical equations for $\mu_\delta[V(t)]$ and $\sigma_\delta[V(t)]$, which determines the dynamics of $\nu_\delta(t)$. A variation in $\mu_\delta[V(t)]$ and $\sigma_\delta[V(t)]$, as given in Equations 7, leads to a shift in the rates, which are then fed back into the dynamical equations.

A set of rates $\nu$ satisfying Equations 6 and 8 is a stationary point of the dynamics (Equations 7), and vice versa. Thus, solving numerically for the stationary states of Equations 7 is one way of solving Equations 6, with the bonus that such solutions are stable, since they attract.

## The Currents

### *Spontaneous Activity*

To proceed, one expresses the mean and variance of the afferent currents in terms of the instantaneous values of the rates in different neural populations that are assumed to behave in a homogeneous way. For example, if the network is expected to sustain only spontaneous activity, one would expect two populations only, a population of excitatory neurons and a population of inhibitory neurons. They would be distinguishable either because the two types of neurons would have different physiological characteristics or because there would be different distributions of synaptic efficacies on the dendrites.

Suppose each neuron receives $C_E(C_i)$ excitatory (inhibitory) synapses on average, whose efficacy has a Gaussian distribution of mean $J_E(J_i)$ and variance $J^2\Delta$ for both. Let the time constants be $\tau_E(\tau_I)$ and their average emission rates be $\nu_E(\nu_I)$. Then,

$$\begin{aligned} \mu_E &= \tau_E(C_E J_E \nu_E - C_i J_i \nu_I) + \mu_{\text{ext}} \\ \mu_I &= \tau_I(C_E J_E \nu_E - C_i J_i \nu_I) + \mu_{\text{ext}} \end{aligned} \tag{9}$$

where $\mu_{\text{ext}}$ is the average afferent, excitatory, nonselective current from outside the module, taken equal for both types of neurons.

The variances of the external currents are $\sigma_{\text{ext}}^2$. The variances of the total afferent currents are:

$$\sigma_E^2 = \tau_E\Big(C_E J_E^2 \nu_E - C_i J_I^2 \nu_I\Big) + \sigma_{\text{ext}}^2$$
$$\sigma_I^2 = \tau_I\Big(C_E J_E^2 \nu_E - C_I J_I^2 \nu_I\Big) + \sigma_{\text{ext}}^2 \qquad (10)$$

When the $\mu$s and the $\sigma$s are introduced in the transduction functions (Equation 2) of the two types of neurons (differing by the integration constants $\tau_E$ and $\tau_I$), one obtains two self-consistent equations (like Equation 6) for the average stationary rates in the two populations.

### *Selective Delay Activity*

A richer example is one where learning has taken place and sets of synapses have been modified in response to stimuli presented. Each stimulus presented to the network produces an increase in the spike rates of neurons in a subpopulation of the module; those are the neurons with *visual response*. Mean-field theory is simple if one assumes that no neuron is visually selective to more than one stimulus. Hebbian learning is then expressed by the fact that synapses between neurons responding to a given stimulus have their average efficacy incresed, $J_E \rightarrow J_+$, whereas synapses between a neuron responsive to a stimulus and one that is not have their average efficacy depressed, $J_E \rightarrow J_-$.

In this case, the neurons in the module can be divided into four distinct, homogeneous groups: (1) neurons selective to the current stimulus (such as those responding to an image currently presented to a monkey); (2) neurons selective to another stimulus in the set used for training but not activated in the present trial; (3) neurons not responsive to any of the stimuli used (hence with unmodified synapses); and (4) inhibitory neurons. If the number of excitatory (inhibitory) neurons in the module is $N_E(N_i)$, if the number of neurons selective to a stimulus is $fN_E$, and if the number of stimuli used is $p$, then the number of neurons in each of the four classes is, respectively, $fN_E$, $(p - 1)fN_E$, $(1 - pf)\,N_E$, and $N_i$.

In this case one has four self-consistency equations (Equations 3 through 6), or the dynamic version (Equations 7), to find the various stationary activity states of the network following learning, at different stages before, during, and after stimulus presentation, and to study their stability. In the process one constructs the $\mu$'s and the $\sigma^2$s for each of the populations (eight expressions in all). For example, the mean and variance of the afferent current to neurons in the selective population are

$$\mu_1 = \tau_E C_E[fJ_+\nu_1 + (1 - fp)J_-\nu_+ + f(p - 1)J_-\nu_-] - C_I J_I \nu_I + \mu_{\text{ext}}$$
$$\sigma_1^2 = \tau_E C_E[fJ_+^2\nu_1 + (1 - fp)J_-^2\nu_+ + f(p - 1)J_-^2\nu_-] + C_I J_I^2 \nu_I + \sigma_{\text{ext}}^2 \qquad (11)$$

in which $\nu_1$, $\nu_+$, $\nu_-$, and $\nu_I$ are, respectively, the rates in the four different classes of neuron described above.

### *Stability and Other Dependence on Parameters*

The example of spontaneous activity is very rudimentary, but not without significant lessons (Amit and Brunel, 1997b). The main lesson obtained from mean-field theory is about stability: in the absence of inhibition, spontaneous activity, with spike rates in the range observed, is not possible. Moreover, inhibition must be strong enough to overcome excitation for the collateral part of the afferent currents, even though there are many fewer inhibitory neurons than excitatory ones. Inhibitory neurons can win by possessing either stronger synapses ($J_I > J_E$) or faster internal dynamics ($\tau_I < \tau_E$). In either of these conditions, spikes can be emitted by neurons of the assembly only because of afferents from outside the module.

Another issue that can be studied in detail in this framework is the range of potentiation, following the appearance of selective delay activity, in which spontaneous activity can coexist with the DAD, both of which are observed experimentally and are stable. Which of them manifests itself depends on whether the stimulus presented is familiar or not. The various regimes of stability are presented in the mean-field bifurcation diagram in Figure 3. The two solid curves are the equilibrium rates of spontaneous (flat, low) and persistent delay activity. Below a potentiation of 2.05, only spontaneous activity is stable, at about 3 Hz. For potentiation between 2.05 and 2.3, both are stable, and the dotted curve delineates their corresponding basins of attraction. To the right of 2.3, the stability of spontaneous activity is destroyed, and only the selective delay activity is stable.

## Simulations Versus Theory

Generic conclusions require a theory, but the theory must be confronted with simulation of the spiking system that the theory purports to describe. This comparison is quite satisfactory (Amit and Brunel, 1997a), even though the assumption about the absence of correlations in the spike processes reaching a neuron via different afferent channels is not fully justifiable, as has become evident from cross-correlations measured on simultaneously "recorded" cells in the simulation.

An example of a confrontation of theory with simulation is presented in Figure 4. A network of 16,000 excitatory and 4,000 inhibitory neurons is connected as described earlier in this article. The distribution of connectivities and of synaptic efficacies is random. Five groups of 1,600 excitatory neurons each have the average synaptic efficacies connecting them potentiated by a factor of 1.9. Each neuron receives 1,600 excitatory afferents from outside the network, at a rate of 4/s$^{-1}$. The simulation is then launched with an initial random distribution of depolarizations. The neurons start in a spontaneous activity state, as is seen in the figure in the

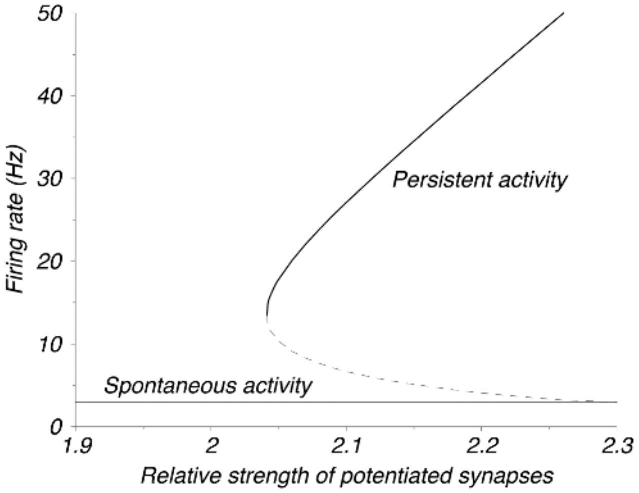

**Figure 3.** Bifurcation diagram: regions in potentiation-rate plane for stable stationary states of spontaneous activity and selective delay activity. Solid curves denote rates in stable states versus potentiation. Dashed curves indicate a stationary, unstable state, with separating basins of attraction of the two solutions (when both exist). For low potentiation (<2.05), there is only spontaneous activity. For intermediate potentiation (≥2.05, ≤2.3), there are two stable states. With high potentiation (≥2.3), spontaneous activity is unstable (after Brunel, 2000).

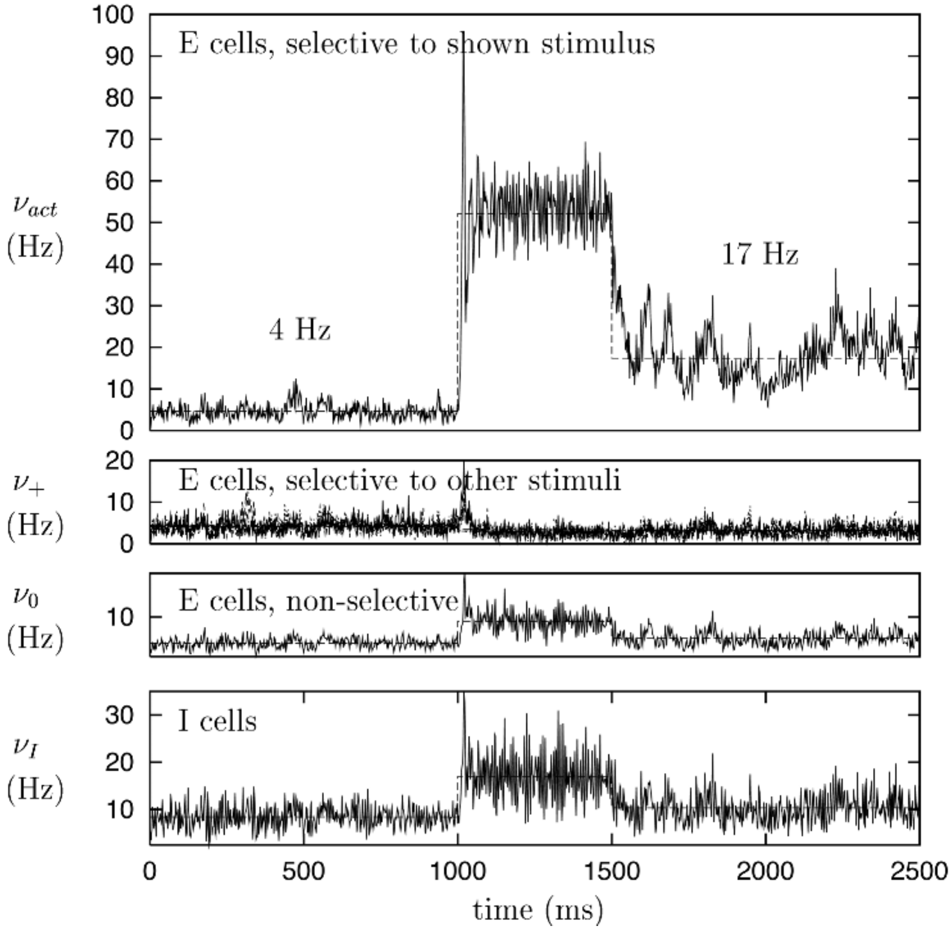

**Figure 4.** Simulations: time evolution of the average emission rate in four neural populations. From the top: an excitatory subpopulation activated by the stimulus (*selective*); excitatory neurons selective to *other stimuli* (grouped together); excitatory neurons nonselective to any stimulus; and the inhibitory population (I). After 1,000 ms of spontaneous activity, a stimulus is presented for 500 ms. When it is removed, the selective subpopulation continues its delay activity at a high rate. Horizontal lines indicate the average rate as given by the dynamic mean-field theory (after Brunel, 2000).

first 1,000 ms. What is plotted is the instantaneous average rate in each population. For the first second, all neurons have low rates. Then a stimulus is presented for 500 ms, by raising the rate of the external afferents to the neurons in one of the populations of selective neurons. The rate in that population rises sharply. Following the removal of the stimulus, one observes 1 s of propagation of a DAD, in which the selective population maintains an elevated rate (lower than under stimulation). The horizontal lines give the mean rate in each population as predicted by mean-field theory.

## Discussion

The extended mean-field approach described in this chapter has been applied in richer situations. In particular, it has provided an account of context correlations generated in learning the DMS paradigm with images organized in fixed sequences (Amit, Brunel, and Tsodyks, 1994). Attractor dynamics in localized circuits has also been applied to the gaze fixation problem (Seung, 1996), after having been extended to include line attractors. Recently, such models have been made much more biologically plausible with respect to robustness and realistic rates (Wang, 1999) by the introduction of receptor dynamics, leading to a successful description of working memory immune to distractors (Brunel and Wang, 2001), and to the modeling of spatial working memory (Compte et al., 2000).

Although fruitful, even extended mean-field theory has its limitations. It deals with uniform populations and stationary states, and hence it is insensitive to transmission delays and nonuniform instabilities. The approach has seen significant extensions capable of satisfactorily handling oscillatory instabilities (Brunel and Hakim, 1999). With the extension of mean-field theory to situations of rich structural complexity, another important step will have been accomplished.

Simulations remain a central tool, functioning as a crucial check on theory. And because the simulation represents an underlying model of the cortical module, the validity of the model as a description of biological reality must often be confronted on levels that theory does not reach, such as simultaneous multicell data, spike emission statistics, and much more.

# Cortical Memory

*Joaquín M. Fuster*

## Introduction

The representation of cognitive functions in the cerebral cortex has been the subject of continuous debate since Broca identified a cortical area involved in spoken language. Essentially, the debate has been taking place between two major schools of thought. On one side are those who propose the parcellation of cortex into discrete regions or modules dedicated to special functions, such as language, memory, and perception, or to their specific contents. This is the "localizationist" point of view, which is essentially similar to that of phrenology but legitimized by the scientific method. On the other side of the debate is the "holistic" position, adopted by those who propose the distribution of cognitive functions in wide and overlapping expanses of cortex. As in any theoretical debate, we also find here the eclectics and compromisers, who espouse an intermediate position: some functions or contents are localized and others are distributed. It is increasingly recognized that memory is one such function, with some of its components localized in neuronal networks that are circumscribed to discrete domains of cortex and others widely distributed in networks that extend beyond the boundaries of cortical areas defined by cellular architecture. Thus, the aggregate of experience and knowledge about oneself and the surrounding world would be represented in cortical networks of widely varying size and distribution. This concept does not exclude extracortical structures from memory storage and function or the possibility that, after being acquired in the cortex, some memory is relegated to some of those structures, such as the basal ganglia. Historically, the concept of cortical network memory has two roots. The first is the indirect empirical evidence, gathered by physicians and experimentalists in the past two centuries, that discrete lesions of the cerebral cortex rarely result in deficits of memory or any of its behavioral manifestations, while commonly affecting sensory or motor functions. Karl Lashley (1950) was the first to obtain systematically that kind of indirect evidence by ablations of cortical areas in animals; from their results, he inferred that memory must be widely distributed in the cortex, and further, that dispersed neuronal assemblies could represent the same memories, or *engrams*. The second root of the concept is theoretical. Hayek (1952) was the first to formalize it by postulating large-scale cortical networks (he called them maps) that would represent all the experience obtained through the senses. Subsequently, that concept gained further theoretical support from the fields of artificial intelligence and connectionism. The fundamental idea is that mnemonic information is stored in distributed, net-like patterns of cortical connectivity that are established by experience. In more recent times, neuroscientists have developed several theoretical variants of that idea by adding to it structural and functional constraints and by extending it to other cognitive functions, such as perception.

This article presents in broad outline a model of network memory in the neocortex that is supported by a large body of empirical evidence from neuropsychology, behavioral neurophysiology, and neuroimaging. Its essential features are (1) the acquisition of memory by the formation and expansion of networks of neocortical neurons through changes in synaptic transmission, and (2) the hierarchical organization of memory networks, with a hierarchy of networks in posterior cortex for perceptual memory and another in frontal cortex for executive memory.

## Formation of Memory

Toward the end of the nineteenth century, Cajal proposed that memory is essentially formed and stored by changes in the connections between nerve cells. That notion was subsequently expressed by many others, and for many years it remained widely accepted but unproved. It was theoretically formulated in considerable detail by Hebb (1949), and more recently received substantial support by the discovery of two general categories of facts (see Kandel, 1991, for a review): (1) the electrical induction of persistent synaptic changes in cellular assemblies of the hippocampus—a phylogenetically ancient sector of cortex—and (2) the induction of similar changes in the neural circuits of invertebrate animals by behavioral conditioning. Less direct evidence indicates that synaptic plasticity is at the foundation of memory in the cerebral cortex (Fuster, 1999) and the cerebellum (Thompson, 1986). It is now widely accepted that the acquisition of memory consists essentially in the modulation of synaptic transmission, and also, to some extent, in the elimination of synapses.

Hebb (1949), referring to the cortex, postulated that "two cells or systems that are repeatedly active at the same time will tend to become associated, so that activity in one facilitates activity in the other." Thus, temporally coincident inputs would tend to associate the neurons that receive them, by facilitating the synapses between them. This principle, which has been called synchronous convergence (Fuster, 1999), would lead to the formation of the hebbian "cell assembly," a basic neural net of cortical representation in sensory and parasensory cortex. Based on data bearing on the plasticity of responses of visual cortical cells to optic stimuli, Stent (1973) made a strong theoretical argument for the operation of that principle in the neocortex.

Whereas simple sensory memories may be formed and represented in cell assemblies, nets, or modules of sensory and parasensory cortex, the neuropsychologal evidence from humans and animals indicates that the more complex memories of individual experience, as well as abstract knowledge, extend into areas of the cortex of association. Temporally coincident or near-coincident experiences of one or more sense modalities will modulate synaptic contacts between cells in those areas, thus leading to the formation of wider networks that represent assorted items of individual memory and, at higher cortical levels, of knowledge, which is the conceptual or semantic form of memory. The boundaries of those larger networks extend beyond those of any given cytoarchitectonic area, however defined.

The formation of the associative neuronal networks that support and contain memory follows gradients of corticocortical connectivity, which have been most thoroughly investigated in the nonhuman primate (Pandya and Yeterian, 1985). That connectivity departs from primary sensory and motor areas and flows into progressively higher areas of unimodal and multimodal association. The connectivity is reciprocal throughout, such that each connective step, from one area to the next, is reciprocated by fibers running in the opposite direction. Some connections converge and others diverge. Thus, at all levels and between levels, three basic structural features can be recognized in connective networks: convergence, divergence, and feedback or recurrence. In addition, cortical areas of one hemisphere are connected, again reciprocally, with homologous areas of the other hemisphere.

To some extent, the connectivity mediating memory formation follows also maturational gradients, in that it proceeds from area to area following the order in which cortical areas have myelinated in early ontogeny (Fuster, 1997). It also follows gradients of sensory and motor processing. As memories increase in complexity, in terms of the variety and complexity of associated experiences and the sensory inputs that convey them, their networks become progressively wider, and thus span progressively more associative cortical areas of polymodal convergence.

Whereas synaptic modulation and synchronous convergence seem essential features of the process of memory network formation, the process in more general terms is one of self-organization (Kohonen, 1984). The networks and their connective substrate are auto-constituted as the result of the interactions of the organism with its environment. Through these interactions, and mostly by synchronous convergence, new cortical nets are formed and old ones expanded in a dynamic process that persists throughout the life of the organism. In the formation of a memory network, synaptic facilitation is produced not only by the simultaneity of external inputs but also by the simultaneity of these inputs with "inputs" internally generated by the concomitant activation or retrieval of preexisting components of the network. Thus, new memory is formed from old memory.

In recent years, there has been increasing neuropsychological evidence that the hippocampus plays a critical role in the formation of neocortical memory networks (Squire, 1987). It has been established that the hippocampus is reciprocally connected with the cortical areas of association, though not with primary sensory or motor cortex (Amaral, 1987). That connectivity courses through and under the cortex of the peri- and entorhinal region, in the medial and inferior aspects of the temporal lobe. In this manner, reciprocal connections link the hippocampus with the associative cortices of the posterior (postrolandic) regions of the cerebral hemispheres as well as with those of the frontal lobe (prerolandic), notably the prefrontal cortex. The mechanisms by which the hippocampus mediates the formation of memory networks in the neocortex are not known. Possibly, long-term potentiation (LTP) is one of those mechanisms. Further, there is reason to suspect that certain excitatory glutaminergic receptors, notably NMDA receptors, take part in the process. That process would result in protein changes in the membrane of cortical cells, which in turn would strengthen their synapses and thus imprint memories in cortical networks. Inputs from the amygdala, a limbic structure essential for the evaluation of the emotional and motivational significance of sensory information, may also intervene in the process.

## Phyletic Memory

The primary sensory and motor cortices lie in the interface between the environment and the cortex of association. Primary sensory cortices provide the inlets of sensory information for the formation of perceptual memory (episodic, semantic, etc.) in posterior cortex of association; primary motor cortex, on the other hand, provides the outlet of frontal association cortex (executive memory) to lower motor structures (e.g., basal ganglia, cerebellum). Thus, primary cortices—ontogenetically the first to myelinate—constitute the cortical gate from sensation to memory, and from memory to action.

It is physiologically plausible to view primary sensory and motor cortices as the foundation of all individual memory, themselves constituting a form of universal memory. These cortices constitute a basic form of memory that I have termed *phyletic memory*. According to this view, phyletic memory is simply the structure of the primary sensory and motor cortex at birth, common to all animals of the same species. Thus, phyletic memory is the most basic of all memories, the memory that the organism has formed through millions of years and countless generations in its interactions with the surrounding world. Those genetically predetermined structures of cortex devoted to the analysis of elementary sensory features and to the integration of the elementary primitives of movement would form the basic template on which all individual memory would grow. In summary, primary cortices can legitimately be called memory, because they retain a form of basic and retrievable information: the memory of the species, the sensory and motor information that the organism has acquired and stored in the course of evolution for survival and procreation. Thus, phyletic memory, the primary sensory and motor cortices, contains already at birth much of the adaptive power of the species. After necessary "rehearsal" in the critical periods of early ontogeny, phyletic memory remains ready for "recall" through a lifetime—ready, that is, to recognize the essential features of the world, and to retrieve and organize the basic patterns of movement for adaptation to the environment. On that foundation of phyletic memory, all the memory of the individual will be developed and hierarchically organized by experience and according to the principles mentioned in the previous section: a hierarchy of perceptual memories will be formed in posterior cortex and a hierarchy of motor memories in frontal cortex.

## Perceptual Memory

All memory acquired through the senses qualifies as perceptual memory. This includes a vast fund of individual experience, from the simplest forms of sensory memory to abstract knowledge—in other words, to all that we commonly understand as the memory or knowledge of events, objects, persons, animals, facts, names, and concepts. Perceptual memories, and their cortical substrate, appear hierarchically organized, as the diagram of Figure 1 schematically represents. Such an organization can be inferred from the gradients of cortical connectivity and from neuropsychological evidence, namely, from the study of the psychological effects of cortical lesions. This evidence, however, is somewhat confounded by the variability between subjects and by the profuse relationships of association between the various categories of memory—in other words, by the heterarchy within the hierarchy.

The base of the perceptual hierarchy is sensory phyletic memory, the structure of primary sensory cortices. Immediately above it, in cortex of sensory association, are the memories of the sensory qualities of objects and experiences, unimodal and polymodal. Further up in the hierarchy, in higher associative cortex, memories become more personal and complex, with specific temporal and spatial tags. These memories fall under the category of what is commonly designated declarative memory, the memory of events and experiences. Finally, at the highest levels of the hierarchy, in areas of the temporal and parietal lobes called transmodal (Mesulam, 1998), resides the knowledge of facts, concepts, and names.

At every stage of the hierarchy of perceptual memory, memory networks are essentially made of connections between neuronal aggregates at that stage and by convergence of inputs from below, ultimately from the senses. Thus, at the first associative sensory stage beyond phyletic memory, networks are formed by associations between sensory representations of the same modality to form assemblies or networks of unimodal sensory memory. Above, in polysensory association cortex, and with inputs from unimodal areas, more complex networks of polymodal memory are formed that associate sensory features of multiple origins. Those polymodal networks constitute the substrate for diverse forms of episodic and sematic memory, with wide distribution in higher association areas of posterior cortex. Networks of the transmodal cortex of areas 39 and 40, including cortex of the superior temporal gyrus (Wernicke's area), probably represent the highest forms of conceptual and semantic knowledge. Lesion of these areas induces certain forms of sensory aphasia and agnosia, including the loss of perceptual memory of speech and objects, or object categories.

In general, memory networks expand as they gain in hierarchical level. They fan up from their sensory base as they penetrate progressively higher layers of cortical organization with progressively broader and higher associations. Once established, memories and their networks are linked not only horizontally, within their hierachical layer, but vertically, between layers (symbolized by vertical bidirectional arrows in Figure 1). A low-level sensory network, for

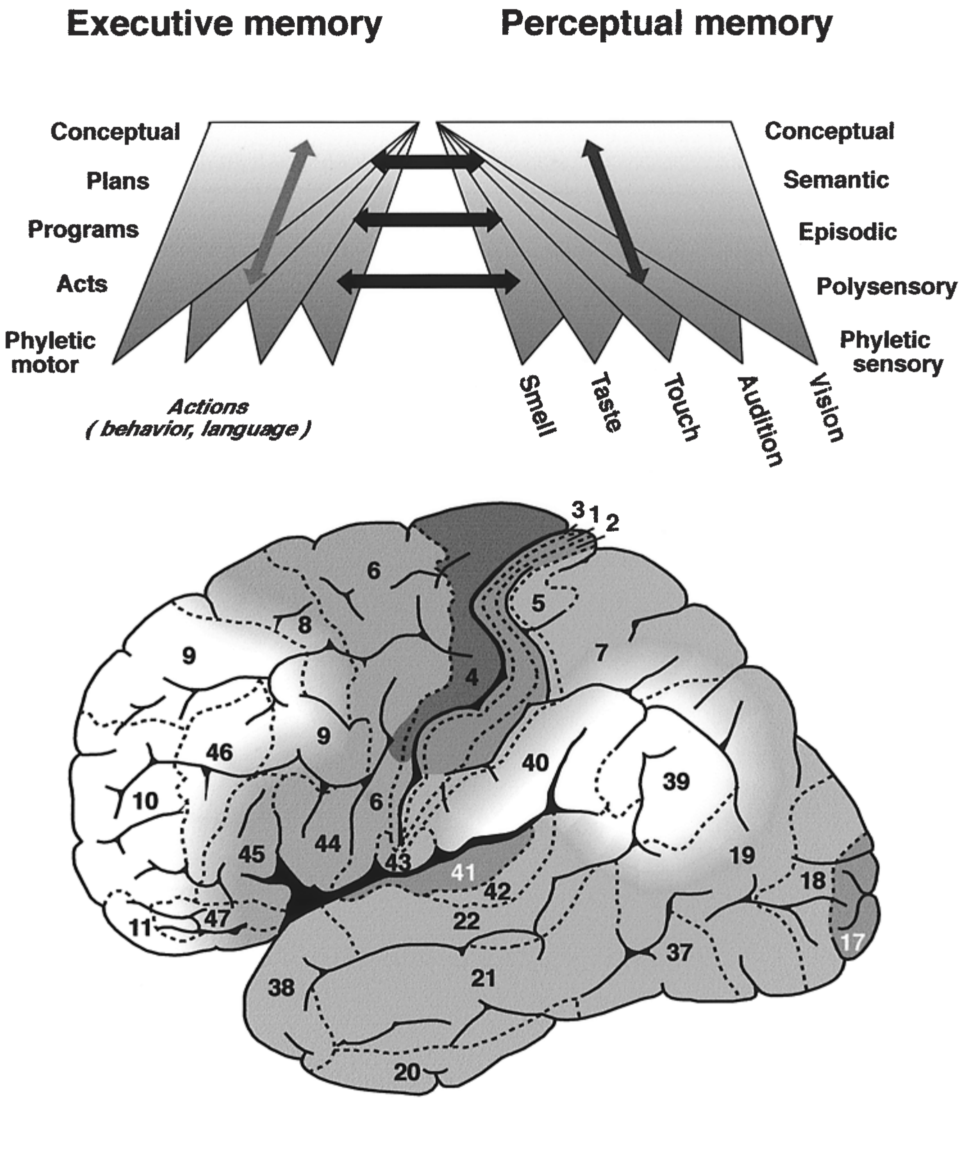

**Figure 1.** Schematic diagram of the hierarchical organization of memories in accord with the model presented in this article.

example, will establish associations with high-level semantic or conceptual networks. This will result from the co-occurrence of new sensory experiences with the activation of the high-level networks they elicit. In any event, the latter networks will be largely formed by ascending connections from lower levels. Assorted sensory experiences with common attributes will contribute to the formation of conceptual networks at the higher, semantic level. As a consequence of these dynamic interactions, networks of lower and concrete content will be nested within the higher-level conceptual and semantic networks that they have helped establish and that represent the higher and more abstract aspects of perceptual memory. As a consequence of these interactions within and between layers, memory networks profusely share cells and fibers. Conversely, any cortical cell and its connections may be part of many memory networks.
