Further, as memory networks gain in hierarchical category, they become not only broader but more resilient, perhaps from increased number and redundancy of associations. Whereas sensory memories are especially vulnerable to discrete local damage (notably the phyletic structure of primary sensory cortices), high-level associative memories are less vulnerable. Since the latter are anchored in multiple sensory experiences, abstract knowledge is less liable to cortical damage than the concrete aspects of declarative memory, such as dates, names, faces, and places. The clinical evidence shows that these concrete elements of memory are especially liable to cortical injury. To some extent, which varies with the individual, these concrete elements of memory are subject to gradual loss as a function of normal aging. On the other hand, it takes a massive cortical lesion for the loss of conceptual perceptual memory to occur, that is, for the loss of what Kurt Goldstein called the "abstract attitude," meaning the utilization of conceptual knowledge in daily life.

## Executive Memory

Motor memory, the representation of motor acts and behaviors, is widely distributed throughout the central nervous system. The spinal cord, the brainstem, and the cerebellum constitute the lowest levels of the hierarchy of brain structures harboring motor memories. These structures are the depositories of much of the motor phyletic memory of the organism at birth. This memory is largely innate, stereotypical, and dedicated to the fulfillment of essential drives. Some of it is conditionable and subject to cortical control and modulation.

The highest levels of motor memory, both phyletic and acquired, are supported by the cortex of the frontal lobe (Figure 1). The cortical networks of motor memory are formed essentially in accord with the same principles that guide the formation of perceptual memory, notably synchronous convergence. Here, however, the simultaneously converging signals are of both sensory and motor origin. This includes visual and auditory stimuli that coincide with motor action, or release it by one mechanism or another, and kinesthetic stimuli that accompany the action; in addition, some of the signals are "efferent copies" of the action as it is executed, copies that are provided by recurrent or collateral inputs from the motor system (corollary discharge). Consequently, many motor networks of the frontal cortex are extensions of perceptual networks of posterior cortex. Long corticocortical connections—in the uncinate fasciculus—would provide the functional substrate for those extensions (horizontal arrows in Figure 1).

At the base of the cortical executive or motor hierarchy is the primary motor cortex of the precentral gyrus, the substrate of phyletic motor memory in the neocortex. It supports the representation and execution of elementary motor acts that are defined by the contraction of particular muscles and muscle groups. Hierarchically above primary cortex is the premotor cortex (area 6), which several lesion and unit studies implicate in the representation of motor acts and programs defined by goal and trajectory (Wiesendanger, 1981; Alexander and Crutcher, 1990). This cortex also participates in the elementary structuring of language. The more complex and novel programs of acquired behavior and language are represented in the prefrontal cortex, which is the highest level of the executive hierarchy. The prefrontal cortex is the cortex of association of the frontal lobe. Both phylogenetically and ontogenetically, it is one of the latest neocortical regions to develop (Fuster, 1997). In the human, it does not reach full maturation until the second decade of life. It receives abundant connections from posterior cortex, limbic formations, and the brainstem.

Neuropsychological studies implicate the prefrontal cortex in the representation of schemas of goal-directed action. Human subjects who have sustained lesions of lateral prefrontal cortex have difficulty remembering and formulating new plans of behavior and structures of language. Monkeys have difficulty learning and executing behavioral tasks that require the sequencing of motor acts, especially if the sequencing contains temporal gaps that have to be bridged by active memory ("working memory"). This kind of behavior is epitomized by the so-called delay tasks (e.g., delayed response, delayed matching). In both the human and nonhuman primate, lesions of the lateral prefrontal cortex impair performance on such tasks. There is some apparent specificity within the lateral prefrontal areas for the kinds of sensory information and motor activity that are processed in those tasks. Regional specificity, however, is secondary to temporal factors. Prefrontal lesions cause deficits in the formation and execution of temporal sequences of behavioral action ("temporal gestalts"), whatever the sensory and motor components of those sequences.

The practice and repeated execution of behavioral sequences seems to lead to the relocation of their representation from prefrontal cortex to lower stages of the motor hierarchy, especially the basal ganglia. Frontal lesions in human subjects induce deficits in the performance of complex voluntary movements without impairing automatic ones. This occurs even if these automatic movements are just as complex and require just as much effort as when they were originally learned. By neuroimaging, it is possible to follow to some degree the migration of executive memories from the prefrontal cortex to other structures of lower hierarchical rank. In the initial stages of the learning of a sequential motor task, certain areas of the dorsolateral prefrontal are activated (Jenkins et al., 1994). As the task becomes routine, parts of the cerebellum and the basal ganglia become more active, and the prefrontal cortex less. Still represented in prefrontal cortex, presumably, are those aspects of the task that are subject to uncertainty or ambiguity. Such is the case with delay tasks, where stimuli and responses contain both uncertainty and ambiguity. This is the reason why the correct performance of these tasks, even after learning, continues to depend on the functional integrity of the prefrontal cortex, and prefrontal cells continue to be involved in that performance.

## Retrieval of Memory

Just as the formation of a memory is an associative phenomenon, so is the retrieval of that memory from permanent storage. Both associative phenomena are interdependent. New memory networks are formed by association between co-occurring sensory inputs and between these inputs and older networks that they activate by association. Therefore, new memory is in many respects the expansion of old memory. Whereas individual memories and their networks are expansions of phyletic memory, new individual networks are expansions of old ones. The essential point is that every act of memory formation is accompanied by retrieval of established memory. Retrieval is indispensable for memory formation. That may be the reason why the hippocampus appears to play an important role in both the acquisition and the recall of memory in the neocortex.

Electrophysiological studies in the monkey and neuroimaging in the human indicate that the retrieval of a memory, whether spontaneous or evoked, essentially consists in the activation of the cortical network that represents it (reviewed in Fuster, 1999). The neuronal mechanisms of retrieval are not known but can be presumed to involve the correlated activation of all the neuronal elements of a perceptual network by the sensory or internal (mental) activation of one of its associated components. If the network has executive or motor components, then the activation will extend to an associated executive network of frontal cortex. Above a certain threshold, that activation of an executive network may lead to the execution of action. If the action is sequential and dependent on serial perceptual inputs, then cell prefrontal assemblies will interact with posterior cortical assemblies in the mechanisms of working memory and preparatory set at the foundation of the perception-action cycle (Fuster, 1997; see also PREFRONTAL CORTEX IN TEMPORAL ORGANIZATION OF ACTION). Those mechanisms are still poorly understood. However, it seems increasingly plausible that they include the reverberation of activity in memory networks through recurrent circuits (Zipser et al., 1993).

## Discussion

This article presents a general connectionist model of memory. It is proposed that memories consist in, and are represented by, widely distributed and profusely interactive networks of neocortical neurons. Memory networks are formed by modulation of synaptic contacts between concomitantly activated neurons representing discrete features of the external and internal environment. This takes place in the neocortex under the agency of limbic structures, notably the hippocampus. Memory formation is a highly dynamic process closely interdependent with retrieval, and memory networks remain in constant change throughout life, subject to expansion by new associations—and to age-related attrition. Memory networks are hierarchically organized in two broad sectors of neocortex: perceptual memory in posterior (postrolandic) cortex and executive memory in frontal (prerolandic) cortex. At the base of each cortical hierarchy there is a layer of phyletic memory (the structure of primary sensory or motor cortex). Above that layer, in cortex of association, lie the memories of the individual, from the lowest perceptual and motor representations to the highest conceptual representations of perception and action. The semantic and conceptual representations of perception lie in transmodal areas of posterior cortex, whereas the schematic and conceptual representations of action lie in areas of prefrontal cortex. Both are interconnected by long corticocortical fibers, thus forming high-level sensorimotor networks. In the organization of complex behavior, the two sectors of neocortex, posterior and prefrontal, interact dynamically at the summit of the perception-action cycle.

# Cortical Population Dynamics and Psychophysics

*Udo A. Ernst and Christian W. Eurich*

## Introduction

Visual cortex is one of the most extensively studied regions in the mammalian brain. Over the past decade, much anatomical, physiological, and psychophysical knowledge about its properties has been accumulated experimentally. Considerable effort has been expended on theoretical and computational work to reproduce basic phenomena and to explain their underlying mechanisms.

In this article, we discuss one specific computational approach that has been successfully applied to a variety of problems on different levels of cortical information processing. The approach describes the cortical population dynamics in the form of structurally simple differential equations for the neurons' firing activities. The model class was introduced by Wilson and Cowan (1972, 1973) and is still very popular for, in our opinion, two reasons: first, it is powerful enough to reproduce a variety of cortical phenomena, and it captures the dynamics of neuronal populations seen in numerous experiments; and second, its degree of complexity is still low enough to allow analytical treatment that yields an understanding of the mechanisms leading to the observed behavior.

In the next section, we introduce the model class and discuss some of its basic properties. The following sections show how this model can be applied to explain dynamical properties of the primate visual system on different levels, from single neuron properties like selectivity for the orientation of a stimulus to higher cognitive functions related to the binding and processing of stimulus features in psychophysical discrimination experiments.

The goal of this article is to show that a model that abstracts from biophysical details is often sufficient to identify possible neuronal mechanisms of cortical information processing. The diversity of the examples we mention demonstrates that even a simplifying approach can place seemingly unrelated or even controversial findings in one coherent, unifying framework.

## The Wilson-Cowan Model Class

A basic introduction to differential equations in the context of neural systems and the class of models described here can be found in Wilson (1999).

### *Single Units*

The basic unit of the model is a neuronal population. The dynamics of an uncoupled population is described by an ordinary differential equation for its activity $A(t)$, which consists of a decay term and the synaptic input $I(t)$ ($\tau$ is a time constant),

$$\tau \frac{dA(t)}{dt} = -A(t) + h(I(t)) \tag{1}$$

The gain function, $h$, describes the activation of a population dependent on its synaptic input $I$. Wilson and Cowan (1972) derived this equation from a more general integro-differential equation by applying a temporal filter (*time coarse graining*). Therefore, the resulting Equation 1 is structurally simple, but not exact: one has to bear in mind that temporal variations on a small time scale have been averaged out. In the original publication of Wilson and Cowan, the activity $A$ was identified by the *proportion* of active neurons in a population. For this reason, the gain function $h$ was chosen to be a sigmoid function that saturates at 1 for high input levels (no more than all neurons can be active at a specific time). However, $A$ can equally well be interpreted as the population's firing rate (this will be the case throughout this article). Then $h$ is no longer bound to saturate at 1, and one of the simplest choices is a function that is 0 up to some threshold, and then increases linearly. This piecewise linear function may allow for an analytical treatment by considering appropriate case distinctions. Omitting the saturation regime at high $I$ does not impose serious restrictions, because cortical neurons usually operate within the linear regime of their gain function. Futhermore, diverging network activity in the model will be an indication of an unphysiological parameter regime in which the overall network activity is not dynamically regulated, as it is likely to be in the cortex.

### *Columns*

Cortical nervous tissue contains both excitatory and inhibitory neurons in a dense network. A general model of this network necessarily has to include both cell types, forming one excitatory population ($e$) and one inhibitory population ($i$). Each population typically represents some hundreds of single neurons. The populations are mutually connected with weights $w_{ee}$, $w_{ie}$, $w_{ei}$, and $w_{ii}$. Index pairs like $ei$ are interpreted as a connection originating at the excitatory population and targeting the inhibitory population. We will identify the resulting dynamical system (Wilson and Cowan, 1972) with the concept of a cortical column:

$$\tau_e \frac{dA_e(t)}{dt} = -A_e(t) + h_e(w_{ee}A_e(t) - w_{ie}A_i(t) + I_e(t)) \tag{2}$$

$$\tau_i \frac{dA_i(t)}{dt} = -A_i(t) + h_i(w_{ei}A_e(t) - w_{ii}A_i(t) + I_i(t)) \tag{3}$$

At this point, we would like to note that two very similar model classes exist in the literature. Their dynamics differ in the sense that in the first class, $A$ describes the activation or the firing rate of a population (in this case the nonlinearity in $h$ is applied to the total synaptic input, $\dot{A} = -A + h(wA + I)$), while in the second class, $A$ denotes the membrane potential (in that case $h$ is applied directly to $A$, $\dot{A} = -A + wh(A) + I$). A reader of the original publications should not be confused, because both variants lead to qualitatively similar results and are often equally well suited to tackle a specific modeling problem.

### *Layers*

A neuronal layer may be described as a multitude of columns arranged in a topographically ordered space. This space may have a varying number of dimensions. For example, some authors have used a one-dimensional chain representing the orientation preference axis; others identify a two-dimensional layer with the surface of the cortical tissue. With $\vec{x}, \vec{x}' \in C$ denoting positions within such a layer, the columns are coupled by appropriately chosen functions $W_{\{ei,ie,ee,ii\}}(\vec{x}, \vec{x}')$ (so-called *lateral couplings*). Mathematically, the neuronal layer is described as a pair of coupled partial differential equations (Wilson and Cowan, 1973):

$$\begin{aligned}\tau_e \frac{\partial A_e(\vec{x}, t)}{\partial t} = {} & -A_e(\vec{x}, t) \\ & + h_e\Big(w_{ee} \int_C A_e(\vec{x}', t) W_{ee}(\vec{x}, \vec{x}') d\vec{x}' \\ & - w_{ie} \int_C A_i(\vec{x}', t) W_{ie}(\vec{x}, \vec{x}') d\vec{x}' + I_e(\vec{x}, t)\Big)\end{aligned} \tag{4}$$

$$\begin{aligned}\tau_i \frac{\partial A_i(\vec{x}, t)}{\partial t} = {} & -A_i(\vec{x}, t) \\ & + h_i\Big(w_{ei} \int_C A_e(\vec{x}', t) W_{ei}(\vec{x}, \vec{x}') d\vec{x}' \\ & - w_{ii} \int_C A_i(\vec{x}', t) W_{ii}(\vec{x}, \vec{x}') d\vec{x}' + I_i(\vec{x}, t)\Big)\end{aligned} \tag{5}$$

The inputs $I_{\{e,i\}}$ are typically calculated by integrating a stimulus $S(\vec{x}, t)$ over an *afferent* coupling function $V_{\{e,i\}}(\vec{x}, \vec{x}')$:

$$I_{\{e,i\}}(\vec{x}, t) = \int_R S(\vec{x}', t) V_{\{e,i\}}(\vec{x}, \vec{x}') d\vec{x}' \tag{6}$$

where $\vec{x}, \vec{x}'$ are elements of an input space $R$. A convenient choice for the lateral as well as the afferent couplings are functions decaying with the distance between two populations, as has been shown in anatomical and physiological studies. Choosing $W$ satisfying $W(\vec{x}, \vec{x}') = W(|\vec{x} - \vec{x}'|)$, the model becomes translationally and rotationally invariant. A commonly used prototype for these kernels is an $n$-dimensional Gaussian function defined as

$$W_{\{ee,ei,ie,ii\}}(|\vec{x} - \vec{x}'|) = \frac{1}{(\sqrt{2\pi\sigma^2_{\{e,i\}}})^n} \exp\left(-\frac{(\vec{x} - \vec{x}')^2}{2\sigma^2_{\{e,i\}}}\right) \tag{7}$$

The computational advantage of these kernels is that the integration reduces to a multiplication in Fourier space, which speeds up computation time considerably.

For most of this article, we will assume that connections originating from inhibitory populations will be longer than those originating from excitatory populations. Following this scheme, the effective coupling between two columns will have the shape of a Mexican hat (difference of Gaussians). This assumption, which is often made in modeling studies, is questionable insofar as long-ranging patchy excitatory connections exist, at least in the mature primary visual cortex. This may not be a problem, because the layout of primary visual cortex revealed by the structure of the orientation preference map suggests that inhibitory couplings dominate, at least over intermediate distances. Nevertheless, we will also discuss which different or additional phenomena are observed in the presence of long-range axons. For a more detailed introduction to neural layers, see LAYERED COMPUTATION IN NEURAL NETWORKS.

## Dynamical Regimes and Orientation Preference

### *Quasi-linear and Marginally Stable Regimes*

With different choices of the system parameters in Equations 4 and 5, almost all model variants exhibit one of two different dynamical behaviors: if the strength of the afferent input dominates over the lateral feedback, a homogeneous and constant input will lead to an activation pattern that is also spatially and temporally constant. This steady state is stable against noise. The parameter regime where this behavior occurs is called the *quasi-linear regime* (upper region in Figure 1). As soon as the inhibitory feedback gets weaker or the excitatory feedback gets stronger, the system enters a second regime, called the *marginally stable regime* (Ben-Yishai, Bar-Or, and Sompolinsky, 1995). Now the steady state is unstable, and even the smallest perturbation leads to the emergence of a pattern of activation clusters commonly called *blobs* (central portion of Figure 1). The mechanism for this type of pattern formation is easy to understand: if the input at one position is slightly increased, this perturbation of the steady state will be amplified by the dominating excitatory feedback, while the longer-ranging inhibition will suppress the activity in the surround of the emerging blob. For related reading, see WINNER-TAKE-ALL NETWORKS.

### *Lateral Feedback and Orientation Selectivity*

The existence of a marginally stable regime could have consequences for the emergence of orientation selectivity in primary visual cortical neurons. Ben-Yishai et al. (1995) observed that the shape of the blobs remains invariant against different input levels. In a one-dimensional model of a cortical hypercolumn, where $\vec{x} \in C$ is identified with the orientation preference $\Phi$, they demonstrated that the response behavior of neurons to oriented gratings is accurately reproduced: the orientation tuning width remains largely invariant under changes of the stimulus amplitude (contrast). This finding indicates that cortical dynamics may be dominated by lateral feedback rather than by feedforward excitation. A weak afferent orientation bias, such as that emerging from a Hubel-Wiesel arrangement of LGN receptive fields, would then suffice to induce a sharply tuned orientation tuning curve. This idea, with its pros and cons and also the experimental evidence for the origin of orientation tuning, is discussed in detail in ORIENTATION SELECTIVITY (q.v.).

## Inhomogeneities and Cortical Maps

### *Localization of Activation Clusters*

In the marginally stable regime, each perturbation lays the seed for the emergence of an activation cluster. This perturbation could be induced by the afferent input, but also by structural inhomogeneities in the model. For example, the lateral coupling function may not be perfectly translationally and rotationally invariant but could be subject to small random jitter. Then, even a homogeneous and constant input would lead to the emergence of activation clusters. Preferentially, these clusters will be located at positions where by

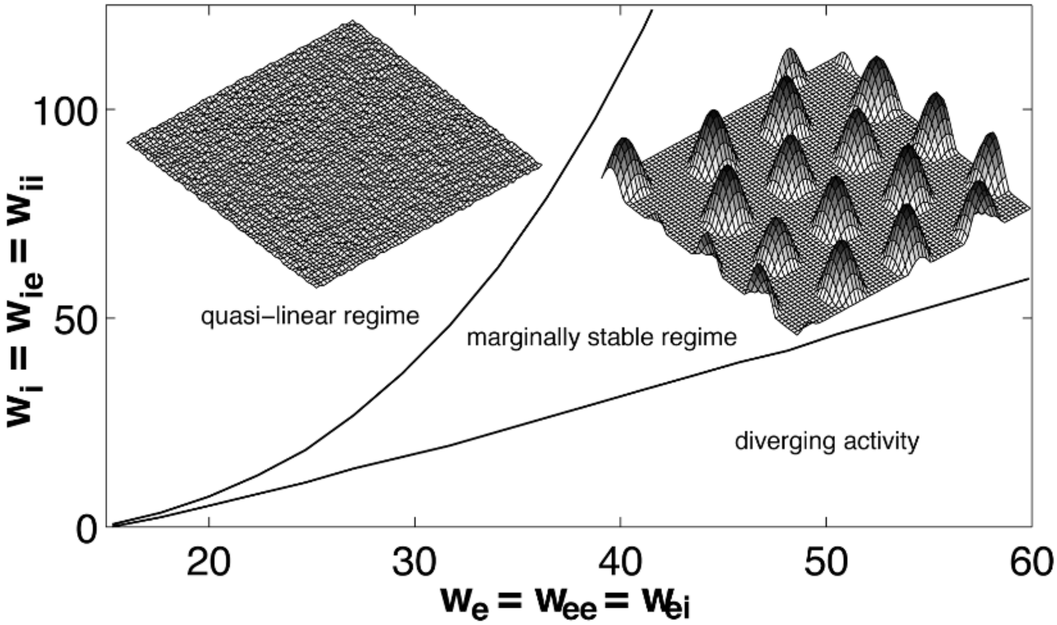

**Figure 1.** Phase diagram of the spatiotemporal Wilson-Cowan equations (Equations 4 and 5) for a two-dimensional sheet of neurons with threshold-linear *h*. Three dynamical regimes can be distinguished, depending on the weights $w_e$ and $w_i$: the quasi-linear and the marginally stable regimes, as described in the text, and a biologically unplausible regime where neural firing rates diverge. Drawings in the quasi-linear and marginally stable regimes show a typical steady-state activity pattern of the excitatory layer for a constant input *I* plus a small amount of noise.

chance the lateral excitatory feedback is slightly stronger than at other positions nearby. If this jitter comes together with inhomogeneous afferent inputs, both effects will add up, and blobs will choose positions where the afferent input plus the lateral feedback will be largest. Note that in this model, the noise breaks the symmetry of the coupling kernels, and the model will no longer be rotationally and translationally invariant.

### Instantaneous Emergence of Cortical Maps

Ernst et al. (2001) simulated a two-dimensional Wilson-Cowan model in which they put a small amount of static noise on the lateral coupling matrix, as can be expected in a biological system, with all its irregularities. They presented moving gratings or bars as stimuli, generating an inhomogeneous afferent input. By recording the model's response to differently oriented gratings (Figure 2*A*), they found that orientation and direction preference maps naturally emerged when the blobs localized at the spatial inhomogeneities in the model cortex (Figure 2*B*).

This model has several advantages over other approaches to map development because it reproduces seemingly controversial findings from experimental studies. First, the structure of the maps shows up within milliseconds and does not require any learning. Second, due to the intracortical origin of the map structure seeded by the random jitter of the lateral connections, the feature maps are identical for stimulation of either of the two eyes. Third, the gratings induce an oscillatory movement of the blobs around their preferred positions, which is different for opposite directions of movement. This suggests a new mechanism for directional selectivity of the neuronal response (for a detailed discussion, see DIRECTIONAL SELECTIVITY). And finally, the model reproduces the known relationships between different kinds of feature maps. Taken together, these properties qualify this approach as a model for the initial phase in cortical development where the coarse layout of the maps is determined, which then could get subsequently refined and rearranged by self-organizing mechanisms (see Swindale, 1996, for an extensive review and discussion).

## Long-Range Connections and Contour Integration

Up to now, the couplings have been chosen as if there were no long-ranging excitatory connections in the brain. However, those connections exist, and they preferentially link neurons having similar orientation preferences. What dynamical phenomena can one expect if these connections are included?

### Long-Range Connections

Several authors employ a connection scheme that locally has the shape of a Mexican hat but extends over that region, sending out additional excitatory connections targeting inhibitory and excitatory populations with a similar orientation preference. The columns in these models have a position $(x_1, x_2)$ within the nervous tissue and an orientation preference $\Phi$; thus, $C \ni \vec{x} = (x_1, x_2, \Phi)$. While the response of the *classical* model without long-range interactions would follow the dynamics described in the previous sections, the addition of long-range connections opens up the possibility that spatially extented stimuli modulate this response. The modulation will depend on the strength, or contrast, and the orientation of the stimuli presented. One important aspect of this excitatory modulation is that the net effect on the column's firing rate depends on activation of the target column, especially in cases where the populations have different thresholds or gains. The reason for this is that long-range input converges onto inhibitory and excitatory target populations; thus, the excitatory target population receives direct excitation and indirect inhibition. The balance between those two sources determines whether the total input inhibits or excites the target population (*differential interaction*).

### Nonclassical Receptive Fields

Models with long-range connections have been examined to find an explanation for the so-called nonclassical receptive fields of neurons. Most visual cortical cells have shown dramatic changes in their response to a stimulus within their normal receptive field, when an additional stimulus has been presented outside that region (this additional stimulus alone would elicit no response). Typical phenomena include an increase in the response, if the two stimuli have orthogonal orientations, and a decrease if the stimuli are parallel in orientation (Sillito et al., 1995). The latter modulatory effect may change its sign when the stimuli are presented at a lower luminance level. These findings can largely be explained by population models with long-range interactions; in particular, it is easy to explain the sign change with dynamical properties relying on

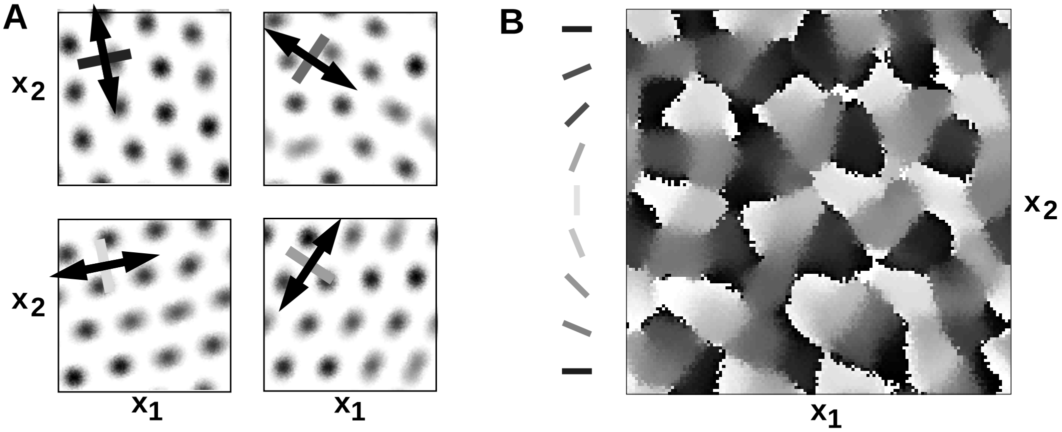

**Figure 2.** Orientation preference arises from the interaction of jitter in the neuronal connections with an oriented moving stimulus in a two-dimensional neural layer (i.e., $\vec{x} = (x_1, x_2)$). *A*, Blob pattern emerging on presentation of moving gratings, covering the whole input space *R*, and having different orientations, as shown by the bars. *B*, Vectorial sum of the single-condition blob patterns in *A* for different orientations, coded in scales of gray. The picture strongly resembles orientation maps obtained experimentally with voltage-sensitive dyes. (Adapted from Ernst et al., 2001.)

the differential interaction scheme (see Stetter, Bartsch, and Obermayer, 2000, and references therein). More information on nonclassical receptive fields can be found in Visual Cortex: Anatomical Structure and Models of Function (q.v.).

### *Association Fields*

Another type of cortical coupling function is motivated by *association fields* measured in psychophysical experiments. Association fields quantify how the presentation of a bar at position $(x_1, x_2)$ with orientation $\Phi$ will increase or decrease the threshold for detecting a bar at position $(x'_1, x'_2)$ with orientation $\Phi'$. The coupling matrix and model dimension are similar to the models employed in the last paragraph, with one important difference: the coupling function $W$ is chosen according to the association field and therefore is not only orientation selective, but also directionally biased. In other words, two columns best responding to oriented bars being aligned in succession will be connected with a positive weight, while two columns best responding to oriented bars being aligned in parallel will be connected with a negative weight (Figure 3*A*) or will remain unconnected.

### *Contour Integration*

An aspect of cortical information processing that can be examined and understood in this type of model is the dynamics of contour integration. Contours can be interpreted as a succession of aligned bars; thus, a coupling matrix based on the association field is especially suited to enhance the activity of columns stimulated by elements of the contour, whereas the activity of columns stimulated by distractors becomes suppressed. Li (1999, 2001) has accumulated evidence that contour integration may be explained by this kind of cortical model (Figures 3*B* and 3*C*). A close relation of modeling work and psychophysical experiment shows that the structural simplicity of the Wilson-Cowan model class allows making specific predictions about certain experiments while opening the door to an understanding of the mechanisms at work behind the scenes.

## Transient Dynamics and Feature Binding

The modeling approaches discussed so far have focused on the long-term behavior of solutions of Wilson-Cowan type of equations. In particular, steady states of the system and their stability have been associated with phenomena of cortical physiology and psychophysics. In this section, we study the transient dynamics of coupled neural populations and link it to perceptual phenomena in the context of feature binding.

### *Feature Inheritance and Shine-through*

The spatiotemporal behavior of the visual system can be assessed psychophysically through experiments in which stimuli are presented successively for short time intervals. The visual system is thus forced to work at its spatial and temporal limit, resulting in illusions that elucidate cortical mechanisms of signal processing.

Two such illusions have recently been described (Herzog and Koch, 2001; Herzog, Fahle, and Koch, 2001). In the so-called *feature inheritance effect* (Figure 4*A*), a single vernier—two bars that are slightly displaced—is presented for a brief time (i.e., 10–30 ms, depending on the individual performance of the subject). The vernier is followed by a double grating of five nondisplaced bars that is presented for 300 ms. Psychophysically, subjects are not aware of the vernier but perceive a displaced grating. That is, the vernier is masked by the grating, which inherits the vernier's displacement. The inheritance effect has also been demonstrated for other fea-

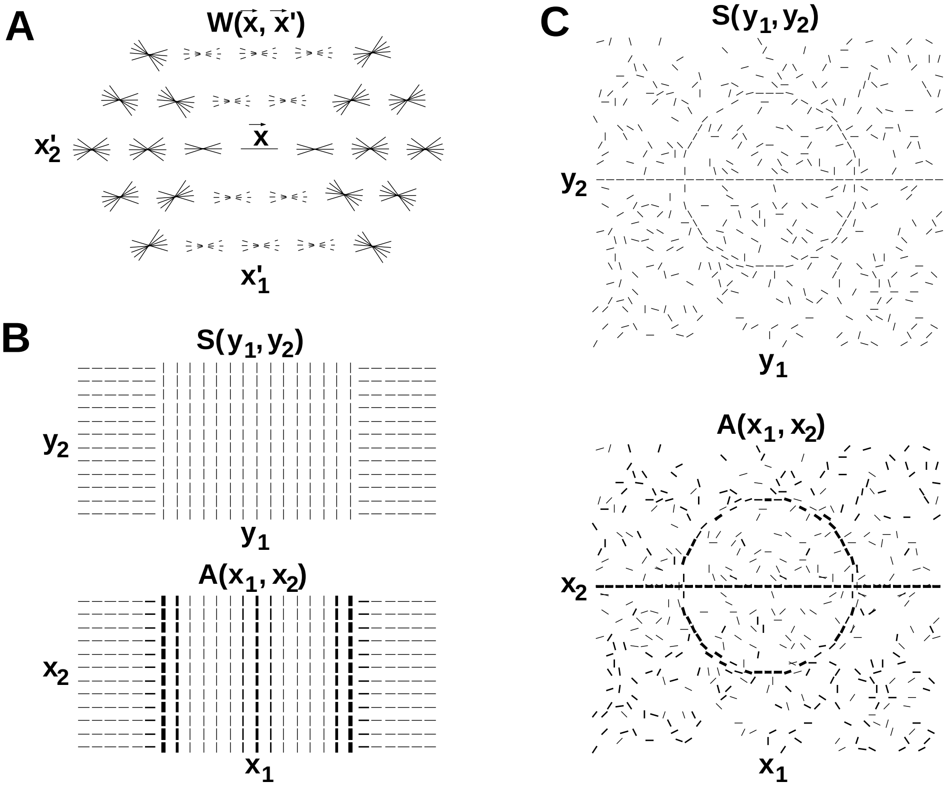

**Figure 3.** *A*, Coupling scheme $W$ connecting the center column at $\vec{x}$ with the surround columns at $\vec{x}'(\vec{x} = (x_1, x_2, \Phi))$. Excitatory connections are marked with thin bars, inhibitory connections with broken bars. The orientation of the bars denotes the difference in orientation preference of the connected columns. *B* and *C*, Sample stimuli $S(\vec{y})$, $\vec{y} \in R$, and the corresponding activation pattern $A(\vec{x})$, $\vec{x} \in C$. The activation level and the orientation preference of the corresponding column are coded by the thickness and the orientation of the bar, respectively. The connection scheme together with the model's dynamics lead to the enhancement of (orientation) discontinuites (*edge detection, B*) and to an increase in the activity of detectors stimulated by a closed contour (*contour integration, C*). (Adapted from Li, 1999.)

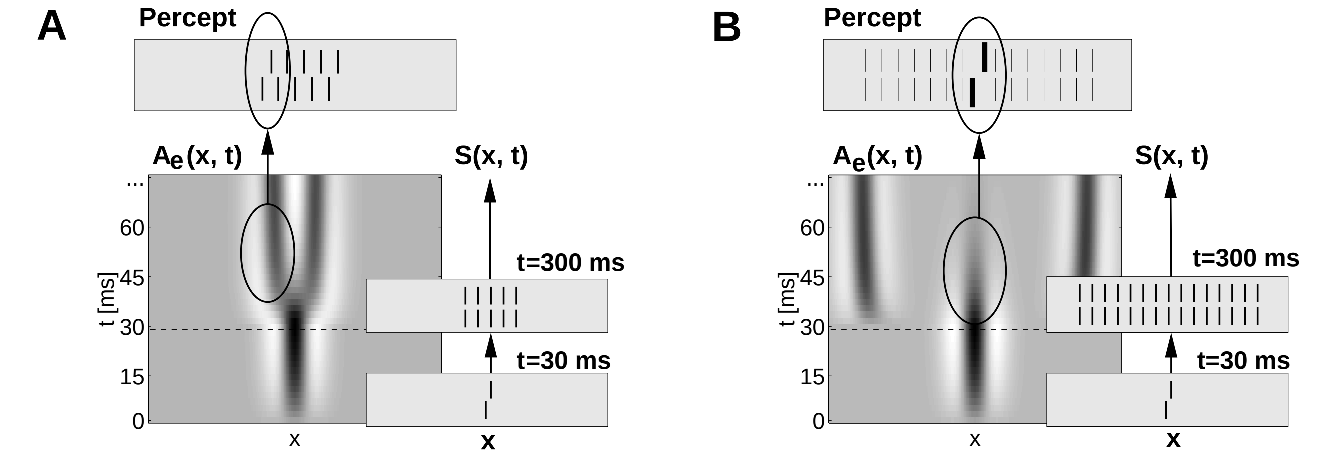

**Figure 4.** Stimuli, visual percept, and simulation result for the feature inheritance and shine-through effects. In the feature inheritance condition (*A*), a single vernier is followed by presentation of a grating of five bars (right panels). The percept is a displaced grating (top). The simulation shows the activity of the excitatory population in gray-scale coding. The central peak resulting from the vernier is rapidly suppressed by the edge activity of the grating. In the shine-through condition (*B*), the vernier is followed by presentation of an elongated grating of 25 bars (right). Perceptually, the vernier looks superimposed on the grating (top). The simulation of the excitatory population reveals that in this case, the central vernier activity persists for a longer time, leading to conscious perception of the shine-through element.

tures, such as orientation and apparent motion (Herzog and Koch, 2001).

Changes in the geometrical arrangement of the grating can modify or even abolish the feature inheritance effect. An example is shown in Figure 4*B*, where an extended grating of 25 bars follows the presentation of the vernier. In this case, subjects are aware of the vernier, which appears superimposed on the grating (*shine-through effect*).

### *Vernier Visibility as a Transient Effect*

The spatiotemporal version of the Wilson-Cowan equations (Equations 4 and 5) can be used to account for the vernier visibility in the different masking conditions. To elucidate the underlying neural mechanisms, a simple, one-dimensional version without the property of orientation tuning is employed. Consider an excitatory and an inhibitory population of cortical neurons arranged along a one-dimensional axis, $C = \mathbb{R}$. The input space is also taken to be one-dimensional, $R = \mathbb{R}$. For reasons of simplicity, we assume symmetry in the weights ($w_{ee} = w_{ei}$; $w_{ie} = w_{ii}$) and in the interaction kernels ($W_{ee} = W_{ei} \equiv W_e$; $W_{ie} = W_{ii} \equiv W_i$). The latter are modeled as Gaussians (cf. Equation 7). The external input current is identical for both populations, $I_e(x, t) = I_i(x, t) \equiv I(x, t)$, and is given by a convolution of the presented spatiotemporal stimulus intensity $S(x, t)$ with a Mexican hat type of filter $V(x - x')$ whose integral vanishes,

$$V(|x - x'|) = \frac{1}{\sqrt{2\pi\sigma_E^2}} \exp\left(-\frac{(x - x')^2}{2\sigma_E^2}\right) - \frac{1}{\sqrt{2\pi\sigma_I^2}} \exp\left(-\frac{(x - x')^2}{2\sigma_I^2}\right)$$

resembling on-off receptive field properties of LGN neurons. The stimulus $S(x, t)$ takes the value 1 if it is part of the vernier or a bar element, and 0 otherwise.

The system parameters—kernel widths, synaptic weights, population time constants, and gain functions—are adjusted considering symmetries and relations in cortical anatomy and physiology.

Numerical results for the feature inheritance and shine-through conditions as described above are given in Figure 4. The gray-scale-coded activities of the excitatory populations show peaks at the position of the vernier and at the edges of the gratings, whereas almost no activity emerges in the bulk of the gratings. A comparison of the central peaks reveals that in the feature inheritance condition (Figure 4*A*), the vernier activity decays earlier than in the shine-through condition (Figure 4*B*). This is due to a strong inhibition by the active neurons representing the nearby edges of the grating. However, in the extended grating comprised of 25 bars, the edges are too far away to exert an influence on the center. The fast suppression of the vernier activity by the small grating shown in Figure 4*A* leads to a complete masking of the vernier element and a subsequent erroneous binding of its feature, the displacement, to the grating. On the other hand, conditions that allow a longer persistence of the vernier activity, like the one shown in Figure 4*B*, result in a conscious perception of the vernier and its displacement. Thus, the occurrence of feature inheritance or shine-through is explained by the transient dynamics of a Wilson-Cowan type of model.

The model can be applied to a number of further stimulus conditions and provides quantitative predictions for the visibility of the vernier element with a single set of model parameters. The model is robust with respect to parameter changes, and the overall results are the same no matter whether the dynamical equations are formulated for the population firing rates or the average membrane potentials. In fact, Li was also able to see the described transient behavior in her cortex model (Li, personal communication). The reduced one-dimensional model presented here also yields an analytical access and allows the identification of neural mechanisms responsible for the observed psychophysical effects (Herzog, Ernst, and Eurich; see http://www-neuro.physik.uni-bremen.de/institute/research/vernier.html)

## Discussion

The Wilson-Cowan model class yields a description of the behavior of coupled neural populations on a coarse time scale. Versions of the model include purely temporal behavior and spatiotemporal behavior in one and two spatial dimensions, and may incorporate further stimulus features such as the orientation of edges as additional model dimensions. The relatively simple structure of the equations allows an analytical and thorough numerical access to the system dynamics. In recent years the model class has been successfully employed to account for various physiological and psychophysical phenomena of the visual system such as orientation selectivity, cortical map formation, figure-ground segregation, feature binding, and masking effects.

Phenomena outside the visual system are beyond the scope of this article. The same holds for several dynamical aspects of the population equations that have not been addressed; among these are hysteresis phenomena and limit-cycle activity (Wilson and Cowan, 1972). For example, Tsodyks et al. (1997) have modeled oscillatory neural activity in rat hippocampus.

An important extension of the Wilson-Cowan model class is obtained if the simplification of time coarse graining is dropped. The search for appropriate equations describing the behavior of neural populations also on fast time scales and under the consideration of noise is a topic of much current interest. A suggestion that has been put forward in this context is the use of a Fokker-Planck equation; see INTEGRATE-AND-FIRE NEURONS AND NETWORKS and Knight (2000) and references therein for a framework of a variety of such approaches.

# Covariance Structural Equation Modeling for Neurocognitive Networks

*Anthony Randal McIntosh*

## Introduction

Covariance structural equation modeling (CSEM) has proven to be an important analytic tool in functional neuroimaging research. Along with other network analytic methods that are focused on relating the interactions between brain areas with cognition, CSEM can provide important insights into the operation of large-scale neurocognitive systems. This review is divided into three sections. The first outlines the theoretical and technical basis for the examination of large-scale neural systems. The second provides a brief summary of some applications of CSEM to human neuroimaging data collected using either positron emission tomography (PET) or functional magnetic resonance imaging (fMRI). There are several applications of CSEM to studies of normal aging and patient populations that will not be reviewed here (Maguire, Vargha-Khadem, and Mishkin, 2001). The article concludes with some speculation on the utility of network analyses in developing brain theory and how it may be used in conjunction with synthetic neural modeling approaches. For related points on this topic, see SYNTHETIC FUNCTIONAL BRAIN MAPPING.

## Theoretical Basis of Network Analysis and the Tools

The driving assumption behind the use of CSEM is that the covariances/correlations of activity are measures of neural interactions. The activity measures may be electromagnetic (e.g., field potentials) or hemodynamic (e.g., cerebral blood flow, oxygen consumption). Neural interactions refer to influences that different elements in the nervous system have on each other via synaptic communication (the term "elements" refers to any constituent of the nervous system, either a single neuron or collections thereof). Activity changes in one neural element usually result from a change in the influence of other connected elements, so focusing only on activity in one area cannot identify the change in afferent influence. Furthermore, it is logically possible for the influences on an element to change without an appreciable change in measured activity. The simplest example would be one in which an afferent influence switches from one source to another without a change in the strength of the influence. Monitoring regional activity alone would miss this shift, but measures of the relation of activity between elements—e.g., the covariance—would not.

### *Structural Equation Modeling*

The foundation for covariance analysis in neuroimaging was laid by Horwitz in a number of papers that looked at regional interrelations in a pairwise manner (Horwitz, Duara, and Rapoport, 1984). Covariance structural equation modeling (CSEM), or path analysis, is a logical extension from this; it uses the anatomical connections between areas in an attempt to characterize the effects between areas, called path coefficients, within a larger functional network (for a complete review, see Bollen, 1989; McIntosh and Gonzalez-Lima, 1994). The covariances among the variables, computed either across subjects within a specific cognitive task or across tasks within a subject, are used to provide weights for the anatomical links in a manner similar to a multiple linear regression.

Covariances used in multivariate analyses can identify the dominant functional and/or effective connections during the performance of a cognitive or behavioral operation. In the context of neuroimaging, *functional connectivity* is a statement that two regions show some non-zero correlation of activity but does not specify how this correlation comes about, while *effective connectivity* is a statement about the direct effect one region has on another, accounting for mutual or intervening influences (Friston, 1994). For the present review, measures of covariances are estimations of functional connectivity while the path coefficients derived from CSEM are estimates of effective connectivity.

In terms of basic equations, consider a four-node network that can be expressed by a series of structural equations (regression equations) as follows:

$$\begin{aligned} A &= \psi_A \\ B &= wA + \psi_B \\ C &= vA + yB + \psi_C \\ D &= xA + zB + \psi_D \end{aligned}$$

where $w$, $x$, $y$, and $z$ are parameters to be estimated (the path coefficients) and $\psi$ denotes a residual influence unique to that region. The residual term is best conceived of unique effects on the region that are not part of the network under consideration.

The network can also be expressed as a series of matrices:

$$\overset{\eta}{\begin{pmatrix} A \\ B \\ C \\ D \end{pmatrix}} = \overset{\beta}{\begin{pmatrix} 0 & 0 & 0 & 0 \\ w & 0 & 0 & 0 \\ v & y & 0 & 0 \\ x & z & 0 & 0 \end{pmatrix}} * \overset{\eta}{\begin{pmatrix} A \\ B \\ C \\ D \end{pmatrix}} + \overset{\psi}{\begin{pmatrix} \psi_A & 0 & 0 & 0 \\ 0 & \psi_B & 0 & 0 \\ 0 & 0 & \psi_C & 0 \\ 0 & 0 & 0 & \psi_D \end{pmatrix}}$$

where $\eta$ contains the variances of the regions, $\beta$ contains the path coefficients, and $\psi$ contains the residuals.

Estimates of the path coefficients and residuals are derived from the original interregional covariances. Let the covariance matrix among regions be $\sigma$, and let the covariances implied by the estimates for $\beta$ and $\psi$ be $\Sigma$, which is computed by

$$\sum = inv(I - \beta)^T * (\psi^T * \psi) * inv(I - \beta)$$

where *inv* denotes matrix inversion, $I$ is an identity matrix, and $T$ denotes a matrix transpose. Initial estimates for $\beta$ and $\psi$ are usually done by using a variation of least squares, and then the estimates are improved through iterative fitting to minimize the difference between $\sigma$ and $\Sigma$. There are a number of different iterative search algorithms and fitting functions that have been used in CSEM, which are reviewed by Bollen (1989).

The path coefficients can also be compared statistically between different tasks or groups. This has been the primary application of CSEM to neuroimaging, where the goal is to determine whether the effective connections within the same anatomical network vary depending on cognitive challenge. Some recent extensions have used CSEM to test hypothesized models of effective connections for specific cognitive operations (Bullmore et al., 2000).

## Empirical Examples

### *Dorsal and Ventral Stream Processing in Perceptual Matching*

One well-established functional distinction in the brain is between object and spatial visual pathways. The foundation for this dual organization can be traced at least as far back as the 1930s, and one of its strongest expressions to date is in the dorsal and ventral cortical processing streams, described by Ungerleider and Mishkin (1982), which corresponds to object and spatial processing pathways, respectively. A similar duality was identified in humans with the aid of PET (Haxby et al., 1991). In an attempt to characterize the interactions within these cortical pathways, McIntosh et al. (1994) used CSEM to explore cortical interactions that were specific to object and spatial processing.

A match-to-sample task for faces was used to explore object vision. For spatial vision, a match-to-sample task for the location of a dot within a square was used. The results from the right hemisphere analysis are presented in Figure 1 (left hemisphere interactions did not differ between tasks). Path coefficients along the ventral pathway from cortical area 19v extending into the frontal lobe were stronger in the face-matching model, while interactions along the dorsal pathway from area 19d to the frontal lobe were relatively stronger in the location-matching model. Among posterior areas, the differences in path coefficients were mainly in magnitude. Occipitotemporal interactions between area 19v and area 37 were stronger in the face-matching model, while the impact of area 17/18 to 19d and the occipitoparietal influences from area 19d to area 7 were stronger in the location matching model.

The anatomical connections allowed for interactions between the dorsal and ventral pathways with connections from area 37 to area 7 and from area 7 to area 21. The interactions among these areas showed task-dependent differences in magnitude and sign. The functional networks show that while the strongest positive interactions in each model may have preferentially been in one pathway, the parallel pathways were not functioning independently. Strong interactions between parallel pathways have been a consistent finding in all CSEM applications to imaging data. Therefore, while a certain pathway or area may be critical for a particular function, operations in the intact brain involve interactions among many regions.

### *Spatial Attention*

Network interactions that underlie cognitive operations are expressed as a change in the effective connections between parts of the network. As is illustrated above, if visual attention is directed to the features of an object, effective connections among ventral posterior cortical areas tend to be stronger, whereas visual attention directed to the spatial location leads to stronger interactions among dorsal posterior areas. Another way that cognitive operations may express is through the modulation of effective connections between regions. In this case, an area may provide an enabling condition to foster communications between regions. Such an effect was the focus of a model of visuospatial attention by Buchel and Friston (1997).

In this fMRI study, subjects alternated between periods of overt attention for a change to a moving visual dot pattern and periods when they were not attending to the display. Two models were evaluated. The first was a feedforward network from primary visual (V1) to dorsal occipital cortex (V5) to posterior parietal (PP) cortices. In this model, the "attend" condition showed stronger path coefficients than when there was no direct attention to the display. The second model assessed whether prefrontal

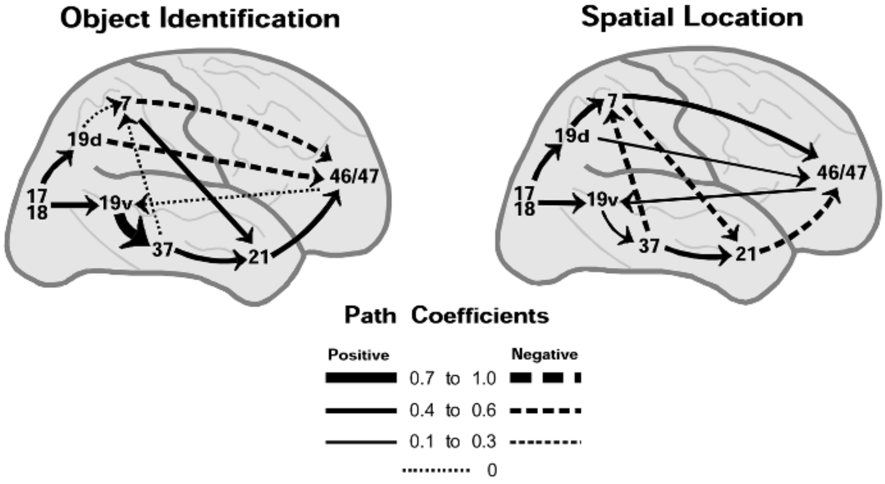

**Figure 1.** Functional interactions between cortical areas in the right hemisphere for object and spatial vision operations. The numbers on the cortical surface refer to Brodmann areas (d = dorsal, v = ventral). The arrows represent the anatomical connections between areas, and the magnitude of the direct effect from one area to another is proportional to the arrow width for each path.

cortex (PFC) had a modulatory effect in the effective connections between V5 and PP. This model had a direct influence from V5 to PP as well as the interaction term where the effect from V5 to PP depended on PFC (PFCmod). The expectation was that if the attentional effects manifest only on the direct connection from V5 to PP, then the estimate for PFCmod would be zero. The authors demonstrated that the modulatory effect was significant for all subjects. This modulatory effect seemed to vary in an activity-dependent manner in which the relation between V5 and PP was stronger during periods when PFC activity was highest.

This model demonstrated two important points. From the methodological point, it shows how more complex neurobiological effects can be modeled in CSEM. Buchel and Friston modeled a simple interaction term, but that same approach can be used to model true nonlinear effects (Bollen, 1989). From the neurobiological perspective, it demonstrates that cognition can be expressed in the brain either as changes in the direct effect between regions, as a modulatory effect, or in some cases both. What CSEM provides is a quantitative method to examine these possibilities.

### *Associative Learning*

One example of the use of network analysis to test specific hypotheses about regional interactions comes from study of sensory learning (McIntosh, Cabeza, and Lobaugh, 1998). The task had subjects learn an association between a tone and a visual stimulus. Using PET, brain activity was measured in response to the tone across acquisition of the association. The expectation was that as the tone acquired behavioral significance, presentation of the tone would elicit activity in visual areas. Because the activation of visual areas would occur without overt visual stimulation, the second hypothesis was that this activation would be mediated through effects from higher-order cortical areas, likely posterior association or prefrontal cortices. The effective connections between visual cortex and anterior regions were quantified by using CSEM to determine which of these candidates exerted the strongest influence on these visual areas.

Activation of occipital cortex in area 18 to the tone was observed as training proceeded, confirming the first expectation. CSEM of influences on area 18 suggested that two areas in particular seem to exert the dominant influence as the association was learned. Superior temporal cortex (auditory association, area 41/42) and prefrontal cortex near area 10 both changed their effect on area 18 from suppressive to facilitory as the association was learned.

This study demonstrated learning-related changes in effective connectivity. Although the areas selected for CSEM were related to behavior, it is not clear whether the changes in effective connectivity impacts directly on learning-related performances changes. Buchel, Coull, and Friston (1999) provided a convincing demonstration that changes in effective connectivity related directly to learning. Subjects learned to associate visually presented objects with their location in space. To confirm that the behavioral changes across the experiment related directly to network dynamics, the changes in effective connections between dorsal and ventral processing stream were correlated with subject's learning rate. A robust correlation was found between the learning rate and the change in the influence of posterior parietal cortex (dorsal stream area) on inferotemporal cortex (ventral stream area). This is consistent with the task demands and demonstrates that network dynamics can be directly related to overt changes in behavior.

### *Awareness and Prefrontal Cortex Interactions*

As a follow-up to the simple associative learning study described above, McIntosh and colleagues further investigated the neural interactions subserving cross-modal learning using differential conditioning (McIntosh, Rajah, and Lobaugh, 1999). Two tones were used that had differential relations to the visual stimuli. One tone was a strong predictor of the presentation of a visual stimulus (Tone+), and the other tone was a weak predictor (Tone−). The sample of subjects was divided perfectly in half into those who were aware of the stimulus associations and those who were not. Furthermore, only *aware* subjects learned the differentiation between the tones, while *unaware* subjects showed no behavioral evidence of learning.

The strongest group difference in brain activity elicited by the tones was in left prefrontal cortex (LPFC) near area 9. In aware subjects, LPFC activity showed progressively greater activity to Tone− than Tone+. In unaware subjects, no consistent changes were seen in LPFC or in any of the other regions. At first, these results seem to confirm the prominent role of PFC in monitoring functions and especially its putative role in awareness. However, PFC activation has also been found in tasks in which there was no overt awareness (Berns, Cohen, and Mintun, 1997). It was thus possible that interactions of PFC with other brain regions,

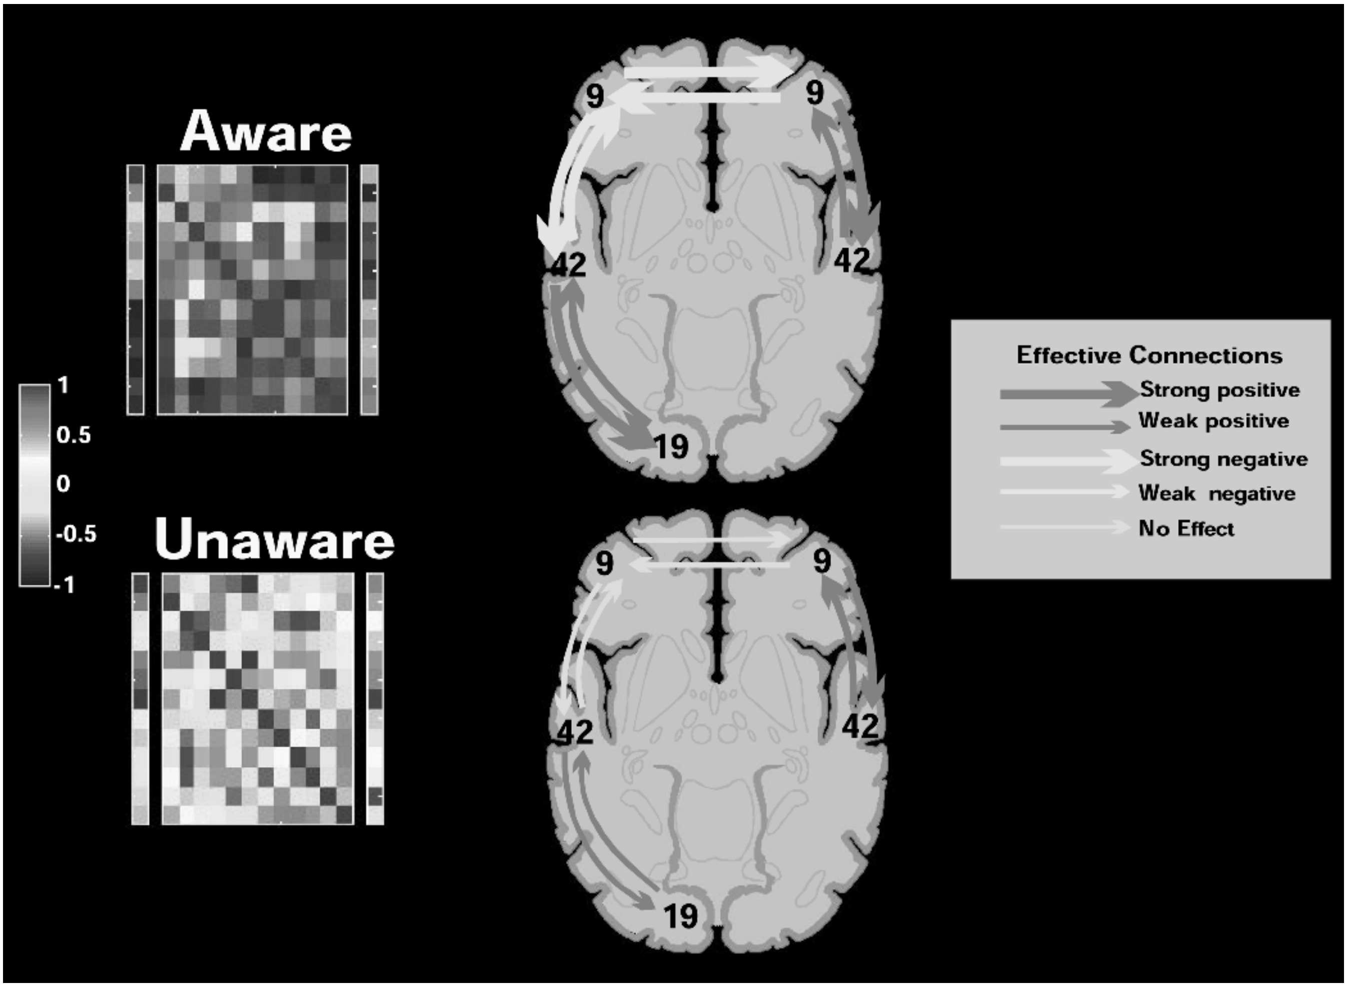

**Figure 2.** Correlation plots and functional networks from late phases of training in a differential sensory conditioning task. The plots on the left of the figure are pseudo-colored matrices of the correlations of left prefrontal cortex area 9 (first column) with sensory and association cortices, and the correlations of all regions with behavior are shown in the last column of the matrix. The correlation values are represented as color gradations, according to the scale on the far left of the figure. The matrices are symmetric about the major diagonals, which are all ones. The right of the figure shows the functional networks for the two groups. Aware subjects showed strong effective connections involving left prefrontal area 9 and other regions. Conversely, the network for the unaware subjects showed no strong left prefrontal involvement.

present in aware but not in unaware subjects, would better describe the neural system underlying awareness in this task.

When the interactions of LPFC was assessed between the two groups, large differences were found in the strength and pattern of functional connections among several brain areas, including right PFC, bilateral superior temporal cortices (auditory association), occipital cortex, and medial cerebellum. These areas were much more strongly correlated in aware subjects than unaware subjects (Figure 2). To explore some of the network interactions within an anatomical reference, CSEM was applied to a subset of these regions.

As may be expected from the correlation matrices, there were significant differences in the effective connections for aware subjects, including robust interactions involving LPFC. The functional network for unaware subjects differed from that for aware subjects, but there were no significant changes in effective connections across the experiment for the unaware group, and the involvement of LPFC was weak. This confirms that LPFC was not interacting systematically across subjects in the unaware group.

## Discussion: Implications for Computational Modeling and Theoretical Efforts

### *Object and Spatial Vision*

Aside from the confirmation of the dorsal/ventral distinction, it was noted that these functionally independent parallel systems could interact during different operations. While there were dominant interactions along dorsal and ventral streams in spatial and object tasks, respectively, there was cross-talk between the two streams, which implies that they need not be functionally independent. The study of Buchel et al. (1999) demonstrates that the interactions between pathways can depend on experience, and the study of Buchel and Friston (1997) suggests mechanisms whereby other cortical areas may modulate the interactions between posterior sensory regions.

### *Neural Context and Network Operations*

A consistent observation in CSEM applications to neuroimaging is that similar areas are engaged in many cognitive functions, and what discriminates these cognitive operations are the pattern of interactions within large-scale networks rather than the involvement of a particular area. This has led to the concept of a *neural context,* in which the functional relevance of a particular region is determined by its interactions with other areas (McIntosh, 1999). Systems-level neuroanatomy shows that brain regions receive projections from many areas and send projections to many others. Neural context emphasizes that the precise pattern of these functionally engaged structural connections defines the translation of brain operations into cognitive operations. Consequently, the same region may show identical levels of activity across many different tasks. Because the pattern of interactions with other connected areas differs, the resulting cognitive operations vary, yet the same region is involved in each task. Stated differently, the neural context within which an area is active embodies the cognitive operation. The implications for computational modeling would be to develop models that can carry out more than one cognitive function through a change in the pattern of interactions among nodes. Thus, the focus would go from trying to model the computations in a single task to deriving a single model configuration that can do multiple tasks.

The relationship between neural modeling and experimental neuroscience continues to mature. The primary utility of modeling comes when they are derived to support specific hypotheses, and serve as frameworks for understanding complex data. Modeling efforts, whether empirically based like CSEM, theoretical, or computational, are all approximations of reality and as such are ultimately false. However, it is not necessarily the model that furthers our knowledge base. Rather, when a model is falsified and subsequently reformulated, scientific progress is made.

# Crustacean Stomatogastric System

*Scott L. Hooper*

## Introduction

The stomatogastric nervous system (STNS) of decapod crustacea generates the rhythmic motor patterns of the four areas of the crustacean stomach—the esophagus, cardiac sac, gastric mill, and pylorus—and contains some of the best-understood central pattern–generating networks in neurobiology. This work has identified four widely applicable properties of STNS networks. First, rhythmicity in these highly distributed networks depends on both network synaptic connectivity and slow (tens to hundreds of milliseconds), active neuronal membrane properties. Second, modulatory influences can induce individual STNS networks to produce multiple outputs, "switch" neurons between networks, or fuse individual networks into single larger networks. Third, modulatory neuron terminals receive network synaptic input. Modulatory inputs can be sculpted by network feedback, and become integral parts of the networks they modulate. Fourth, network synaptic strengths can vary as a function of pattern cycle period and duty cycle. Similar complex properties are present in many biological neural networks (see Ion Channels: Keys to Neuronal Specialization; Half-Center Oscillators Underlying Rhythmic Movements; Oscillatory and Bursting Properties of Neurons). Introducing such neurons into artificial neural networks may afford significant functional advantages.

## Background

### Morphology

All known STNS motor neurons and interneurons are monopolar and have inexcitable somata; synaptic contacts and the voltage-dependent channels underlying slow-wave activity are located in neuropil processes. Spike initiation zones are located near the axon and are electrically distant from the cell body (Selverston et al., 1976).

### *Synapses*

Input and output synapses are located side by side on neuropil processes. Neuronal output thus results from local integration in the neuropil instead of the whole-cell integration present in neurons with distinct pre- and postsynaptic regions (Selverston et al., 1976). In the two best-studied STNS networks, the pyloric and gastric networks, synaptic release is a graded (analogue) function of membrane potential (Graubard, Raper, and Hartline, 1983). Multiple transmitters and receptors, each with their own time course, are present in STNS networks. In particular, many STNS synapses induce slow responses with characteristic times as long as 100 ms (Miller, 1987).

### *Cellular Properties*

STNS neurons display a variety of active, long-duration cellular properties. Many show postinhibitory rebound (PIR); i.e., inhibition induces a subsequent, postsynaptic membrane–generated, active depolarization above rest (Selverston et al., 1976). Some are endogenous oscillators—neurons that spontaneously depolarize and hyperpolarize in a rhythmic fashion. Others have "plateau properties." A plateau neuron has, in addition to a stable rest potential, a quasi-stable depolarized plateau membrane potential. Plateau transitions are regenerative; depolarization from rest above a threshold voltage activates voltage-dependent conductances that drive the neuron to the plateau, and small hyperpolarizations from the plateau induce active repolarization to rest (Russell and Hartline, 1978). Plateau properties nonlinearly transform inputs in amplitude and time in that small-amplitude inputs can induce a full transition, and brief inputs (tens of microseconds) induce long-lasting responses (uninhibited plateaus can last for seconds). STNS models suggest that oscillation, plateaus, and PIR are essential for reproducing the dynamic properties of STNS networks (Golowasch et al., 1992; Marder and Selverston, 1992; Nadim et al., 1998).

### *Neuromodulation*

Synaptic strength and cellular properties in STNS networks are altered by modulatory influences. These influences can induce individual neurons to express plateaus or to become endogenous oscillators (Harris-Warrick, Nagy, and Nusbaum, 1992), and dramatically increase the functional repertoire of STNS neurons and networks.

## Mechanisms of Central Pattern Generation

The pyloric network is the best-understood STNS network and will be used to illustrate several general principles that underlie rhythmic pattern generation in this and other systems. The pyloric network is a central pattern generator, i.e., it endogenously generates rhythmic patterns without timing cues from the rest of the nervous system. The right portion of Figure 1 shows simultaneous recordings from all six pyloric neuron types. Each cycle consists of a sequence of bursts of action potentials from the pyloric neurons (Figure 1 shows two cycles). Pyloric dilator (PD) motor neuron activity is classically used to define the beginning of the sequence; they and the anterior burster (AB) interneurons fire together. The lateral pyloric (LP) and inferior cardiac (IC) motor neurons fire next, and finally the pyloric (PY) and ventricular dilator (VD) motor neurons fire. The network's synaptic connectivity (Miller, 1987) is shown in Figure 1, left. Small circles represent inhibitory chemical synapses, resistors represent bidirectional electrical coupling, and the diode represents rectifying electrical coupling (current flows only in the direction of the arrow). The white neurons are glutamatergic and induce rapid, short-lasting inhibition in their followers; the black neurons are cholinergic and induce slow, long-lasting inhibition.

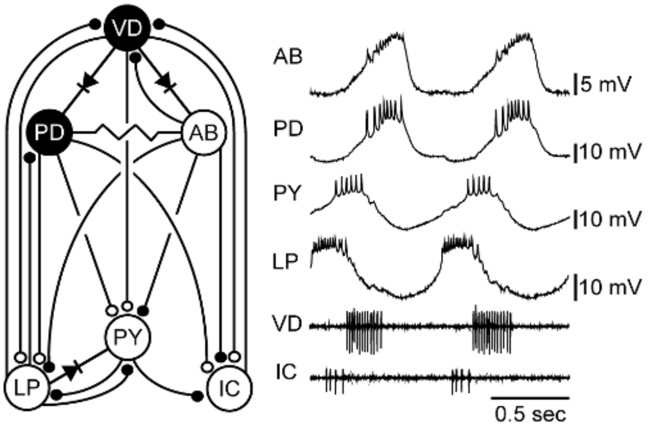

**Figure 1.** Pyloric network synaptic connectivity (left) and output (right). Small circles represent chemical synapses, resistors represent bidirectional electrical coupling, and the diode represents rectifying electrical coupling. Calibration bar: 20 mV for PD and LP neurons, 10 mV for other neurons.

It might be difficult initially to understand how a network dominated by inhibitory synapses is rhythmically active. One solution would be for all network neurons to be endogenous oscillators, and under some circumstances all pyloric neurons can be (Bal, Nagy, and Moulins, 1988). However, the network also produces a slow, but correctly ordered, rhythmic output even in cases in which none of its neurons are endogenous oscillators (Miller, 1987). This rhythmicity arises because the network has multiple locations in which two neurons inhibit each other. Mutual inhibition can lead, in neurons possessing PIR and plateau potentials, to a synaptically based rhythmicity called half-center oscillation. Rhythmicity arises in this synaptic arrangement because the inhibition caused by one neuron's firing induces a delayed PIR, plateau, and firing in the second. The inhibition of the first neuron caused by the second neuron's firing induces in turn a delayed PIR, plateau, and firing in the first neuron, after which the process repeats. This multiplicity of mechanisms makes it difficult to ascribe specific aspects of network function to specific network neurons. Network rhythmicity and pattern instead arise emergently from a combination of neuronal cellular properties and the network's distributed synaptic connectivity.

Nonetheless, a qualitative understanding of pyloric activity can be achieved by considering the cellular properties of the network's neurons and the network's synaptic interconnectivity. The AB neuron is generally the fastest oscillator and drives the PD neurons through their electrical coupling. These neurons inhibit all other pyloric neurons. The LP and IC neurons rebound most quickly after this inhibition and fire next. These neurons inhibit the VD and PY neurons, but eventually the PY neurons rebound and fire. PY neuron firing inhibits the IC and LP neurons and releases the VD neuron from inhibition. The PY and VD neurons are turned off by the next AB/PD neuron burst, and the cycle repeats.

## Multifunctional Networks

The pyloric network produces different outputs in response to modulatory inputs (Harris-Warrick et al., 1992). Pyloric network complexity may thus exist to allow construction of many functional

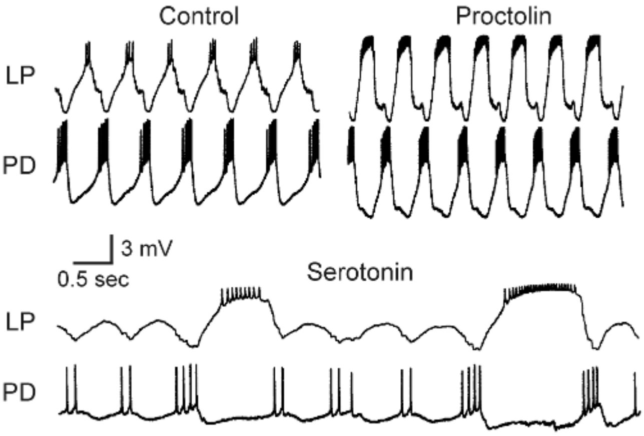

**Figure 2.** Proctolin (top right panel, $10^{-6}$M) and serotonin (bottom panel, $10^{-4}$M) induce the pyloric network to produce different motor patterns. (Modified from Marder, E., Hooper, S. L., and Eisen, J. S., 1987, Multiple neurotransmitters provide a mechanism for the production of multiple outputs from a single neuronal circuit, in *Synaptic Function* (G. M. Edelman, W. E. Gall, and M. W. Cowan, Eds.), New York: Wiley, pp. 305–327.)

configurations from a single anatomical network. Figure 2 shows the pyloric outputs induced by the neuromodulators proctolin and serotonin. Proctolin increases LP neuron activity (top trace). Serotonin induces a pattern in which, instead of the LP and PD neurons bursting in alternation, the LP neuron bursts once every two to three PD neuron bursts. Network multifunctionality is not limited to the pyloric network; the gastric mill network also produces multiple outputs. Work in in vivo and semiintact preparations shows that these networks produce multiple outputs in the animal as well, and thus the multiple outputs observed in vitro (and the network switches and fusions noted below) may be behaviorally relevant. Direct evidence for this contention exists in two cases. The first is modulation of the gastric mill rhythm by a cholecystokinin-like hormone whose hemolymph concentration rises after feeding. The second is feedback from stomach proprioceptive neurons that contain acetylcholine and serotonin and that have short-acting, classical (cholinergic) and long-lasting modulatory (serotonergic) effects that would increase pyloric and gastric mill activity (Turrigiano and Heinzel, 1992).

The cellular targets of several modulators are known (Harris-Warrick et al., 1992). This work has two generally relevant results. First, many modulators alter the inherent cellular properties of their target neurons. Second, because directly affected neurons alter the activity of other network neurons, and because these changes modify the responses of directly affected neurons, network activity changes cannot be explained solely by considering the directly affected neurons. Network rearrangements are instead global responses of the entire network, and so not only network rhythmicity but also network modulatory responses are *distributed* functions in these networks.

## Neuron Switching and Network Fusion

Until now the four STNS networks have been treated as separate entities. However, the stomach is anatomically compact, adjoining stomach regions are mechanically coupled, and coordination of the motor patterns these networks produce is likely critical for behavior. Considerable internetwork connectivity exists, and network boundaries are variable. These interactions range from simple coordination between networks to cases in which neurons are switched between networks to cases in which networks fuse to form new networks. Figure 3 shows an example of fusion (Meyrand, Simmers, and Moulins, 1991). The upper panel shows simultaneous recordings, obtained under control conditions, of the VD and PD neurons (pyloric network) and the gastric mill (GM) and lateral posterior gastric (LPG) neurons (gastric mill network). The bottom panel shows the activity of these neurons after discharge of an identified modulatory neuron; the two networks now produce a single conjoint rhythm different from either the pyloric or the gastric rhythm.

The mechanisms underlying network switching and fusion are known in two cases. In one (a switch), the change was due to plateau suppression in the switching neuron (Hooper and Moulins, 1989); in the other (a fusion), it was due to increased strength of an internetwork synaptic connection (Dickinson, Mecsas, and Marder, 1990). Nevertheless, the effects on total network activity again could be understood only by considering the entire network. Long-lasting cellular properties and distributed network architecture thus underlie not only STNS central pattern generation and multifunctionality, but also many aspects of internetwork interaction and restructuring.

## Sculpting of Modulatory Input by Network Local Feedback

Many STNS modulatory fibers arise from physically distant cell bodies. The terminals of these fibers receive presynaptic input from, and can serve as integral members of, the networks they modulate. Figure 4 shows one such input, modulatory commissural neuron 1 (MCN1) (Coleman, Meyrand, and Nusbaum, 1995). MCN1 chemically excites the lateral gastric (LG) neuron and interneuron 1 (Int1) of the gastric mill network, and is electrically coupled to the LG neuron (Figure 4*A*). When MCN1 is active, Int1 fires first, owing to MCN1's fast chemical synapse onto it. Int1 firing inhibits the LG neuron, and this reduces the effectiveness of MCN1's electrical input to the LG neuron (left, Figure 4*B*). MCN1's slow chemical excitation eventually brings the LG neuron to threshold. LG neuron firing inhibits Int1, presynaptically inhibits

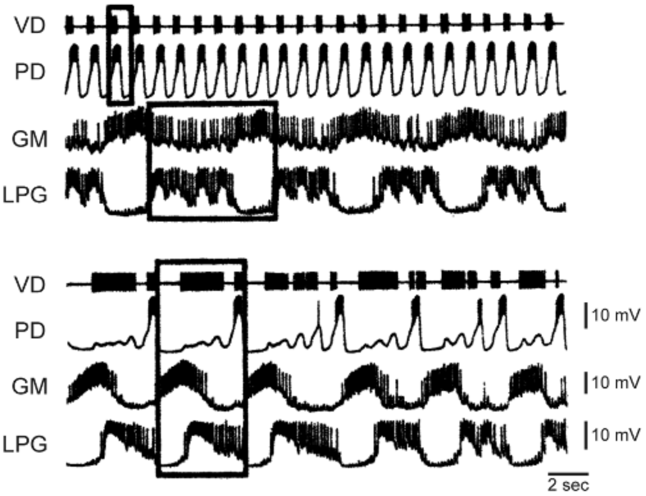

**Figure 3.** A defined modulatory input fuses networks that are generally distinct (top panel; pyloric, VD, PD neuron traces; gastric mill, GM, LPG neuron traces) into a single network that produces a novel output (bottom panel). (From Meyrand, P., Simmers, J., and Moulins, P., 1991, Construction of a pattern-generating circuit with neurons of different networks, *Nature*, 351:60–63, Figure 3. © 1991, Macmillan Magazines Ltd. Reprinted with permission.)

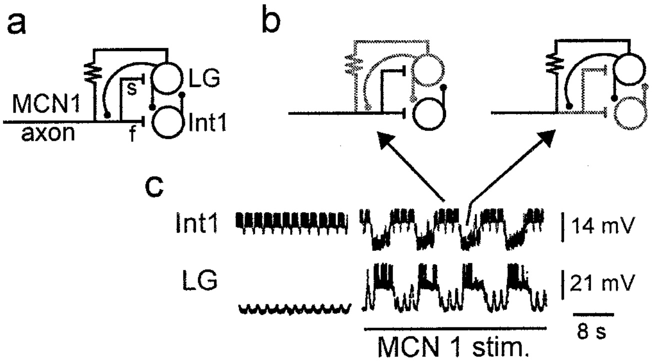

**Figure 4.** Presynaptic inhibition can sculpt modulator input, and make input terminals integral parts of the networks they modulate. *A*, Synaptic connectivity pattern. MCN1 (a descending modulatory input) makes a fast excitatory synapse onto Int1 and a slow excitatory synapse onto the lateral gastric (LG) neuron. The LG neuron is electrically coupled to, and presynaptically inhibits, the MCN1 axon. The LG neuron and Int1 inhibit each other. *B*, Local feedback rhythmically switches the active mode of MCN1 input. *C*, Tonic MCN1 input (MCN1 active in right panel) activates the gastric mill network. (From Coleman, M. J., Meyrand, P., and Nusbaum, M. P., 1995, A switch betweent two modes of synaptic transmission mediated by presynaptic inhibition, *Nature*, 378:502–505. © 1995, Macmillan Magazines Ltd. Reprinted with permission.)

MCN1's chemical input to the LG neuron and Int1, and increases the effectiveness of MCN1's electrical input to the LG neuron (right, Figure 4*B*). This electrical input maintains LG neuron activity for a period, but eventually, owing to the lack of MCN1 excitatory chemical input, the LG neuron ceases firing. This removes the LG neuron's presynaptic inhibition of MCN1 input to Int1, Int1 is driven to fire, and the cycle repeats. This switching between different modes of MCN1 input to the gastric mill network, itself driven by gastric activity, continues throughout gastric cycling (Figure 4*C*, right, arrows; the left part shows gastric mill activity before MCN1 activity).

## Dependence of Synaptic Strength on Pattern Activity

As noted earlier, modulatory effects cannot be fully understood without considering the entire network. A striking example is the observation that synaptic strength depends on pattern cycle period (Figure 5; Manor et al., 1997). The panels show PD neuron response to rhythmic, square-wave LP neuron depolarizations (recall that pyloric neurons release transmitter as a graded function of membrane potential) at 2.5-s (left) and 0.75-s (right) periods. The PD neuron response is much less at the faster period: Inputs that alter pattern period can thus alter synaptic strength without directly affecting synaptic transmission. These activity-dependent synaptic strength changes clearly would be fundamentally important in shaping network response to modulation, and provide additional evidence of the interlinking of direct and indirect responses that allow these networks to respond to modulatory input in a global fashion.

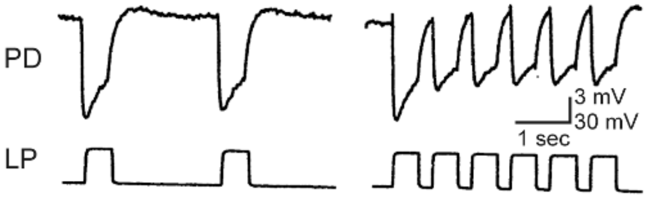

**Figure 5.** LP to PD neuron synaptic strength varies as a function of LP neuron cycle period. PD neuron postsynaptic response is much less at a 0.75-s LP neuron cycle period (right) than at a 2.5-s period (left). (Modified from Manor, Y., Farzan, N., Abbott, L. F., and Marder, E., 1997, Temporal dynamics of graded synaptic transmission in the lobster stomatogastric ganglion, *J. Neurosci.*, 17:5610–5621.)

## Discussion

Work in a well-defined invertebrate nervous system has revealed several cellular and synaptic properties essential for biological function that often are not included in artificial neural networks. Chief among these are the following:

1. Synapses with different characteristic time courses present in the same network.
2. Neurons with long-lasting (tens to hundreds of milliseconds) voltage-dependent conductances that give rise to complex, long-duration cellular characteristics (oscillation, plateaus, PIR).
3. Neuromodulatory inputs that alter synaptic strength and inherent cellular properties.
4. Local feedback that alters neuromodulatory input activity and makes modulatory inputs an integral part of the network they modulate.
5. Network synaptic strengths that depend on network activity (cycle period, duty cycle).

Modeling work shows that many of the functional characteristics (rhythmic pattern production, multiple pattern production, neuron switching, network fusion) of STNS networks require model neurons and networks that incorporate these properties (Golowasch et al., 1992; Marder and Selverston, 1992; Nadim et al., 1998). Including model neurons with similar properties in neural network simulations may enhance artificial neural network capability and deepen understanding of both artificial and biological neural network function.

# Data Clustering and Learning

*Joachim M. Buhmann*

## Introduction

Intelligent data analysis extracts symbolic information and relations between objects from quantitative or qualitative data. A prominent class of methods are clustering or grouping principles which are designed to discover and extract structures hidden in data sets (Jain and Dubes, 1988). The parameters that represent the clusters are either estimated on the basis of quality criteria or cost functions or, alternatively, they are derived by local search algorithms that are not necessarily following the gradient of a global quality criterion. This approach to inference of structure in data is known as unsupervised learning in the neural computation literature. Clustering as a fundamental pattern recognition problem can be characterized by the following design steps:

1. *Data representation*: What data types represent the objects in the best way to stress relations between the objects, e.g., similarity?
2. *Modeling*: How can we formally characterize interesting and relevant cluster structures in data sets?
3. *Optimization*: How can we efficiently search for cluster structures?
4. *Validation*: How can we validate selected or learned structures?

It is important to note that the data representation issue predetermines what kind of cluster structures can be discovered in the data. Vectorial data, proximity or similarity data, and histogram data are three examples of a wide variety of data types that are analyzed in the clustering literature. On the basis of the data representation, the modeling of clusters defines the notion of groups of clusters in the data and separates desired group structures from unfavorable ones. We consider it mandatory that the modeling step yields a quality measure that is either optimized or approximated during the search for hidden structure in data sets. Formulating the search for clusters as an optimization problem allows us to validate clustering results by large deviation estimates; i.e., robust cluster structures in data should vary little from one data set to a second data set generated by the same data source.

The reader should note that the clustering literature in pattern recognition and applied statistics as well as in communications and information theory pursues two apparently different goals, namely, either (1) *density estimation* or (2) *data compression*. Both goals, however, are tightly related by the fact that the correct identification of the probability model of the source yields the best code for data compression. Mathematically, data compression aims at optimal partitionings of the data, and stochastic sampling of partitions yields density estimates that are optimized in the maximum entropy sense. This issue is addressed in more detail later in this article.

## Data Representations for Clustering

Various data types have been introduced in the pattern recognition literature. Mathematically, we distinguish between the object or design space $\mathbb{O}$ that contains different object configurations $\mathbf{o} \in \mathbb{O}$ and the measurement space $\mathcal{F}$ with measurements $\mathbf{x} \in \mathcal{F}$. Objects might be faces of people, and the corresponding measurements might be intensity or range images. A datum is defined as a relation between a design space $\mathbb{O}$ and a measurement space $\mathcal{F}$. This relation $(\mathbf{o}, \mathbf{x}) \in \mathbb{O} \times \mathcal{F}$ can represent a functional dependence $\mathbf{x} : \mathbf{o} \mapsto \mathbf{x}(\mathbf{o})$ between objects and measurements or a stochastic dependence $\mathbf{P}\{\mathbf{x}|\mathbf{o}\}$. The following categories of data types are most commonly used in data analysis problems:

- *Vectorial data* characterize an object $\mathbf{o}$ by a number of attributes which are combined to a $d$-dimensional feature vector $\mathbf{x}(\mathbf{o}) \in \mathcal{F} \subset \mathbb{R}^d$.
- *Distributional data* of an object $\mathbf{o}$ are described by an empirical probability distribution or histogram $\mathbf{P}\{\mathbf{x}|\mathbf{o}\}$ over features $\mathbf{x} \in \mathcal{F}$.
- *Proximity data* are characterized by pairwise comparisons between objects according to a proximity measure, e.g., $\mathbf{x}(\mathbf{o}_i) := \{D(\mathbf{o}_i, \mathbf{o}_j) \in \mathbb{R}; 1 \le j \le n\}$. Dissimilarity measures $D(.,.)$ often fulfill additional properties, e.g., nonnegativity, vanishing self-dissimilarity, symmetry, and the triangular inequality.

Various polyadic data types such as co-occurrence data (e.g., word bigrams in linguistics, consumer behavior data in economics) or even more complex data types (trigrams) are occasionally considered in the empirical sciences but are not further discussed here.

## Modeling Cluster Structure

The goal of clustering is to assign objects with similar properties to the same clusters and dissimilar objects to different clusters. Mathematically, assignments of objects to clusters is represented by an assignment function $m : \mathbb{O} \to \{1, 2, \ldots, k\}$, $\mathbf{o} \mapsto m(\mathbf{o})$. Data clustering pursues the goal to determine a partitioning of object space into subsets $\mathcal{G}_\alpha \equiv \{\mathbf{o} \in \mathbb{O} : m(\mathbf{o}) = \alpha\}$, $1 \le \alpha \le k$. The space of all clustering solutions is the set of all assignment functions $\mathcal{M} = \{m : \mathbb{O} \to \{1, 2, \ldots, k\}\}$. The quality of these partitions is evaluated by an appropriate homogeneity measure for the respective data type. Depending on the clustering goal, either the quality is optimized or the optimum is approximated that might yield a unique solution or a set of approximating solutions. The most commonly used clustering costs are invariant under permutations of the cluster indices. Hierarchical and topological clustering methods impose additional structure on the partitions. These principles are briefly sketched for all three data types.

### *Central Clustering or Vector Quantization*

Clustering $n$ objects that are represented as vectorial data $\mathscr{X} := \{\mathbf{x}_i \in \mathscr{F} : 1 \leq i \leq n\}$ induces a partitioning of the feature space $\mathscr{F} \subset \mathbb{R}^d$. The set of objects is partitioned into clusters in such a way that the average distance from data points to their cluster centers $\mathscr{Y} = \{\mathbf{y}_\nu \in \mathscr{F} : 1 \leq \nu \leq k\}$ is minimized. The representation of data $\mathbf{x}_i$ by the centroid $\mathbf{y}_{m(i)}$ induces distortion/quantization costs $D_{i,m(i)}$ due to information loss. The functional form of $D_{i,m(i)}$ depends on the weighting of data distortions, in which quadratic costs $D_{i,m(i)} = \|\mathbf{x}_i - \mathbf{y}_{m(i)}\|^2$ and $k$-means $\mathbf{y}_\alpha = \Sigma_{\mathbf{o}_i \in \mathscr{G}_\alpha} \mathbf{x}_i / |\mathscr{G}_\alpha|$ is the most common choice. More general distortion measures like $l_p$-norms are occasionally considered. The cost function for $k$-means clustering is defined as

$$H^{cc}(m;\ \mathscr{X}) = \sum_{i \leq n} \|\mathbf{x}_i - \mathbf{y}_{m(i)}\|^2 \tag{1}$$

In neural networks, the centroids $\mathbf{y}_{m(i)}$ can be implemented by neural feature detectors that are equipped with radially symmetric receptive fields and a global activity normalization. The size $k$ of the cluster set, i.e., the complexity of the clustering solution, has to be determined a priori or by a problem-dependent complexity measure (Buhmann and Kühnel, 1993). A minimum of the cost function formulated in Equation 1 can be found by varying the assignments $m(i)$, which effectively is a search in a discrete space with exponentially many states. The optimization procedure implicitly yields the cluster means $\{\mathbf{y}_\nu\}$ by estimating optimized assignments $\{m(i)\}$. A supervised version of central clustering is discussed as Learning Vector Quantization (q.v.) in the literature.

### *Distributional Clustering*

Distributional data represent the co-occurrence of objects and features by histograms (Pereira, Tishby, and Lee, 1993). Denote by $\mathscr{D} = \mathscr{O} \times \mathscr{F}$ the data space, i.e., the product space of objects $\mathbf{o} \in \mathscr{O}$ and features $\mathbf{x} \in \mathscr{F}$. In information retrieval, objects might be documents and features might be keywords. The $\mathbf{o} \in \mathscr{O}$ is characterized by an empirical conditional distribution $\hat{\mathbf{P}}\ \{\mathbf{x}|\mathbf{o}\}$ (histograms); i.e., we count the occurrence of a feature value $\mathbf{x}$ given the object $\mathbf{o}$.

In distribution clustering, objects are grouped according to the similarity of their histograms $\hat{\mathbf{P}}\{\mathbf{x}|\mathbf{o}\}$, with a cluster-specific prototypical distribution of features $\mathbf{P}\{\mathbf{x}|\theta_{m(\mathbf{o})}\}$ that is parametrized by $\theta_\alpha$. The natural distortion measure between two histograms is defined by the Kullback-Leibler divergence (see Learning and Statistical Inference), i.e., $D_{\mathbf{o},m(\mathbf{o})} = \hat{\mathbf{P}}\{\mathbf{o}\} D^{\mathrm{KL}}(\hat{\mathbf{P}}\{\mathbf{x}|\mathbf{o}\} \| \mathbf{P}\{\mathbf{x}|\theta_{m(\mathbf{o})}\})$. This idea behind distributional clustering closely resembles $k$-means clustering when the Euclidian distance is replaced by the KL-divergence. The costs of distributional clustering sum up all distortions of objects, i.e.,

$$H^{\mathrm{hc}}(m,\ \theta;\ \mathscr{X}) = |\mathscr{O}| \sum_{\mathbf{o} \in \mathscr{O}} \hat{\mathbf{P}}\{\mathbf{o}\} D^{\mathrm{KL}}(\hat{\mathbf{P}}\{\mathbf{x}|\mathbf{o}\} \| \mathbf{P}\{\mathbf{x}|\theta_{m(\mathbf{o})}\}) \tag{2}$$

The costs formulated in Equation 2 define the log-likelihood of a statistical model that explains the data $\mathscr{X}$ by a mixture of data sources: (1) select an object $\mathbf{o} \in \mathscr{O}$ with probability $\mathbf{P}\{\mathbf{o}\}$; (2) choose the cluster $\alpha$ according to the cluster membership of $\alpha = m(\mathbf{o})$; (3) select $\mathbf{x} \in \mathscr{F}$ according to the class-conditional distribution $\mathbf{P}\{\mathbf{x}|\theta_{m(\mathbf{o})}\}$. A very insightful relation to rate distortion theory with side information (Cover and Thomas, 1991) has been described in Tishby, Pereira, and Bialek (1999) and it is called the information bottleneck method.

### *Pairwise Clustering*

Clustering nonmetric data that are characterized by proximity information and not by explicit Euclidean coordinates can be formulated as a graph optimization problem. Given is a graph $(\nu, \varepsilon)$ with weights $\mathscr{D} := \{D_{ij}\}$ on the edges $(i, j)$. The vertices denote the objects to be grouped and the edge weights encode dissimilarity information. Compact clusters are represented by a partition of the vertex set with small dissimilarities between all objects that belong to the same cluster. To simplify the notation, the subset of edges with one vertex in cluster $\alpha$ and one vertex in cluster $\beta$ is denoted by $\varepsilon_{\alpha\beta} = \{(i, j) \in \varepsilon : \mathbf{o}_i \in \mathscr{G}_\alpha \wedge \mathbf{o}_j \in \mathscr{G}_\beta\}$. A meaningful cost function for pairwise clustering that primarily avoids grouping dissimilar objects into one cluster is defined by

$$H^{\mathrm{pc}}(m;\ \mathscr{D}) = \sum_{\nu \leq k} \left( |\mathscr{G}_\nu| \sum_{(i,j) \in \varepsilon_{\nu\nu}} \frac{D_{ij}}{|\varepsilon_{\nu\nu}|} \right) \tag{3}$$

Preferred clusters are subsets of objects with minimal average intracluster dissimilarities, weighted by the cluster size $|\mathscr{G}_\nu|$. This cost function has the remarkable and, for applications, extremely valuable invariance that the assignments do not change if all dissimilarities are changed by the same off-diagonal offset $D_0$; i.e., arg $\min_m H^{\mathrm{pc}}(m; D) = \arg\min_m H^{\mathrm{pc}}(m; \tilde{D})$, with $\tilde{D} = D_{ij} + D_0(1 - \delta_{ij})$.

An alternative to the pairwise clustering cost function in Equation 3 has been proposed by Shi and Malik (2000) in the context of image segmentation. The clustering criterion

$$H^{\mathrm{nc}}(m;\ \mathscr{D}) = \sum_{\nu \leq k} \left( \frac{\displaystyle\sum_{(i,j) \in \varepsilon_{\nu\nu}} D_{ij}}{\displaystyle\sum_{(i,j) \in \varepsilon : i \in \mathscr{G}_\nu \vee j \in \mathscr{G}_\nu} D_{ij}} \right) \tag{4}$$

weighs the intracluster compactness with the integrated dissimilarities between objects $i \in \mathscr{G}_\nu \vee j \in \mathscr{G}_\nu$ in cluster $\nu$ and all other objects. Good approximate solutions to Equation 4 can be found by spectral graph theory. Originally, this method was developed for similarity data $S_{ij} = \exp(-D_{ij}/\Delta)$ and it was formulated as a minimization of the normalized cut of similarities between two clusters.

A pairwise clustering principle based on local object similarity rather than global cluster compactness has been suggested in Blatt, Wiseman, and Domany (1997) exploiting an analogy to granular magnets. Locality is achieved by the exponential transformation $S_{ij} = \exp(-D_{ij}/\Delta)$, which effectively decouples objects with $D_{ij} \gg \Delta$. The granular magnet concept has been abstracted to the method of typical (multiway) cuts (Gdalyahu, Weinshall, and Werman, 2001), which produces randomized approximations to clustering solutions with small intercluster similarity. The costs for this percolation-type model is given by

$$H^{\mathrm{mc}}(m;\ S) = \sum_{(i,j) \in \varepsilon} S_{ij} - \sum_{\nu \leq k} \sum_{(i,j) \in \varepsilon_{\nu\nu}} S_{ij} = \sum_{\nu \leq k} \sum_{\substack{\mu \leq k \\ \mu \neq \nu}} \sum_{(i,j) \in \varepsilon_{\nu\nu}} S_{ij} \tag{5}$$

The identity in Equation 5 relates similarity to neighbors of the same cluster to the combinatorial optimization problem to find a multicut in the graph $(\nu, \varepsilon)$. $H^{\mathrm{mc}}(m; S)$ stresses local consistency in clustering, whereas $H^{\mathrm{pc}}(m; D)$ emphasizes global compactness of clusters. The granular magnet clustering model generalizes the nearest neighbor linkage method, a popular graph theoretic clustering technique (Duda, Hart, and Stork, 2001).

### *Topological and Hierarchical Clustering*

The four proposed clustering criteria for vectorial, histogram, and proximity data evaluate cluster configurations in a permutation-invariant way. In neurobiology, a topological organization of neurons is often imposed to ensure that nearby neurons process related information in feature space. Respective network structures are known as Self-Organizing Feature Maps (q.v.). All the introduced clustering principles (Equations 1–5) can be generalized to topology-preserving clustering methods by replacing the unique assignments $\mathbf{o} \mapsto m(\mathbf{o})$ with probabilistic assignments $\mathbf{o} \mapsto \alpha$ with probability $\mathbf{T}_{m(\mathbf{o}),\alpha}$. The cost function for clustering vectorial data translates to

$$H^{\text{som}}(m;\ \mathscr{X}) = \sum_{i \le n} \sum_{\nu \le k} \mathbf{T}_{m(i),\nu} \|\mathbf{x}_i - \mathbf{y}_\nu\|^2 \qquad (6)$$

In case that $\mathbf{T}$ defines a $\tilde{d}$-dimensional neighborhood system, the costs in Equation 6 prefer arrangements of centroids on a $\tilde{d}$-dimensional smooth manifold in the $d$-dimensional feature space. The additional quantization errors inflicted by the probabilistic assignments are also known in the information theory literature (Cover and Thomas, 1991) as index confusion $\nu \to \alpha$ due to channel noise. The same principle can be formulated for histogram clustering and for pairwise clustering.

In many application areas a hierarchical partitioning of the object space is favored over unconstraint or topological partitions. The reasons for this preference either are computational, since tree-like structures support rapid data access and efficient algorithmics, or else the data source is hypothesized to be of a tree-like nature. The assignments of objects to clusters have to observe an inclusion principle (Jain and Dubes, 1988) that ensures that subpartitions at a fine level observe the partitions higher up in the tree. It is important to include information of the tree topology in the clustering criterion. Cluster trees resemble decision trees in classification, and they can be naturally implemented in biological brains by layered neural networks.

## Optimization

The clustering cost functions can be minimized by various deterministic or stochastic methods from combinatorial and continuous optimization. A widely used class of methods estimates the clustering parameters in an iterative way by first keeping the continuous cluster parameters (centroids, prototype histograms) fixed and optimizing the assignments. In a second step, the continuous parameters are calculated from the new assignments.

### *The* k*-Means Algorithm*

A well-known algorithm for on-line estimation of prototypes in central clustering is the $k$-means algorithm (MacQueen, 1967). The $k$ means $\{\mathbf{y}_\nu : 1 \le \nu \le k\}$ are initialized by the first $k$ data points $\{\mathbf{x}_i : 1 \le i \le k\}$. A new data vector $\mathbf{x}_{t+1}$, $t \ge k$ is assigned to the closest mean $\mathbf{y}_\alpha$ according to the nearest neighbor rule

$$m(t + 1) = \arg\min_\nu \|\mathbf{x}_{t+1} - \mathbf{y}_\nu\| \qquad (7)$$

with ties being handled appropriately. The new mean vector is adjusted in response to data vector $\mathbf{x}_{t+1}$ according to the learning rule

$$\mathbf{y}^{(t+1)}_{m(t+1)} = \mathbf{y}^{(t)}_{m(t+1)} + \frac{1}{|\mathscr{G}_{m(t+1)}|} (\mathbf{x}_{t+1} - \mathbf{y}^{(t)}_{m(t+1)}) \qquad (8)$$

All other means $\mathbf{y}_\nu$, $\nu \ne m(t + 1)$ remain unchanged. The learning rule in Equation 8 adjusts the closest mean $\mathbf{y}_\alpha$ proportional to the deviation $(\mathbf{x}_{t+1} - \mathbf{y}^{(t)}_\alpha)$ normalized by the number of data vectors that have already been assigned to this cluster center.

### *Probabilistic Partitioning Algorithms*

The class of stochastic optimization algorithms with Simulated Annealing and Boltzmann Machines (q.v.) as the most prominent techniques plays an eminent role in pattern recognition. The variables of the optimization problem, e.g., the assignments in clustering, are treated as random variables of a stochastic (Markovian) process. The Markov chain Monte Carlo algorithm samples from a set of data partitionings, all of which are considered to be compatible with the data. The size of this set has to be controlled by a cluster validation scheme. Robust clustering methods are derived from the maximum entropy principle, which states that assignments are distributed according to the Gibbs distribution

$$\mathbf{P}(m;\ \mathscr{X}) = \exp(-(H^{\text{cc}}(m;\ \mathscr{X}) - F)/T), \qquad (9)$$

$$F = -T \log \sum_{m \in \mathscr{M}} \exp(-H^{\text{cc}}(m;\ \mathscr{X})/T) \qquad (10)$$

The "computational temperature" $T$ serves as a Lagrange parameter for the expected costs. The free energy $F$ in Equation 10 can be interpreted as a smoothed version of the original cost function $H^{\text{cc}}$ (Rose, Gurewitz, and Fox 1990). The cost function $H^{\text{cc}}$, which is linear in the assignments, yields a factorized Gibbs distribution

$$\mathbf{P}(m;\ \mathscr{X}) = \prod_{i \le n} \frac{\exp(-D_{i,m(i)}/T)}{\sum_{\mu \le k} \exp\ (-D_{i,\mu}/T)} = \prod_{i \le n} \mathbf{P}_{i,m(i)} \qquad (11)$$

$$\mathbf{P}_{i,\nu} := \frac{\exp(-D_{i,\nu}/T)}{\sum_{\mu \le k} \exp(-D_{i,\mu}/T)}, \quad \forall \nu \in \{1, \ldots, k\} \qquad (12)$$

$\mathbf{P}_{i,\nu}$ denote expectation values of assignments. The centroids have to maximize the entropy of the Gibbs distribution, which yields the centroid constraint

$$0 = \sum_{i \le n} \mathbf{P}_{i,\nu} \frac{\partial}{\partial \mathbf{y}_\nu} D_{i,\nu}, \quad \forall \nu \in \{1, \ldots, k\} \qquad (13)$$

The Gibbs distribution in Equation 11 can also be interpreted as the complete data likelihood for mixture models with parameters $\mathscr{Y}$. Basically, the Gibbs distribution of the $k$ clusters describes a mixture model with equal priors for each component and equal, isotropic covariances. The assignments $m(i)$ and their expectations $\mathbf{P}_{i,\nu}$ correspond to the unobservable variables in mixture models and the component densities, respectively. Algorithmically, the centroids and the expected assignments are estimated in an iterative fashion by solving the centroid Equation 13 for fixed expected assignments and, subsequently, inserting the centroids in Equation 12 (Rose et al., 1990; Buhmann and Kühnel, 1993).

The temperature parameter $T$ controls the uncertainty of the clustering problem; i.e., in the limit $T \to 0$, the solution of Equation 12 corresponds to hard clustering with Boolean assignments $\mathbf{P}_{i,\nu} \in \{0, 1\}$ of a data vector $\mathbf{x}_i$ to the closest cluster center $\mathbf{y}_\nu$. Large temperature represents the uncertain limit with partial assignments of data vectors to several clusters ($0 \le \mathbf{P}_{i,\nu} \le 1$). The reader should note that the iterative search for solutions of Equations 12 and 13 is guaranteed to yield a local minimum of the costs that, however, could be far from the global minimum.

### *Gaussian Mixture Models*

*Natural* clusters in data sets are modeled by a mixture of stochastic data sources (McLachlan and Basford, 1988). Each component of this mixture, a data cluster, is described by a univariate probability density that is the stochastic model for an individual cluster. The sum of all component densities forms the probability density of the mixture model

$$P(\mathbf{x};\ \Theta) = \sum_{v \le k} \pi_v p(\mathbf{x};\ \theta_v) \tag{14}$$

Let us assume that the functional form of the probability density $P(\mathbf{x};\ \Theta)$ is completely known up to a finite and presumably small number of parameters $\Theta = (\theta_1, \ldots, \theta_k)$. For the most common case of Gaussian mixtures, the parameters $\theta_v = (\mathbf{y}_v, \Sigma_v)$ are the coordinates of the mean vector and the covariance matrix. The a priori probability $\pi_v$ of the component $v$, which is assumed to be known, is called the mixing parameter.

Adopting this framework of parametric statistics, the detection of data clusters reduces mathematically to the problem of how to estimate the parameters $\Theta$ of the probability density for a given mixture model. A powerful statistical technique for finding mixture parameters is the maximum likelihood method (Duda et al., 2001); i.e., one maximizes the probability of the independently, identically distributed data set $\{\mathbf{x}_i : 1 \le i \le n\}$ given a particular mixture model. For analytical purposes it is more convenient to maximize the log-likelihood

$$L(\Theta) = \sum_{i \le n} \log\ P(\mathbf{x}_i;\ \Theta) = \sum_{i \le n} \log \left( \sum_{v \le k} p(\mathbf{x}_i;\ \theta_v)\pi_v \right) \tag{15}$$

which yields the same maximum likelihood parameters $\Theta$. The straightforward maximization of Equation 15 results in a system of transcendental equations with multiple roots. The ambiguity in the solutions originates from the lack of knowledge of which mixture component $v$ has generated a specific data vector $\mathbf{x}_i$, and therefore which parameter $\theta_v$ should be influenced by $\mathbf{x}_i$ in the estimation procedure.

An efficient solution to overcome the computational problem of how to estimate parameters of mixture models with the maximum likelihood method is provided by the Expectation-Maximization (EM) algorithm (Dempster, Laird, and Rubin, 1977). The EM algorithm estimates the unobservable assignments in a first step. The estimates are denoted by $\mathbf{P}_{i,v}$. On the basis of these maximum likelihood estimates $\{\mathbf{P}_{i,v}\}$, the parameters $\Theta$ are calculated in a second step. An iteration of these two steps renders the following algorithm for Gaussian mixtures:

- *E-step*: The expectation value of the complete data log-likelihood is calculated conditioned on the observed data $\{\mathbf{x}_i\}$ and the parameter estimates $\hat{\Theta}$. This yields the expected assignments of data to mixture components, i.e.,

$$\begin{aligned} \mathbf{P}_{i,\alpha}^{(t+1)} &= \frac{p(\mathbf{x}_i;\ \hat{\mathbf{y}}_\alpha^{(t)},\ \hat{\Sigma}_\alpha^{(t)})\pi_\alpha}{\sum\limits_{v \le k} p(\mathbf{x}_i | \hat{\mathbf{y}}_v^{(t)},\ \hat{\Sigma}_v^{(t)})\pi_v} \\ &= \frac{\pi_\alpha |\hat{\Sigma}_\alpha^{(t)}|^{-1/2} \exp(-½\ (\mathbf{x}_i - \hat{\mathbf{y}}_\alpha^{(t)})^T (\hat{\Sigma}_\alpha^{(t)})^{-1} (\mathbf{x}_i - \hat{\mathbf{y}}_\alpha^{(t)}))}{\sum\limits_{v \le k} \pi_v |\hat{\Sigma}_v^{(t)}|^{-1/2} \exp(-½\ (\mathbf{x}_i - \hat{\mathbf{y}}_v^{(t)})^T (\hat{\Sigma}_v^{(t)})^{-1} (\mathbf{x}_i - \hat{\mathbf{y}}_v^{(t)}))} \end{aligned} \tag{16}$$

- *M-step*: The likelihood maximization step estimates the mixture parameters, e.g., centers and variances of the Gaussians (Duda et al., 2001, p. 89):

$$\hat{\mathbf{y}}_\alpha^{(t+1)} = \frac{\sum\limits_{i \le n} \mathbf{P}_{i,\alpha}^{(t+1)} \mathbf{x}_i}{\sum\limits_{i \le n} \mathbf{P}_{i,\alpha}^{(t+1)}}, \tag{17}$$

$$\hat{\Sigma}_\alpha^{(t+1)} = \frac{1}{\sum\limits_{i \le n} \mathbf{P}_{i,\alpha}^{(t+1)}} \sum_{i \le n} \mathbf{P}_{i,\alpha}^{(t+1)} (\mathbf{x}_i - \hat{\mathbf{y}}_\alpha^{(t+1)})(\mathbf{x}_i - \hat{\mathbf{y}}_\alpha^{(t+1)})^T \tag{18}$$

Note that Equations 17 and 18 have a unique solution after the expected assignments $\{\mathbf{P}_{i,\alpha}^{(t+1)}\}$ have been estimated. The monotonic increase in the likelihood up to a local maximum guarantees the convergence of the EM algorithm.

### *Mean Fields for Pairwise Clustering*

Minimization of the quadratic cost function formulated in Equation 3 turns out to be algorithmically complicated because of pairwise, potentially conflicting correlations between assignments. The deterministic annealing technique, which produces robust reestimation equations for central clustering in the maximum entropy framework, is not directly applicable to pairwise clustering since there is no analytical technique known to capture correlations between assignments $m(i)$ and $m(j)$ in an exact way. Mean field annealing, however, approximates the intractable Gibbs distribution by the best factorial distribution. The influence of the random variables $m(j)$, $j \ne i$, on $m(i)$ is treated by a mean field that measures the average feedback on $m(i)$. Mathematically, the approximation problem to calculate the Gibbs distribution is replaced by a minimization of the Kullback-Leibler divergence between the approximating factorial distribution and the Gibbs distribution (Hofmann and Buhmann, 1997). A maximum entropy estimate of the mean fields $h_{iv}$ yields the transcendental equations

$$\mathbf{P}_{i,v} = \frac{\exp(-h_{iv}/T)}{\sum\limits_{\mu \le k} \exp(-h_{i\mu}/T)} \tag{19}$$

$$h_{iv} = \frac{1}{n\pi_v} \sum_{(i,j) \in \varepsilon} \mathbf{P}_{j,v} \left( D_{ij} - \frac{1}{2n\pi_v} \sum_{(j,r) \in \varepsilon} \mathbf{P}_{r,v} D_{jr} \right) \tag{20}$$

The variables $h_{iv}$ depend on the given distance matrix $D_{ik}$, the averaged assignment variables $\{\mathbf{P}_{i,v}\}$, and the cluster weights $\pi_v := \Sigma_{i \le n} \mathbf{P}_{i,v}$. Equation 20 suggests an algorithm for learning the optimized cluster assignments that resembles the EM algorithm. In the E-step, the assignments $\{\mathbf{P}_{i,v}\}$ are estimates for given $\{h_{iv}\}$. In the M-step, the $\{h_{i,v}\}$ are reestimated on the basis of new assignment estimates. This iterative algorithm converges to a consistent solution of assignments for the pairwise data clustering problem that locally maximizes the entropy.

## Cluster Validation

One of the most important problems in data analysis, besides proper modeling, is to test solutions of pattern recognition problems for robustness. The influence of noise in the data on the estimates of cluster centers in central clustering should be minimal in the large data limit. The data analyst, therefore, requests that the clustering solution should be similar if the clustering algorithm partitions a second data set from the same data source. This robustness requirement limits the number of clusters that can be reliably inferred from the data. If too many clusters are supposed to be estimated, then the noise will strongly influence the values of the clustering parameters.

The field of statistical learning theory addresses robustness questions and model complexity issues in the context of supervised learning, in particular for classification and regression. The same trade-off between the complexity of the hypothesis class and the amount of data limits the inference precision in unsupervised learning tasks as data clustering. Theoretical results have to estimate the probability of large deviations between solutions found on two different sample sets. Assume that the cluster solution is quantified by the costs $H(m;\ \mathscr{X})$ and that we have two data sets, $\mathscr{X}^{(1)}$ and $\mathscr{X}^{(2)}$. The costs $H(m;\ \mathscr{X})$ might have the combinatorial forms of Equations 1–5, or they could be the log-likelihood (Equation 15) for density estimation. The optimal cluster assignments with respect to the two data sets are $m^{(1)}$ and $m^{(2)}$. A robustness criterion based on large deviation theory should bound from above the probability

$$\mathbf{P}\{H(m^{(1)};\ \mathscr{X}^{(2)}) - H(m^{(2)};\ \mathscr{X}^{(2)}) > \varepsilon\} \leq \delta \qquad (21)$$

i.e., we require that the optimal solution on the first data set also perform well on a second data set $\mathscr{X}^{(2)}$ with high probability $1 - \delta$. Statistical learning theory relates this deviation to the complexity of the solution space $\mathcal{M}$. Algorithmically, such a complexity control can be implemented by cross-validation, where the algorithm stops to further improve the solution in the optimization process when the costs on the second sample set increase again. This procedure tries to avoid overfitting of model parameters to the data.

Classical strategies to validate clustering solutions are based on Bayesian model selection. The number of modes in mixture model inference can be limited by regularization, e.g., by the minimum description length principle (Duda et al., 2001), which implements the Occam's razor principle for inference (see MINIMUM DESCRIPTION LENGTH ANALYSIS). Alternatives to this criterion are the Bayesian information criterion (BIC), Akaike's information criterion (AIC), or the network information criterion (NIC) (Ripley, 1996), all of which penalize the complexity of the model, e.g., the number of clusters and their cluster parameters. These criteria are asymptotic ($n \rightarrow \infty$) in nature.

## Discussion

Data clustering as one of the most fundamental information processing procedure to extract symbolic information from subsymbolic data follows the four design steps of pattern recognition: (1) data representation, (2) structure definition, (3) structure optimization, and (4) structure validation. It is still very speculative how these mathematical structures are implemented in biological brains. Neurons with localized receptive fields might provide the neural correlate of centroids in Euclidian feature spaces. Relational data might be represented by neurons that function as comparators. The stochastic dynamics of neurons naturally introduces randomness in the search process for compact cluster structures, and thereby introduces robustness against fluctuations in the data analysis process.

# Databases for Neuroscience

*Jeffrey S. Grethe*

## Introduction

The advancement of science depends heavily on researchers' ability to share, exchange, and organize large quantities of heterogeneous data in an efficient manner. This is especially true for researchers who are involved in the construction of simulations of the nervous system. Data spanning a wide range of disciplines (e.g., anatomy, physiology, behavior) are needed to conceptualize, design, and validate such simulations. The need for informatics research related to databases is highlighted by the increasingly important role it has played in various scientific communities to help achieve their goals. This is most evident in the molecular biology community (Persidis, 1999; Roos, 2001), where since the beginning of the 1980s, a large collection of specialized data repositories has been constructed. As part of these developments, the National Center for Biotechnology Information (http://www.ncbi.nlm.gov) was established to develop and maintain public databases and tools for searching and analyzing genomic information. These tools have resulted in incredible scientific advancement within the genomic community, most notably the dissemination of information concerning the human genome (http://www.ncbi.nlm.nih.gov/genome/guide/human/). The success of the Human Genome Project has influenced the application of informatics research to other disciplines, namely, neuroscience.

The amount of neuroscience information being collected is increasing dramatically. This information explosion makes it difficult to search and organize basic research data (Huerta, Koslow, and Leshner, 1993). To that end, the Human Brain Project (http://neuroinformatics.nih.gov) was initiated in September 1993 to provide informatics tools to help manage this data explosion. A main component of the initiative is to provide neuroscientists access to information at all levels of integration through a collection of network-accessible databases. Just as bioinformatics proved to be indispensable for the growth of the molecular biology community, neuroinformatics will become a key component in future neuroscience research. However, the neuroscience community faces some unique challenges.

Neuroscience data are extremely varied and complex. A myriad of structured, textual, graphical, and other information captures experimental results, hypotheses, scientific assumptions, conclusions, formal presentations of theories, and observations. This poses a particularly interesting and important problem for informatics research: to build on state-of-the-art techniques and mechanisms to accommodate the characteristically distinct needs of neuroscience, develop solutions to those problems, and transfer these results to the neuroscience community. Over the last decade, neuroinformatics research has begun to provide mechanisms for the storage of data from varied neuroscientific disciplines (see Table 1 for an overview of database projects). Owing to the great diversity of the databases being developed, we cannot discuss each of these database projects in detail here. Therefore, this article presents and discusses several issues regarding the development of databases for the neuroscience community (for other reviews, see Chicurel, 2000; Kötter, 2001).

## Issues in the Development of Neuroscience Databases

### *Diversity of Neuroscience Data*

The interplay of anatomical structure, biochemical processes, and electrical signals gives rise to natural and disease processes. To investigate the underlying mechanisms responsible for these processes, information from varied sources must be integrated. For example, the search for clinical treatments for Parkinson's disease requires information from a wide variety of sources. Information concerning neurotransmitters and receptors, anatomical pathways, neuronal properties, and the information processing that occurs across areas of the basal ganglia must be synthesized and related to clinical, pharmacological, and genetic information. As this example illustrates, neuroscience is an extremely diverse field involving many disciplines. In addition to its diversity, the information of interest to neuroscience researchers is archived throughout the world and stored in a myriad of formats that are accessible through a variety of interfaces and retrieval languages. The data sources can include conventional databases that are accessed through a database query language to web archives accessed by a web browser. Compounding the problem for the neurosciences is that unlike the genomic community, in which data tend to be stored in a few large databases, the neurosciences community will have to be able to access a large, heterogeneous collection of databases.

To be able to integrate such diverse sources, the various communities within the neurosciences must begin to develop standards for their community's data. Currently, in these communities, there exist many different and incompatible data formats that do not allow for the free exchange of data. In addition to needing standards for the raw data themselves, these communities must also develop standards for the description of the actual data (i.e., a formalized description of the meta-data). A possible solution to this problem can be found in the adoption of extensible markup language (XML) technologies. XML (Bosak and Bray, 1999) is a markup language that allows one to describe semistructured representations of information. More specifically, it allows one to annotate data with semantic tags that describe the structure and content of the data. For example, in the modeling community, the Neural Open Markup Language (NeuroML) (Goddard et al., 2001) is being developed to allow researchers to describe models at varying levels of complexity, from cell membranes to large-scale neural networks. In addition to the ability to exchange data within a community, integration of data from diverse biological disciplines will be needed. In contrast to integration problems found in typical database federations (i.e., different representations of the same information), the neurosciences must be able to integrate data from sources with heterogeneous data and representations. One possible solution for this type of integration has been to extend the conventional wrapper-mediator architecture with domain-specific knowledge (Gupta, Ludäscher, and Martone, 2000).

### *Data Representation*

Data representation is a critical issue for many of the database projects that are currently under way in the neurosciences. One of the first and most central issues in representing data from the brain is the manner in which one describes the fundamental objects of neuroscience. As an example, one need only to look at the classification of brain areas. Currently, there are a number of classification schemes that are not completely compatible. The problem becomes even worse when one considers the difficulty in classifying analogous brain regions across species. How, then, is one supposed to represent location of brain data within a database? Just specifying the textual location might not be sufficient. One partial solution to this problem would be to reference all locations as three-dimensional coordinates within a reference coordinate system (Mazziotta et al., 1995).

The complexity of the experimental paradigms is another critical issue for the representation of neuroscience data. The field of neuroscience is evolving rapidly, and the diversity of these descriptors does not allow one to know a priori what information will need to be stored for future experiments. To address this problem, many database projects stress the importance of an extensible foundation (Nadkarni et al., 1999; Arbib and Grethe, 2001; Gardner et al., 2001) that allows for varying information to be archived in a structured fashion.

### *User Access*

For researchers to be able to navigate and integrate all the information to be provided, user interfaces need to be developed that will give the researcher a seamlessly integrated view of the information concerning a particular topic. These interfaces for neuroscience information would provide a number of novel opportunities that are not available when access is provided only to individual pieces of information. However, the vast amount of information available to researchers over the Internet poses several issues when one attempts to integrate this information. These issues include knowing where the relevant information is located, being able to access that information, integrating and transforming the data into a unified framework, and methods for visualizing the data in an appropriate way.

It is important to realize that the multidisciplinary nature of neuroscience dictates an important additional requirement for these interfaces. Researchers who wish to examine data related to a specific topic will not be experts in every aspect of that topic. For example, a neurochemist studying the kinetics and binding properties of various neurotransmitter receptors might not be aware of the latest clinical information regarding the neurotransmitter in question. Using structured review and summary information as a framework for the presentation of data from varied sources will be imperative when data are to be provided to such a diverse user community.

### *A Case Study*

With support from the National Science Foundation, the National Institutes of Health, and the Keck Foundation, the fMRI Data Cen-

**Table 1.** Databases Being Developed for the Neurosciences. This table provides a list of databases covering a wide range of subdisciplines within the neurosciences. All databases listed include a brief description, a URL, and a notation as to what forms of data the database is primarily concerned with.

| Database | Description | Data |
|---|---|---|
| 3D Neuron Centered Database<br>**http://www-ncmir.ucsd.edu/NCDB/** | System integrating three-dimensional cellular microscopic data characterizing the realistic locations, surface morphology, and cellular constituents | Cellular, morphology |
| Brain Image Database (BRAID)<br>**http://braid.rad.jhu.edu/** | Archive of normalized spatial and functional neuroimaging data with an analytical query mechanism | Neuroimaging |
| BrainInfo<br>**http://braininfo.rprc.washington.edu/** | Helps to identify structures in the brain and provides additional information about these structures | Anatomy |
| BrainMap<br>**http://ric.uthscsa.edu/projects/brainmap.html** | Database for meta-analysis of author-supplied activations from select human functional brain-mapping literature | Neuroimaging |

ter (Van Horn et al., 2001) was established in the autumn of 1999 with the objective of creating a mechanism by which members of the neuroscientific community may more easily share functional neuroimaging data. By building a publicly accessible repository of raw data from peer-reviewed studies, the Data Center aims to create a successful environment for the sharing of neuroimaging data in the neurosciences. By increasing the number of scientists who can examine, consider, analyze, and assess the neuroimaging data that have already been collected and published, the center hopes to speed the progress of understanding cognitive processes, the neural substrates that underlie them, and the diseases that affect them. The development of such an archive for neuroimaging data posed certain challenges.

The most critical issue that needed to be addressed in the building of the Data Center was the representation of the data to be archived. In and of itself, raw functional imaging data may not be particularly useful. Proper analysis requires at least knowledge of how the data were acquired. Therefore, in addition to the data sets themselves, the Data Center must store all technical descriptions of the data necessary for someone other than the study's authors to accurately reproduce and interpret the original results. This includes both the information regarding the scanning parameters and the experimental protocols (information and timing of the stimuli) presented to the subject during the collection of the data. The Data Center cannot know a priori all the descriptors required for studies being submitted and therefore relies on an extensible framework for the storage of the data.

The descriptors that are used in describing a neuroimaging experiment constitute one type of meta-data (i.e., data that contain information about the data). These meta-data will allow the data to be organized in a suitable fashion for keyword-based queries. However, it is also important to be able to offer the researcher the ability to query the content of the imaging data directly. Querying the raw functional data directly is not feasible, owing to the amount of imaging data present in the archive (e.g., studies archived at the Data Center can be on the order of hundreds of megabytes to tens of gigabytes). To be able to perform content-based queries on the image data, concise meta-data need to be generated to describe the individual images and time series of images. The meta-data can then be used as a means to quickly find studies of interest based on features derived from the data themselves. Researchers may then further examine these data using more rigorous analysis methods.

Another critical challenge for the Data Center was the protection of human subjects data. This problem is not unique to the Data Center; any database archiving data from human subjects must comply with U.S. government regulations on the protection of such data. To that end, the Data Center makes every reasonable effort to ensure that all data included within the Data Center's archive are anonymized so that data being used by researchers cannot be linked back to the individual subjects who provided it. Neuroimaging data are also unique in that the data themselves can be used as an identifier. It is possible to reconstruct recognizable images of a subject's face from high-resolution structural magnetic resonance data. To that end, all structural data must be stripped (i.e., removal of facial features) before being included in the data archive.

Currently, the Data Center hosts a web site where authors from around the world have been submitting entire, raw data sets from peer-reviewed journals. Visitors to the Data Center's web site may search its holdings via a MEDLINE-inspired query interface. This allows researchers to easily access and search the Data Center's resources without the need to learn a new interface and query language. A researcher who finds data sets of interest can request that they be shipped to him or her on either CD (at no charge) or digital tape. As of July 2002, the Data Center had shipped over 400 data requests to researchers in over 35 countries.

By providing raw neuroimaging data, tools for screening the details of the experimental and scanner protocols, as well as techniques for data discovery and mining, the Data Center will give researchers access to a much larger pool of data than can be found in any single fMRI study. Thus, dynamic analyses across data sets and experiments may be performed, new statistical techniques can be developed, improved techniques for image processing can be investigated, and novel neuroscientific questions may be explored.

## Conclusion

Providing scientists access to an ever increasing collection of information in a coherent framework is vital to the future advancement of science. Already in 1985, a National Academy of Sciences report (Morowitz, 1985) suggested that biological research had reached a point at which "new generalizations and higher order biological laws are being approached but may be obscured by the simple mass of data." It is hoped that the continued progress of neuroinformatics in the development of databases and tools for neuroscience will help researchers navigate the masses of data and information that are being generated. In addition to the development of tools for the community, the success of neuroinformatics will depend on how these technologies are accepted by the community at large. The future success of neuroscience databases and neuroinformatics in general will require the neuroscience community to make a paradigm shift similar to those that have already taken place in the molecular biology community.

# Decision Support Systems and Expert Systems

*Nikola Kasabov*

## Introduction

The complexity and the dynamics of many real-world problems, such as decision making and the prediction of economic and financial indexes, decision making in medicine, knowledge discovery in bioinformatics, adaptive intelligent control of industrial processes, on-line decision making based on a large amount of continuous and dynamically changing information on the World Wide Web, and many other problems, impose certain requirements on the information systems, methods, and tools used for this purpose. The information systems and tools must:

- Deal with different types of data and knowledge.
- Adjust incrementally to dynamic changes in the operating environment, accommodating new data and introducing new variables and features as needed without the requirement of redesigning or retraining the whole system. Such adaptation may have to occur in an on-line, real-time mode.
- Update the system's knowledge in a dynamic way.
- Explain in an appropriate way what knowledge is contained in the system, or what knowledge has been learned during the system's operation.

The area of information science and artificial intelligence that is concerned with these issues is called *decision support systems*. A decision support system is an information system that helps humans make a decision about a given problem, under given circumstances and constraints. A decision-making system is a system that makes final decisions and takes actions. Some examples are automated trading systems on the Internet, or systems that grant loans through electronic submissions.

*Expert systems* belong to the subject area, as they are information systems that contain expert knowledge about a particular problem and perform inference when new data are entered that may be partial or inexact. They provide a solution that is expected to be similar to the solution provided by experts in the field. An expert system usually consists of several parts: (1) a knowledge base, where the expert knowledge resides; (2) a database, where historical and new data are stored; (3) an inference machine, which provides different types of inferences; (4) an efficient interface to users; (5) an explanation module, which provides an explanation of *how* and *why* a certain decision was recommended by the system; and (6) a module that learns and accumulates new knowledge, based on the system's operation and on new incoming data (see Duda and Shortliffe, 1983; Kasabov, 1996).

In the rest of this article we will use the collective term *decision system* to refer to either a decision support system, or a decision-making system, or the most sophisticated among them, the expert system.

Because decision systems deal with different types of data and problem knowledge in different modes (e.g., static versus dynamic data, fixed versus adaptive knowledge, off-line versus on-line mode, and so on), different methods and approaches have been used to build them. These methods include statistical methods (e.g., clustering, principal components analysis, hidden Markov models), mathematical modeling, finite automata, methods used in artificial intelligence (e.g., logic systems, rule-based systems, case-based reasoning, different types of neural networks), and hybrid methods that combine all of the foregoing (Duda and Shortliffe, 1983; Kasabov, 1996).

Decision systems, as presented here, are both human-oriented and human-like systems. The human brain is the ultimate decision system. This article discusses how neural networks, which are vague analogues of the human brain, can be employed in a decision system. We will be concerned with the human-like implementation of decision systems, which is one of their aspects. But the most important aspect of decision systems is their functionality. Because decision systems help humans in the decision process, they should be comprehensible by humans; they should incorporate elements of human-like thinking and human-like information and knowledge processing; and they must be human oriented.

Neural networks and connectionist-based systems have been applied in decision systems as either learning machines or knowledge representation machines, or both. The following listing enumerates some of these applications.

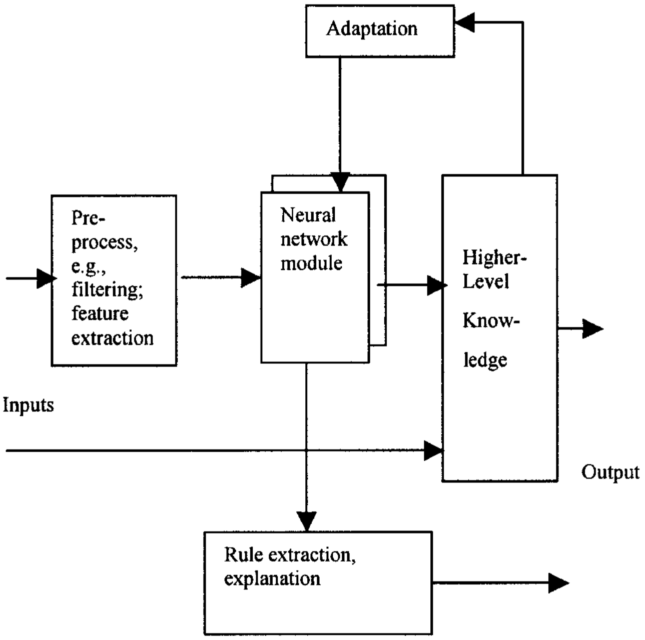
1. Neural networks are used as low-level data-processing and pattern-matching modules, while rule-based modules are used for higher-level decision making (Fu, 1989; Kasabov, 1990). Neural networks are incorporated as part of a production system or of a first-order logic system for decision support.
2. A base consisting of a fixed set of flat rules is incorporated into a connectionist structure with a predefined built-in inference mechanism (Gallant, 1993). No learning is applied.
3. All elements of a production system (e.g., rules, facts, inference machine) are represented in different connectionist modules (Touretzky and Hinton, 1988). No learning is applied on the structure.
4. Trainable knowledge-based neural networks that have fixed structures in terms of number of neurons and connections are used to accommodate both knowledge (rules) and data (Fu, 1989; Towell and Shavlik, 1993; Cloete and Zurada, 2000). Such knowledge-based neural networks are the fuzzy neural networks (Kasabov, 1996).
5. Knowledge-based neural networks that develop (evolve) their structure, their functionality, and their knowledge in time from incoming data, starting from an initial set of knowledge (if such is available), are used for building adaptive, incremental, online learning decision systems (Kasabov, 2002).

We will call a decision system that has neural network modules in its structure a *connectionist-based decision system* (CBDS). The following discussion presents different architectures and applications of such systems, starting with the general framework of a CBDS.

## General Framework of a Connectionist-Based Decision System

The framework of a CBDS is shown in Figure 1. It consists of the following parts:

- Preprocessing part (e.g., to perform data filtering and feature extraction).
- Neural network part, consisting of neural network modules that are trained on data and incorporate knowledge.
- Higher-level knowledge-based part (e.g., rules for producing final decisions).
- Adaptation part. This part evaluates the system's performance and makes changes to the system's structure and functionality. For example, output error can be used to adjust relevant neural network modules.



Adaptation

Neural network module
Higher-Level Know-ledge
Inputs
Output
Rule extraction, explanation

**Figure 1.** A framework of a connectionist-based decision system (CBDS).

- Rule extraction and explanation part. This part uses both extracted rules from the neural network modules and rules from the decision part to explain *what* the system "knows" about the problem it is designed to solve, and *why* a particular decision for a concrete input vector has been made.

Different types of neural networks (e.g., multiplayer perceptrons, self-organizing maps, radial basis functions, fuzzy neural networks) can be used as part of a CBDS. The most commonly used networks are the knowledge-based neural network.

## Knowledge-Based Neural Networks

Knowledge-based neural networks are prestructured neural networks that allow for data and knowledge manipulation, including learning from data, rule insertion, rule extraction, adaptation, and reasoning (Towell and Shavlik, 1993; Cloete and Zurada, 2000; Mitra and Hayshi, 2000). Knowledge-based neural networks have been developed either as a combination of symbolic AI systems and neural networks, or as a combination of fuzzy logic systems and neural networks, or as other hybrid systems.

The knowledge represented in knowledge-based neural networks is mainly in the form of different types of IF-THEN rules. Some of them are listed below:

1. Simple propositional rules (e.g., IF $x_1$ is A AND/OR $x_2$ is B, THEN $y$ is C, where A, B, and C are constants, variables, or symbols of true/false type) (Gallant, 1993).
2. Propositional rules with certainty factors (e.g., IF $x_1$ is A ($\mathrm{CF}_1$) AND $x_2$ is B ($\mathrm{CF}_2$), THEN $y$ is C ($\mathrm{CF}_c$)) (Fu, 1989; Touretzky and Hinton, 1988).
3. Zadeh-Mamdani fuzzy rules (e.g., IF $x_1$ is A AND $x_2$ is B, THEN $y$ is C, where A, B, and C are fuzzy values represented by their membership functions).
4. Takagi-Sugeno fuzzy rules (e.g., IF $x_1$ is A AND $x_2$ is B, THEN $y$ is $a.x_1 + b.x_2 + c$, where A, B, and C are fuzzy values and $a$, $b$, and $c$ are constants)
5. Rules that have associated degrees of importance and certainty degrees (e.g., IF $x_1$ is A ($\mathrm{DI}_1$) AND $x_2$ is B ($\mathrm{DI}_2$), THEN $y$ is C ($\mathrm{CF}_c$), where $\mathrm{DI}_1$ and $\mathrm{DI}_2$ represent the importance of each of the condition elements for the rule output, and the $\mathrm{CF}_c$ represents the strength of this rule) (Kasabov, 1996).
6. Rules that represent associations of clusters of data from the problem space (e.g., Rule $j$: IF [an input vector $x$ is in the input cluster defined by its center ($x_1$ is $\mathrm{A}_j$, to a membership degree of $\mathrm{MD}_{1j}$, AND $x_2$ is $\mathrm{B}_j$, to a membership degree of $\mathrm{MD}_{2j}$) and by its radius $\mathrm{R}_{j\text{-in}}$], THEN [$y$ is in the output cluster defined by its center ($y$ is C, to a membership degree of $\mathrm{MD}_c$) and by its radius $\mathrm{R}_{j\text{-out}}$, with Nex($j$) examples represented by this rule] (Kasabov, 2002).
7. Temporal rules (e.g., IF $x_1$ is present at a time moment $t_1$ (with a certainty degree and/or importance factor of $\mathrm{DI}_1$) AND $x_2$ is present at a time moment $t_2$ (with a certainty degree/importance factor $\mathrm{DI}_2$), THEN $y$ is C ($\mathrm{CF}_c$)).
8. Temporal, recurrent rules (e.g., IF $x_1$ is A($\mathrm{DI}_1$) AND $x_2$ is B($\mathrm{DI}_2$) AND $y$ at the time moment $(t - k)$ is C, THEN $y$ at a time moment $(t + n)$ is D($\mathrm{CF}_c$)).

There are several methods for rule extraction from a knowledge-based neural network. Three of them are explained below:

1. Activating a trained knowledge-based neural network on input data and observing the patterns of activation.
2. Rule extraction through analysis of the connections in a trained knowledge-based neural network.
3. Methods that combine 1 and 2.

In terms of applying knowledge-based neural networks to make new inferences, three types of methods can be used:

1. Rules extracted from a knowledge-based neural network are interpreted in another inference machine (e.g., fuzzy inference, production system).
2. The rule-based learning and reasoning modules constitute an integrated connectionist structure, so that reasoning is performed in the connectionist structure.
3. The two options above are combined in one CBDS.

In terms of learning and rule extraction in a knowledge-based neural network, we can differentiate the following cases: (1) off-line learning and static rule set extraction: first, learning is performed, and then rules are extracted, which is an one-off process; (2) on-line learning: rules can be extracted at any time during a continuous on-line learning process.

In terms of learning and optimization in a knowledge-based neural network, there are three cases: (1) globally optimized networks: for every new example all the connections change during learning; (2) locally optimized networks: for a new example only few connections change. Local optimization in a knowledge-based neural network would allow for adjusting the network to accommodate new data through tuning a small number of elements, and also for extracting locally meaningful rules. The rules can be tuned as the system works.

(3) Fuzzy neural networks are neural networks that can be interpreted in terms of fuzzy rules; neuro-fuzzy inference systems are fuzzy systems that can be structurally represented in a connectionist way (Kasabov, 1996; Cloete and Zurada, 2000). A review of neuro-fuzzy systems for rule generation has been published by Mitra and Hayashi (2000).

One example of a fuzzy neural network is shown in Figure 2 (Kasabov, 1996, 2002). The architecture consists of five layers of neurons and four layers of connections. The first layer of neurons receives the input information. The second layer calculates the

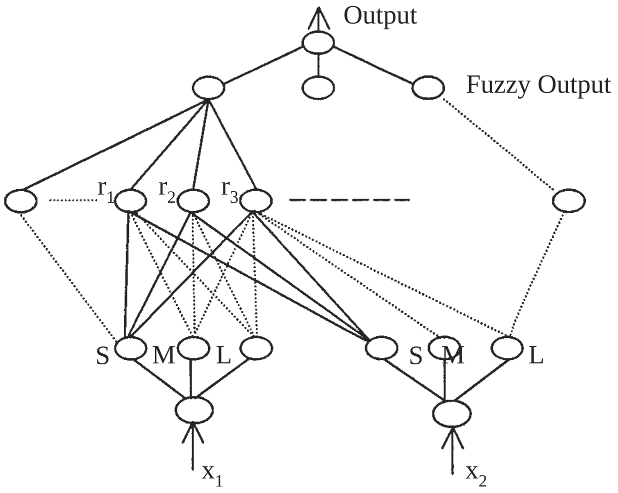

**Figure 2.** A simple neuro-fuzzy inference system with two inputs, three membership functions, and one output. Rule node $r_1$ can be represented as a rule: IF $x_1$ is S and $x_2$ is S, THEN output is S (certain statistical and linguistic parameters are attached).

fuzzy membership degrees to which the input values belong to predefined fuzzy membership functions, e.g., small, medium, or large. The membership functions can be kept fixed or can change during training. The third layer of neurons represents associations between input and output variables, or fuzzy rules. The fourth layer calculates the degrees to which output membership functions are matched by the input data, and the fifth layer does defuzzification and calculates values for the output variables.

## Static Versus Dynamic, Evolving CBDS

A static CBDS is trained on a data set, but it is not continuously updated and adjusted on any new data during its operation. It may be trained regularly on new data plus the previously used data so that the system learns the new data and maintains the previous information as well (the plasticity/stability dilemma). An example is given below.

*Example: A CBDS for mortgage approval.* A neural network is trained on data for decision making on mortgage approval (the data are also available from the web site http://divcom.otago.ac.nz/infosci/KEL/data). The following attributes are used: Input1: character (0—doubtful; 1—good); Input2: total asset; Input3: equity; Input4: mortgage loan; Input5: budget surplus; Input6: gross income; Input7: debt-servicing ratio; Input8: term of loan; Output: decision (disapprove; approve). In a particular experimental CBDS, neural networks are trained on ten different sets of data, each of them containing both positive (applications are approved) and negative (applications are rejected) examples. Each trained neural network is tested on another data set of positive and negative examples. The generalization error of the neural network is evaluated. Rules are extracted from the trained neural network that explains the decision process. The trained neural network is not incrementally trained on new data and it is used as part of a CBDS.

*Dynamic, evolving CBDS systems* evolve their structure, their functionality, and their knowledge from incoming data rather than having a predefined structure and a fixed set of rules. They learn and improve continuously over time, as is shown in Figure 3. An example of a set of methods that can be used to build an evolving CBDS is the evolving connectionist systems (ECOS) paradigm (Kasabov, 2002).

Evolving CBDS systems adapt to a changing environment, possibly in real time. They can learn in a "lifelong" learning mode, and they are able to explain what they have learned in terms of rules and other types of knowledge. An evolving CBDS would have a modular, open structure evolving over time. Initially, the neural network can be a mesh of nodes (neurons) with very few connections between them, predefined through prior knowledge or "genetic" information. An initial set of rules can be inserted in this structure. Gradually, through self-organization, the system becomes more and more "wired." The network learns different patterns (exemplars, prototypes) from the training examples. For example, in an ECOS architecture, a node is created and designated to represent an individual example if this example is significantly different from the previous ones (with the level of differentiation established through dynamically changing parameters). In addition to a growing procedure, a pruning procedure is defined. It allows for removing neurons and their corresponding connections that are not actively involved in the functioning of the ECOS, thus making space for new input patterns. Different modes of learning in ECOS are possible, among them are an active learning mode (learning is performed when a stimulus—input pattern—is presented and kept active) and a passive (e.g., sleep) learning mode (learning is performed when there is no input pattern presented at the input of the ECOS).

Adaptive CBDS usually operate as on-line decision systems that make decisions and adjust their knowledge through an incremental, continuous learning from incoming data. Such systems, for example, learn the dynamic changes in a stock index, or adjust their knowledge to include new gene discoveries in Bioinformatics.

*Example: On-line financial decision making based on on-line prediction of the MIB30 stock index.* Figure 4 shows the use of a neural network for on-line learning and prediction 5 days ahead of the moving average values of the MIB30 stock index (the Milan stock index). Here, an evolving fuzzy neural network (Kasabov, 2002) is used as the neural network. The neural network is trained on-line on consecutive data vectors. Inputs to the neural network are 5-day moving averages of the following variables: DJ($t$), DJ($t - 1$), MIB30($t$), MIB30($t - 1$), euro/US\$($t$), euro/US\$($t - 1$).

At any time of the functioning of the evolving fuzzy neural network, rules can be extracted. The rules represent the current asso-

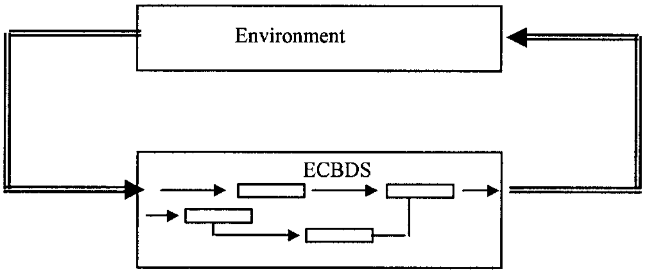

**Figure 3.** Adaptive, evolving CBDS learn their structure and functionality through interaction with the environment

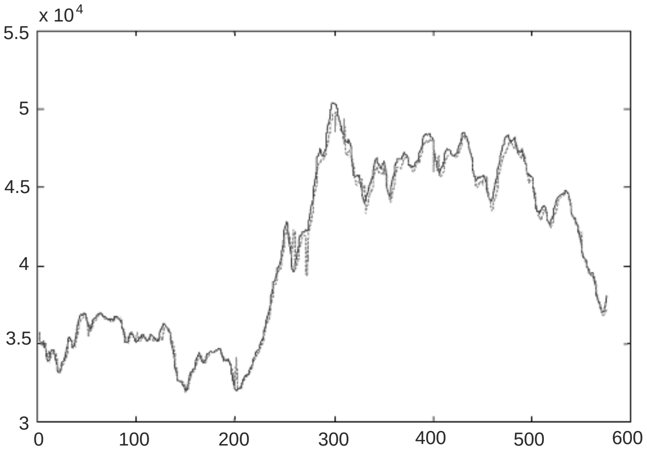

**Figure 4.** Adaptive CBDS in financial decision making, showing the process of on-line learning and prediction 5 days ahead of the MIB30 index. Chart shows the desired versus the predicted output value for 576 consecutive days.

ciation between the input variables and the output variable, as is illustrated in the rule below:

*Rule*: IF [DJ($t$) is (Medium 0.828) and DJ($t - 1$) is (Medium 0.840) and MIB30($t$) is (Low 0.885) and MIB30($t - 1$) is (Low 0.887)] (receptive field $=$ 0.808), THEN MIB30($t + 5$) will be (Low 0.852) (accommodated training examples 182 out of 576).

## Connectionist-Based Decision Systems in Economics and Finance

Beltraffi, Margarita, and Terna (1996) describe a variety of CBDS systems in the area of finance and economics. These include CBDS for solving problems such as stock trading, portfolio decision, exchange rate prediction, fraud detection, credit scoring, and many more. Some CBDS systems contain expert rules and make decisions similar to the decisions made by experts, as illustrated in the next example.

*Example: A CBDS for simulation and prediction of decisions made by the European Central Bank (ECB) on interest rate intervention (Rizzi et al., 2002).* The ECB meets regularly to make a decision on the interest rate for the European Union countries. Modeling this decision-making process is extremely difficult, as it requires both the comprehensive knowledge the ECB members have and fast adaptation to new situations. The system developed by Rizzi et al. (2002) consists of two parts. The first part has several neural networks that use six groups of economic indicators (total of 17 variables) and produces intermediate outputs that include the predicted values for some time series. These values, as well as other economic variables, are fed into a rule-based system that consitutes the second part of the system. The system finally suggests what ECB decisions on the interest rate might be expected at the next three consecutive meetings. Figure 5 shows some test results. The system learns and improves over time after each new datum is entered.

## Connectionist-Based Decision Systems in Bioinformatics

Processing a large amount of data, such as in medicine, biochemistry, or molecular biology, and making decisions based on this information is a task where CBDS systems have been successfully applied. Baldi and Brunak (2001) have demonstrated the application of machine learning techniques, including neural networks, to solving difficult problems, such as DNA promoter recognition, RNA splice junction identification, secondary structure protein prediction, and so on.

*Example: CBDS for RNA splice junction identification.* Figure 6 shows a simple three-layer perceptron neural network for identifying a biological feature, such as a splice junction from an input RNA sequence. The neural network has 60 inputs, which is the length of the RNA window sequence, five intermediate neurons (nodes), and one output neuron to encode for the feature (1—present, 0—not present). (The data set used for training is available at http://www.ics.uci.edu/~mlearn/MLRepository.html.) The splice junction predicted by the trained neural network from new input data should be further analyzed before a final decision is made.

An on-line training and prediction system for the same problem that is based on an evolving fuzzy neural network is available at http://divcom.otago.ac.nz/infosci/kel/CBIIS/GenIn/. The system can also extract rules, such as the rule shown below:

*Rule*: IF -----C--C-C-TCC-G--CTC-GT-C--GGTGAGTG--GGC---C---G-GG-C--CC- THEN [Junction Exon-Intron] Receptive field $=$ 0.216. Examples covered by the rule are 26 out of 1,000.

## Future Directions for Connectionist-Based Decision Systems

CBDS systems are a fast-growing area. New applications expected to be developed include new techniques for learning, data mining, and knowledge discovery, and practical applications in finance and economics, bioinformatics and life sciences, process control and manufacturing, medicine, and the social sciences.

# Dendritic Learning

*Bartlett W. Mel*

## Introduction

In most neurons of the vertebrate central nervous system (CNS), dendritic trees are the primary input surfaces of neurons, receiving thousands to hundreds of thousands of synaptic contacts from other neurons. During development, a period during which the brain is first “wired up,” the physical interface between axons and dendrites is extremely dynamic (Cline, 1999), involving large-scale growth, retraction, and remodeling of axonal and dendritic arbors on time scales of minutes to hours. In the adult nervous system, contrary to the connectionist view that neural plasticity is limited to the strengthening and weakening of existing synaptic connections, evidence suggests that physical remodeling of axons and dendrites, including the formation of new synaptic contacts and elimination of existing ones, continues to some degree throughout life (Klintsova and Greenough, 1999). Given that dendrites are highly complex structures both anatomically and physiologically and are the principal substrates for information processing within the neuron itself (Stuart, Spruston, and Häusser, 1999), the question arises as to the consequences of axodendritic structural plasticity for learning and memory. In other words, does experience-dependent remodeling of the physical interface between axons and dendrites have any special role in the long-term storage of information in the brain, beyond that associated with the establishment of the brain’s basic neuron-to-neuron wiring diagram?

A critical assumption of most models of learning and development holds that the *neuron* is the appropriate level of granularity for analysis, where the outcome of learning is expressed in terms of changes in the strengths of connections $w_{AB}$ between point neurons $A$ and $B$ (see HEBBIAN SYNAPTIC PLASTICITY). The enormous physical complexity of individual neurons compels us to consider other types of plasticity, however. For example, activity-dependent rules appear to modulate the density and spatial distribution of the ion channels governing a cell’s basic electrical behavior (see ACTIVITY-DEPENDENT REGULATION OF NEURONAL CONDUCTANCES), and can modulate neurite outgrowth and branching (van Ooyen et al., 2002). Both examples involve changes in the neural substrate that are not naturally described in terms of changes in neuron-to-neuron connection strengths.

In this article, we explore the possibility that long-term learning in the mature brain may depend on structural remodeling at the interface between axons and dendrites, a process that continues throughout life. In particular, we cite evidence for the view that long-term storage may involve the correlation-based sorting of synaptic contacts onto the *many separate dendrites* of a target neuron, just as conventional models of neural development typically involve the sorting of synaptic contacts onto the *many separate neurons* of a target population (see DEVELOPMENT OF RETINOTECTAL MAPS; OCULAR DOMINANCE AND ORIENTATION COLUMNS; SELF-ORGANIZING FEATURE MAPS). This shift in granularity is justified by the assumption that individual dendrites, or parts of dendritic trees, act as separately thresholded neuron-like subunits, functionally analogous to the point neurons that populate coarser-grained models of learning and development. We focus on the main projection neurons of cortical tissue, pyramidal cells, although our discussion likely applies to other types of cells as well.

## The Neuron as Two-Layer Neural Network

The dendrites of pyramidal cells contain a large number and variety of voltage-dependent channels that profoundly influence their integrative behavior (Häusser, Spruston, and Stuart, 2000). A variety of evidence from intracellular recordings and imaging studies suggests that active spike-like responses can be localized within individual thin branches (Schiller et al., 2000), supporting the idea that individual dendritic branches can act as surrogate "neurons" capable of separately thresholding their synaptic inputs.

Anatomical hints are similarly supportive of such a possibility. If advantages accrue to a cell that maintains multiple integrative subregions within its dendritic tree, one might expect pyramidal cell morphologies to maximize the number of subunits available for independent synaptic processing, subject to practical constraints such as that the cell remain of manageable size, that nonlinear synaptic interactions remain confined to individual subunits, and so on. Pace, Tieman, and Tieman (2000) found that among layer 4 stellate cells of the cat striate cortex, the number of long, thin, terminal sections is nearly constant (around 40) and is independent of the number of primary dendritic branches emanating from the cell body (Figure 1). Given that most of the synapses onto basal dendrites lie on the long, thin, unbranched terminal sections (Elston and Rosa, 1998), the data of Pace et al. suggest a developmental program that tightly regulates the production of mutually isolated dendritic subunits, and then arranges for synapses to be formed primarily there.

What are the implications of this type of morphology for synaptic integration? Cable theory (Koch, 1999) suggests that a dendritic arbor consisting of many thin-branched subtrees radiating outward from a much larger-diameter cell body or dendritic trunk is ideally suited to isolate voltage responses within individual thin branches. Indeed, the possibility that dendritic trees could support complex multisite nonlinear operations, including logic-like operations, has been explored in a number of modeling studies (see Mel, 1999; Segev and London, 2000).

One recent study utilized a simplified model pyramidal cell whose dendrites contained AMPA/NMDA synapses and low concentrations of voltage-dependent $Na^+/K^+$ channels capable of generating dendritic spikes (Archie and Mel, 2000). When total synaptic drive to the cell was held constant but was distributed in varying spatial patterns to two dendritic branches, the average firing rate of the cell was approximated by a sum-of-squares model. The finding is intriguing in that it suggests a possible connection between the computation carried out within the dendrites and the quadratic "energy" models used to describe several types of visual receptive field properties (Mel, 1999). This study provided the first direct test of the "sum of subunits" model for synaptic integration, in which (1) the thin dendritic branches act like separately thresholded nonlinear subunits and (2) the outputs of the thin branch subunits are summed linearly via the main trunks and cell body prior to global thresholding:

$$y(\mathbf{x}) = g\left(\sum_{i=1}^{m} \alpha_i b\left(\sum_{j=1}^{k} w_{ij}x_{ij}\right)\right) \qquad (1)$$

where $m$ is the number of subunits, $k$ is the number of synapses per subunit, $w_{ij}$ is the weight, and $x_{ij}$ is the activity of the $j$th input to the $i$th subunit, $b$ is the subunit nonlinearity, $\alpha_i$ is the coupling of the $i$th subunit to the cell body, and $g$ is a global output nonlinearity. Of interest, Equation 1 also describes the input-output relation of a conventional two-layer neural network.

## Structural Plasticity at the Axodendritic Interface

The possibility that neurons contain multiple, separately thresholded dendritic subunits has profound implications for the mechanisms governing the formation and remodeling of the axodendritic interface, and for the physical substrate for long-term information storage in neural tissue. The point may be illustrated from the perspective of axon $i$ in the process of "choosing" which subunit $s \in \{1 \ldots k\}$ to enervate on postsynaptic neuron $j$ during learning or development. The subunit thresholding function $b$, which generates nonlinear interactions among the set of inputs to each subunit, ensures that $i$'s effectiveness in driving cell $j$ depends not just on its own activity $x_i$ and associated weights $w_{ijs}$, but also on the activity and weights of the other axons providing input to the same subunits. Thus, given compartmentalized neurons, the "receptive field" of the neuron changes, in general, when any single axon withdraws

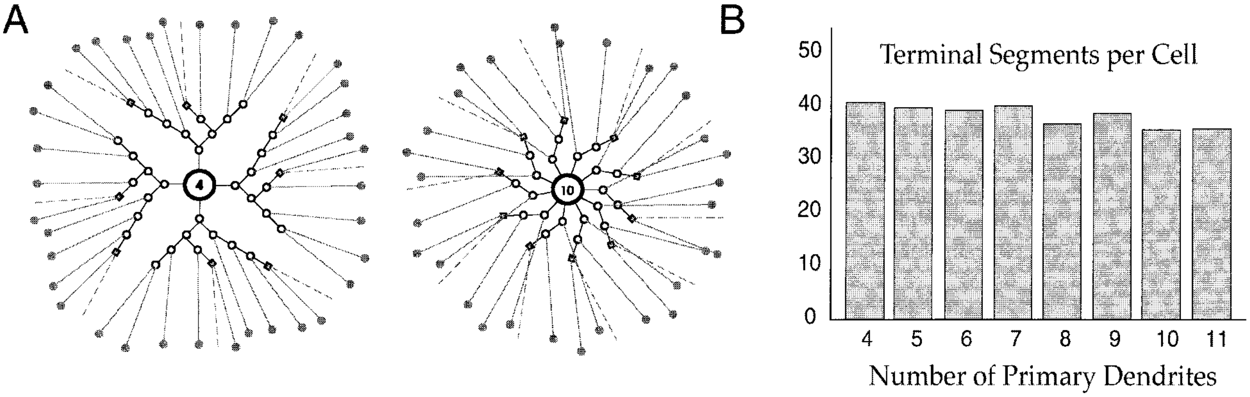

**Figure 1.** Evidence for regulation of number of functional dendritic subunits. *A*, Schematics of spiny-stellate cell morphology in cat visual cortex derived from 3D reconstructions, shown for cells with four or ten primary dendrites. *B*, Number of unbranched terminal segments per cell is nearly constant (around 40) for cells with widely varying numbers of primary dendrites. (Adapted with permission from Pace, Tieman, and Tieman, 2000.)

a synaptic contact from one subunit and forms a new contact on another, even when the "change of address" involves two branches of the same postsynaptic cell. By contrast, learning models operating at neuron-level granularity, which encode only the overall connection strength between pairs of neurons, lack the parameters needed to represent such changes.

### *Partnership Combinatorics*

The possibility that learning-related mechanisms could orchestrate the correlation-based sorting of synaptic contacts, not just onto whole neurons but a level down, on to specific dendritic subunits, raises the question of whether the physical interface between axons and dendrites in cortical tissue is amenable to this type of fine-scale structural plasticity. The question is important in that, when a neuron contains subunits, its capacity to absorb learned information is closely tied to the *addressing flexibility* of the tissue, that is, the flexibility to establish arbitrary partnerships between presynaptic axons and postsynaptic dendritic subunits (Poirazi and Mel, 2001).

It is now well established that axons, dendrites, and spines are highly dynamic structures, both during development and in the adult brain (Cline, 1999; Klintsova and Greenough, 1999). One model of neural development holds that (1) synapses are initially formed between axons and dendrites in a random, activity-independent fashion, and (2) synapses that are frequently coactivated with their neighbors within the same postsynaptic compartment are structurally stabilized and retained, while those that are poorly correlated with their neighbors are eliminated. If, however, the relevant postsynaptic unit is the individual thin dendrite rather than the whole neuron, then these same neurobiological mechanisms could also drive the separate mapping of like-activated synaptic cohorts onto distinct dendritic subregions.

Although the idea is intriguing, a serious practical difficulty arising from the need to establish on-demand partnerships between arbitrary pairs of axons and dendrites is that of physical proximity, or the lack thereof: it is unreasonable to expect that during the course of learning, particularly in the densely packed neuropil of the mature brain, axons or dendrites should be regularly required to advance and retract over long distances in search of appropriate partnerships.

What physical properties of axons and dendrites might enhance their partnership flexibility, minimizing the need for long-distance travel to form arbitrary pairings between presynaptic axons and dendritic subunits? Axonal and dendritic arborizations are heavily interdigitated within the three-dimensional (3D) volume of the cortical neuropil, an arrangement that maximizes the probability of a close approach between any given axon and any given compartment of a postsynaptic cell. This qualitative observation is illustrated by the montage of an axon and a dendrite shown in Figure 2.

## Implications of Dendritic Subunits and Structural Plasticity for Long-Term Memory Storage

We recently set out to quantify the excess trainable storage capacity contained in the selective mapping of synaptic contacts onto dendritic subunits, and to characterize how this excess capacity depends on dendritic geometry (Poirazi and Mel, 2001). We compared the capacity of a subunit containing neuron with $m$ branches (subunits) and $k$ synapses per branch (Equation 1) to that of a point neuron with the same number of synaptic sites but a linear summation rule, that is, with $b(x) = x$ in Equation 1. The two neuron models were thus identical except for the presence or absence of a fixed subunit nonlinearity.

Assuming synaptic contacts of unit weight—although any of the $d$ input lines could form multiple connections to the same or different branches—we derived upper bounds on the capacity of a linear ($B_L$) versus nonlinear ($B_N$) cell:

$$B_L = 2\log_2\binom{s+d-1}{s}$$

$$B_N = 2\log_2\binom{\binom{k+d-1}{k}+m-1}{m} \qquad (2)$$

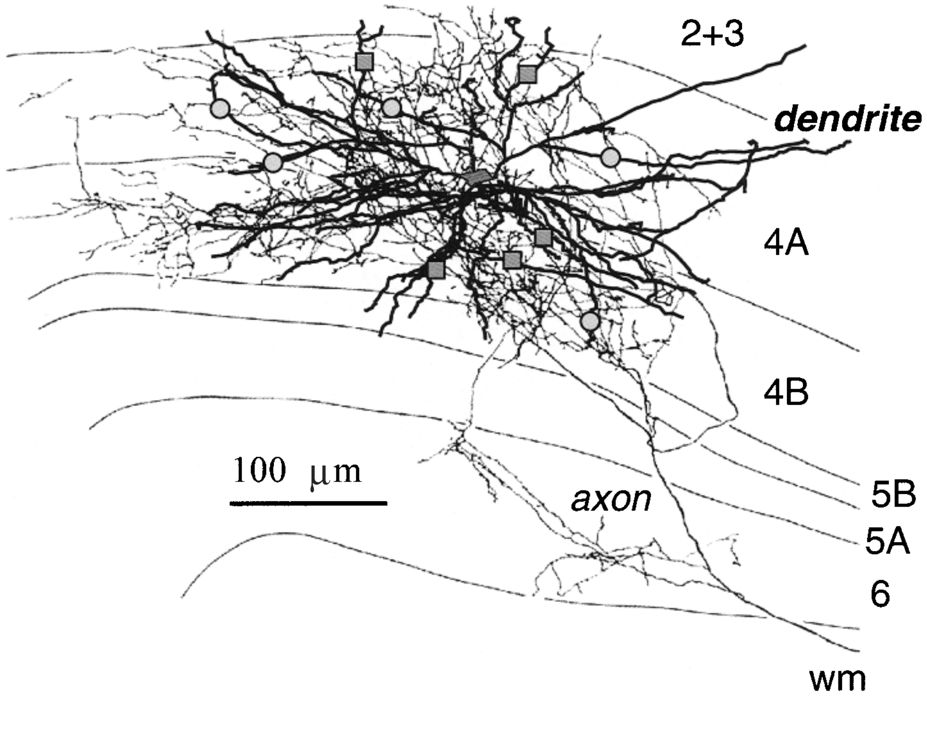

**Figure 2.** Interdigitated axonal and dendritic trees provide an ideal interface for flexible partnering between a presynaptic axon and the several dozen dendritic subunits of a single postsynaptic neuron. The picture was created by superimposing a dendritic arbor from a cat layer 4 spiny stellate cell (courtesy of Judith Hirsch) on a thalamocortical afferent taken from Freund et al. (1985, *J. Comp. Neurol.*, 242:263). Geometric symbols illustrate locations where minor extensions or retractions could lead to the establishment of new contacts (circles) and the elimination of old contacts (squares) between the axon and dendrite during the course of learning.

The expressions in each case estimate the number of distinct input-output functions that can be expressed by the respective model when assigning $s = m \cdot k$ synaptic contacts with replacement from $d$ distinct input lines. The combinatorial terms take into account the redundancies associated with the two models, that is, the changes in synaptic connectivity that have no effect on the cell's "receptive field"; the logarithm converts the raw function counts into *bits*. $B_L$ and $B_N$ are plotted in Figure 3*A* for a cell with 10,000 synaptic contacts and three values of $d$. Capacity is shown on the $y$-axis for a range of cell geometries represented along the $x$-axis. The values of $B_L$ are shown on the left and right edges of the plot, since the capacity of a point neuron is equivalent to a subunitized neuron in a degenerate state with either a single branch containing 10,000 synapses or with 10,000 branches containing one synapse each. The peak capacity occurs for cells containing approximately 1,000 subunits of size 10, where the optimal geometry depends little on $d$ over the order-of-magnitude range tested.

The optimal subunit size predicted by Equation 2 ($k = 10$) is considerably smaller than would be expected for a pyramidal cell, whose individual thin terminal branches typically contain hundreds of synapses. This discrepancy could be explained in part by our assumption here that synaptic weights are binary valued; in pilot runs with multivalued weights, the optimal subunit size was pushed to substantially larger values ($k = 25$ for 4-level weights). Furthermore, the assumption that all input axons have ready access to all dendrites is unlikely to hold in neural tissue. Wherever this assumption is violated, pressure would exist to grow longer dendritic subunits, thereby permitting each subunit to gain access to a larger fraction of the "input vector."

### *Empirical Testing of Memory Capacity*

To validate the analytical model, we trained both linear and nonlinear cells on random old/new classification problems using a stochastic gradient descent learning rule (Poirazi and Mel, 2001). Memory capacity was measured for cells with different dendritic geometries by determining the size of the training set that could be internalized with a recognition error rate of 2%. A comparison of analytical versus empirical capacities for both linear and nonlinear cells is shown in Figure 3*B*. The curves are remarkably similar in form, with peak capacity occurring for cells of similar shape. The optimal nonlinear cell with 10,000 synapses outperformed its size-matched linear counterpart by a factor of 46, learning 27,400 versus 600 patterns at the 2% error criterion. In further experiments with a population of independently trained cells, we found the excess storage capacity available to a structural learning rule could easily approach two orders of magnitude (Poirazi and Mel, 2001).

## Discussion

Several types of evidence were cited that call into question the classical "point neuron" as a model for a pyramidal cell or other large dendritic neuron of the CNS. We presented an alternative model supported by physiological, anatomical, and modeling studies, in which the output of the cell represents the sum of a moderately large set of separately thresholded dendritic subunits—a formulation that at a mathematical level is identical to that of a

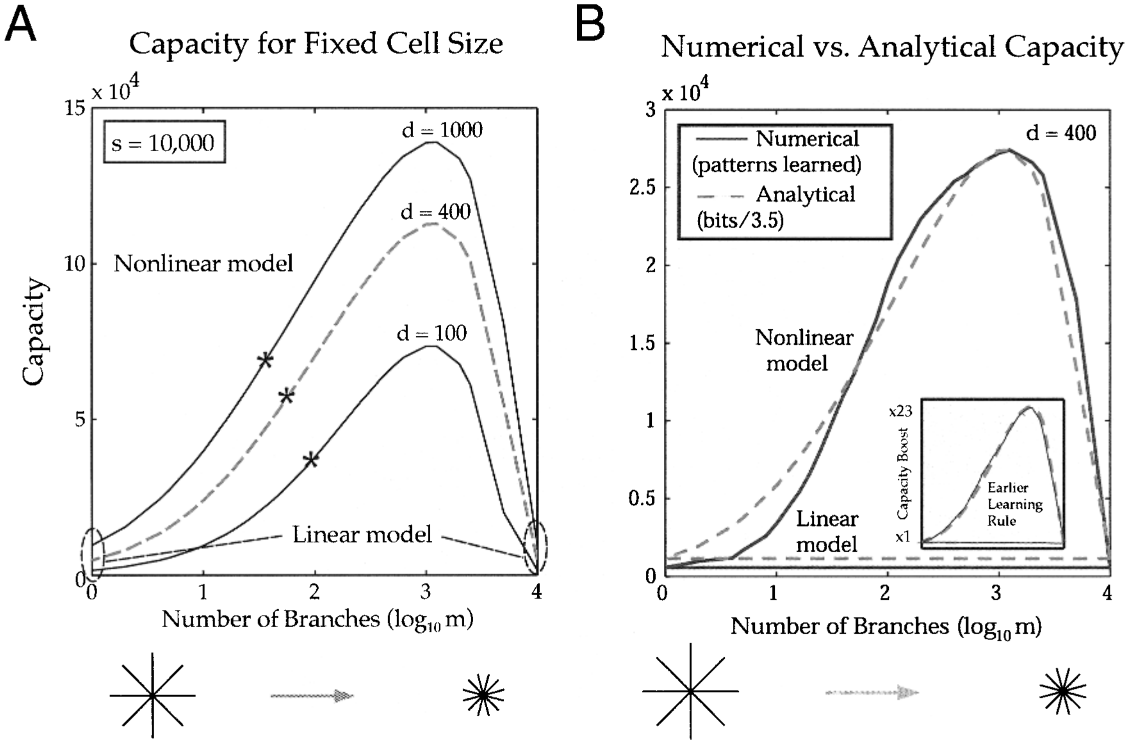

**Figure 3.** Linear versus nonlinear cell capacity as a function of branch geometry. *A*, Capacity of a nonlinear cell with 10,000 sites for three values of *d*. Cells at both ends of the *x*-axis have a capacity equivalent to that of the linear model. Asterisks indicate the half-maximum capacity. *B*, Comparison of memory capacity predicted by analysis with that found empirically in random memorization problems. Dashed lines show analytical curves for linear and nonlinear cells (nonlinear capacity curve corresponds to dashed curve in *A*). Solid curves show capacity measured empirically at 2% error criterion. Analytical curves were scaled down together by a factor of 3.5, to align peak analytical and empirical capacity values for nonlinear model. (Adapted from Poirazi and Mel, 2001.)

conventional artificial neural network built from two layers of point neurons. Multisubunit neurons, if and where they are used in the brain, could help to minimize hardware-associated costs, including brain size, processing delays, error-signal management overhead, and so on.

Although the validity of the subunitized-neuron hypothesis remains to be proved empirically, we have nonetheless explored some of its major consequences for learning and memory. The two main consequences are as follows. First, in a functionally compartmentalized neuron, the formation of new synapses and the elimination of old ones during learning can no longer be viewed simply as a means to increase or decrease the overall connection strength between two neurons, a common interpretation of new synapse or spine formation. Indeed, the concept of "overall connection strength between two neurons" is no longer well-defined, in the sense that the interaction between two neurons can no longer be captured by a single positive or negative coefficient. The granularity has changed: we must now worry about the role of learning-related mechanisms in tuning the connection strengths between a many-fingered presynaptic fiber and the multiple dendritic subunits of a given postsynaptic cell.

Second, from the perspective of learning theory, this change in granularity brings with it a large increase in the number of modifiable parameters available to the neural tissue. And this a not a purely theoretical construct: we have found in simulation studies that these extra parameters translate directly into additional long-term storage capacity, hidden in the fine structure of the axodendritic interface. Interestingly, other sources of "hidden" capacity have been proposed to exist, based on still other kinds of modifiable parameters, including a cell's capacity to discriminate among time-varying signals by varying passive time constant and spike threshold (Zador and Pearlmutter, 1996), or to maximize mutual information between input and output firing rates by varying properties of the resident voltage-dependent ion channels (Stemmler and Koch, 1999). Future experiments will ultimately determine the extent to which these reservoirs of structure-, channel-, or time-based capacity are in fact exploited within the living brain.

## Introduction

We are fortunate to be in the midst of the "dendritic revolution" that emerged when the first edition of the *Handbook* appeared in 1995. For the first time ever, systematic and intimate electrical and optical visits became possible to the dendrites (Figure 1)—the largest component of the mammalian brain in both surface area and volume. These ongoing visits have yielded a much more fascinating picture of the electrical behavior and chemical properties of dendrites than one could have imagined only a few years ago. It is now clear that the dendritic membrane hosts a variety of nonlinear voltage-gated ion channels that endow dendrites with potentially powerful computing capabilities. Our century-old perception of dendrites as electrical devices that carry information unidirectionally, from the many dendritic (input) synapses to the soma and (output) axon, has undergone a dramatic revision. The surprising finding is that dendrites of many central neurons also carry information "backward," via active propagation of action potentials (APs) from the axon to the dendrites. These "backpropagating APs" trigger plastic changes in the dendritic input synapses, and these changes are believed to be the fundamental processes that underlie learning and memory in the brain. Our view of dendrites as static elements has also changed: we now know that the fine morphology as well as the electrical properties of dendrites change dynamically, in an activity-dependent manner. Indeed, one of the major challenges in the years to come is to understand how these changes are correlated with the behavior and learning of the animal.

This article affords a brief introduction to the newly discovered charms of dendrites. For the dendritic-minded reader, several recent reviews are recommended, including the book *Dendrites*, edited by Stuart, Spruston, and Häusser (1999), the quartet of reviews of work on dendrites in *Science* (October 27, 2000), and the review by Euler and Denk (2001).

## Dendrites—What Made the Revolution Possible

A combination of several new technologies has made it possible to view dendrites with unprecedented acuity, notably differential-

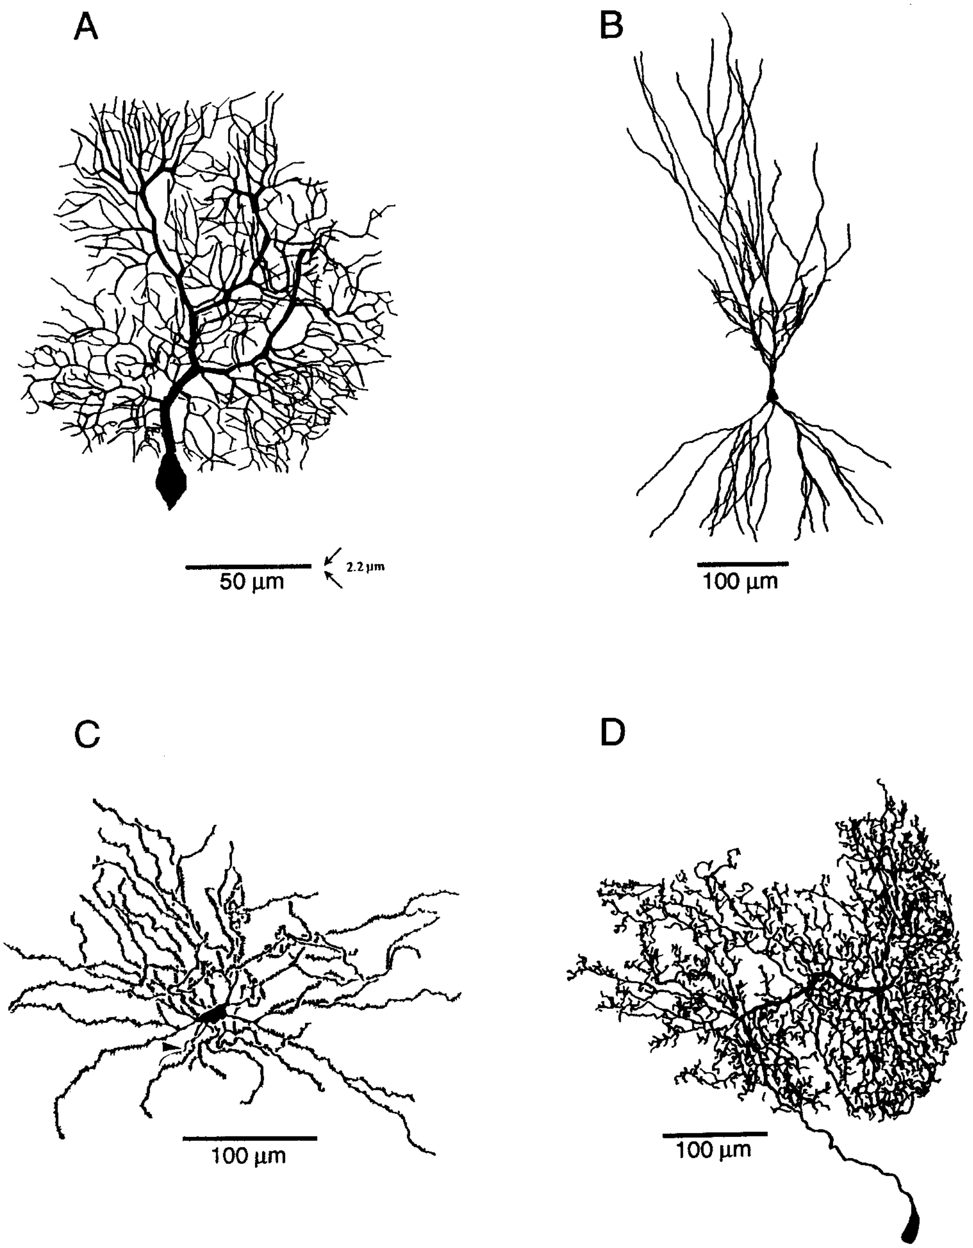

**Figure 1.** Dendrites have unique shapes, a feature that is used to characterize neurons into types. In many neuron types, synaptic inputs from a given source are preferentially mapped into a particular region of the dendritic tree. *A*, Cerebellar Purkinje cell of the guinea pig (reconstructed by M. Rapp). *B*, CA1 pyramidal neuron from the rat (reconstructed by B. Claiborne). *C*, Neostriatal spiny neuron from the rat. (Courtesy of C. Wilson.) *D*, Axonless interneurons of the locust (reconstructed by G. Laurent). Typically, synaptic inputs are distributed nonrandomly over the dendritic surface. interference contrast (DIC) video microscopy and two-photon microscopy (for a review, see Euler and Denk, 2001). These methods allow researchers to systematically record electrically (using microelectrodes) and optically (using ion-dependent dyes) from identified dendritic locations. Consequently, the effect of a single synaptic input can be monitored in both its dendritic origin and simultaneously in the soma/axon region. Direct measurements of the electrical properties of the dendritic ion channels are now feasible (Johnston et al., 1996; Reyes, 2001); and, with molecular methods (Crick, 1999), specific membrane proteins in dendrites can be marked and manipulated to identify the type and distribution of the various receptors and ion channels in the dendritic membrane. When combined with sophisticated analytic and numerical models, the beginnings of a functional picture emerge from these diverse experimental data. Some of the key experimental and theoretical findings are described below.

## Fundamental Facts About Dendrites: Morphological Face, Electrical Character, and Synaptic Inputs

Table 1 summarizes the functionally important facts about dendrites. Because dendrites come in many shapes and sizes, such a summary inevitably presents only a rough range of values. Nonetheless, several important functional conclusions can be drawn from this table.

1. *Morphologically,* dendrites tend to ramify, creating large and complicated trees. Dendrites are thin processes, starting with a diameter of a few micrometers near the soma; the branch diameter typically falls below 1 $\mu$m with successive branching, often reaching a distance of 1 mm from the soma. Many (but not all) types of dendrites are studded with abundant tiny branches, or appendages, called dendritic spines. When present,

**Table 1.** Range of Values for Dendritic Machinery

| Morphology | Physiology | Synaptology |
|---|---|---|
| Diameter near soma: 1–6 $\mu$m | *Passive properties of dendrites*[a] | No. of synapses/neuron: 500–200,000 |
| Diameter at distal tips: 0.3–1 $\mu$m | Membrane resistivity ($R_m$): 1–100K $\Omega$cm$^2$ | Type I (excitatory): 60%–90%[c]; distributed, majority on spines |
| Average path length: 0.15–1.5 mm | Axial resistivity ($R_i$): 70–300 $\Omega$cm | |
| Total dendritic length: 1–10 mm | Membrane capacitance ($C_m$): 1–2 $\mu$F/cm$^2$ | Type II (inhibitory): 10%–40%[c]; near soma, some on spines |
| Dendrite area: 2,000–750,000 $\mu$m$^2$ | Membrane time constant ($\tau_m$): 1–100 ms | |
| Dendritic trees/neuron: 1–16 | Dendrite space constant ($\lambda$): 0.2–1 mm | |
| Dendritic tips/neuron: 10–400 | Electrotonic length ($L = x/\lambda$): 0.2–2 | *Excitatory synaptic input*[d] |
| Dend. spines/neuron: 300–200,000 | Soma input resistance ($R_N$): 1–$10^3$ M$\Omega$ | AMPA: $g_{\text{peak}}$: 0.1–0.3 ns: $t_{\text{peak}}$: 0.3–1 ms (may increase with distance from soma) |
| Spine density/1 $\mu$m dendrite: 0.5–14 | Input resistance at tips ($R_T$): $10^2$–$10^3$ M$\Omega$ | |
| Spine length: 0.1–2 $\mu$m | Steady-state attenuation factor: | NMDA: $g_{\text{peak}}$: 0.05–0.5 ns; $t_{\text{peak}}$: 5–50 ms |
| Spine neck diameter: 0.04–0.5 $\mu$m | Soma → tip: 1.1–2 | |
| Spine head diameter: 0.3–1 $\mu$m | Tip → soma: 2–15 | *Inhibitory synaptic input*[e] |
| Spine volume: 0.005–0.3 $\mu$m$^3$ | | $\text{GABA}_\text{A}$: $g_{\text{peak}}$: 0.4–1 ns; $t_{\text{peak}}$: 0.2–1.2 ms |
| | *Excitable properties of dendrites*[b] | $\text{GABA}_\text{B}$: $g_{\text{peak}}$: 0.1–0.3 ns: $t_{\text{peak}}$: 40–150 ms |
| | $Ca^{2+}$ channels (L, N, P type)—local dendritic $Ca^{2+}$ AP: $Ca^{2+}$ concentration in spines | |
| | $Na^+$ channels: Fast activating/inactivating—supports soma → dendritic backpropagating AP | |
| | $K^+$ channels, $I_A$, and mixed current, $I_h$—Increased density with distance from soma—"shock absorbers," linearization, and temporal normalization. | |

[a] The passive properties of dendrites can be strongly modulated by synaptic activity as well as by voltage-gated channels.

[b] Characterization of the voltage-gated ion channels in dendrites (i.e., type, distribution, density, and kinetics) is only beginning to emerge through the use of molecular probes and patch clamp techniques. For reviews, see Koch and Segev (1998, chap. 5) and Reyes (2001).

[c] Based on data from cortical and hippocampal pyramidal neurons.

[d] See, e.g., Stern, P., Edwards, F. A., Sakmann, B., 1992, Fast and slow components of unitary EPSCS on stellate cells elicited by focal stimulation in slices of rat visual-cortex, *J. Physiol. (Lond.)*, 449:247–278.

[e] See, e.g., Otis, T. S., De Koninck, Y., and Mody, I., 1993, Characterization of synaptically elicited $\text{GABA}_\text{B}$ responses using patch-clamp recordings in rat hippocampal slices, *J. Physiol. (Lond.)*, 463:391–407.

Dendritic Spines (q.v.) are the major postsynaptic targets for *excitatory* synaptic inputs.

2. *Electrically*, dendrites can be characterized by their *passive* properties (the passive "skeleton"), to which the (nonlinear) synaptic- and voltage-dependent ion channels are added. The passive (near resting potential) skeleton can be characterized by the specific membrane resistivity, $R_m$, of dendrites, which is relatively high ($R_m$ is on the order of 1,000–100,000 $\Omega$cm$^2$), implying that the dendritic membrane is a good electrical insulator. With a specific capacitance, $C_m$, of approximately 1 $\mu$F/cm$^2$, the dendritic membrane time constant, $\tau_m$ (which sets the range for the time window for the integration of synaptic inputs), is on the order of $\tau_m = R_m C_m =$ 10–100 ms. The axial (longitudinal) resistivity of the dendritic cytoplasm, $R_i$, ranges between 70 and 300 $\Omega$cm, and this, together with the small dimensions of distal arbors, implies a large input resistance (impedance) in the dendrites. The increase in dendritic diameter as one approaches the soma implies a large attenuation factor (on the order of 100) of the peak synaptic potential as it spreads from its origin at the distal dendritic site to the soma (Figure 3*A*, *B*).

The *active* properties of dendrites are the outcome of the excitable channels embedded in their membrane. It has been known for years that some types of dendrites, most notably the cerebellar Purkinje cell, can even generate local dendritic AP. More recently, data have indicated that many central neurons can generate dendritic spikes under favorable conditions, and indeed, most of the different types of excitable ion channels in neurons are hosted by the dendrites. Dendrites of different neuron types (e.g., hippocampal CA1, layer V pyramids) bear different combinations of ion channel types, which to a large extent dictate the input-output style of these neurons. A large amount of new information about these ion channels has accumulated in the past few years (see, e.g., Koch and Segev, 1998; Reyes, 2001). These nonlinear ion channels have significant consequences for the computational capabilities of dendrites.

3. *Synaptically*, dendrites of central neurons are covered with synaptically activated (transmitter-gated) receptors. The AMPA and NMDA receptors for glutamate are typically associated with excitatory inputs, whereas $\text{GABA}_\text{A}$ and $\text{GABA}_\text{B}$ receptors are typically associated with inhibition. These receptors are not randomly distributed over the dendritic surface (Pettit and Augustine, 2000), and their density can be dynamically modified in an activity-dependent manner. In many, but not all, types of central neurons, the inhibitory-mediated receptors are more proximal than the excitatory synapses (see Shepherd, 1998).

Both the excitatory and the inhibitory synaptic inputs operate in most cases by locally increasing the conductance of the postsynaptic membrane (opening specific ion channels). Therefore, the synaptic input itself perturbs the electrical properties of dendrites, and thus the synaptic input is inherently nonlinear. The time course of the synaptic conductance change may vary by one or two orders of magnitude. The fast excitatory (AMPA) and inhibitory ($\text{GABA}_\text{A}$) inputs operate on a time scale of a few milliseconds and have a peak conductance on the order of 1 ns; this peak conductance is approximately ten times larger than the slow excitatory (NMDA) and inhibitory ($\text{GABA}_\text{B}$) inputs, which both act on a time scale of 10–100 ms.

## Dendritic Modeling

In two groundbreaking studies, Rall (1959, 1964) established the theoretical foundation that allowed the morphological, electrical, and synaptic properties of dendrites to be linked together in a functionally meaningful framework (see Segev, Rinzel, and Shepherd, 1995). Rall's passive cable theory for dendrites, complemented by his compartmental modeling approach, laid the groundwork for a quantitative exploration of the integrative (input-output) function of dendrites.

### Passive Cable Theory for Dendrites

Rall described current flow (and the spread of the resultant voltage) in morphologically and physiologically complicated passive dendritic trees using the one-dimensional cable equation

$$\frac{\partial^2 V}{\partial X^2} = \frac{\partial V}{\partial T} + V(X,T) \qquad (1)$$

where $V$ is the voltage across the membrane (interior minus exterior, relative to the resting potential); $X = x/\lambda$, where $x$ is the distance along the core conductor (cm) and the *space constant*, $\lambda$, is defined as $\sqrt{r_m/r_i}$; and $T = t/\tau_m$, where the *time constant*, $\tau_m$, is $r_m c_m$. Further, $r_m$ is the membrane resistance for unit length (in $\Omega$cm), $c_m$ is the membrane capacitance per unit length (in F/cm), and $r_i$ is the cytoplasm resistance per unit length (in $\Omega$/cm). A complete derivation of the cable equation can be found in the chapter by Rall (in Koch and Segev, 1998, chap. 2; see also Jack, Noble, and Tsien, 1983, and PERSPECTIVE ON NEURON MODEL COMPLEXITY).

The solution to Equation 1 depends on, in addition to the electrical properties of the membrane and cytoplasm and dimensions of the dendritic tree, the boundary condition at the ends of the segment toward which the current flows. Rall showed that Equation 1 could be solved analytically for passive dendritic trees with arbitrary branching. He modeled the dendritic tree as a collection of short cylindrical segments (Figure 2*B*), where the tree attached to the end of each segment acts as a sink for the longitudinal current (i.e., a "leaky end").

An example of such a solution for the steady-state case is depicted in Figure 3*A* and for the transient case in Figure 3*B*. Several important implications of Figure 3 are discussed later in this article and in Segev and London (2000). Recent extensions of the passive cable theory for dendrites have used the different moments of the transient synaptic potential to explicitly define the notion of input synchrony and propagation delay in dendrites (reviewed in Koch and Segev, 1998, chap. 2). The correspondence between cable theory and the Schrödinger eigenvalue problem for the one-dimensional bounded motion of a particle in quantum mechanics was also used to study the effect of spatially nonuniform membrane conductance on signal transfer in dendrites (see Stuart et al., 1999, chap. 9).

### Compartmental Modeling Approach

The compartmental modeling approach complements cable theory by overcoming the assumption that the membrane is passive and that the input is a current source. Mathematically, the compartmental approach is a finite-difference (discrete) approximation to the (nonlinear) cable equation. It replaces the continuous cable equation (Equation 1) with a set, or a matrix, of ordinary differential equations; typically, numerical methods are employed to solve this system (which can include thousands of compartments and thus thousands of equations) for each time step. In the compartmental model, dendritic segments that are electrically short are assumed to be isopotential and are lumped into a single RC (circuit of resistors and capacitors) (either passive or active) membrane compartment (Figure 2*C*). Compartments are connected to each other via a longitudinal resistivity according to the topology of the tree. Hence, differences in physical properties (e.g., diameter, membrane properties) and differences in potential occur between compartments rather than within them. When the dendritic tree is divided into sufficiently small segments (compartments), the solution to the compartmental model converges with that of the continuous cable model. Compartments can represent a patch of membrane with a variety of voltage-gated (excitable) and synaptic (time-varying) channels. Popular public domain computer programs have been developed to simulate compartmental modeling; the most notable are NEURON (NEURON SIMULATION ENVIRONMENT) and GENESIS (GENESIS SIMULATION SYSTEM). A review of the compartmental modeling approach can be found in Koch and Segev (1998, chap. 3).

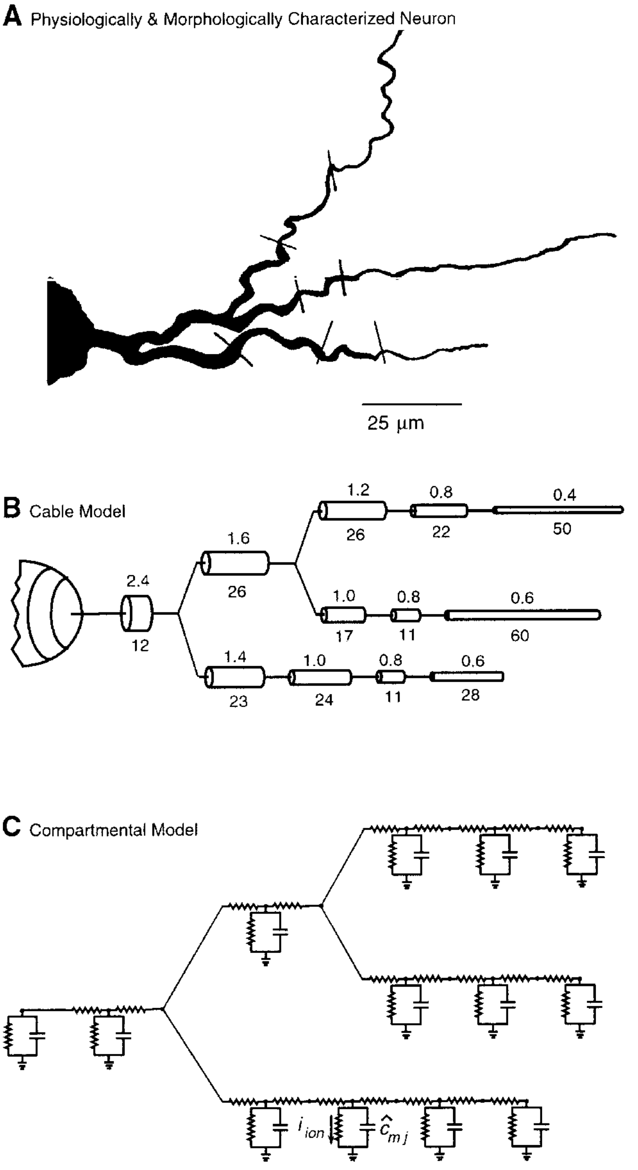

**Figure 2.** Dendrites (*A*) are modeled either as a set of cylindrical membrane cables (*B*) or as a set of discrete, isopotential RC compartments (*C*). In the cable representation (*B*), the voltage at any point in the tree is computed from Equation 1 and the appropriate boundary conditions are imposed by the tree. In the compartmental representation the tree is discretized into a set of interconnected RC compartments; each is a lumped representation of a sufficiently small dendritic segment. Membrane compartments are connected via axial, cytoplasmic resistances. Here the voltage can be computed at each compartment for any nonlinear input and voltage- and time-dependent membrane properties.

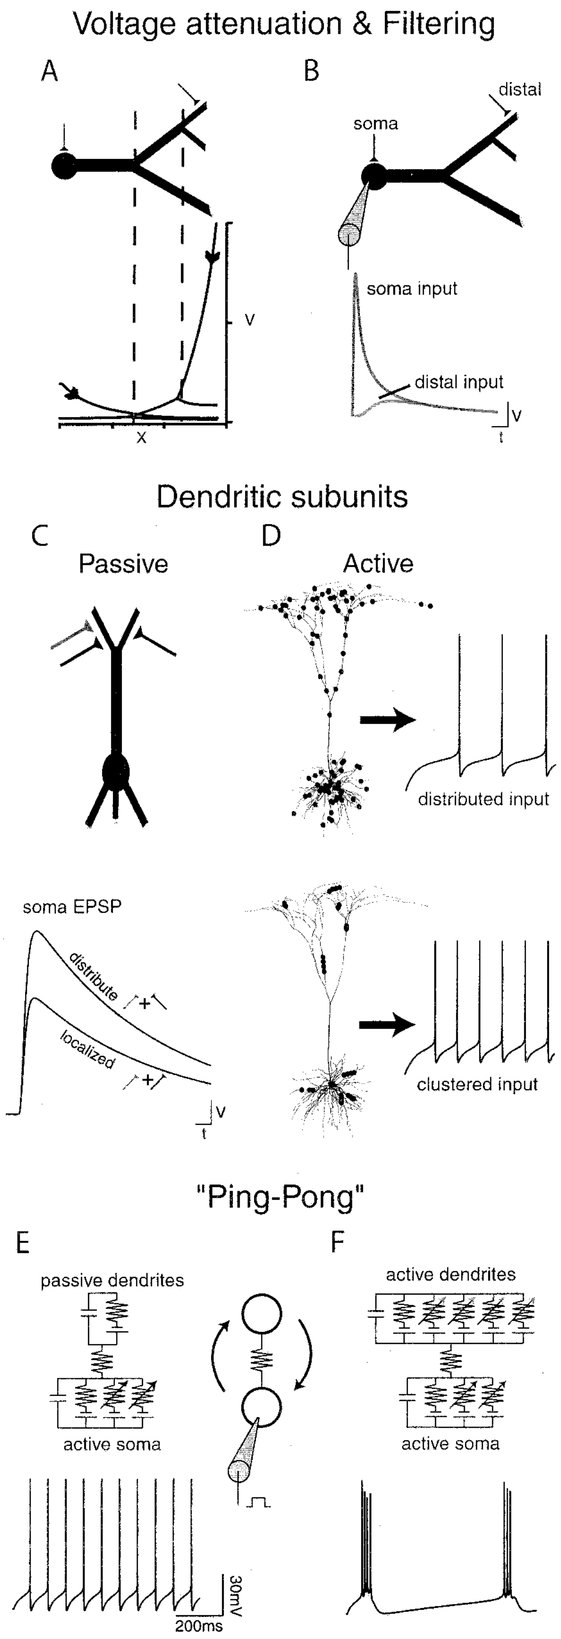

**Figure 3.** Effects of dendrites on synaptic inputs processing. *Top panel,* Passive dendrites impose voltage attenuation and low-pass filtering on their synaptic inputs. (*A*) Voltage response to a brief current pulse in a simple branched dendritic model (top). Attenuation of voltage peak is plotted for two cases, somatic input and dendritic input. The attenuation is asymmetric and is much steeper in the dendrite-to-soma direction. The voltage response at the input site is much larger for the distal dendritic input (large input impedance). (*B*) Voltage is transient at the soma for somatic input and dendritic input. The filtering effect of the dendrite gives rise to a temporal delay and to an increase in half-width of the distal dendritic input. *Middle panel,* The soma output depends on the degree of synaptic clustering on dendritic subunits. (*C*) In passive dendrites, sublinear summation of synaptic inputs is less pronounced (saturation is reduced) when the inputs are distributed in different dendritic arbors. (*D*) In excitable dendrites, a certain degree of spatial clustering of excitatory synapses (bottom) may result in a significant boosting of the synaptic charge that reaches the soma, because it produces larger local dendritic depolarization that may activate the local excitable channels. As a consequence, the axon fires more vigorously (right). One hundred excitatory synapses were used in both cases: *top,* ten clusters of ten synapses each; *bottom,* 100 clusters of one synapse each. Each synapse was activated 40 times per second for 1 s. *Bottom panel,* Backward-forward "Ping-Pong" interaction between the ion channels in the soma/axon region and the excitable channels in dendrites shapes the output pattern of spikes firing in the axon. Two models of a cortical pyramidal neuron were used, one with passive dendrites (*E*) and the other with excitable dendrites (*F*). For passive dendrites, the axon fires regularly in response to steady soma depolarization, whereas in the model with excitable dendrites, it fires repeated spike bursts. The geometry of the dendritic tree plays a crucial role in this "Ping-Pong" interaction.

## Interaction Between Dendrites and Synapses: Main Insights

The theoretical background just outlined and the many results from modeling and experimental studies on dendrites over the last 40 years provide important insights into the input-output properties of dendrites. These properties can be summarized as follows:

*Attenuation.* Dendritic trees are electrically distributed (rather than isopotential) elements. Consequently, voltage gradients exist over the tree when synaptic inputs are activated locally. In passive dendrites, the voltage tends to attenuate much more severely in the dendrite-to-soma direction (up to a few hundredfold for brief synaptic inputs at distal sites) than in the opposite direction (Figure 3*A*). This attenuation implies that many (several tens) of excitatory inputs should be activated within the integration time window of about 1 $\tau_m$, in order to build up enough depolarization to reach the threshold for spike firing at the soma and axon. Several experimental as well as theoretical studies (e.g., Reyes, 2001) have proposed that voltage-dependent currents might amplify or "boost" distal synaptic inputs while propagating toward the soma, but it is still an open question to what extent these mechanisms operate in the in vivo situation.

In contrast to the severe attenuation of the voltage *peak amplitude* in passive dendrites, the attenuation of the synaptic charge is relatively small. In many situations the charge is the relevant parameter for determining the firing rate at the axon, and thus, in these cases, the "cost" of placing the synapse at the dendrites rather than at the soma is quite small. Active dendritic currents can boost the synaptic charge, and this boosting is expected to be larger at distal dendritic sites, where the local input resistance (and local depolarization) is large. For example, synapses that are located on excitable dendritic spines (see Dendritic Spines) can trigger regenerative activity that may spread and indirectly activate nearby dendritic regions (a "chain reaction" between active dendritic spines). Synaptic inputs that are mediated by NMDA receptors may implement a similar mechanism for amplification, in which a certain degree of spatial clustering of excitatory inputs is more likely to activate these NMDA receptors and enhance charge transfer to the soma. In this case, the output at the axon depends sensitively on the size and site of the "cluster" (Figure 3*D*).

*Filtering.* With passive (RC) properties, dendrites behave like low-pass filters for their synaptic inputs. As a result, synaptic potentials are delayed and become significantly broader as they spread away from the dendritic input site (Figure 3*B*). The large sink imposed by the tree at distal arbors enhances the decay of local synaptic potentials; smaller enhancement (and thus broader local potentials) is expected at more proximal input sites. The difference in the width of the synaptic potential at different parts of the dendritic tree implies multiple time windows for synaptic integration in the tree. At the soma, the time window for synaptic integration is primarily governed by $\tau_m$, whereas at distal dendritic arbors it may be as short as 0.1 $\tau_m$ or less (Koch and Segev, 1998, chap. 2, p. 65). The massive synaptic activity present in vivo greatly affects the apparent membrane conductance and effectively changes the properties of the dendritic filter (Koch and Segev, 1998, chap. 3, p. 125). Extensive background activity can reduce the effective membrane time constant by tenfold. The presence of voltage-activated currents in the dendrites also affects dendritic filtering. Slow currents might turn the dendrites into bandpass filters by suppressing very slow frequencies (Hutcheon and Yarom, 2000). These bandpass filters can be sharpened by the presence of amplifying currents, such as persistent sodium. Other currents might change the apparent capacitance of the filter (Reyes, 2001).

*Dendritic inhibition—local veto operation.* Inhibitory synapses (which are associated with a conductance change in series with a battery whose value is near the resting potential) are more effective when located on the path between the excitatory input and the "target" region (soma) than when placed distal to the excitatory input. Thus, when strategically placed, inhibitory inputs can specifically veto parts of the dendritic tree and not others (see Rall, 1964; Koch, Poggio, and Torre, 1982; Jack et al., 1983; Segev et al., 1995).

*Spatiotemporal integration.* Because of dendritic delay, the somatic depolarization that results from activation of excitatory inputs in the dendrites is very sensitive to the temporal sequence of the synaptic activation. It is largest when the synaptic activation starts at distal dendritic sites and progresses proximally. Activation of the same synapses in the reverse order in time will produce smaller somatic depolarization. Thus, the output of neurons with dendrites is inherently *directionally selective* (see Perspective on Neuron Model Complexity).

*Gain control.* Active dendritic currents (both inward and outward) may serve as a mechanism for synaptic gain control. The membrane potential dynamically controls active conductances in the membrane, which in turn modify the integrative capabilities of the neuron (e.g., its input resistance, electrotonic length); hence the neuron output depends on its state (its membrane potential). Active currents (e.g., outward $K^+$ current) can act to counterbalance excitatory synaptic inputs (negative feedback) and thus stabilize the input-output characteristics of the neuron. At other voltage regimes, active currents may effectively increase the input resistance and reduce the electrotonic distance between synapses (positive feedback), with the consequence of nonlinearly boosting a specific group of coactive excitatory synapses (Stuart et al., 1999, and references in Segev and London, 2000).

*Ping-Pong interactions between synaptic inputs and dendritic spikes.* The presence of dendritic spikes (both backpropagating $Na^+$ spikes as well as local $Ca^{2+}$ spikes) in some neuron types may lead to interesting and nontrivial interactions in the tree. For example, a precise temporal coincidence between the backpropagating $Na^+$ spike and a distal synaptic input in the apical tree of cortical pyramids may trigger a broad dendritic $Ca^{2+}$ spike that, in turn, leads to a burst of $Na^+$ spikes at the axon (Reyes, 2001). Thus, a burst of $Na^+$ spikes in the axon reflects the co-occurrence of input to a basal tree (which generates a backpropagating spike) and an excitatory input to the distal apical tree. Theoretical studies show that slow ion currents in the dendritic tree may interact with the fast spike-generating mechanism at the soma/axon hillock, and this "Ping-Pong" interaction can give rise to many complex spiking patterns in the axon, ranging from regular, high-frequency spiking to spike bursting (Figure 3*E*; for details, see Koch and Segev, 1998, chap. 5, p. 206).

## Computational Function of Dendrites

Different brain areas are specialized in computing specific functions, and each of these areas consists of different types of dendritic structures. Do the unique morphology and electrical properties of the dendrites in a given brain area play a key role in implementing the computational task of this particular piece of brain? Unfortunately, in most cases it is hard to define the specific computational function the neuron executes. Furthermore, we rarely know the nature of the synaptic output that a particular neuron receives while the system computes. Therefore, current theoretical efforts are focusing on exploring the kinds of computations that neurons could potentially implement with their dendrites and synaptic inputs. Several such computations were mentioned earlier; here the major ones are discussed more fully.

### *Selectivity for Direction of Motion*

Because the depolarization in the axon is sensitive to the spatiotemporal order of synaptic activation over the dendritic surface, neurons with dendrites can compute the direction of motion (see Figure 4 and PERSPECTIVE ON NEURON MODEL COMPLEXITY; for details, see Segev et al., 1995; Koch and Segev, 1998). Already at the vertebrate retina some ganglion cells show directional selectivity such that their firing rate is significantly higher when a visual stimulus moves in one direction (preferred direction) rather than the opposite direction (null direction; Figure 4). Whether this computation is implemented postsynaptically by the dendrites of the ganglion cells or is already computed in neurons that are presynaptic to the ganglion cells is still under debate (see Taylor et al., 1999, and Borg-Graham, 2000—references in Euler and Denk, 2001). This debate highlights the need to record from dendrites during the processing of sensory input; recent developments in optical recording from dendrites are likely to provide a direct means of exploring the computational role of dendrites (Single and Borst, 1998; Euler and Denk, 2001)

Indeed, the most direct evidence for dendritic computation comes from work by Single and Borst (1998; see also reviews in Segev and London, 2000, and VISUAL COURSE CONTROL IN FLIES). This study explored the processing of visual information in the fly, in which a population of large interneurons, the tangential cells (TCs), spatially integrates the output signals of many thousands of columnar neurons, each of which is sensitive to a very small part of the visual scene. These TCs are all motion-sensitive: they are excited by motion in one direction and are inhibited by motion in the opposite direction. By combining intracellular recordings and calcium imaging from dendrites in vivo, two major processing steps that are implemented by the TC dendrites were identified. Through the processing of opponent input elements having opposite preferred directions, the directional selectivity of presynaptic neurons is significantly enhanced in the TCs. It was also shown that dendritic filtering helps distinguish a change in contrast due to stimulus motion from changes due to purely local patterns of the stimulus. The result of this integration is a graded depolarization in the axon of the tangential cells; this depolarization represents information about image velocity with high fidelity (Single and Borst, 1998).

### *Coincidence Detection*

Neurons with dendrites can function simultaneously in multiple time windows. Distal arbors act more like coincidence detectors, whereas the soma acts more like an integrator when brief synaptic inputs (i.e., AMPA and $\mathrm{GABA_A}$) are involved (Koch and Segev, 1998, chap. 2). Active dendrites provide an additional mechanism for coincidence detection based on local dendritic $Na^+$ spikes (see SINGLE-CELL MODELS) or on the temporal coincidence between backpropagating $Na^+$ spikes and local excitatory synaptic input, which gives rise to a broad local dendritic $Ca^{2+}$ spike and a corresponding burst of $Na^+$ spikes in the axon (see Reyes, 2001, and Figure 4). $Ca^{2+}$ accumulation in dendritic spines can also serve as a detector for coincidence between back propagating $Na^+$ spikes and excitatory input to the spine (see DENDRITIC SPINES).

The coincidence detector (CD) neurons in the auditory brainstem constitute a special case (Agmon-Snir, Carr, and Rinzel, 1998). These neurons possess bipolar dendrites, each of which receives excitatory synaptic inputs from only one ear. The neuron fires only if the inputs arriving from both ears occur within a very narrow time window (tens of microseconds); this is used by these cells to detect interaural time differences, and therefore the location of the sound source. The problem is how to distinguish a strong input arriving from one ear and an input that arrives simultaneously from both ears. This task cannot be achieved by a neuron that sums its inputs linearly. Agmon-Snir et al. (1998) have shown, using a simplified model of CD neurons, that a strong input arriving at one dendrite (from one ear) cannot drive the cell to fire, because of synaptic saturation, whereas inputs that reach both dendrites summate more linearly with each other at the soma and can trigger an output spike. Thus, segregation of the inputs from each ear to different dendrites, together with the inherent nonlinearity of synaptic summation, improves sound localization.

### *Feature Extraction, Input Classification, and Logical Operations*

Neurons with dendrites can implement a multidimensional classification task where the neurons' output is sensitive to a specific combination of active synapses over the dendritic tree (Stuart et al., 1999, chap. 11). For example, biophysical modeling of cortical pyramidal neurons shows that, with appropriate mapping of synaptic inputs from the lateral geniculate body (LGN) to the dendritic tree, and using local dendritic nonlinearities (mediated via NMDA receptors or excitable channels), these model neurons exhibit several nonlinear features of visual neurons, including phase invariance orientation tuning (a critical feature of complex cells), binocular disparity, and nonlinear boosting of tuning curves (Figure 4).

AND-NOT type of logical operations could be implemented by strategically placed excitatory and inhibitory synaptic inputs over the dendritic tree (Koch et al., 1982, and Figure 4). Because neurons with dendrites can function as many quasi-independent functional subunits, the dendritic tree as a whole can implement a rich repertoire of logical operations. Also, within each of these functional subunits, very localized plastic processes can take place (e.g., on a single dendritic spine; see DENDRITIC SPINES).

### *Dendritic Learning*

Over the past few years, it has become evident that dendrites are not static elements. Rather, there is a continuous change in the morphology of dendritic spines (Segev and London, 2000) and a dynamic change in the distribution of ion channels and synapses on the dendritic surface. Two recent computational studies suggest that these plastic properties of dendrites might play a role in learning. Stemmler and Koch (1999) demonstrated that by changing the distribution of membrane ion channels in a dendritic compartment via a learning rule, the neurons' output can optimize the representation of sensory information. The segregation of ion channels between the dendritic compartment and the soma axon compartment is critical for this mechanism to work. Poirazi and Mel (see DENDRITIC LEARNING) have shown that by spatially reallocating (reshuffling) synapses that are temporally correlated so that they will contact nearby dendritic locations, active dendritic subunits are created whereby the coactivation of synapses within a subunit results in significant synaptic boosting by local nonlinear dendritic mechanisms. This spatial clustering of temporally correlated inputs over the dendritic tree greatly increases the input classification capacity of the neuron.

## Discussion

Nature apparently uses dendrites as the basic building blocks for a wide range of nervous systems, from the simplest organism to the most sophisticated one (us?). Dendrites, therefore, need to provide

| Computation | Implementation<br>(Biophysical mechanism) | Example |
|---|---|---|
| Direction selectivity | 1. Dendritic delay + temporal sequence of synaptic activation<br>2. Asymmetric mapping of inhibition and excitation<br>3. Integration of many local direction selective detectors |  |
| Coincidence detection | 1. Backpropagating Na spike + Dendritic Ca spike<br>2. Input segregation on dendrites + synaptic saturation<br>3. Backpropagating Na spike + NMDA (Ca in spines)<br>4. Local dendritic Na spike generated by priciesly timed excitation<br>5. Short local delays in thin dendrites |  Ca channels (high density)<br>apical<br>soma<br>Soma input alone<br>soma<br>dendrite<br>Apical & soma input together<br>dendritic Ca spike<br>Burst of Na spikes in soma |
| Logical operation | 1. "On path" dendritic inhibition + distal excitation (AND-NOT)<br>2. Local spike in dendritic spines (AND, OR) |  $e_1$ AND-NOT $i_1$<br>$e_1$<br>$i_1$<br>$e_3$ OR $e_4$<br>$e_3$<br>$e_4$<br>$e_5$<br>$e_6$<br>$e_5$ AND $e_6$ |
| Feature extraction | 1. Mapping synaptic inputs to distinct nonlinear dendritic subunits |  |

**Figure 4.** Summary of dendritic computation.

a good solution for the real-life problems that behaving animals must deal with, and the challenge is to explore how the intricacies of dendrites provide such credible solutions. In principle, dendrites could optimize several constraints simultaneously, from the wiring requirements of neural networks to chemical and electrical constraints imposed by the nervous system.

In terms of brain connectivity, dendrites enable the spatial segregation of different types of inputs at different dendritic regions, thus providing a natural means of preserving strong local interactions among specific types of input sources and, at the same time, integrating different input sources onto the same postsynaptic neuron.

The electrical distributed structure of dendrites can give rise to functional subtrees that are partially electrically decoupled from each other. In each of these subtrees, local operations could take place, including local synaptic boosting, local dendritic spiking, local dampening of the backpropagating spike, and so forth. The spatiotemporal (backward-forward) interaction between the different dendritic subtrees could result in a wide range of firing repertoires that would be hard to replicate with spherical (isopotential) neurons. The dendritic tree also behaves like a sink for the excitable channels in the axon; thus it tends to stabilize network activity.

From a chemical perspective, dendrites with their fine diameters and their specialization, such as dendritic spines, allow rapid and very specific activity-dependent local changes to take place in intracellular ion concentrations (e.g., of $Ca^{2+}$ ions). This chemical compartmentalization provides the means for triggering local plastic processes (local "synaptic learning," local morphological changes in dendritic spines). Moreover, the maintenance of ion gradients between the two sides of the dendritic membrane consumes energy. In this context, dendrites may optimize the ratio between membrane area (required for connecting a large number of synapses onto a single neuron) and cell volume, thus reducing energy consumption.

Whether or not dendrites contribute to network computation should be assessed within a wider framework, namely, in terms of the effect of the complexity of the computation executed by a single neuron on the network function. Artificial neural networks typically assume that neurons are simple computational units and that the computation that the nervous system performs emerges as a collective phenomenon. In this framework, the computation at the single neuron level (e.g., orientation selectivity) merely reflects network dynamics. However, as was shown in this article, real neurons can potentially do much more than integrate their input and compare it to a fixed threshold. Moreover, in some cases (mainly in invertebrates), it is clear that single identified neurons actually perform many of the computations required for accomplishing a specific behavioral task.

Thus, the challenge to neural modelers is to better understand whether, and how, the complexity of the single neuron significantly enhances the computational capacity of the network. Once theoretical studies are able to proceed hand in hand with direct measurements obtained from dendrites during actual behavior (and while their nervous system is computing), we will gain a better understanding of the computational role of dendrites. At this point the "dendritic revolution" will come to a close.

# Dendritic Spines

*William R. Holmes and Wilfrid Rall*

## Introduction

The function of dendritic spines has been debated ever since they were discovered by Ramón y Cajal in 1891. Although it was widely believed that spines were important for intercellular communication, this was not demonstrated until 1959 when Gray, using the electron microscope, showed that synapses are present on spines. Why should synapses exist on spines, rather than on dendrites? What role does spine morphology play in their function? Early theoretical studies of these questions focused on the electrical resistance provided by the thin spine stem and suggested that changes in stem diameter might be important for synaptic plasticity. Later investigations found that if voltage-dependent conductances were present on spines, then spines could increase the computational possibilities of a cell. Recent studies suggest that spines are isolated compartments in which highly localized calcium signals can occur. The amplitude and time course of these calcium signals can initiate localized cascades of biochemical reactions important for synaptic plasticity. (For reviews, see Harris, 1999; Nimchinsky, Sabatini, and Svoboda, 2002; and Sabatini, Maravall, and Svoboda, 2001.)

## Spine Morphology

Dendritic spines are short, appendage-like structures found on many different cell types. Spines are composed of a bulbous "head" connected to the dendrite by a thin "neck" or "stem." An excitatory synapse is usually found on the spine head, and some spines also have a second, usually inhibitory, synapse located near or on the spine neck. Spines typically are small in size, but because they occur in densities of 1–2 spines/$\mu$m or more, spine membrane area can comprise 40–60% of the total neuron membrane area.

Attempts have been made to classify spines based on their size, shape, and dendritic location. Jones and Powell (1969) categorized spines as sessile (stemless) or pedunculated (having a peduncle, or stem), with sessile spines more common in proximal regions and pedunculated spines in distal regions. Peters and Kaiserman-Abramof (1970) classified spines as (1) stubby, (2) mushroom shaped, or (3) thin or long-thin (Figure 1). Stubby spines were most numerous in proximal regions, long-thin spines dominated distal regions, and mushroom-shaped spines were distributed almost uniformly. These categories are arbitrary since spine shape varies continuously and all types of spines are found in all areas. In some brain regions, it has not been possible to categorize spines in any systematic manner, but categories and a range of dimensions are useful for models.

## Passive Models of Spine Function

Models in which the spine is represented as a passive electric circuit show that the resistance of a thin spine stem can attenuate a synaptic input delivered to the spine head. This can be seen by considering the circuit pictured in Figure 2.

Assuming a constant synaptic conductance, currents flowing in the spine head can be described by Kirchhoff's law as:

$$V_{SH}/R_{SH} + g_{syn}(V_{SH} - V_{EQ}) + V_{SH}/(R_{SS} + R_{BI}) = 0 \quad (1)$$

where the first term is leakage current across the spine head membrane, the second is the synaptic current, and the third is the flow of current through the spine stem to ground. Because $R_{SH}$ is large, the first term is negligible compared to the other two terms and can be ignored. With this simplification, the steady-state spine head potential is

$$V_{SH} = V_{EQ}/[1 + 1/\{g_{syn}(R_{SS} + R_{BI})\}] \quad (2)$$

Similarly, the currents in the dendrite are described as

$$V_{BI}/R_{BI} + (V_{BI} - V_{SH})/R_{SS} = 0 \quad (3)$$

which can be rearranged as

$$V_{BI} = V_{SH}R_{BI}/(R_{BI} + R_{SS}) \quad (4)$$

Combining Equations 2 and 4, the voltage at the dendrite is

$$V_{BI} = V_{EQ}/[1 + 1/(g_{syn}R_{BI}) + R_{SS}/R_{BI})] \quad (5)$$

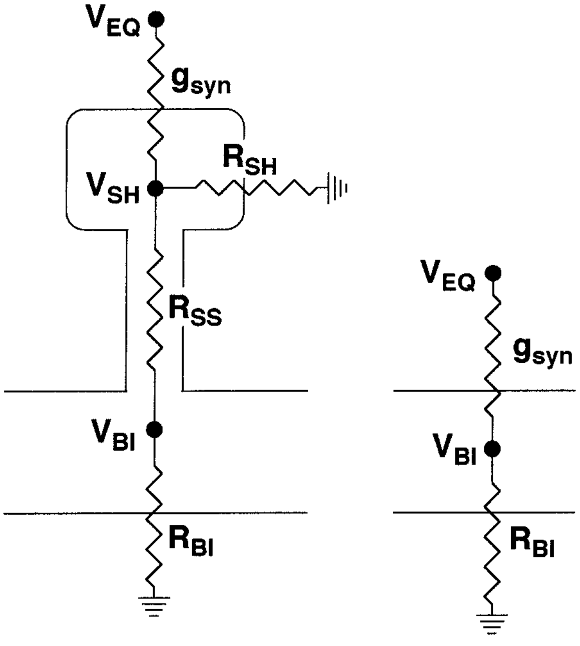

**Figure 2.** Electrical circuit of a dendritic spine. $V_{EQ}$ is the synaptic reversal potential, $V_{SH}$ is the voltage in the spine head, and $V_{BI}$ is the voltage in the dendrite at the base of the spine. $R_{SH}$ is the spine head resistance, $R_{SS}$ is the spine stem resistance, and $R_{BI}$ is the branch input resistance at the base of the spine. $g_{syn}$ is the synaptic conductance. The corresponding circuit for input on a dendrite is shown on the right.

If, however, the synapse were on the dendrite, Kirchhoff's current law says that

$$g_{syn}(V_{BI} - V_{EQ}) + V_{BI}/R_{BI} = 0 \qquad (6)$$

Rearranging, we have

$$V_{BI} = V_{EQ}/[1 + 1/(g_{syn}R_{BI})] \qquad (7)$$

The only difference between Equations 5 and 7 is the presence of the ratio $R_{SS}/R_{BI}$ in the denominator of Equation 5, and this term accounts for voltage attenuation when the synapse is on the spine instead of the dendrite.

Spines also attenuate synaptic current. The synaptic currents for spine and dendritic inputs can be computed by substituting expressions for $V_{SH}$ and $V_{BI}$ in Equations 2 and 7 in place of V in $g_{syn}(V - V_{EQ})$. The resulting currents are given by the right side of Equations 5 and 7 divided by $R_{BI}$. The size of the synaptic current entering the spine is attenuated because, for identical $g_{syn}$, the voltage in the spine head owing to input there is closer to $V_{EQ}$ than the voltage change with a dendritic input.

The $R_{SS}/R_{BI}$ ratio in these equations suggests another possible function for dendritic spines. If a neuron can adjust spine stem morphology (and hence $R_{SS}$), then spines provide a mechanism to allow synaptic weights to be modified (Rall, 1978). For this mechanism to be important, the value of $R_{SS}/R_{BI}$ should lie between 0.1 and 10 times $1 + 1/(g_{syn}R_{BI})$, because within this range a small change in $R_{SS}/R_{BI}$ can have a significant effect on $V_{BI}$ (see Equation 5). Early experimental estimates of $R_{SS}/R_{BI}$ suggested that it might lie in this effective operating range. This encouraged investigators to look for spine dimension changes in various experimental situations. However, recent estimates of $g_{syn}$, $R_{SS}$, and $R_{BI}$ suggest that $R_{SS}/R_{BI}$ may not fall in this range. For example, if $g_{syn} = 0.5$ nS and $R_{BI} = 200$ MΩ, then $1/(g_{syn}R_{BI}) = 10$. This means that $R_{SS}$ should be 220–2,200 MΩ; morphological measurements and imaging experiments indicate, however, that $R_{SS}$ is 5–150 MΩ in many neuron types (Svoboda, Tank, and Denk, 1996). This would seem to rule out the possibility that the function of spines can be explained by changes in passive electrical properties caused by changes in spine dimensions.

## Models of Excitable Spines

If voltage-dependent conductances exist on spines, then spines might exist to amplify synaptic inputs. Early theoretical studies showed that postsynaptic potential and charge transfer were five- to ten-fold larger for synaptic input on spines with voltage-dependent conductances than for input to passive spines. Subsequent studies found that interactions among excitable spines could create a number of interesting computational possibilities for information transfer (reviewed in Segev and Rall, 1998). Chain reactions of spine head action potentials, spreading a certain distance proximally and distally, were theoretically possible. Considerable amplification of the initial input could occur even if only a small percentage of spines possessed voltage-dependent channels. Alternatively, subthreshold depolarization could inactive channels and prevent amplification of later inputs.

Although the prediction that spines exist to amplify synaptic input has received some limited experimental support, the level of amplification is likely to be much less than predicted by the models for two reasons. First, the models assume large densities of voltage-dependent ionic channels in spines (~500–1000 channels per spine) while recent estimates place the number of calcium channels in spines at 1–20 (Sabatini and Svoboda, 2000). Second, the models require a large $R_{SS}$ to get the interesting interaction effects. The latest models reduce the required $R_{SS}$ value to 95 MΩ by assuming kinetics for a low threshold calcium action potential in the spine head, but this value is still at the high end of the 5–150 MΩ range quoted earlier.

## Models of Calcium Diffusion in Spines

The theoretical studies described above searched for a function for spines that depended on the electrical resistance of the spine neck. Besides providing an electrical resistance to current flow, the thin spine neck provides a *diffusional* resistance to the flow of ions and molecules. The spine neck, by restricting the flow of materials out of the spine head, might effectively isolate the spine head and provide a localized environment where reactions specific to a particular synapse can occur.

Calcium is a prime candidate for a substance that might be selectively concentrated in the spine head. Calcium is important for a large number of metabolic processes and has been shown to be necessary for the induction of long-term potentiation (LTP), but high concentrations of calcium can lead to cell death. Spines might provide isolated locations where high concentrations of calcium can be attained safely without disrupting other aspects of cell function.

Compartmental models of dendritic spines that included calcium diffusion, buffering, and extrusion tested this idea. The models predicted that calcium influx at the spine head could produce transient spine head calcium concentrations greater than 10 $\mu$M, while an equivalent influx at the dendrite would produce only a small concentration change. Spine head calcium concentration changes greater than 10 $\mu$M were subsequently observed experimentally.

Large increases in calcium concentration occur because of the small volume of the spine head and because incoming calcium cannot be buffered or pumped out instantaneously. These large transient increases are restricted to the spine head because of the diffusional resistance of the spine neck. The thin spine neck acts as a constriction that slows calcium diffusion. Any calcium that does enter the spine neck is further hindered from diffusing to the dendrite by the presence of calcium buffer and pumps in the spine neck. Calcium that diffuses through the spine neck to the dendrite has little effect on dendritic calcium concentration because of the large dendritic volume.

### *Spines Allow Coincidence Detection*

Amplification of spine head calcium concentration can occur with backpropagating action potentials, allowing spines to detect temporal coincidence of pre- and postsynaptic activity. Although calcium can enter spines via voltage-gated calcium channels or be released from internal stores, in most cells, most spine head calcium enters through NMDA receptor channels. These ligand-gated channels are subject to voltage-dependent magnesium block. Theoretical studies predict a sharp increase in spine head calcium influx when synaptic input occurs slightly before action potential invasion of spines. This occurs because the voltage boost provided by the action potential relieves magnesium block of the NMDA receptor channels. Increases in spine head calcium concentration with coincident pre- and postsynaptic activity has been observed experimentally in a number of labs (e.g., Yuste et al., 1999).

### *Modeling Calcium-Induced Plasticity in Spines*

Spine head calcium concentration changes are important because synaptic plasticity involves cascades of biochemical reactions that are activated or deactivated to different degrees depending on temporal characteristics of the calcium signal. For example, large increases in spine head calcium concentration allow calcium to bind to calmodulin and the calcium-calmodulin complex then activates a number of kinases including calcium-calmodulin-dependent protein kinase II (CaMKII). CaMKII constitutes 20% of the total protein in the postsynaptic density and is thought to play a key role in LTP induction. Recent spine models include predictions of levels of CaMKII activation in the spine head for various input conditions (Holmes, 2000).

The CaMKII pathway is just one of many pathways affected by calcium. Future spine models will study how dozens of different molecules and proteins interact, form signaling complexes, and produce LTP. This is a daunting task, but progress has been made defining network pathways and compiling the necessary rate constants.

### *Factors Affecting Spine Calcium Dynamics*

A number of factors affect the dynamics of the spine head calcium transient. The most important of these are buffer concentration, the magnitude and duration of the calcium current, and spine shape. Buffer concentration and calcium currents in spine heads have been difficult to quantify experimentally, but the range of spine shapes is known for several neuron types. Simulations suggest that spines with fat spine necks are not able to concentrate calcium as quickly or to the same high levels as spines with long-thin necks. Thus, spine shape changes that occur with LTP (Yuste and Bonhoeffer, 2001) are likely to affect the rates and types of calcium-dependent reactions that can occur in a particular spine. During development spines are particularly motile and experimental advances now allow these spine morphology changes to be observed in real time (Matus, 2000). These motility changes can continuously alter calcium decay kinetics in spines.

## Discussion

Early theoretical work with passive spine models showed the importance of the electrical spine stem resistance for synaptic transmission and demonstrated how synaptic weights might be modified by changes in this resistance. Later modeling showed that input could be amplified or transformed in a variety of interesting ways if spines have excitable membrane. However, experimental measurements suggest that spine stem *electrical* resistance is too small to play a significant role in electrical signaling in all but a small percentage of spines.

The current hypothesis is that spines, by restricting diffusion of substances away from the synapse, provide a safe, local, and isolated environment in which specific biochemical reactions can occur. In particular, the spine stem provides a *diffusional* resistance that allows calcium to become concentrated in the spine head and calcium-dependent reactions to be localized to the synapse. This could be very important for plasticity changes, such as those that occur with long-term potentiation. Spine morphology may determine the magnitude of the diffusional resistance and play a role in determining, or restricting, the types of biochemical reactions that can take place at a synapse.

# Development of Retinotectal Maps

*Geoffrey J. Goodhill*

## Introduction

A common feature of many axonal projections between different regions of the nervous system is their organization into topographic maps, whereby nearby cells in the input structure project to nearby cells in the output structure. How do such maps form? The best studied example of this phenomenon is the formation of maps from the retina to more central targets. In frogs, fishes, and chicks, the main visual center is the optic tectum. During development, fibers grow from each retina to the opposite tectum, crossing at the optic chiasm, to form a "retinotopic" map. This map is oriented such that the nasal-temporal and dorsal-ventral axes of each retina map to the caudal-rostral and lateral-medial axes of each tectum, respectively (Figure 1*A*). In mice, there are topographic projections from the retina to both the superior colliculus (SC) and the lateral geniculate nucleus (LGN). The SC receives connections only from the contralateral eye, as in the retinotectal projection in frogs, fishes, and chicks, whereas the LGN receives in addition a small

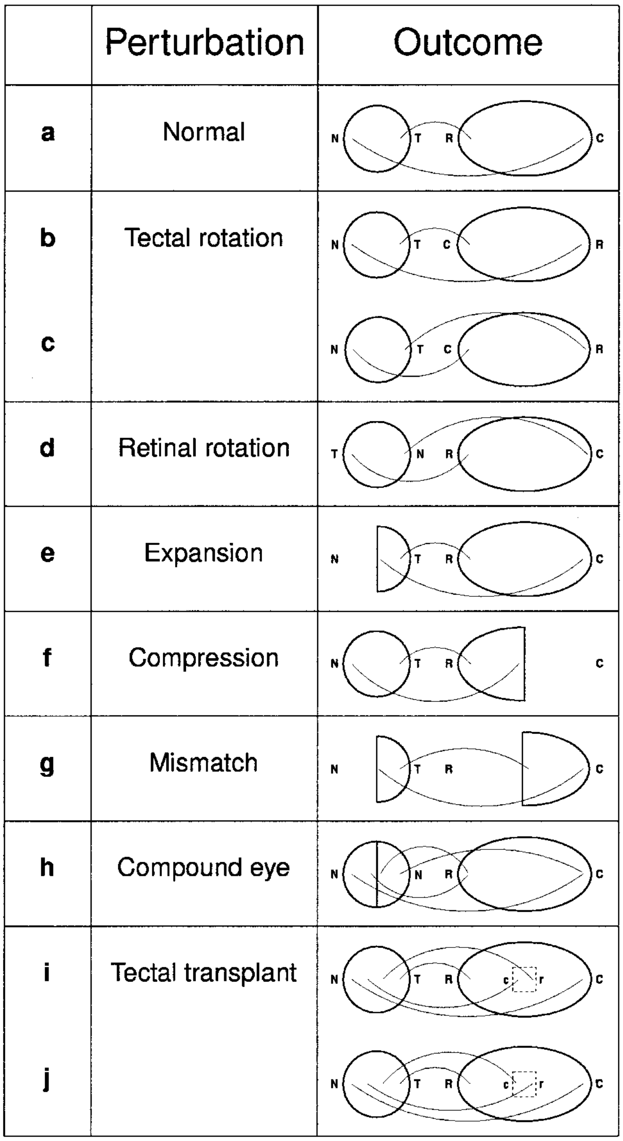

**Figure 1.** Summary of the outcomes of surgical manipulation experiments in the retinotectal system. The circle represents the retina and the ellipse represents the tectum. N, nasal; T, temporal; R, rostral; C, caudal. See text for more details.

ipsilateral projection. For many purposes, this system can be considered as a sheet of retinal ganglion cells connected to a sheet of tectal/SC/LGN cells by a bundle of ganglion cell fibers. Although there is wide variation among species in the degree of order existing in the optic nerve, it is almost always the case that the final map in the tectum is ordered to a greater extent than is the optic nerve (reviewed in Udin and Fawcett, 1988). The development of such maps appears to proceed in two stages: the first involves axon guidance independent of neural activity, while the second involves the refinement of initially crude patterns of connections by processes dependent on neural activity. This article focuses on the former events (see also Axonal Path Finding); for a discussion of the latter see Self-Organizing Feature Maps and Ocular Dominance and Orientation Columns.

## Experimental Data

### *The Chemospecificity Hypothesis*

The main hypothesis driving experimental work in this area has been the idea of "chemospecificity," proposed by Sperry in 1963:

> The establishment and maintenance of synaptic associations [is] conceived to be regulated by highly specific cytochemical affinities that arise systematically among the different types of neurons involved via self-differentiation, induction through terminal contacts, and embryonic gradient effects. . . . [I propose] an orderly cytochemical mapping in terms of two or more gradients of embryonic differentiation that spread across and through each other with their axes roughly perpendicular. These separate gradients successivly superimposed on the retinal and tectal fields and surroundings would stamp each cell with its appropriate latitude and longitude expressed in a kind of chemical code with matching values between the retinal and tectal maps (p. 707).

The most obvious test of this hypothesis is to uncover the molecular identity of these gradients and show that the pattern of these molecules is crucial for proper map formation. However, such a molecular approach has borne fruit only very recently (see below). Instead, much research immediately following Sperry until the 1980s adopted the approach, more rooted in classical embryology, of disrupting the normal development (or, more typically, regeneration) of this system and comparing the outcome with the predictions of Sperry's hypothesis. These experiments are summarized in the next section and in Figure 1. For more detailed discussions, including original references, see Udin and Fawcett (1988), Holt and Harris (1993), and Goodhill and Richards (1999).

### *Surgical Manipulations*

*Shifting connections.* In fishes and frogs, the retina expands radially during development, while the tectum expands mostly along one dimension. The retinotectal map remains ordered throughout this time, indicating that the retinotectal projection is continually shifting.

*Ectopic targeting.* Retinal axons entering the tectum via abnormal trajectories can still find their appropriate termination sites.

*Rotation.* If in *Xenopus* a presumptive tectum is rotated early enough during development, a map is formed that is normal relative to the whole animal (Figure 1*B*), whereas later rotations lead to a rotated map (Figure 1*C*). Initially it was thought that eye rotation could also lead to both a normal outcome if performed early enough and a rotated outcome if performed later. However, more recent experiments have always found rotated maps (Figure 1*D*).

*Retinal ablation ("expansion").* The map formed after removal of half of the retina initially covers half the tectum, but then gradually expands to fill the whole tectum (Figure 1*E*). Axon terminal density remains the same. If the optic nerve is then made to regenerate again, an expanded map is immediately formed.

*Tectal ablation ("compression").* If half of the tectum is ablated, the regenerated map is compressed into the remaining tectal space (Figure 1*F*). If "mismatched" halves of the retina and tectum are ablated, a topographic map still forms (Figure 1*G*).

*Compound eye experiments.* When a whole eye is created by fusing together two half-eye rudiments before connections are made, with the two halves being from opposite eyes but of the same type (i.e., nasal, ventral, or temporal), they each map across the whole tectum in the mirror image of each other (Figure 1*H*). When fragments smaller than half a retina are substituted early in development ("pie-slice" eyes), the retinal fragments map appropriately for their original position, although they can also show some degree of reprogramming.

*Translocation.* If two parts of the tectum are reciprocally translocated, regenerating retinal axons innervate their normal piece of tectum, and also appropriately reverse their order if the tectal fragment is rotated (Figure 1*I*). However, in some cases a map can be formed that ignores the translocation; i.e., the fibers tend to align with fibers in the surrounding tectum, regardless of the orientation of the transplant (Figure 1*J*).

*Branching.* In frogs and fishes, retinal axons grow to their final termination zones directly. In chicks and rodents, however, retinal axons grow past their final termination zone initially, form axon collaterals along the whole axon shaft (but preferentially in their topographically correct region), and then select their specific topographic termination zone by stabilizing an axon collateral while the distal part of the axon is pruned back.

### *Direct Evidence for Molecular Gradients*

A major breakthrough in the understanding of the molecular basis of retinotectal map formation came in the mid-1990s, with discoveries centering on the erythropoetin-producing hepatocellular (Eph) family of receptor tyrosine kinases and their associated ligands, the ephrins (reviewed in Flanagan and Vanderhaeghen, 1998, and O'Leary, Yates, and McLaughlin, 1999). The Eph/ephrins come in two families, A and B, with promiscuous binding within a family but little affinity between families. It now appears that the A family is important for mapping along the rostral-caudal axis of the tectum, while the B family may be important for mapping along the dorsal-ventral axis.

In chick retina (and on the axons of retinal ganglion cells), Eph A3 is expressed in an increasing nasal to temporal gradient, while Eph A4 and A5 are uniformly expressed (Figure 2). In chick tectum, levels of both ephrin-A2 and ephrin-A5 rise from rostral to caudal, with the latter being restricted to more caudal locations and rising more steeply. In mouse retina, Eph A4 and Eph A5 are expressed, with Eph A4 being expressed uniformly and Eph A5 expressed in an increasing nasal to temporal gradient. In mouse SC, levels of ephrin-A5 rise from rostral to caudal, while levels of ephrin-A2 drop off at both ends of the SC.

A GPI-linked molecule, possibly ephrin-A5, in rostral tectum can preferentially induce branch formation of temporal retinal axons in chicks, and ephrin-A5 has been shown to act as a promotor of axonal branching in the formation of layer-specific circuits in the cortex. Ephrin-A2 and ephrin-A5 are also expressed in the retina in an increasing temporal to nasal gradient, though the functional implications of this phenomenon are still unclear. Several lines of evidence suggest that these receptor-ligand interactions are *repulsive.*

## Theoretical Models

The development of retinotectal maps has inspired a large number of theoretical models. Some models have attempted to closely match the large array of data specific to the system in particular species; others have postulated more abstract and generic mechanisms for topographic map formation that can be applied across many systems. This section reviews in historical order some of the models designed to account for the initial activity-independent stage of map formation and specific results, such as expansion, compression, translocation, and rotation of maps.

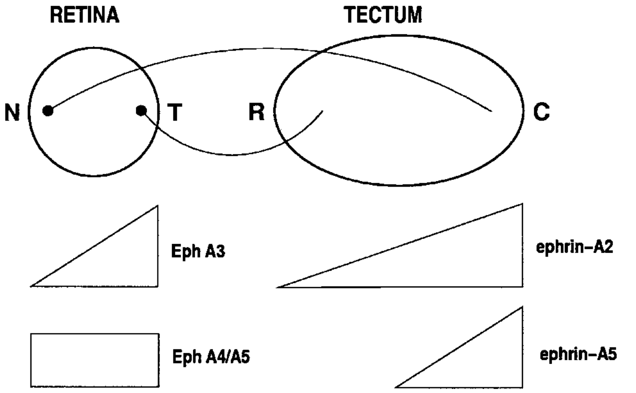

**Figure 2.** The normal retinotectal mapping and the distribution of Eph receptors and ephrin ligands in the chick. Note that the gradients run in opposite directions. Gradient shapes are not precisely linear. N, nasal; T, temporal; R, rostral; C, caudal.

### *Prestige and Willshaw's Model*

Prestige and Willshaw (1975) were the first to formalize notions of chemospecific matching suggested by Sperry's hypothesis. They distinguished between two forms of chemical matching, which they termed group I and group II (or type I and type II). In group I matching, each presynaptic cell *j* has an affinity for just a small neighborhood of postsynaptic cells, with peak affinity for the cell topographically matching to *j* in the postsynaptic sheet. Although such a rigid scheme can form a map under normal conditions, it cannot account for certain experimental data without invoking the unsatisfactory notion of respecification. In group II matching,

> *all* axons have maximum affinity for making and retaining contacts at one end of the postsynaptic sheet of cells, and progressively less for the cells at greater distances from that end. Similarly, all postsynaptic cells have maximum affinity for axons from one end of the postsynaptic set, and axons remote from this end have correspondingly less likelihood of retaining *any* contact. We may thus talk of *graded affinity* within both pre- and postsynaptic sets . . . (pp. 82–83).

Simulations showed that this mechanism is capable of forming an ordered map if competition is introduced, in the form of normalization. Prestige and Willshaw specified that each presynaptic cell could make only a fixed number of contacts $N_{\text{pre}}$ among the postsynaptic cells, and similarly each postsynaptic cell could only support a fixed number of contacts $N_{\text{post}}$ from presynaptic cells. This ensures an even spread of connections: without competition for postsynaptic sites, every presynaptic cell would connect only to the highest-affinity end of the postsynaptic set, while without competition for presynaptic sites, every postsynaptic cell would receive connections only from cells at the highest-affinity end of the presynaptic set. However, to explain compression and expansion of retinotectal maps, Prestige and Willshaw found that it was necessary to make the additional assumption ("regulation") that $N_{\text{pre}}$ and $N_{\text{post}}$ were also altered. For instance, if half the postsynaptic set is removed, then, unless $N_{\text{post}}$ is increased, connections will only be made from the highest-affinity end of the presynaptic set.

## The Arrow Model

In the "arrow" model of Hope, Hammond, and Gaze (1976), it is assumed that (1) retinal fibers that terminate next to each other in the tectum are able to compare their relative positions of origin, and (2) retinal fibers can identify both rostral-caudal and medial-lateral axes of the tectum (this could be implemented in terms of a polarity gradient of marker along each of these axes). The procedure is then basically the bubblesort algorithm, although a biological implementation for this is not described. Starting from initially random connections in which each retinal fiber contacts one tectal cell, two retinal fibers that terminate next to each other in the tectum are chosen at random. Their retinal positions are compared, and if they are appropriate, the sites of termination of the fibers are exchanged. This simple algorithm is capable of forming topographic maps under normal conditions, and also rotated maps when a piece of the tectal array is rotated. However, it fails to account for the translocated map experiments.

## The Tea Trade Model

Willshaw and von der Malsburg (1979) proposed a model based on Sperry's idea that map formation is somehow dependent on induction of molecules from the retina into the tectum. The model is expressed in terms of molecular markers, but markers intrinsic only to the presynaptic sheet. There are no preexisting markers in the postsynaptic sheet: it is assumed that presynaptic markers are transported to the postsynaptic sheet via induction along retinal axons. Several markers exist in the presynaptic sheet, the sources of which are spaced out in the presynaptic sheet at fairly regular intervals. An analogy presented to explain the working of the model was the import of tea from plantations in India to British towns; hence the name "tea trade model."

Initially, markers diffuse in the presynaptic sheet until a stable distribution is set up. It is assumed that each presynaptic axon then induces the vector of markers existing at that point in the presynaptic sheet into the postsynaptic sheet, where the markers diffuse according to the same rule as in the presynaptic sheet. The rate of induction at each synapse is proportional to the strength of that synapse. Synaptic strengths are updated periodically according to the degree of similarity between the vector of markers each fiber carries and the vector of markers already existing at those points it contacts in the postsynaptic sheet. Synaptic updating occurs with a molecular analogue of Hebb's rule: the strength of connection between presynaptic cell $i$ and postsynaptic cell $j$ is increased in proportion to the similarity of their vectors of molecular markers. A slight overall bias in the connection strengths is specified initially in order to provide a global orientation for the map. Synaptic strengths are normalized by division so that each presynaptic cell can only support a certain total strength of connections. This ensures that every presynaptic axon makes contacts in the postsynaptic sheet. Willshaw and von der Malsburg (1979) showed that such a process reaches a stable state and can form appropriate maps under normal conditions, and also correctly predict the outcome of a range of results under abnormal conditions. In particular, some regeneration experiments can be accounted for under this scheme by assuming that when regeneration occurs, the postsynaptic sheet holds a "memory" of the previous pattern of innervation in terms of the previous stable distribution of markers. An algorithm similar to the tea trade model was analyzed mathematically for the one-dimensional case by Häussler and von der Malsburg (1983).

## Gierer's Model

Gierer (1983) proposed a model based on the matching of preexisting gradients in retina and tectum as in the chemoaffinity hypothesis. He imagined that mapping is controlled by the concentration of an inhibitory substance $p(x, u)$, where $x$ indicates tectal position and $u$ indicates retinal position. $p$ is produced by a reaction of the graded distribution of a retinal marker present on the tips of retinal axons with a graded distribution of a tectal marker. Axons then grow down the gradient of $p$ to a minimum, stopping when $\partial p/\partial x = 0$.

For this to form a map, it is obviously required that the position of this minimum vary smoothly as a function of retinal origin $u$; in the simplest case when $x = u$. There is an infinite number of combinations of gradient shapes and reaction rules that accomplish this; Gierer specifically considered exponential gradients. He also suggested a possible mechanism for gradient change in response to surgical manipulations such as retinal or tectal ablation. Reminiscent of the tea trade model, the idea is that

> retinal fibre terminals induce, in the tectum, a slow increase in source (e.g. an enzyme) producing an additional contribution to $p$, and that the rate of increase is proportional to the local density of retinal fibre terminals. If the sources thus produced persist on the tectum while fibre terminals continuously move to respecified positions of minimal $p$, this process will eventually smooth out differences in the density of fibre terminals, giving rise to compression or expansion in the dimensions of ablation (p. 84).

The specific trajectories that axons might take to their targets under such a gradient matching scheme were also simulated.

Honda (1998) presented a simpler model in which axons grow to the tectal position where the retinal receptor concentration $R[u]$ times the tectal ligand concentration $L[x]$ equals a constant $S$, or $R[u]L[x] = S$, where $S$ is the same for all axons. A brief analytical investigation of this type of model can be found in Goodhill and Richards (1999).

## Fraser's Model

In a more abstract vein, Fraser (e.g., Fraser and Perkel, 1990) introduced the notion that the state of the system could be described by an "adhesive free energy" $G$, which depends on how successfully a number of constraints are satisfied. In his model the form of the final mapping is found from minimizing $G$ by simulated annealing. The constraints employed (in order of decreasing weighting in $G$) are (1) a position-independent adhesion between retinal and tectal cells, (2) a general competition among retinal axons for tectal space, (3) a tendency for neighboring axon terminations in the tectum to stabilize if those axons come from neighboring positions in the retina, (4) a dorsoventral gradient of adhesive specificity in retina and tectum, and (5) an anteroposterior gradient in retina and tectum. Although this model accounts (at least qualitatively) for a large proportion of the experimental literature, a developmental mechanism that could perform such a minimization was not provided.

## Cowan's Model

Whitelaw and Cowan (1981) attempted to integrate both marker- and activity-based mechanisms in map formation by combining a gradient of adhesive specificity with activity-dependent synaptic updating. Changes in synaptic strengths are multiplied by the degree of "adhesion" between the corresponding pre- and postsynaptic cells, and both pre- and postsynaptic normalization are employed. The model predicts a range of the experimental literature (including expansion and compression, mismatch, rotation, and compound eye experiments), and also draws attention to experimental evidence contradictory to the induction hypothesis of the tea trade model. More recent additions to this model, for instance a tendency for fibers to stick to their retinal neighbors, have increased the range of data it can account for (see, e.g., Weber et al., 1997).

## Discussion

Consideration of the wide variety of data described in the preceding sections—Eph/ephrin gradients, disturbances of normal development and regeneration, and branching—suggests two major limitations of previous models. First, few of them take into account recent discoveries regarding molecular gradients and their role in retinotectal mapping. Second, most of the previous models take synaptic strengths as their primary variable between arrays of retinal and tectal locations. They generally assume each retinal location is initially connected to all tectal locations, or at least to a topographically specific subset. Synaptic strengths are then updated according to rules that depend in various ways on correlated activity, competition for tectal space, molecular gradients, and fiber-fiber interactions. However, these last three effects enter only as terms modulating the development of synaptic strengths. With rare exceptions, actual movement or branching of axons to find their correct targets is not considered. The key experimental results that future computational models of retinotectal map formation should attempt to account for, besides normal map development, include the results of single and multiple knockout experiments of the relevant Eph receptors and ephrin ligands, results of experiments in which Eph/ephrins are misexpressed in retina or tectum, the correct guidance of retinal axons that enter the tectum by ectopic routes, and the results of retinal and tectal ablation and transplantation experiments.

# Developmental Disorders

*Annette Karmiloff-Smith and Michael S. C. Thomas*

## Introduction

Connectionist models have recently provided a concrete computational platform from which to explore how different initial constraints in the cognitive system can interact with an environment to generate the behaviors we find in normal development (Elman et al., 1996; Thomas and Karmiloff-Smith, 2002a). In this sense, networks embody several principles inherent to Piagetian theory, the major developmental theory of the twentieth century. By extension, these models provide the opportunity to explore how shifts in these initial constraints (or boundary conditions) can result in the emergence of the abnormal behaviors we find in atypical development. Although this field is very new, connectionist models have already been put forward to explain disordered language development in Specific Language Impairment (Hoeffner and McClelland, 1993), Williams syndrome (Thomas and Karmiloff-Smith, 2002b), and developmental dyslexia (Seidenberg and colleagues; see, e.g., Harm and Seidenberg, 1999) and to explain unusual characteristics of perceptual discrimination in autism (Gustafsson, 1997; Cohen, 1998). In this article, we examine the types of initial computational constraints that connectionist modelers typically build in to their models and how variations in these constraints have been proposed as possible accounts of the causes of particular developmental disorders. In particular, we examine the claim that these constraints are candidates for what will constitute innate knowledge. First, however, we need to consider a current debate concerning whether developmental disorders are a useful tool to explore the (possibly innate) structure of the normal cognitive system. We will find that connectionist approaches are much more consistent with one side of this debate than the other.

## Developmental Disorders and Modularity

Cognitive neuropsychology assumes that the adult cognitive system has a modular structure, whereby the system can be decomposed into specialized functional components (although whether these components correspond to localized areas of the brain or can be captured by brain-imaging techniques remains an open question). In addition, cognitive neuropsychology assumes that that selective behavioral deficits in adults with brain damage can reveal this modular structure. Developmental disorders can also produce apparently specific deficits in the end state of development. For example, Williams syndrome (WS), a developmental disorder caused by a microdeletion of contiguous genes on one of the alleles of chromosome 7, is characterized by a behavioral profile of relative proficiency in language, face processing, and theory-of-mind (attributing mental states to others) but severe deficits in other skills such as visuospatial processing, number, and problem solving (Karmiloff-Smith, 1998). In hydrocephalus with associated myelomeningocele (a protrusion of the membranes of the brain or spinal cord through a defect in the skull or spinal column), language can be the only area of proficiency. Individuals suffering from Specific Language Impairment (SLI) show the opposite pattern, often apparently performing within the normal range in all domains except language. In autism, even individuals with normal IQs are selectively impaired in tasks that require judging another's mental states (Baron-Cohen, Tager-Flusberg, and Cohen, 1993).

Evidence in many of these disorders of specific high-level deficits at the end of development has encouraged some researchers to view developmental disorders as offering the same theoretical insights into the static structure of the cognitive system that cases of adult brain damage provide. Where such disorders are of a genetic origin, selective developmental deficits are interpreted as revealing innate underpinnings for such structure. For example, Baron-Cohen et al. (1993) have argued that in individuals with autism, an apparent deficit in reasoning about mental states can be explained by the impairment of an innate, dedicated module for such reasoning (the theory-of-mind module). Van der Lely (1997) maintains that selective behavioral deficits in the language performance of children with grammatical SLI can be explained by damage to an underlying, innate module representing syntactic (rule-based) information. Clahsen and Almazan (1998) have proposed that a behavioral deficit in WS language supports the view that while their syntactic skills are "intact," individuals have a deficit to a specific aspect of their (modular) language knowledge: that of accessing information about words that are exceptions to syntactic rules.

However, there are a number of problems with the adult brain damage approach to developmental disorders (Karmiloff-Smith, 1998; Thomas and Karmiloff-Smith, in press). These boil down to the suspicion that such an approach massively underestimates the complexity of the path from gene to behavior. The prevalence of many-to-many, very indirect mappings in the relationship of genes to cognition undermines the claim that direct specific mappings will exist between particular genes and individual high-level cognitive abilities. To the extent that genes are involved in the causal chain of several cognitive domains, it will be less likely that they code anything specific to a single domain. Indeed, direct mappings are unlikely, given that spatial distributions of gene expression in the brain are rarely narrowly confined to subsequent areas of functional specialization in the adult brain and therefore seem unable to code directly for domain-specific developmental outcomes. Even if they could, the idea that behavioral deficits that are identified in the end state of a developmental disorder could reflect the impairment of a single functional module is predicated on the dubious assumption that the rest of the cognitive system could nevertheless develop normally. For this to be true requires either that functional modules develop independently of overall brain growth or that the content of modules is fixed in advance (i.e., the content is innately specified). But neither of these assumptions is likely to be true. With regard to the first, Bishop (1997) has argued persuasively that interactivity rather than independence is the hallmark of early development. With regard to the second, it seems likely that modular structure in the cognitive system and in the brain is an outcome of development rather than a precursor to it and that the neonate brain does not support innate representations with specific content (Elman et al., 1996; Johnson, 1997). A growing number of studies show how both neural localization and neural specialization for biologically important functions, such as species recognition (Johnson, 1997) and language (Neville, 1991), take place gradually across development.

An alternative to the use of the adult brain damage model is the neuroconstructivist approach (Elman et al., 1996; Karmiloff-Smith, 1998). This approach views developmental disorders in terms of different developmental trajectories, caused by initial differences at a neurocomputational level. Thus, there might be differences in the microcircuitry of the brain or the firing properties of neurons, as opposed to discrete lesions to particular large-scale brain structures or pathways. In this view, development is an interactive process in which the cognitive system self-organizes in response to interactions with a structured environment. Interestingly, this approach suggests that people with developmental disorders may exhibit strengths as well as weaknesses. This prediction is consistent with the superior face recognition skills found in WS and the superior perceptual discrimination abilities found in autism. Neuroconstructivism further suggests that equivalent behavior across normal and abnormal phenotypes may mask different underlying cognitive processes. The notion that an ability is "intact" or "spared" because there is no apparent deficit at the behavioral level employs terminology from the adult brain damage model that may be misleading. To take an example, people with Williams syndrome can display scores on some language and face-processing tasks that are in the normal range. Nevertheless, closer examination suggests that different *cognitive* processes underlie the equivalent *behavioral* scores (Karmiloff-Smith, 1998).

## Initial Constraints in Connectionist Models

Current connectionist models of developmental disorders employ alterations to the initial model constraints that, after training, lead to an end state exhibiting behavioral deficits. Connection weights are usually randomized so that the normal network has no specific knowledge prior to training. Thus, it follows that the atypical network has no specific deficit in knowledge prior to training. The behavioral deficits that emerge when these atypical networks are trained are often quite different from the effects of damaging a normal network model after training has been completed. This holds even when the network manipulations are the same in each case (Thomas and Karmiloff-Smith, in press). Thus, current connectionist models are more consistent with the neuroconstructivist approach to developmental disorders than with the adult brain damage approach.

What, then, are the initial constraints that connectionist modelers build into their models of cognitive development? And how do changes to these constraints alter the trajectory of development? In fact, the constraints that connectionist models build in are quite strong ones, and this may come as a surprise to some readers. Connectionist models are often mischaracterized as being unitary, homogeneous, seamless, or undifferentiated domain-general learning devices, whereby the environment is all-powerful in shaping the behavior of the final system. In fact, current connectionist models have a great deal of pre-existing structure built into them prior to any exposure to their training environment. What is general about connectionism are the principles of computation (Seidenberg, 1993). When the general principles of computation are combined with the boundary conditions for a specific domain, the result is a domain-specific model. It is the generality of these principles that gives the connectionist approach its explanatory power. That is, connectionism seeks not just to formulate descriptive generalizations about empirical phenomena, but also to show how they derive from underlying and independently motivated principles (Seidenberg, 1993). However, connectionist models are just as reliant on the constraints of a given domain as they are on the computational principles. Without justified limitations in the design of network models, they become overpowerful data-fitting devices that can at best provide descriptively adequate accounts of cognitive abilities. In short, connectionist models of development do include initial structure but not initial representational content (Elman et al., 1996). The point is that in interacting with a training environment, networks create representational content and become increasingly structured. This additional structure reflects the nature of the training environment.

The structure or boundary conditions that these models build in prior to training typically involve the following:

1. *The initial state of the network, in terms of the number of units, layers, connections, and the pattern of connectivity, collectively known as the network architecture.* The architecture determines the computational power of the network and the type of computations to which the network will be suited. For example, recurrent networks are suited to processing sequential information, whereas associative networks are suited to pattern recognition. The a priori choice of the architecture will have a central role in determining the adequacy of the network in modeling a given domain of cognitive development. A reduction in the number of processing units, or the elimination of internal (hidden) processing units, will restrict the computational power of the network and, depending on the nature of the domain, cause some or all parts of the problem to be learned inadequately. Addition of layers of internal units beyond a single layer tends to delay learning, without a marked increase in effective computational power. Increase of hidden units within a single layer tends to improve performance on the training set but may impair generalization beyond the training set.
2. *The way a particular cognitive problem is presented to the network, in terms of the input and output representations.* For a given domain, the representations determine the nature of the computational problem that the network will face. When the network has to extract a function from the training set (such as a general rule or regularity), the representational scheme will be crucial in determining how transparent or opaque this function is to the network. For instance, if a network is given a training set in a form that masks the relevant similarity between those items in the problem domain that obey a rule, the network will have difficulty in extracting this regularity.
3. *The learning algorithm that the network will use to change its connection weights (and, potentially, its architecture).* Most networks are trained by changing weights to minimize some cost function, such as the difference between the actual output and a target output. The rate at which weights are changed can have an impact on the success of a network in learning a problem. In particular, in complex domains, if weights are changed too quickly, the network may commit too early to a partial solution to the problem and be resistant to change with subsequent training. The learning algorithm is key in determining the plasticity of the network to further learning. Some algorithms allow online changes to network architecture depending on how well the network is learning a problem. The way in which the network's computational power is altered on-line will again have a considerable influence on the success of the network in capturing a cognitive ability (see 1 above).
4. *The regime of training that the network will undergo.* After modelers determine the network and the learning rule, they then expose the network to a training set. Often, the network is exposed to the entire training corpus from the start of training. However, in some cases, the network might be trained on an initially limited training set, perhaps based on assumptions about the nature of a child's early learning environment. This initial restriction will affect later training. It may aid learning if the smaller set is representative of the larger set or if it allows the construction of internal representations that will be useful in learning the larger set. On the other hand, it may impair learning if the initial training set contains detail that is irrelevant to the full domain. Alterations in network parameters early in training may have the same effect as restricting the initial training set, as Elman's work on learning syntax with recurrent networks has demonstrated (Elman et al., 1996).

In the connectionist framework, these constraints represent some of the candidates for innateness (although, equally, in principle, any of the constraints could also be experience dependent). Alterations in one or more of these constraints may then lead to the emergence of disordered representations and impaired behavior in a model of atypical development.

We have noted that these models do not support innate representational content in that their weights are initially randomized. However, it is an open question as to whether initial computational constraints (along with sensory input determined by the individual's interaction with the environment) are sufficient to drive development. One possible addition is the postulation of innate attentional predispositions (Elman et al., 1996). In this theory, innate knowledge is built into the subcortical part of brain in the form of a low acuity predisposition to attend certain stimuli. This predisposition then ensures the representation of input that will subsequently drive learning in the more powerful cortical system. For example, such an innate predisposition in face recognition might encourage the newborn infant to attend preferentially to visual stimuli containing a single blob positioned centrally below two blobs (see Johnson, 1997). Innate predispositions provide another candidate factor that might be altered in the start state of the atypical system.

In general, current connectionist models of normal development do not restrict themselves to computational constraints and innate attentional predispositions in their start states, since these models incorporate high-level, domain-specific representations. These models must therefore be seen as a halfway house. In the future they need to be extended to show how their domain-specific representations emerge from some prior process operating over lower-level information (and with its own computational constraints).

We now turn to consider recent examples of connectionist models of developmental disorders.

## Recent Models

### *Autism*

Autism is a developmental disorder characterized primarily by a central triad of deficits in social interaction, communication, and imagination but also by a range of secondary deficits. These include a restricted repertoire of interests, an obsessive desire for sameness, excellent rote memory, improved perceptual discrimination, and an impaired ability to form abstractions or generalize knowledge to new situations. Evidence from neuropathological investigations of the brains of affected individuals is suggestive of abnormal wiring patterns in various brain regions, perhaps caused by deficits in neuronal migration during fetal development, curtailment of normal neuronal growth, and/or aberrant development. Cohen (1998) has argued that these structural deficits are consistent with too few neurons in some brain areas, such as the cerebellum, and too many neurons in other areas, such as the amygdala and hippocampus. Cohen has proposed that simple connectionist models trained on categorization tasks can link such differences in neurocomputational constraints to some of the secondary deficits found in autism. In some cases, children with autism have trouble acquiring simple discriminations and attend to a restricted range of stimuli, while in others, children with autism have good discrimination and indeed very good memory but seem to rely on representing too many unique details of stimuli. Cohen showed that simple backpropagation networks with too few hidden units showed a failure to learn classifications tasks, while those with a surfeit of hidden units showed very fast learning, but subsequently generalization became poor, and the network increasingly responded according to particular details of the training set.

In a related proposal, Gustafsson (1997) speculated that the combination of a failure to generalize and heightened perceptual discrimination might be traced to the atypical development of cortical feature maps. In particular, he suggested that higher-than-normal levels of within-layer inhibition in the initial cortical sheet would lead to overly fine-tuned perceptual features, permitting good discrimination but preventing good generalization.

Although Gustafsson did not support this idea with implementations, related work by Oliver et al. (2000) offers an insight into how feature map formation can be developmentally disrupted by changes in the initial properties of a self-organizing connectionist network. Oliver et al. employed a neurobiologically constrained network in which a two-dimensional output layer received information from a single input retina. The network was shown a set of stimuli in the form of bars lying across the input retina. Oliver et al. showed that, using their initial parameter set, the output layer formed a topographic map of the possible inputs: Certain areas of the output layer specialized in responding to each input, and areas representing similar inputs were adjacent to each other in the output layer. Oliver et al. then re-ran the model, disrupting the network in different ways before exposing it to the training stimuli. They varied the threshold of the output units, disrupted the connectivity between the input and the output layers, disrupted the connectivity responsible for lateral inhibition in output layer, and changed the similarity of the input stimuli to each other. These manipulations demonstrated that tiny differences in the initial constraints under which the model developed could have a very significant impact on the outcome of development. The resulting topographic map suffered a range of disruptions, including output units failing to specialize at all or simply turning off, specialization emerging but not in organized areas, and organized areas emerging but without adjacent areas representing similar-looking bars.

Much work remains to be done to develop these proposals exploring the neurocomputational underpinnings of developmental disorders such as autism and, in particular, to relate disordered feature maps or hidden unit numbers to higher-level cognitive deficits such as those in social interaction, communication, and imagination that characterize autism. Nevertheless, such work importantly illustrates a new conception of such disorders in terms of development operating under atypical constraints, rather than in terms of deficits to high-level modules in a static model of the normal adult cognitive system.

### *Developmental Dyslexia*

This disorder has been the focus of much connectionist research, given the success of models in capturing the normal processes of reading. A number of models by Seidenberg and colleagues have sought to change initial constraints in models of reading to simulate either surface dyslexia (in which the subject has difficulty reading words that are exceptions to normal rules of pronunciation), phonological dyslexia (in which the reading of novel words is impaired), or a combination of both. Typically, these models learn mappings between codes representing orthography, phonology, and semantics. Surface dyslexia has been simulated by employing “too few” hidden units in the model or by reducing the learning rate. Phonological dyslexia has been simulated by degrading the phonological representations in some way, for instance, in the type of coding scheme used. For example, Harm and Seidenberg (1999) pretrained one part of their model to develop appropriate phonological representations prior to learning the reading task. When this “phonological” part of the model was impaired, either by reducing its initial computational power or by limiting the size of the connection weights it could develop, the result was a network exhibiting phonological dyslexia at the end of training on the reading task.

### *Specific Language Impairment*

Hoeffner and McClelland (1993) sought to capture deficits found in the morphosyntax of subjects with SLI, specifically their difficulty in the learning of rule-based inflectional morphology in verbs. Hoeffner and McClelland employed an attractor network mapping between semantic codes and phonological codes. They simulated SLI by changing the initial phonological representations, in line with a hypothesis that SLI may be caused by early perceptual impairments. Specifically, they impaired the network’s ability to represent word-final stops and fricatives (including /t/, /d/, and /s/). Although the model they used didn’t show an ideal fit to the normal data when unimpaired, it nevertheless captured a number of the key deficits of SLI when trained with impaired representations, particularly a selective difficulty with the formation of regular (+ed) past tenses. In this case, the initial phonological deficit obscured precisely the information that the network required to be able to learn the relevant generalizations about regular past tense formation. However, it should be noted that the perceptual deficit account of SLI remains controversial, and this disorder may well turn out to be heterogeneous, with several different causes.

### *Williams Syndrome*

Recent work in our laboratory has examined underlying deficits in the language of individuals with Williams syndrome (WS). Their language was initially thought to be “spared,” but closer examination revealed a number of subtle deficits. It had been reported that individuals with WS show difficulties in forming the past tense of irregular verbs while showing good performance on the regular, rule-based past tense formations (Clahsen and Almazan, 1998). Our recent empirical work suggests that much of this apparently selective deficit is due to an overall delay in language development (young children also find irregular verbs difficult). However, individuals with WS do appear to show a deficit in generalizing knowledge of inflectional patterns to novel forms. These two patterns (selective difficulty with irregular inflections versus reduced levels of generalization) continue to be argued for in the literature on WS language.

Thomas and Karmiloff-Smith (2002b) set out to explore whether alterations to the initial computational constraints of a connectionist model of past tense development could account for either of these patterns of data. The past tense network mapped from verb stem to past tense form in the presence of lexical-semantic information. Various theoretical claims have been made that the WS language system develops under different constraints. These include the proposals that their phonological representations may be atypical and perhaps rely on sensitive auditory processing, that their lexical-semantic representations may show anomalous organization, or that lexical-semantic information about words may be poorly integrated with phonology. To explore the viability of these different accounts to explain the pattern of performance in the past tense task, Thomas and Karmiloff-Smith altered the initial constraints of the network model to implement each type of lower-level deficit.

The results revealed that reduced generalization was consistent with atypical phonological representations (specifically with reduced similarity and redundancy) or interference in integrating lexical-semantic and phonological knowledge. A range of computational constraints caused poorer acquisition of irregular verbs; these verbs are in the minority, and their acquisition can be disrupted under nonoptimal learning conditions. However, attenuated activation from lexical-semantics was able to selectively delay irregular acquisition, offering a link to one of the proposed deficits in WS. Finally, the model demonstrated for the first time precisely how different computational constraints interact in a system in the process of development: The atypical trajectory that is found in WS may arise from the combination of more than one altered constraint.

Further empirical work remains to be carried out to clarify which of the WS patterns is the correct one. However, this modeling work has determined which of the competing accounts are viable within an existing developmental framework and therefore provided a focus for future investigations. Once again, this contrasts with previous theoretical work that construed the WS language system in terms of selective deficits to a static model of the normal adult language system (e.g., Clahsen and Almazan, 1998).

## Discussion

Developmental disorders can inform the study of normal development because they provide a broader view of the parameter space within which development takes place. The empiricist argues that the environment specifies a capacity so strongly that systems with a wide variety of initial structures must come to reflect it. The nativist argues that the environment specifies a capacity so poorly that the system must come equipped with pre-existing structure if it is to find the correct solution given the environmental input. The neuroconstructivist argues that the robustness of the cognitive system to changes in its initial setup (as long as we can come to understand precisely what these changes are) will tell us how evolution has placed its bets concerning the capacities that can be trusted to emerge through experience and the capacities that must be given a firmer guiding hand through development. Connectionist models provide a powerful tool with which to investigate the role of initial computational constraints in determining the trajectory of both typical and atypical development. For developmental disorders in which selective deficits in high-level behaviors are reported, the connectionist framework ensures that these deficits are properly seen in terms of the outcome of the developmental process itself.

# Diffusion Models of Neuron Activity

*Luigi M. Ricciardi and Petr Lánský*

## Introduction

We offer a survey of one-dimensional stochastic diffusion models for the membrane depolarization of a single neuron, with emphasis on the related first-passage-time (FPT) problems, namely, on the determination of the neuronal output. In complex deterministic neuronal models, such as the Hodgkin-Huxley or the Fitzhugh-Nagumo models, the generation of action potentials is automatically included, being itself an essential component of the equations defining and characterizing these models. By contrast, for simple models (usually stochastic, such as those reviewed here), a firing threshold has to be introduced; the generation times of the action potentials are then identified with the instants when the membrane depolarization, which is modeled on the analogy of a particle randomly diffusing in a liquid, equals the firing threshold. Although these times are unique for deterministic models, in the case of stochastic models, and apparently also for many types of real neurons, the time interval that elapses between an action potential and the next one is at least partly random. In the sequel, such a time interval will be viewed as a random variable. The properties of this random variable are mathematically investigated by studying the related FPT problem.

Hereafter, we shall make use of the formalism of stochastic differential equations (SDEs). These equations can be heuristically described as ordinary differential equations in which a rapidly and irregularly fluctuating term (usually involving white noise, in additive or mutiplicative forms) is also present; they are also referred to as to Langevin equations, after the renowned physicist Paul Langévin. To elucidate the nature and the assumptions underlying diffusion models, in a couple of paradigmatic instances we shall sketch how neuronal stochastic diffusion models can be constructed from first principles, that is, without resorting to SDEs. We shall thus indicate how the much-celebrated Wiener and Ornstein-Uhlenbeck (OU) neuronal models stem from simple Markov processes with discrete state spaces after a suitable limiting procedure.

The broad applicability and intuitive appeal of the OU model follow from the circumstance that, if formulated by means of an SDE, up to the stochastic term it coincides with the most common phenomenological deterministic neuronal model, the so-called "leaky integrate-and-fire model." Hence, the OU model represents a natural bridge between deterministic and stochastic modeling of neurons' activity. The success of the Wiener model, which is a special case of the OU model, is instead based on the fact that it is largely solvable in closed form. For this reason, it may serve as a prototype for possible comparisons.

Besides the OU and Wiener models, which are characterized by additive noise terms appearing in the corresponding SDEs, diffusion models with multiplicative noise will also be reviewed. Although neuronal models of the diffusion type are primarily used for the description of steady-state firing under a constant stimulation, some results that are obtained in the case of periodic stimulation will also be mentioned. Irrespective of the type of applied noise, the approach employed here is based on frequency coding presumption.

Stochastic diffusion models are not primarily aimed at direct comparisons with experimental data, being mathematical abstractions of less tractable but more realistic or transparent models. They mainly serve to study the properties of other models by mathematical methods and to produce qualitative predictions, as in the extensive investigations performed on the possibility of stochastic resonance in neurons and neuronal models. For this reason, direct analyses of experimental data by diffusion models are relatively rare. For some references on this matter, see Inoue, Sato, and Ricciardi (1995). More references and expanded commentary can be found in a recent review article (Lánský and Sato, 1999). Additional references and detailed treatment of some models are in Ricciardi (1977) and Tuckwell (1988). For a review on the FPT problem for diffusion processes, see Ricciardi and Sato (1989).

## Diffusion Processes and Neuronal Modeling

From a biophysical point of view, neuronal models of single cells reflect the electrical properties of the membrane via electric circuit models that contain energy storage elements. Such circuit models can be described by means of differential equations for the membrane potential. A consistent body of data, recorded from a large variety of different neuronal structures and under different experimental conditions, suggests that the presence of stochastic variables should in general be included in the mathematical models of the neuron's input-output activity, even though the role and influence of these variables are expected to depend on the nature of the specific questions one wishes to answer. Hereafter, we assume that there is a random component, generally denoted as *noise*, embedded in the neuron's input. A second source of noise can be attributed to the neuron itself, where a random component is added to the incoming input signal. Taking this fact into account, the differential equation describing the neuronal membrane potential then includes a noisy term, and hence becomes itself an SDE whose solution can sometimes be approximated by a diffusion process. In other cases—for instance, when the neuron has very few synaptic inputs near the trigger zone—a Poisson-driven differential equation may be a biologically more appropriate model.

Here we shall assume that the membrane potential between two consecutive neuronal firings (spikes) is represented by a scalar diffusion process $X(t)$. Such a process can be described by the SDE

$$\begin{gathered} dX(t) = \mu[X(t), t]dt + \sigma[X(t), t]dW(t), \\ P\{X(t_0) = x_0\} = 1 \end{gathered} \tag{1}$$

where $\mu$ and $\sigma$ are real-valued functions of their arguments satisfying certain regularity conditions, and $W(t)$ is the standard Wiener process. (See Ricciardi, 1977, for an expository discussion of SDEs.) The Wiener process has historically been exploited as the first mathematical model of Brownian motion, namely, the highly irregular and ceaseless motion characterizing all particles immersed in a fluid, irrespective of their nature, that was discovered by Robert Brown as early as 1827. Only in the year 1905 was a mathematical explanation of this mysterious phenomenon provided by Albert Einstein. In the mid-1930s Einstein's theory was refined, completed, and made mathematically more rigorous and general by various physicists and mathematicians, including Norbert Wiener, after whom a fundamental stochastic diffusion process was named. In short, the foundations of a new branch of the theory of stochastic processes were laid, based on a formalism involving equations similar to those describing the time change of the temperature in each point of a metal rod initially heated at one point, or the change of density in each point of a liquid after dropping in it a specified amount of salt. Thus were the "diffusion equations" born.

A stochastic process $W(t)$ is said to be a Wiener process if

(a) $W(0) = 0$.
(b) $W(t)$ has stationary independent increments.
(c) For every $t > 0$, $W(t)$ is normally distributed.
(d) For all $t > 0$, $E[W(t)] = 0$.

These axioms imply $\mathrm{Var}[W(t)] = a^2t$, where $a^2$ is a positive parameter, usually representing an empirical characteristic of the process, to be determined by observations. In this paper, we refer to the so-called *standard Wiener process* for which $a = 1$. The reference level for $X(t)$ in Equation 1 is usually taken to be equal to the resting potential. The initial voltage—namely, the reset value instantly attained following a spike—is often assumed to be equal to the resting potential: $X(t_0) = x_0$, where $t_0 \in \mathbb{R}$ denotes the initial time after spike generation.

Because of the simplicity of Equation 1, the process of the action potential generation is not an inherent part of the model, as it is in more complex models, and so the existence of a firing threshold potential $S(t)$—customarily assumed to be a deterministic function of time such that $S(t_0) > x_0$—must be imposed here. The model neuron fires whenever such a threshold potential is reached; then $X(t)$ is instantly reset to its initial value $x_0$. This situation corresponds to an FPT problem for the associated diffusion process. The interspike intervals are identified with the FPT of $X(t)$ across $S(t)$, namely, with the random variable

$$T = \inf_{t \geq t_0} \{t : X(t) > S(t)\}, \quad X(t_0) = x_0 \tag{2}$$

The importance of interspike intervals is due to the generally accepted hypothesis that the information transferred within the nervous system is usually encoded by the timing of neuronal spikes.

In addition, the reciprocal relationship holding between the firing frequency and the interspike interval naturally leads to the problem of determining the probability density function (pdf) of $T$, namely, the function $g[S(t), t|x_0, t_0] = \partial_t P\{T \leq t\}$. Particularly when this density cannot be obtained analytically (which is practically the rule) or when it is too difficult to give sufficiently precise estimations of it, the analysis is focused on its statistical moments, and primarily on the mean $E(T)$ and variance $D^2(T)$. The coefficient of variation, $D(T)/E(T)$, is also used, as it is a measure of the relative spread of the distribution and of its deviation from exponentiality. The reciprocal relationship between the firing frequency, on the one hand, and the interspike interval on the other hand suggests plotting the inverse of the value of $E(T)$ versus the intensity of stimulation (reflected by $\mu$) as a stochastic counterpart of the input-output frequency curve.

In the following, we shall restrict our considerations to constant thresholds, and hence we shall set throughout $S(t) = S$, with $S > x_0$. The more realistic models based on time-dependent thresholds, aimed to simulate various aspects of the time varying behavior of the neuron, are mainly used to mimic the relative refractory period, namely, the time change of sensitivity of the neuron to incoming stimuli after a spike has been released. Hence, time-dependent thresholds should be characterized by a very large initial value (possibly infinity), followed by a decay to the constant value $S$. A realistic example of such a threshold is provided by the function $S(t) = S + S_1 \exp(-t/\gamma)$, where $S_1$ denotes a very large positive constant and $\gamma > 0$ determines how fast the asymptotic value $S$ is approached.

An alternative description of the process $X(t)$ is obtained via the so-called *diffusion equations approach*. First, one defines the transition pdf of $X(t)$ conditional on $X(t_0) = x_0$:

$$f(x, t|x_0, t_0) = \frac{\partial}{\partial x} P\{X(t) \leq x | X(t_0) = x_0\} \tag{3}$$

It can then be seen that in most cases, $f$ satisfies the Fokker-Planck (FP) equation

$$\frac{\partial f}{\partial t} = -\frac{\partial}{\partial x}[A_1(x, t)f] + \frac{1}{2}\frac{\partial^2}{\partial x^2}[A_2(x, t)f] \tag{4}$$

with initial condition $\lim_{t \downarrow t_0} f(x, t|x_0, t_0) = \delta(x - x_0)$, and the Kolmogorov (K) equation

$$\frac{\partial f}{\partial t_0} + A_1(x_0, t_0)\frac{\partial f}{\partial x_0} + \frac{1}{2}A_2(x_0, t_0)\frac{\partial^2 f}{\partial x_0^2} = 0 \tag{5}$$

with initial condition $\lim_{t_0 \uparrow t} f(x, t|x_0, t_0) = \delta(x_0 - x)$, where $\delta$ denotes the Dirac delta function. Here the coefficients $A_1(x, t)$ and $A_2(x, t)$ are the *infinitesimal moments*, or the *drift*, and *infinitesimal variance*, defined as

$$\begin{aligned} A_i(x, t) &:= \lim_{\Delta t \downarrow 0} \frac{1}{\Delta t} E\{[X(t + \Delta t) - X(t)]^i | X(t) = x\} \\ &= \lim_{\Delta t \downarrow 0} \frac{1}{\Delta t} \int (y - x)^i f(y, t + \Delta t|x, t)dy \qquad (6) \\ &\quad (i = 1, 2) \end{aligned}$$

It is essential to mention that the quantities $A_1(x, t)$ and $A_2(x, t)$ are related in the following way (Ricciardi, 1977) to the functions $\mu$ and $\sigma$ considered in Equation 1:

$$A_1(x, t) = \mu(x, t) \tag{7}$$

$$A_2(x, t) = \sigma^2(x, t) \tag{8}$$

Equations 1, 4, and 5 characterize the class of diffusion processes. While the description by Equation 1 is more intuitive and suitable for computer simulations, Equations 4 and 5 are suitable for analytical and numerical treatments of the model. The parameter $A_1(x, t)$ (Equation 7) reflects the strength of the signal impinging on the neuron, while the parameter $A_2(x, t)$ (Equation 8) characterizes the level of noise associated with the signal. If we are interested in modeling the *spontaneous* or *resting* activity of a neuron or its *steady-state* response to a constant stimulus—which is usually required before attempting to model the neuron's response to time-varying stimuli—independence of time can be assumed in Equations 7 and 8. Then, the neuronal output modeld by FPT is a renewal process (intervals between firings are independent and identically distributed random variables), so that without any loss of generality, we can set $t_0 = 0$.

## Neuronal Models with Additive Noise

### *Wiener Process*

The year 1964 marks the beginning of the history of neuronal models based on diffusion processes. Indeed, in a much-celebrated article, Gerstein and Mandelbrot (1964) postulated that for a number of experimentally monitored neurons subject to spontaneous activity, the firing pdf could be modeled by the FPT pdf of a Wiener process. Actually, these authors were able to show that, by suitably choosing the parameters of the model, the experimentally recorded interspike interval histograms of many units could be fitted to an excellent degree of approximation by means of the FPT pdf of a diffusion process, characterized by the constant infinitesimal moments

$$A_1(x) = \mu, \quad \mu \in \mathbb{R} \tag{9}$$

$$A_2(x) = \sigma^2, \quad \sigma \in \mathbb{R}^+ \tag{10}$$

As is well known, in this case the transition pdf (Equation 3) is normal, with mean $\mu t + x_0$ and variance $\sigma^2 t$. By means of the methods outlined, for instance, in Ricciardi (1977), one can prove that the FPT pdf of such a process is given by

$$g(S, t|x_0) = \frac{S - x_0}{\sigma\sqrt{2\pi t^3}} \exp\left[-\frac{(S - x_0 - \mu t)^2}{2\sigma^2 t}\right] \qquad x_0 < S \tag{11}$$

which in statistical literature is known as the Inverse Gaussian distribution. For $\mu \geq 0$, neuronal firing is a sure event, since the function in Equation 11 is normalized to unity. If one takes $\mu < 0$, the above FPT pdf can be interpreted as the firing pdf conditional on the event "firing occurs." The case $\mu = 0$ is also of interest, since Equation 11 expresses a so-called "stable law." This case provides an interpretation of numerous experimental results indicating that the shapes of histograms are sometimes preserved when the adjacent interspike intervals are summed. Making use of Equation 11, the moments of the density $g(S, t|x_0)$, i.e., the moments of the interspike intervals (that exist for all $\mu > 0$), can be calculated (Ricciardi et al., 1999).

To provide an interpretation of the model based on assumptions formulated in Equations 9 and 10, let us imagine that the neuron's membrane potential undergoes a simple random walk under the effect of excitatory and inhibitory synaptic actions. For simplicity, let us assume that the neuronal dynamics develops on a discrete time scale 0, $\tau$, $2\tau$, . . . , with $\tau > 0$ as an arbitrary time unit. Passing to the limit as $\tau \to 0$, it can be shown (Ricciardi, 1977) that the random walk can be made to converge to the diffusion process having drift $\mu$ and infinitesimal variance $\sigma^2$, in other words, to a Wiener process. This procedure provides the simplest example in which the Wiener model for neuronal activity can be constructed.

The assumptions underlying this model are undoubtedly oversimplified, as some well-known electrophysiological properties of neuronal membrane are not taken into account. Therefore, the Wiener process should be viewed as a statistical descriptor of data rather than as a biologically sound model. However, it must be stressed that the fittings of some experimental data by the FPT pdf (Equation 11) is truly remarkable (see Gerstein and Mandelbrot, 1964).

We should finally point out that if a time-varying threshold is introduced to account for relative refractoriness—which is mainly relevant in high firing rate conditions—the determination of the firing pdf for the Wiener neuronal model cannot be generally accomplished analytically. Hence, ad hoc numerical methods had to be devised.

### *Ornstein-Uhlenbeck Process*

Despite the excellent fitting of some data, the neuronal model based on the Wiener process has been the object of various criticisms, chiefly because it does not include the well-known spontaneous decay of the membrane depolarization. A diffusion model that includes this specific feature is the Ornstein-Uhlenbeck (OU) neuronal model. This is defined as the diffusion process characterized by the following drift

$$A_1(x) = -\frac{x}{\vartheta} + \mu \qquad (12)$$

and by the constant infinitesimal variance given in Equation 10. The new parameter $\vartheta > 0$ in Equation 12 reflects the required decay (the membrane time constant). This model is referred to as the "leaky integrator stochastic neuronal model." Comparing Equations 12 and 9, we see that now the drift is state dependent. However, in the limit as $\vartheta \to \infty$, the moments of Equation 12 are identical to those in Equation 9, meaning that the OU model yields the Wiener (or perfect integrator) model in the limit of an infinitely large time constant. Recalling Equations 1, 7, and 8, we can interpret the OU model as generated by the following SDE:

$$dX(t) = \left[-\frac{X(t)}{\vartheta} + \mu\right]dt + \sigma dW(t), \quad P\{X(t_0) = x_0\} = 1 \qquad (13)$$

where $W(t)$ is the standard Wiener process.

Equation 13 can be taken as defining the OU model. However, such a model can also be obtained from first principles by using the formalism of diffusion equations. To this end, let us initially assume that the neuron is subject to a sequence of excitatory and inhibitory postsynaptic potentials of constant magnitudes $e > 0$ and $i < 0$ occurring in time in accordance with two independent Poisson processes of parameters $\alpha_e$ and $\alpha_i$, respectively. The membrane potential is thus viewed as a stochastic process $X(t)$ in continuous time with a discrete space consisting of the lattice $x_0 + ki + he$ $(h, k = 0, \pm 1, \ldots)$ with the points of discontinuity randomly occurring in time. Again, let $x_0$ $(x_0 < S)$ denote the fixed initial depolarization at which the sample paths start at the fixed initial time $t_0 = 0$. The firing pdf is thus modeled as the pdf of the instants when the sample paths for the first time reach, or cross in the upward direction, the threshold $S$. In Ricciardi et al. (1999) it is shown that if the input rates are made larger and larger and the postsynaptic potentials are simultaneously made smaller and smaller (with a suitable constraint), the membrane potential "converges" to the diffusion process having infinitesimal moments given by Equations 10 and 12 with $\mu = 0$. The case $\mu \neq 0$ can be obtained by a slightly more complicated model in which multiple Poisson-distributed excitatory and inhibitory inputs impinge on the neuronal membrane. Equation 13, in turn, can be obtained by a limit procedure starting from the differential equation expressing the spontaneous exponential decay of the membrane depolarization after including in it excitatory and inhibitory Poisson-distributed independent input processes.

Solving either the FP equation (Equation 4) or the K equation (Equation 5) with parameters of Equations 10 and 12 under the appropriate delta-initial conditions, and then setting $t_0 = 0$ (since the process is temporally homogeneous), one obtains (cf. Ricciardi and Sacerdote, 1979):

$$f(x, t|x_0) = [2\pi V(t)]^{-1/2} \exp\left\{-\frac{[x - M(t|x_0)]^2}{V(t)}\right\} \qquad (14)$$

Hence, at each time $t$ the transition pdf (Equation 14) is normal with mean $M(t|x_0) = \mu\vartheta[1 - \exp(-t/\vartheta)] + x_0 \exp(-t/\vartheta)$ and variance $V(t) = \sigma^2\vartheta[1 - \exp(-2t/\vartheta)]/2$.

It must be pointed out that the OU model differs from the Wiener model in several respects. First, an equilibrium regime exists, since in the limit as $t \to \infty$, the pdf (Equation 14) becomes normal with mean $\mu\vartheta$ and variance $\sigma^2\vartheta/2$. Furthermore, attainment of the firing threshold is a sure event, irrespective of the value of $\mu$. However, in contrast to the Wiener model, the FPT problem is in general very complicated, even in the case of constant thresholds.

Two distinct firing regimes can be established for the OU model. In the first one, the asymptotic mean depolarization $\lim_{t\to\infty} M(t|x_0) = \mu\vartheta$ is far above the firing threshold $S$, and the interspike intervals are relatively regular (deterministic firing). In the second one, it is $\mu\vartheta \ll S$, and firing is caused only by random fluctuations of the depolarization (stochastic or Poissonian firing). The term Poissonian firing is motivated by the circumstance that as the thresholds move farther and farther above the steady-state depolarization $\mu\vartheta$, the firing patterns achieve the characteristics of a Poisson point process.

Equally important to the construction of a model is its verification. Although the Wiener model has often been tested by with experimental data, only relatively recently has the OU model been systematically fitted to interspike histograms (Inoue et al., 1995), owing to the very complicated and cumbersome procedure required for estimating the parameters of the model from interspike intervals data. The available—and as yet unexploited—methods for estimating parameters are based on intracellular recording of the sample paths of $X(t)$ (Lánský, 1983).

The models encountered in the application of diffusion processes to theoretical neuroscience have been predominantly time homogeneous, as reflected in the fact that the functions $\mu$ and $\sigma$ in Equation 1 do not depend on $t$. Recently, however, an interest in stochastic resonance (a cooperative effect that may arise out of the coupling between deterministic and random dynamics in a nonlinear system) has motivated studies on diffusion neuronal models with time-dependent parameters. As already mentioned, in the OU model two distinct regimes can be identified, deterministic and Poissonian firing. In the first regime, the signal ($\mu$ term) is large enough that firing events occur even in the absence of noise. The noise-activated regime corresponds to the situation in which the drift term alone is not sufficient to cause firings, which are instead induced by the noise. The methods of stochastic resonance extend this view mainly to subthreshold periodic signals. Two sources of periodicity can be expected in the signal: either an *endogenous periodicity* or a periodicity of input intensities, the *exogenous periodicity* (Lánský, 1997). Both these instances are included in the following model of the membrane depolarization:

$$\begin{gathered} dX(t) = \left[-\frac{X(t)}{\vartheta} + \mu + A\cos\omega t\right]dt + \sigma dW, \\ P\{X(t_i) = x_0\} = 1,\ t \geq t_i \end{gathered} \qquad (15)$$

where the notation is the same as in Equation 13, $A > 0$ is a constant characterizing the amplitude of the input signal, $t_i$ is the time of the last release of an action potential, and $\omega$ is the angular frequency of the driving force modulation ($2\pi/\omega$ is the modulation period). After each firing the membrane potential is instantly reset to its initial value $x_0$. For exogenous periodicity, the phase of the signal continues after a spike, while in the endogenous case it is always reset, which simplifies the calculations. In the case of endogenous periodicity, the intervals between firing form a renewal process, which quite naturally leads us to consider an FPT problem for the OU process (Equation 13) and a periodic boundary. It is intuitive that by a suitable transformation, an FPT problem for the process modeled by Equation 15 through a constant threshold $S$ can be changed into an FPT problem for a time-independent OU model through a periodic boundary. For exogenous periodicity a different method has to be invoked. In both cases there exists an optimum level $\sigma$ of noise for which the input frequency $\omega$ is best reflected in the output signal (Bulsara et al., 1996; Shimokawa, Pakdaman, and Sato, 1999; Plesser and Geisel, 2001).

It should not pass unnoticed that the deterministic versions of Equations 13 and 15, obtained in the limit $\sigma \to 0$, have long been known in the literature as the Lapicque model, or *leaky integrator* neuronal model (Tuckwell, 1988), presently revived within the context of artificial neural networks.

We conclude this section by pointing out that, especially for experimental purposes, it is sufficient to obtain information only on shape and location of the firing pdf, without finer details. This can be achieved via some of the moments of the firing time. The knowledge of the moments can also, at times, provide some extra valuable information. For example, after a systematic computations of mean and variance of the firing time and of the skewness (a measure of the deviation from symmetry of the firing pdf expressed as the ratio of the third-order central moment to the cube of the standard deviation), for a variety of thresholds and initial states a striking and unsuspected feature of the OU model has emerged: for boundaries of the order of a couple of units or more above the steady-state depolarization $\mu\vartheta$, the variance of the firing time equals the square of its mean value, to an excellent degree of approximation. Moreover, the skewness is equal to 2 to a very high precision. Finally, the goodness of these approximations increases with increasing values of the threshold. When all this information was put together, the conjecture emerged that the firing pdf is susceptible to an excellent exponential approximation for a wide range of thresholds. In addition, these "experimental observations" have led to quantitative results concerning the asymptotic exponential behavior of the FPT pdf not only for the OU process, but also for a wider class of diffusion processes, both for constant and for time-varying boundaries (see Ricciardi et al., 1999, and references therein).

As expected, the convergence to the exponential distribution for increasing thresholds is accompanied by a large increase in the mean firing time. This is in agreement with the finding that for some neurons, the histograms of the recorded interspike intervals are increasingly better fitted by exponential functions as the firing rates decrease.

## Neuronal Models with Multiplicative Noise

In order to embody additional physiological features of real neurons, several alternative models have been proposed. It is well known (and as reflected in the Hodgkin-Huxley model), the change in membrane depolarization caused by a synaptic input depends on its current value. Basically, the depolarization of the membrane caused by an excitatory postsynaptic potential decreases linearly with decreasing distance of the membrane potential from the excitatory reversal potential, $V_E$. In the same manner, the hyperpolarization caused by an inhibitory postsynaptic potential is smaller if the membrane potential is closer to the inhibitory reversal potential, $V_I$. In this way the depolarization $X(t)$ is confined to the interval $(V_I, V_E)$, whereas in the models presented in the preceeding section it was considered unrestricted. Inequalities $V_I < x_0 < S < V_E$ express obvious conditions relating reversal potentials, initial depolarization, and firing threshold. Although the only diffusion model of linear summation (with exponential decay) of the input signal is the OU process (Equation 13), there is a whole class of diffusion processes that are appropriate if reversal potentials are taken into account. In all these models the drift takes the form

$$A_1(x) = -\frac{x}{\vartheta} + \mu_1(V_E - x) + \mu_2(x - V_I) \qquad (16)$$

where the parameter $\vartheta > 0$ is the membrane time constant, as in Equation 12, and $\mu_1 > 0$, $\mu_2 < 0$ are new parameters reflecting excitation and inhibition, now separately specified, in contrast to the case of Equation 12. Although both moments given by Equations 12 and 16 are linear, the interpretations underlying the two drifts are significantly different. Indeed, in Equation 12 there is a constant "leakage term" $\vartheta^{-1}$, while for the models with reversal potentials the leakage $(\vartheta^{-1} + \mu_1 - \mu_2)$ is explicitly input dependent.

The diffusion models that take into account the existence of the reversal potentials always lead to a multiplicative noise effect. This is in agreement with the general notion that an additive noise is generated by events independent of the transmitted message, whereas the multiplicative noise arises inside the processing unit, viz., inside the system. Common forms of infinitesimal variance in models with reversal potentials are the following:

$$A_2(x) = \sigma^2(x - V_I) \qquad (17)$$

$$A_2(x) = \sigma^2(x - V_I)(V_E - x) \qquad (18)$$

$$A_2(x) = \sigma_1^2(x - V_E)^2 + \sigma_2^2(x - V_I)^2 \qquad (19)$$

The first one stresses the importance of the inhibitory reversal potential, which restricts the state space of $X(t)$ from below; the second and third form of the infinitesimal variance attribute equal relevance to both reversal potentials. The main difference between infinitesimal variances in Equations 17 and 18, on the one hand, and Equation 19 on the other lies in the fact that for model 19, the reversal potentials lose their natural role of boundaries of the depolarization (Hanson and Tuckwell, 1983). This fact strongly handicaps model 19. In models characterized by Equations 17 and 18, the behavior at the boundaries $V_I$ and $V_E$ is mathematically rather subtle.

Similarly to the OU model, the statistical moments of $T$ can be calculated for the models defined by Equations 17 and 18. As for the OU process, here also the asymptotic exponentiality holds for low excitation levels. Thus, the only (though very substantial) effect stemming from the models we have considered with reversal potentials consists of the parameter interpretation. From the modeling point of view, the variety of forms identified for the infinitesimal variance and the linear form of the drift are not unexpected. Indeed, these models are meant to reflect, through an "equivalent" noisy ordinary differential equation, the properties, at a single location, of a spatially distributed neuron with noisy inputs, thus corresponding to a stochastic partial differential equation. The linear drift describes the passive electrical circuit properties of the membrane at the trigger zone and the mean effect of the noisy input. The infinitesimal variance, on the other hand, must take into account not only the diversity of spatial configurations for different neurons, but the location and type of synaptic input on that neuron as well. Hence, a variety of forms for this term in the diffusion equation are conceivably appropriate.

It must be emphasized that for neuronal diffusion models originating from SDEs that include either additive or multiplicative noise terms, the FPT problem is in general intractable with analytical tools. However, some efficient procedures have been devised to obtain accurate numerical evaluations of $g$ for the general case of time-varying firing thresholds and for arbitrary diffusion models (not necessarily of the OU type). This is an important target, because to calculate the unknown FPT pdf, one would have to solve Equations 4 or 5 under the appropriate initial delta conditions, and usually, as well, in the presence of complicated boundary conditions when the resulting equations are singular—a very difficult task that rarely leads to analytical solutions. Efficient numerical algorithms are thus especially desirable if one has to deal with time-varying neuronal thresholds. The standard procedure is based on the remark that the FPT pdf $g[S(t), t|x_0, t_0]$ can be proved to be a solution of the following integral equation:

$$f[S(t), t|x_0, t_0] = \int_0^t f[S(t), t|S(\tau), \tau]g[S(\tau), \tau|x_0, t_0]d\tau \qquad (20)$$

with $x_0 < S(t_0)$. This is a first-kind Volterra integral equation whose solution is made complicated by the circumstance that the kernel $f[S(t), t|S(\tau), \tau]$ exhibits a singularity of the type $1/\sqrt{t - \tau}$ as $\tau \uparrow t$. Hence, the problem of determining $g[S(t), t|x_0, t_0]$ from Equation 20 via numerical methods is by no means trivial. Furthermore, all classic available algorithms necessitate the use of large computation facilities and sophisticated library programs. As a consequence, they are expensive to run and not suitable for suggesting to the modeler in real time how to identify the various parameters to fit the recorded data.

An entirely different approach that is quite general, although specifically useful for handling neuronal firing problems, was therefore developed. The guiding idea is to prove that the singular Equation 20 can be replaced by a nonsingular second-kind Volterra integral equation for $g$ that possesses an extra degree of freedom, which can be used to remove the singularity of the kernel or, in some instamces, to directly obtain a closed-form expression for $g[S(t), t|x_0, t_0]$. (See Ricciardi et al., 1999, and references therein for a description of the method and of related computational algorithms.)

## Discussion

In this article we have outlined a few stochastic models for single neurons' activity based on the theory of diffusion processes. As we have sketched out, prediction of the firing pdf is a difficult problem whose solution can usually be approached only by numerical or simulation procedures. It must be stressed that the neuronal behavior described by diffusion models ultimately implies that for time-constant input, the neuron's output is a renewal process. However, one can conceive models aimed, for instance, at simulating the clustering effect in spike generation. Serial dependence among interspike intervals can be modeled in various ways, for instance by adjusting the reset value after each spike in the OU process. Another possibility consists of the inclusion of some kind of feedback in the model, usually the often experimentally observed *self-inhibition*. A further generalization is achieved by taking into account the spatial properties of a neuron. In the simplest way, this can be done by assuming that the model neuron consists of two compartments: (1) the dendritic compartment, described by a standard diffusion model, and (2) the trigger-zone compartment, including the spontaneous decay of depolarization and the firing mechanism (Lánský and Rodriguez, 1999).

To conclude this bird's-eye view of the topic, we would like to mention an alternative approach to the construction of diffusion models that are able to fit experimental data: reversing the problem. That is, instead of formulating a neuronal model $X(t)$ based on some reasonable assumptions, and then trying to compute the firing pdf as an FPT pdf through a preassigned threshold, one can proceed as follows. First, construct the histogram of the experimentally recorded spike train and try to fit it by a function $g(S, t|x_0)$, with $S$ and $x_0$ parameters to be determined by the standard methods. Once this task has been accomplished, ask the following questions: Can $g(S, t|x_0)$ be viewed as the FPT pdf, through the threshold $S$, of a diffusion process conditioned on $X(0) = x_0$? If the answer is yes, can such a process be uniquely determined? This is, so to speak, the inverse of the FPT problem. Quite surprisingly, a precise answer to this question can be provided, at least in principle (Capocelli and Ricciardi, 1972).

In summary, for modeling purposes we have essentially looked at a neuron as a black box, characterized by an input and an output, for which two distinct problems can be posed: (1) to determine the output for a given input, which has led us to an FPT problem, and (2) to guess the input by analyzing the output, which could be viewed as the *inverse* of an FPT problem. In both cases the class of input functions had to be specified beforehand in order to make these problems mathematically sound. The need for such a specification, in conjunction with a large body of well-known experimental data, has led us to assume that input stimulations and random components are such that the neuron's membrane potential is ultimately modeled by one-dimensional diffusion processes. A sketch of some of the ensuing diffusion models for neurons' activity, and their place in the biological literature, was the object of this article.

# Digital VLSI for Neural Networks

*Dan Hammerstrom*

## Introduction

The computational overhead required to simulate artificial neural network (ANN) models, whether simplistic or realistically complex, is a key problem in the field because of the computational complexity of these models. Network simulations are required both for research and for commercial products. Most researchers currently perform these simulations on standard computer technology, such as high-end workstations or personal computers. However, as the field progresses, researchers are moving to larger and ever more complex models that challenge even the fastest computers.

A reasonably realistic neural model could approach one million neurons and tens of billions of connections, where a "connection" is a data transfer path between two neurons. In addition to size, the models themselves are becoming more complex as we move from simple inner products to spiking neurons with temporal time course that require a convolution to be performed at each synapse.

For these reasons, there has been much interest in developing custom hardware for ANNs. The inherent parallelism in ANN and connectionist models suggests an opportunity to speed up the simulations. Their simple, low-precision computations also suggest an opportunity to employ simpler and cheaper, low-precision digital hardware implemented by full-custom silicon or by field-programmable gate arrays (FGPAs).

This chapter discusses digital electronic implementations of ANNs. First, we look at the differences between digital and analog design techniques with a focus on performance/cost trade-offs. Second, we consider the use of traditional processors in parallel configurations for ANN emulation. Third, to convey a sense of some of the issues involved in designing digital structures for ANN emulation, a custom digital ANN processor is discussed: the Adaptive Solutions CNAPS. Although this chip is no longer produced, it is still being used. Its simple architecture makes it a good vehicle to understand the trade-offs inherent in emulating neural structures digitally. Fourth, we look briefly at FPGA technology as a promising alternative for digital implementation of ANNs.

## Why Digital?

### *Performance/Cost*

One commonly held belief in the ANN research community is that analog computation, in which signals are transmitted and manipulated as strengths, generally voltage or current, is inherently superior to digital computation, in which signals are transmitted and manipulated as serial or parallel streams of 1s and 0s. But in fact, both technologies have advantages and disadvantages. The best choice depends on a variety of factors.

Why is analog appealing? An important reason is that it provides 10–100 times greater computational density than digital computation. *Computational density*—the amount of computation per unit area of silicon—is important because the cost of a chip is generally proportional to its total area. In analog circuitry, complex, nonlinear operations such as multiply, divide, and hyperbolic tangent can be performed by a handful of transistors. Digital circuitry requires hundreds or even thousands of wires and transistors to perform the same operations. Analog computation also performs these operations using far less power per computation than digital computation.

If analog is so good, why are people still building digital chips, and why are most commercial products digital? One important reason is familiarity. People know how to build digital circuits, and they can do it reliably, no matter the size and complexity of the system. This is partly the legacy of having thousands of digital designers all over the world constantly tweaking and improving design techniques and software. It is also easier to create a digital version of a computation, in which a computer program represents the algorithm, than an analog version, in which the circuit itself represents the algorithm. This is particularly true if you are trying to build a system that is robust and reliable over the wide temperature and voltage ranges needed in commercial products. Analog design is an uncommon capability, and it is becoming less common as people find that they can do more with digital circuitry. For example, digital signal processors now perform most of what was once the domain of analog circuitry. Another advantage of the digital emulation of neural networks is that it significantly eases the integration of the neural network portion of the design with the larger digital system to which it connects.

### *Flexibility*

Another factor working in favor of digital is that analog designs are generally algorithms wired into silicon. Such designs are inflexible. Though there is an interesting class of designs that are programmable analog. Perhaps the most powerful and widely studied is the Cellular Neural Network (Chua and Roska, 2001).

Digital designs can be either hardwired or programmable. Their flexibility is a major benefit, since it allows software control as well as an arbitrary level of precision (low to high and fixed or floating point). The price of this flexibility is reduced performance/cost, but the result is a chip that can solve a larger part of a problem. It also leads to a device that has broader applicability and can track incremental algorithm improvements by changing the software, not by redesigning the circuitry.

The role flexibility plays in system performance/cost can be understood more clearly by examining *Amdahl's law* (Hennessy and Patterson, 1991) that describes the execution time benefits of parallelizing a computation. Briefly, a computing task has portions or *subtasks* that often can be executed in parallel. Other, sequential tasks cannot begin until a previous task has been completed, which forces a sequential ordering of these tasks.

Amdahl's law states that no matter how many processors are available to execute subtasks, the speed of a particular task is roughly proportional to the subtasks that cannot be executed in parallel. In other words, sequential computation dominates as parallelism increases. Amdahl quantifies the relationship as follows:

$$S = 1/(op_s + (op_p/p))$$

where $S$ is the total speed-up, $op_s$ is the number of operations in the serial portion of the computation, $op_p$ is the number of operations in the parallel portion, and $p$ is the number of processors. As $p$ gets large, $S$ approaches $1/op_s$.

For example, suppose we have two chips to choose from. The first can perform 80% of the computation with a 20× speed-up on that 80%. The second can perform only 20% of the computation but executes that 20% with a 1000× total system speed-up. Plugging into the equation, the first chip gives us a total speed up of over 4×, while the second—and "faster"—chip has only a 1.25× total system speed-up. A programmable device that accelerates several phases of an application generally offers a much larger benefit than a dedicated device.

Below we discuss FPGAs, which are flexible to the point of allowing the arbitrary configuration of physical digital circuitry.

They are a promising approach to efficiently implementing the inherent parallelism of neural-like structures.

### *Signal Intercommunication*

One difference between silicon and biological networks is that for silicon, internode communication is relatively more expensive than for biological systems. Although several levels of wire interconnect (8–10 today) are available in most silicon processes, each level is restricted to two-dimensional interconnection because wires on the same level cannot pass over or touch one another.

Two-dimensional layout and large expensive wires require us to modify our biologically derived computational models to more closely match the strengths and weaknesses of the implementation technology. To show the need for such modifications, Bailey and Hammerstrom (1988) modeled a hypothetical neural circuit. This circuit, modest by biological standards, had one million "neurons" with one thousand inputs each, or one billion connections total.

The first calculation assumed a direct implementation—that is, one connection per wire. This billion-connection ANN required tens of square meters of silicon for dedicated communication pathways. Since silicon averages tens of dollars per square centimeter, such a system is too costly to be practical. These costs result from a theorem showing that the metal area required by direct communication is proportional to the *cube* of the fan-in or "convergence" at each node.

Their second calculation assumed a multiplexed interconnect structure, one in which several connections shared a metal wire. Wire multiplexing adds complexity at each end. Likewise, an address must be sent with each data packet to identify the sender, and some decoding must be performed on that address. Bailey and Hammerstrom (1988) showed that with the proper communication architecture, a 100× reduction in silicon area over the direct approach was possible with little impact on performance. Since only a few nodes will be active in any given time interval for these large networks, multiplexing interconnect makes even more sense.

Even analog designers of neuromorphic circuitry have recognized the need for multiplexed interconnect. However, analog voltages and currents are difficult to multiplex. One alternative is to represent analog values by using pulses. There are several ways in which pulses can be used to represent information, including pulse rate, phase, and interpulse interval. It is possible for different pulse streams to share a single wire by sending, at the time the pulse occurs, the address of the pulse stream. This approach is called address event representation, or AER (Boahen, 2000). Pulse or "spike" signal representation is also much more neurobiologically plausible.

## Digital Neural Networks: Off-the-Shelf Processors

One successful approach to high-speed ANN simulation has been to use arrays of commercial microprocessors. This approach works because desktop machines, thanks to Moore's law, have achieved a tremendous level of performance/cost. Moore's law states that the number of transistors that can be manufactured economically on a single silicon die doubles every 24 months. Moore's law has held constant for roughly 32 doublings, which is truly impressive. There are not many industries that can claim exponential growth over such a long period.

In addition to raw clock speed, another effect of Moore's law is that more transistors are available to dedicate to specialized functionality. Today, the latest microprocessors offer on-board single instruction multiple data (SIMD) parallel coprocessors. For Intel, these coprocessors have evolved from MMx to SSE (Pentium III) and now to SSE2 (Pentium 4) (Intel, 2001). The Motorola/IBM PowerPC has the similar AltiVec system. Although these coprocessors have been designed primarily for basic image processing, video codecs, and graphics, they can also be used to emulate certain ANN models.

A problem these machines have, though, is limited memory bandwidth. Most applications have a fair amount of referencing locality, in which a collection of physically contiguous addresses are referenced multiple times. Reference locality allows the processor to use several layers of cache memory (the Pentium IV has three). However, neural network algorithms typically require that an entire network be accessed for each state update. Since this network can be very large, it generally does not fit in the caches. Consequently, there is a significant slowdown as the processor ends up waiting for data from memory.

Perhaps the best approach is to use a commercial multiprocessor computer that hides the memory bandwidth problems by providing large numbers of processors. For example, the NASA Ames Research Center has several large Silicon Graphics parallel machines (Shan et al., 2000). The largest currently has 1024-processors. These systems use very high-speed interconnects and are able to emulate large, complex neural network structures. Our research group at OGI has simulated simple association networks approaching one million nodes on this machine.

However, such computational power is typically not available to the average researcher. One popular alternative has been to build large computer clusters using relatively inexpensive PCs. Often known as Beowulf clusters (Reschke et al., 1996), these systems connect large numbers of simple processors and are typically built from off-the-shelf hardware (PCs and LAN switches). The software is usually free. Programming is done by using traditional languages and MPI (the message-passing interface) or PVM (parallel virtual machine). Unfortunately, the interprocessor communication tends to be fairly slow relative to the computation, which compromises the total speed-up to some degree. However, they can be fairly efficient if complex models of the neuron are used that require more computation than intercommunication.

As neural network models become larger and more complex, the model connectivity issues become a major factor in the speed of emulation regardless of the hardware platform. Real neural structures demonstrate *sparseness*, that is, a small subset of all possible connections are actually made, and *locality*, that is, there is a higher probability of connections to neurons that are physically near each other. However, ANN models have typically not exhibited significant sparseness or locality, which is another reason for researchers to study more biologically plausible systems so that we can create structures that are computationally robust and have sparse, localized connections.

## Digital Neural Networks: Full Custom Processors: CNAPS

Designing specialized architectures that are customized for ANN simulation permits significant improvements in performance/cost, since the processors and their interconnection architecture are optimized for the computations they perform. This section discusses the Adaptive Solutions CNAPS architecture, which was, for a time, a successful commercial product but is no longer produced. It represents the specialized functionality end of the design spectrum of digital chips.

The CNAPS architecture (Hammerstrom, 1995) had multiple processor nodes (PNs) connected in a one-dimensional structure, forming a SIMD array (Figure 1). SIMD architectures have one instruction storage and decode unit and many execution units, simplifying system design and reducing costs. Unlike a PC cluster, each CNAPS PN did not have program storage and sequencing hardware, and each executed the same instruction each clock. Node

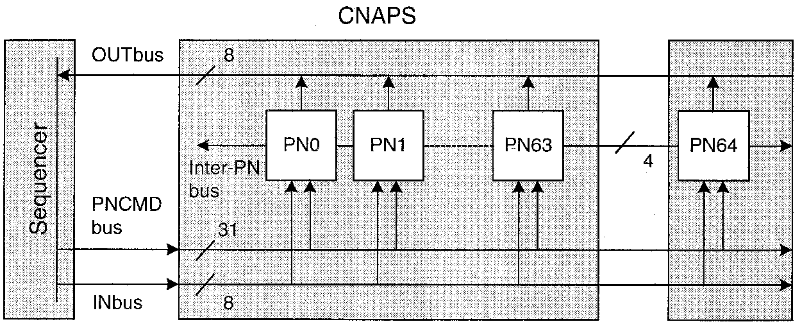

**Figure 1.** CNAPS architecture. This is a single instruction multiple data (SIMD) architecture, in which all processor nodes (PNs) execute the same instruction during each clock. There is a single broadcast data bus that allows efficient one-to-many and many-to-many communication.

outputs were broadcast from each PN to all the others over a single broadcast bus.

Another major simplification of the CNAPS architecture, which is found in other digital ANN chips, was the use of limited-precision, fixed-point arithmetic. Many researchers have shown that floating point and high precision are unnecessary in ANN simulation (Fahlman and Hoehfeld, 1992). CNAPS supported 1-, 8-, and 16-bit precision in hardware. Consequently, the PNs were smaller and cheaper. This reduced precision was more than adequate for the applications implemented on CNAPS.

The CNAPS architecture had 64 PNs per chip. At the then frequency of 25 MHz, each chip executed at a rate of 1.6 billion connections computed per second. A single chip executed back-propagation learning at a rate of 300 million connection updates per second; each update consists of reading the weight associated with the connection, modifying it, and then writing it back. Each PN (Figure 2) had 4096 bytes of on-chip local memory, used to store synaptic weight data and other local values. Hence, a 64 PN chip could store up to 256 KB of information. Multiple chips could be combined to create larger, more powerful systems. The general programmability of the device allowed it to execute a large range of functions, including many non-ANN algorithms such as the discrete Fourier transform, nearest neighbor classification, image processing, and dynamic time warping.

Figure 3 shows a simple two layer network mapped to a CNAPS array. The network nodes are labeled CN0–CN7; the processor nodes are labeled PN0–PN3. Multiple network nodes map to a single processor node; in this example, one node from each layer is mapped to a single PN. For feedforward calculation, assume that the outputs of nodes CN0–CN3 have been computed. To compute the inner product of nodes CN4–CN7, the output value of node CN0 is broadcast on the bus to all PNs in the first clock. Each PN then multiplies the CN0 output with the corresponding weight element, which is different for each PN. On the next clock, CN1's output is broadcast, and so on. After four clocks, all 16 products have been computed: $O(n^2)$ connections in $O(n)$ time.

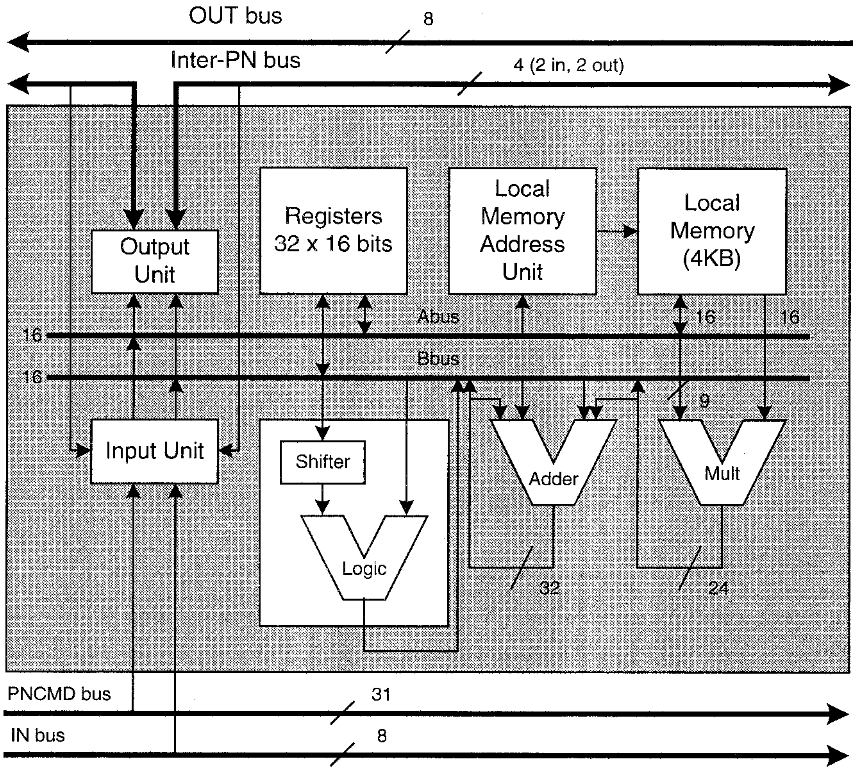

**Figure 2.** CNAPS PN architecture. A single PN has a multiplier, accumulator, logic/shifter unit, register file, and separate memory address adder. Each PN also has its own memory for storing weights, lookup tables, and other data. Each PN generates its own unique address to memory.

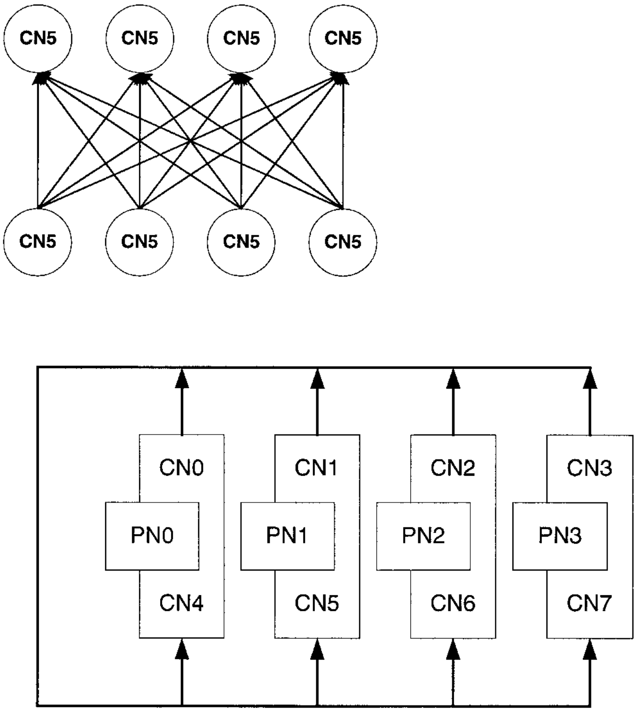

**Figure 3.** Mapping of a simple two-layer feedforward network to the CNAPS array. When emulating a feedforward network, each layer is spread across the PN array. The neuron outputs of one layer are broadcast sequentially to all PNs while they compute the multiply accumulations for the next layer of neurons.

## Digital Neural Networks: Field Programmable Gate Arrays

Perhaps the most promising approach to emulating neural models digitally is the FPGA (Sharma, 1998). Briefly, an FPGA is a device with a large number of generic logic blocks and generic interconnect between those blocks. The functions that the logic blocks implement and how these blocks are connected to one another are determined by configuration bits that are loaded into the chip as one would load a program into a computer's memory. Because of Moore's law, it is now possible to buy FPGAs that are capable of emulating millions of logic gates at frequencies approaching several hundred megahertz. There are very sophisticated design tools that allow logic to be expressed in a high-level hardware description language and then be converted to FPGA configuration bits by an automated synthesis process. These devices can implement large neural structures in parallel (see, for example, Hatano et al., 1999).

Although FPGAs are appearing with larger on-chip memory, they still cannot approach the density of commercial DRAM. So for emulating very large networks, off-chip memory needs to be used to store the various parameters and state information associated with each neuron. However, unlike traditional processors, FPGAs are capable of supporting the access to several high-speed memory structures at once. Consequently, a board with several FPGAs could emulate networks at much higher speeds than a high-speed desktop PC. In addition, the inherent parallelism in each FPGA would allow parallel implementation of the various structures within the neuron, such as sophisticated spike-based computation.

## Discussion

It is difficult to predict technology trends, but speculation is always possible. Today, most ANNs are used for pattern recognition. The final stage of most pattern recognition algorithms involves checking a series of classification results to see whether they fit in the larger context of the domain in question. Including this contextual knowledge can be as simple as spell checking, or it can be as complex as accessing high-order rules or schemas that reflect complex syntactical and semantic relationships. Since classification is imperfect, contextual processing, which makes knowledge of such higher-order relationships available to the classification process, is essential to guarantee the accuracy of the final result.

Although the results are still speculative, research (Ambros-Ingerson et al., 1990; Braitenberg and Schüz, 1998) has shown that scaling to large contexts requires networks with relatively sparse interconnect and sparse activation, in which only a few nodes are actively firing at a time. On the basis of research into VLSI connectivity (Bailey, 1993), digital-based systems can handle such networks more efficiently than analog. Therefore, at some point in the processing, the data will probably need to be converted from analog to digital representation. Today, the conversion is done at or just after the input transducer. On the basis of the state of analog technologies, systems of the future will probably take advantage of the computational density of analog VLSI to perform the feature extraction and some preliminary classification at the front end, with conversion to digital form for contextual processing and final classification by "higher-level brain regions."

# Directional Selectivity

*Norberto M. Grzywacz and David K. Merwine*

## Introduction

Directional selectivity refers to a neuron's ability to produce substantially different responses for stimulus motions of different direction. A directionally selective (DS) cell will fire many spikes in response to object motion in one direction (the preferred direction) while responding weakly, if at all, for motion in the opposite (null) direction. This directional "trigger feature" is often essentially independent of the contrast, contrast polarity, color, shape, or speed of the moving object. Cells displaying directional selectivity are found in the retinas and visual cortices of all the major vertebrate classes. These neurons support a host of visual tasks, ranging from motion perception, image segregation, and deblurring to the control of eye movements. The extraction of direction of motion is so crucial for vision that it is the first motion-related variable encoded in the visual pathway.

It is impossible, however, to determine the direction of a motion using an individual DS neuron. First, because these neurons have relatively small receptive fields, they can only report motion components that are perpendicular to the gradient of illumination. This phenomenon is known as the aperture problem. Second, motions orthogonal to the preferred-null axis will elicit intermediate, ambiguous responses. Moreover, nonmotion parameters, such as contrast, and motion parameters, such as speed, will affect the amplitude of the DS cell's response. However, by comparing over a population of DS cells, the true direction of a motion can be determined. One needs to compare the responses of DS neurons with different preferred directions. Regardless of object contrast or speed, the neuron whose preferred direction is closest to the actual direction of visual motion will have the largest response. Thus, a comparison of responses over a population of DS neurons can disambiguate the veridical motion direction.

### *Optic Flow*

According to physics, the most fundamental variable of motion is velocity, a vector composed of direction and speed. Animals perceive three-dimensional (3D) velocities in the world through the world's two-dimensional (2D) projection onto these animals' retinas. Therefore, the true values of velocity in the world cannot be directly determined using the information from the eyes. A more useful velocity-related variable for the animal is *optic flow*. This is the spatial distribution of velocity vectors that is obtained by projecting the moving 3D world onto the 2D retina. An example of the utility of optic flow analysis occurs when an animal moves forward in a straight line. The resultant optic flow is that of an expansion, and the animal can maintain its heading by keeping the focus of expansion constant (see also Motion Perception: Navigation). To find this focus, information about directional selectivity must be combined across the image by "higher" cortical areas. One area that may contribute to this computation is the middle superior temporal cortex (MST), which appears to contain neurons tuned to expansion and contraction (for a review, see Andersen, 1997).

Mathematically, the most popular definition of optic flow uses the image constraint equation $dE/dt = 0$, where $E$ is the brightness of the image (see Grzywacz, Harris, and Amthor, 1994, for details and references). This equation assumes that brightness varies slowly over time and defines the optic flow $\vec{v}$ as

$$\nabla E \cdot \vec{v} + \frac{\partial E}{\partial t} = 0 \tag{1}$$

This brightness-related definition is not unique, as nonmotion parameters, such as reflectance, can influence the solutions of the equation. Other definitions emphasize different useful components of the motion. For instance, the directional components alone have proved sufficient for determining heading direction as well as for recovering structure from motion and performing image-segregation tasks.

### *Speed*

Before we embark on a detailed discussion of directional selectivity, we would like to comment briefly on the measurement of speed. This variable is considerably more difficult to measure than direction, as a local determination of speed in the image requires precise spatiotemporal information. In contrast, a measure of direction of motion requires two fairly imprecise positional measurements separated in time. For this reason, the visual system computes local speed with relatively less precision than direction and does so at a later stage of processing.

Computational models have been proposed that use DS signals to obtain local speed (reviewed in Grzywacz et al., 1994). For instance, Grzywacz and Yuille developed such a model by using model DS cells with receptive field profiles based on Gabor functions. They organized these cells in a 3D space whose coordinates were the optimal temporal frequency and the two components of optimal spatial frequency of the cells. They found that any arbitrary translation with constant velocity would yield maximal responses that fell on a plane in this space. Local speed and direction could then be determined by measuring the slant and tilt of this plane. Grzywacz and Yuille proposed a plausible neural architecture for performing this measurement.

## Theory of Directional Selectivity

Reichardt, Poggio, and colleagues (Poggio and Reichardt, 1976) described the theoretical requirements for any model of directional selectivity (see also Motion Perception, Elementary Mechanisms). The first requirement is spatial asymmetry. If a neuron responds better to a motion coming from the left than to a motion coming from the right, then there must be some difference in the inputs from the left and right sides of the cell's receptive field.

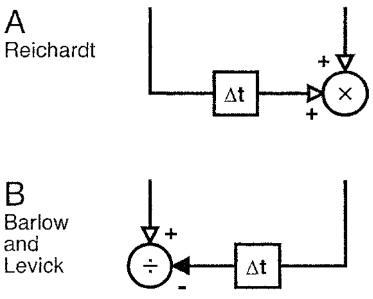

**Figure 1.** Models for directional selectivity. In each case, preferred direction is from left to right. The lines with arrows are inputs to the nonlinear interaction sites (circles). These inputs originate at different spatial locations as indicated by the nonarrow ends of the lines. Boxes with "Δt" symbols indicate that their corresponding lines are slow. Hence, movement going from the slow line to the fast line will generate signals that arrive together at the interaction sites but the opposite movement will not. In the Reichardt model, a multiplication exploits this difference to create directional selectivity. In the Barlow and Levick model, the difference is exploited by an inhibitory (possibly division-like) interaction.

Models for this asymmetry have always included a temporally asymmetric component, that is, some difference in time course between the left- and right-side inputs. However, this need not be the case. For example, the left-side input could "gate" the right-side input (Grzywacz et al., 1994). In this case, the cell will fire only when the motion comes from the left and opens the gate, before reaching the right-side input.

The second requirement for directional selectivity is a nonlinear mechanism. A spatiotemporal asymmetry alone will yield a directional difference in the responses (i.e., differing waveforms, depending on the direction of stimulus motion). However, such an asymmetry alone is not sufficient to produce two different single-number responses for preferred- and null-direction motions, a requirement to decide what the estimated direction of motion is. Poggio and Reichardt's work proves that, without a nonlinear mechanism, any numbers obtained from the waveforms of the responses will be equal for all directions of motion. The nonlinearity can be as simple as a threshold or the gating mechanism mentioned above, but it must be present.

Figure 1*A* illustrates the simplest model proposed by Reichardt and colleagues for the insect's retinal directional selectivity (RDS). For simplicity, the model uses inputs from only two locations. The proposed spatial asymmetry in this model is temporal. Inputs from the preferred side (the side first encountered by an object moving in the preferred direction, left in the figure) are propagated to the interaction site on a slow time scale compared with those from the null side. The proposed nonlinearity for the interaction is a multiplication. Thus, if an object moves in the preferred direction at an appropriate speed, the slowness of the left-side pathway is compensated for by the earlier arrival time of the stimulus, causing both inputs to arrive at the decision site at the same time, yielding a positive multiplication. For null-direction motions, the inputs will arrive at the decision site separately, and the result of the multiplication will be zero. The multiplicative nonlinearity therefore acts as a coincidence detector.

This multiplicative nonlinearity is one of many quadratic nonlinearity models supported by insect data. Poggio and Reichardt used the Volterra series formulation to examine the predictions common to all quadratic models of directional selectivity. For such a formulation of a smooth, time-invariant, nonlinear interaction between the responses to stimuli in spatial locations $a(z_a)$ and $b(z_b)$, the output is

$$y(t) = h_{0,0} + \sum_{m=1}^{\infty} \sum_{j=0}^{m} h_{j,m-j} *^{m} z_a^{(j)} z_b^{(m-j)} \tag{2}$$

where $*^m$ is the $m$th-order convolution and where $h_{j,m-j}$ are the $m$th-order kernels of the interaction. The $m$th-order kernel describes the nonlinear interaction between the responses to stimuli at $m$ different instants in time. A quadratic nonlinearity is one for which if $m \geq 3$, $h_{j,m-j} = 0$. A quadratic nonlinearity thus describes multiplicative interactions between pairs of stimulus responses.

Two predictions of quadratic nonlinearity models are frequency doubling and superposition of nonlinearities. Frequency doubling is the appearance in the Fourier spectrum of the response to moving sinusoidal gratings of energy at a frequency of twice the fundamental but not at frequencies higher than that. In superposition of nonlinearities, the average of the nonlinear response to a grating composed of two sinusoidal gratings of different frequencies (whose ratio is a rational number) is equal to the sum of the responses to the two individual gratings. Both frequency doubling and superposition of nonlinearities can be used to test whether a system computes directional selectivity solely through quadratic nonlinearities.

## Retinal Directional Selectivity

Although DS retinal neurons have been described in a number of vertebrates, the vast majority of work has been performed in the rabbit. In this animal, two types of DS cells have been described. The first, the On-Off DS ganglion cell, responds well to moving spots, bars, edges, or gratings of both contrast polarities over a broad range of speeds. Additionally, these cells can detect the direction of motion of long edges for displacements less than the spacing between photoreceptors, hence mediating directional hyperacuity. Four subtypes of On-Off DS cell exist, one each for temporal, nasal, superior, and inferior motions. Each subtype independently tiles the retinal surface and thus can independently sample the visual world. The second DS cell type (the On DS cell) responds only to bright edges and to considerably slower speeds than those preferred by the On-Off type. The On DS cells exist in three subtypes whose preferred directions are aligned with the animal's semicircular canals. These cells have receptive fields whose areas are more than three times larger at any given eccentricity than the On-Off type, and their tiling is correspondingly less dense (Vaney et al., 2001). The On DS type supports optokinetic nystagmus through projections to subcortical areas. As they are infrequently encountered, the mechanisms responsible for these cells' directional selectivity have not been well investigated, and they will not be considered further here.

### *Spatial Asymmetry*

Although a spatial asymmetry is required for generating a DS circuit, no obvious asymmetry exists in the anatomical structure of the On-Off DS cell. The dendritic trees of these ganglion cells have a unique, looping morphology. But there is no relationship between asymmetries in the tree and the cell's preferred direction of motion (Vaney et al., 2001). Therefore, the spatial asymmetry has been conjectured to exist in the connectivity between DS cells and their inputs. No spatially asymmetric connections have been conclusively identified to date. However, two strong candidates exist. First, cross-correlational and anatomical studies of the cholinergic amacrine cell and the On-Off DS cell suggest that the former makes spatially asymmetric connections to the latter. Support for this suggestion comes from the elimination of DS responses to moving gratings by cholinergic antagonists (Grzywacz, Amthor, and Merwine, 1998). Second, asymmetric connections may also exist from some GABAergic amacrine cells to the DS cells. GABA antagonists strongly reduce directional selectivity.

### *Nonlinearities*

In their seminal work on rabbit retinas, Barlow and Levick (1965) performed two-slit apparent-motion experiments on DS cells. They discovered that when two stimuli were presented in null sequence (as if an object were moving in the null direction), then the number of spikes elicited was far less than the sum of the spikes for each stimulus in isolation. From this, they concluded that RDS arises from a nonlinear, *inhibitory* mechanism that "vetoes" responses to null sequences (equivalent to the logical AND-NOT operation). As shown in Figure 1*B*, their proposed spatial asymmetry has two components. A central component is excitatory and is conducted to the interaction site quickly. A second, inhibitory component is offset to the null side and is conducted with a delay. Thus, an asymmetry exists in both the sign and time course of the two spatially separated components. This asymmetry causes motions in the preferred direction to yield responses, while responses to null-direction motions are vetoed. However, despite Barlow and Levick's proposal, this veto mechanism turns out not to be a perfect veto. Studies reviewed by Grzywacz et al. (1994) show that a better description for the inhibitory interaction is a division-like nonlinearity, as shown in Figure 1*B*.

Torre and Poggio proposed a biophysical implementation of Barlow and Levick's inhibition (see Grzywacz et al., 1994, for a review). Because RDS can be elicited by motions spanning remarkably short distances almost anywhere within the DS cell's receptive field (Barlow and Levick, 1965), Torre and Poggio suggested that the inhibition acted separately within each branch of the cell's dendritic tree. To constrain the computation spatially, they suggested that the inhibition works through a synapse that causes local changes of membrane conductance (shunting inhibition) and little hyperpolarization. To understand such a synapse, consider a patch of membrane receiving excitatory ($g_e$) and shunting inhibitory ($g_i$) synaptic conductances. Setting without loss of generality the resting and inhibitory reversal potentials to zero, the voltage $V$ obeys

$$C\,\frac{dV(t)}{dt} + (g_e(t) + g_i(t) + g_{\text{leak}})V(t) = g_e(t)E_e + g_{\text{leak}}E_{\text{leak}} \tag{3}$$

where $C$ is membrane capacitance, $g_{\text{leak}}$ is the membrane's leak conductance, and $E_e$ and $E_{\text{leak}}$ are reversal potentials of $g_e$ and $g_{\text{leak}}$, respectively. When $g_i \gg g_e$, then $V$ falls toward the following equilibrium value:

$$V(t) \rightarrow \frac{g_e E_e + g_{\text{leak}}E_{\text{leak}}}{g_i} \tag{4}$$

which is small, because $g_i$ is large. Therefore, this inhibition is division-like rather than subtraction-like. Torre and Poggio argued that a shunting-inhibition mechanism might also be consistent with the insect's quadratic nonlinearity, because, for sufficiently low contrasts, one can ignore the higher-order nonlinearities, as in a Taylor series approximation. However, experimentally a quadratic approximation is not valid for rabbit DS cells, as they fail both the frequency-doubling and superposition-of-nonlinearities tests even at near-threshold contrasts.

Although a shunting-inhibition mechanism can theoretically produce the localized interactions necessary to explain many DS properties, it has not been possible to record intracellularly within dendrites to test this mechanism. Recently, two additional nonlinearities have been proposed that could support dendritically localized directional selectivity. First, it has been suggested that this nonlinearity could be due to excitatory voltage-dependent conductances at the dendrites. There is evidence of dendritic spikes in rabbit's ganglion cells. Second, it has been proposed that the unusual predominance of NMDA glutamatergic receptors on DS cells may have functional significance. The NMDA channel has a nonlinear behavior, due to channel blockade by magnesium ions at hyperpolarized potentials. Therefore, glutamatergic binding must occur *during depolarization* for the channel to operate. Even weak, null-direction inhibition could cause the NMDA channel to hyperpolarize and close. It could therefore act as the veto site hypothesized by Barlow and Levick (1965). When tested in magnesium-free medium, RDS is severely reduced, suggesting a critical role for NMDA receptors. The NMDA, spiking, and shunting nonlinearities need not be mutually exclusive, and each could play an important role in supporting robust RDS.

### *Pre- or Postsynaptic Nonlinearities?*

In addition to the null-direction inhibition just described, it is known that preferred-direction motions facilitate DS cell responses (Barlow and Levick, 1965). If the spatiotemporal parameters of the stimulus are appropriate, then preferred-direction facilitation can be as strong as null-direction inhibition (reviewed in Grzywacz et al., 1994). Facilitation is believed to come to the DS cell from the cholinergic amacrine cells. A spatial asymmetry has been shown to exist in the input-output relationship of these cells' dendrites. These dendrites receive excitatory inputs along their length, but they release excitatory transmitter (ACh) and may receive inhibitory inputs (through GABA) only at their tips (Figure 2*A*). If the GABA-inhibition acts in a division-like manner, then each dendrite contains a spatial asymmetry and a nonlinearity, and thus can act as an autonomous DS unit. Hence, it has been proposed that DS signals are at least partially generated presynaptically and flow from the cholinergic dendrites to the DS cell. DS cells would then

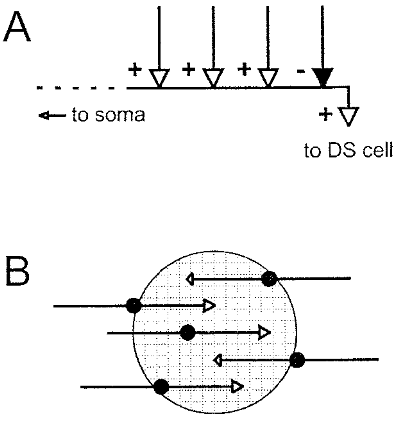

**Figure 2.** Schemes for presynaptic retinal directional selectivity. *A*, Model of a cholinergic-dendritic DS subunit. The bent line represents a dendrite of the cholinergic amacrine cell making a synapse onto a DS cell. This dendrite receives excitatory inputs throughout its length (open arrows) and inhibitory inputs (filled arrow) near the synaptic ending. Therefore, the output synapse is directionally selective, as the dendrite behaves like a Barlow-and-Levick model (Figure 1*B*). *B*, Spatial relationship between cholinergic dendrites and the DS cell's receptive field (circle). Arrowhead size indicates synaptic strength, and black discs mark the cholinergic somas. Although all dendrites are directionally selective, the DS cell receives more inputs from the left than from the right. Consequently, its preferred direction is to the right.

preferentially sample from dendrites with the same preferred direction (Figure 2*B*).

There is accumulating evidence, however, that both pre- and postsynaptic asymmetries may be involved in RDS. Complete blockade of cholinergic synapses does not fully eliminate RDS to moving bars (Grzywacz et al., 1998). The residual direction selectivity is GABAergic and appears to be postsynaptic. In turn, GABA blockade not only does not always eliminate RDS, it occasionally reverses its preferred and null directions. Computer simulations of the cholinergic-dendritic RDS can account for these reversals as a result of synaptic saturation (reviewed in Grzywacz et al., 1994). Thus, asymmetric postsynaptic inhibition and asymmetric presynaptic facilitation may act cooperatively to produce robust RDS for a broad range of visual stimuli.

### *Development*

The development of RDS is not well understood. In turtles, RDS emerges late in development, that is, after the establishment of concentric receptive fields, inhibitory surrounds, and orientation selectivity (selectivity to spatial orientation of anisotropic stimuli, such as lines) (Sernagor and Grzywacz, 1995). Evidence suggests that turtle RDS may emerge at the expense of orientationally selective (OS) cells. It has thus been proposed that turtle DS cells are modified OS cells. This late emergence of RDS suggests two hypotheses for its development: (1) it requires light exposure, and/or (2) it requires the late emergence of an inhibitory drive onto the network mediating orientation selectivity.

In rabbits, however, RDS emerges relatively early. The percentage of DS cells and DS cell gap-junctional coupling patterns both appear adult-like within a few days of eye opening. Directionally selective responses have been recorded from rabbit retinas before eye opening. Therefore, some authors have suggested that rabbit RDS is initially generated in the presynaptic cholinergic circuit. The primary excitatory stimulus for this mechanism would be the bursting spontaneous waves of activity known to occur during development (see Sernagor and Grzywacz, 1995, for references on developmental spontaneous activity). In this case, the first challenge for the DS cells would be to connect selectively to cholinergic dendrites of similar orientation. (Recall that the amacrine cell dendrites can each act as a DS subunit.) A Hebbian correlational process that would reinforce statistical biases in the initial contacts from the cholinergic dendrites to proto-DS cells could produce this selectivity. GABAergic null-direction inhibition would then be added to the cell's established directional preference.

## Cortical Directional Selectivity

DS cells are found in multiple locations in the cortices of mammals, beginning with simple DS cells in the lateral geniculate nucleus (LGN) input layers of the primary visual cortex (V1). Nearly every simple and complex cell in mammalian V1 has some degree of directional selectivity. However, the strength of directionality varies widely. For example, only about 20% of macaque V1 DS cells achieve preferred-versus-null response ratios greater than 3:1 (De Valois et al., 2000). In comparison, rabbit retinal DS cells typically have preferred-null ratios around 10:1. As with the retinal DS cells, the preferred direction of motion cannot be accounted for by any spatial asymmetries in the dendritic trees of the cortical DS cells. However, unlike retinal DS cells, cortical DS cells are highly selective for the orientation and spatial frequency of the moving stimulus. Moreover, it is often possible to predict the preferred direction of motion for a simple DS cell from its spot-mapped receptive field. This has led to the development of quasilinear models of cortical directional selectivity, which we discuss below.

There is abundant evidence that cortical directional selectivity supports motion perception. Perceptual decisions in motion tasks correlate with the performance of cortical DS neurons (Andersen, 1997). Furthermore, lesions and/or current injections in MT affect motion integration tasks, biasing motion perception in specific and replicable ways (Salzman et al., 1992). In addition to the contribution of cortical DS cells to perception, they probably also assist in the control of eye movements. For instance, neuroanatomical data demonstrate that both MT and MST send large projections to the dorsolateral pons, an area known to be involved in smooth-pursuit eye movements.

### *Hierarchy*

As a first-order approximation, motion is computed hierarchically in the cortex (Andersen, 1997). The hierarchy begins with the simple and complex DS cells in layers IV and VI of cortical area V1, as just described. (In animals phylogenetically close to primates, retinal DS cells project primarily to subcortical centers. Evidence suggests that directional selectivity in the primary visual cortex is computed independently from RDS.) The DS cells in V1 project to the MT cortical area (MT or V5) and to V2, which also projects to MT. Directional selectivity becomes more complex in MT; that is, cells there typically have very large, orientation-independent receptive fields, and many will respond best to the composite motion of a plaid, as opposed to its individual components. From MT, the motion pathway projects to MST, wherein directional selectivity information is further combined to produce neurons sensitive to complex motions, such as rotation, expansion, and contraction (Andersen, 1997).

### *Psychophysical Models*

One class of models for the first stage of cortical directional selectivity is based on human psychophysics and is similar to the Reichardt model in Figure 1*A*. In these models a slow, laterally displaced input and a fast central input are multiplied. As described above, the two signals from these inputs will arrive simultaneously, yielding a response, for only one direction of object motion. Another class, called motion-energy models (Adelson and Bergen, 1985), proposes a distributed spatiotemporal asymmetry and a squaring nonlinearity (Figure 3*A*). The distributed spatial asymmetry occurs because different locations in the receptive field have different impulse responses. This property is known as space-time (S-T) inseparability and is illustrated in Figure 3*B*. For this type of space-time arrangement, it is only for preferred-direction motions that the responses of all areas occur simultaneously. Simple linear summation then results in differential responses to preferred- and null-direction motions, and the squaring nonlinearity converts this directional difference into directional selectivity.

### *Physiological Models*

There is substantial physiological evidence for S-T inseparability in simple DS cells in visual cortex. Figure 3*C* shows an idealized simple-cell receptive field map as would be obtained from reverse-correlation experiments (De Valois et al., 2000). The cell contains on and off subregions with different time courses in different portions of space, resulting in an oriented spatiotemporal receptive field. Assorted variations of linear energy-motion models with static nonlinearities have been proposed that can account for approximately 50%–80% of the response of simple DS cells (Reid, Soodak, and Shapley, 1991; De Valois et al., 2000). However, the correlation between simple-cell S-T profile and direction selectivity varies widely in V1. Cells in layer IVB show very high correlation, those in IVA show only moderate correlation, and those in layer

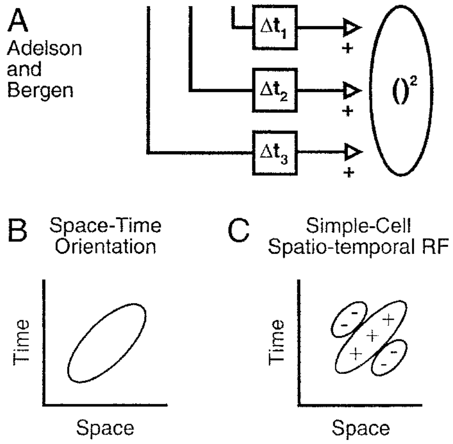

**Figure 3.** Motion-energy models of cortical directional selectivity. *A*, The Adelson and Bergen model. The symbols here are as in Figure 1, with "$( )^2$" indicating a squaring operation. *B*, Space-time orientation. If in *A*, $\Delta t_3 < \Delta t_2 < \Delta t_1$, then a plot of the response of the model to stimulation at different positions in space looks like this figure; that is, it is oriented in space-time. Hence, a motion going from left to right will have a positive slope in this plot and cause much response, whereas the opposite motion will not. *C*, Idealized representation of a simple-cell receptive field. The inhibitory flanks help to inhibit motions in the null (nonpreferred) direction (lines with negative slopes).

VI show very low correlation, despite equivalent directional tuning (Murthy et al., 1998). Thus, S-T structure alone cannot fully account for simple DS cell responses. In addition, quasilinear models of simple cells generally overestimate nonpreferred responses and sometimes underestimate preferred responses (Reid et al., 1991). And linear feedforward models also do not predict onset transients, which are commonly observed. Therefore, inhibitory (Reid et al., 1991; Heeger, 1993) or excitatory (Douglas and Martin, 1992) nonlinear feedback interactions between cortical cells have been proposed to account for these discrepancies. It has also been suggested that nonpreferred direction suppression might be due to a cortical inhibitory network devoted to response normalization (Heeger, 1993).

Although it has been accepted for many years that magnocellular cells from the LGN provide the input to the motion system, motion-energy models require inputs to simple DS cells that differ in latency (or temporal phase). Magno cells all have essentially identical response timings and therefore could not provide the range of latencies needed without an intracortical mechanism for creating delays (De Valois et al., 2000). It has been shown that blockade of cortical $\text{GABA}_\text{A}$ inhibition reduces but does not eliminate S-T inseparability. Thus, intracortical inhibition may contribute to, but cannot be solely responsible for, input latency differences. Humphrey, Saul, and Fiedler (1998) note that about 40% of parvocellular geniculate cells display absolute phase delays and long latencies (lagged cells) relative to the remaining parvo cells (nonlagged cells). Because lagged and nonlagged timing signatures are identifiable in simple-cell receptive fields, these authors attribute S-T inseparability to converging lagged and nonlagged parvo cell inputs with spatially shifted receptive fields. De Valois et al. (2000), however, suggest that the requisite latency differences arise from two classes of nondirectional (preferred-null ratios <3:1) cortical cells, which receive inputs from magno and parvo cells. Both nondirectional types can be found in a single cortical column and have appropriate differences in response waveforms. Additionally, these two nondirectional cell types are often shifted 90° in spatial phase, though centered on the same spatial location. Thus, they have exactly the spatiotemporal profile required to detect direction of motion using a linear energy-motion model.

Complex DS cells are generally found in the upper and lower layers of V1. Unlike most simple DS cells, complex DS cells lack first-order (linear) S-T oriented receptive fields. However, these cells show second-order (quadratic) S-T structure. In other words, it is the interactions between two sequentially stimulated locations in the cell's receptive field that are S-T inseparable. Thus, dynamic nonlinearities have been proposed to account for complex-cell directional selectivity. These nonlinearities would facilitate or inhibit, respectively, the responses to preferred- or null-direction motions. Similarly, S-T separable simple cells have also been shown to display some second-order, that is, nonlinear S-T structure. Because there is evidence for complex-to-simple-cell interactions, it has been proposed that directional selectivity and second-order S-T inseparability in simple cells arise from complex-cell inputs.

### *Development*

At least 5% of the cells in areas V1 and V2 of the kitten are directionally selective at eye opening. Thus, some of the cortical directional selectivity is either genetically coded or epigenetically derived through developmental spontaneous activity. Interestingly, selective biases in the distribution of preferred directions can be produced in kittens by exposing them to stripes moving in a particular direction after eye opening. In addition, one can nearly eliminate cortical directional selectivity by raising animals in an environment that is illuminated only by brief, low-frequency, stroboscopic flashes of light. Under these rearing conditions, only about 10% of V1 cells develop directional selectivity, and their directional selectivity is considerably weaker than normal. Not surprisingly, elimination of S-T inseparability accompanies the loss of directional selectivity (Humphrey et al., 1998). Perceptually, strobe-reared cats require contrasts at least ten times higher than normal to determine the direction of a moving grating. Furthermore, these elevations in contrast threshold can be permanent. No recovery of S-T structure or improvement in contrast threshold was found in two cats that had received 12 years of training following strobe rearing. Thus, it appears that some critical period exists during development during which directional selectivity must be established or it is forever compromised.

Based on the loss of S-T inseparability during strobe rearing, some authors have modeled the development of cortical directional selectivity as due to inputs with different response timings forming connections with a common cortical cell. These connections would self-organize through a Hebbian process that would strengthen the synaptic connections of well-correlated inputs (Humphrey et al., 1998). Strobe rearing would restrict the range of timings that could be associated, and therefore could eliminate cortical directional selectivity.

## Discussion

In this article, we have discussed the first step in the perception of motion—the determination of motion direction. This information is encoded by ensembles of directionally selective neurons both in the retina and within multiple visuocortical nuclei. Elucidating the cellular mechanisms subserving directional selectivity has been a major goal of neurobiologists for nearly 40 years.

# Dissociations Between Visual Processing Modes

*Bruce Bridgeman*

## Introduction

The visual system has two kinds of jobs to do. One is to support visual cognition or perception—knowledge about the identities and locations of objects and surfaces in the world. Another, sensorimotor, function is to control visually guided behavior. The two functions require different kinds of visual information.

The cognitive function is concerned with pattern recognition and with the positions of objects relative to one another. Executing this function requires extensive interaction between bottom-up image data and top-down information about objects, faces, etc. Qualitative location information may be adequate for this function; humans are poor at quantitatively estimating distances, directions, etc. if the measures of these abilities are perceptual judgments rather than motor behaviors.

The sensorimotor function, in contrast, needs quantitative egocentrically calibrated spatial information to guide motor acts. It does not need the minute-of-arc acuity of the cognitive function, however: calibration is more important than resolution. As a result, the brain's sensorimotor representations can be much smaller than those supporting cognition.

It is an empirical question whether these two functions, the cognitive and the sensorimotor, should be modeled as a single visual representation with two readouts or as separate maps of visual space. There is now extensive evidence for two distinct maps or sets of maps of visual space in the brain, one set handling perception and the other supporting visually guided behavior (Figure 1). Evidence comes from physiological recordings from the separate maps, from neurological patients in which one system or the other is damaged, from fMRI and PET scans of humans doing cognitive or sensorimotor tasks, and from psychophysical work in which different spatial values are inserted into the two systems simultaneously.

Some of the earliest evidence for the two-visual-systems distinction came from experiments in hamsters, where lesions of the midbrain's superior colliculus led to the inability to orient appropriately in a T-maze, combined with preserved abilities in pattern discrimination. In other animals, visual cortex lesions disturbed pattern discrimination without interfering with maze orienting (Schneider, 1969). This forebrain-midbrain distinction changed over the course of evolution, as both spatial orientation and pattern recognition became corticalized in primates.

## Neurophysiology

The visual pathways begin as a unified system, from the retinas through the lateral geniculate nucleus of the thalamus to the primary visual cortex of the occipital lobe. From here, visual signals are relayed to approximately 27 topographic maps in other visual areas (Visual Scene Perception). This characteristic of visual systems raises a question: do all of these maps work together in a

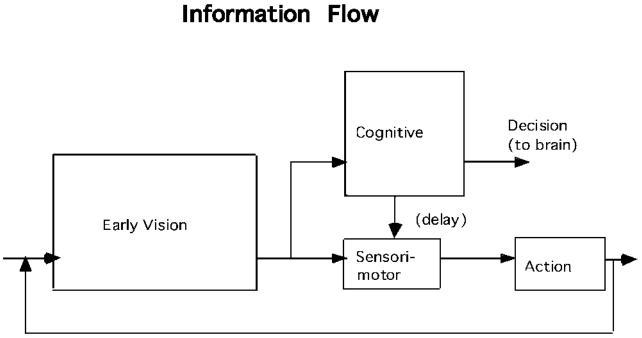

**Figure 1.** Information flow in cognitive and sensorimotor visual pathways. Visual image input is from the left, and cognitive or motor output to the right.

single visual representation, or are they functionally distinct? If they are distinct, how many functional maps are there and how do they interact?

The evidence reveals that the multiple maps support at least two functionally distinct representations of the visual world. The representations do not always function independently, but communicate with one another in some ways. Each representation uses several of the retinotopic maps; cognitive and sensorimotor representations correspond roughly to pathways into temporal and parietal cortex, respectively (Mishkin, Ungerleider, and Macko, 1983).

The temporal pathway consists of a number of regions in which neurons generally respond to stimuli in larger and larger regions of the visual field, but require increasing amounts of specific features or properties to excite them. This processing pathway culminates in the inferotemporal cortex, which specializes in pattern recognition problems involving choice and discrimination. Neurons in this region typically respond to very large areas of the visual field, usually including the fovea, and their responses are highly modified by visual experience and by the nature of the visual task currently being executed.

The parietal pathway, in contrast, specializes in physical features of the visual world, such as motion and location. One area contains a map of the cortex that specializes in motion of objects, whereas others contain neurons that respond both to characteristics of the visual world and to intended movements (Grasping Movements: Visuomotor Transformations). The areas serving the sensorimotor functions of vision are only a small part of the parietal lobe; dividing the cognitive and sensorimotor functions into temporal and parietal areas is a convenient first approximation, but several areas anatomically superior to the primary visual cortex (in occipito-parietal regions) are involved in the "temporal" stream. Some areas are involved in both functions.

A key task of the parietal stream is transformation of visual information into motor coordinates. As a first approximation, parietal visual cortex can be divided into five regions: (1) the lateral intraparietal area activated by both saccades and attention; (2) the parietal reach region that is activated by pointing and is also modulated by eye position; (3) the anterior intraparietal area active during visual grasp and also tactile manipulation; (4) the caudal intraparietal sulcus involved in object matching and grasping; and (5) the ventral intraparietal area, responding to visual motion toward the face (Culham and Kanwisher, 2001). Parietal regions are central to attention, eye movements, and orienting.

The spatial function can be further subdivided into two pathways that reflect different modes of spatial coding. Receptive fields of neurons in the lateral intraparietal area are spatially corrected before each rapid eye movement, so that they respond to stimuli that will be in their retinotopic receptive fields (i.e., in retinally based coordinates) following a planned eye movement (Duhamel, Colby, and Goldberg, 1992). The changes in these receptive fields can also be conceived as activity that signals candidates for planned eye movements.

A second coding scheme is seen in parietal area 7a. Neurons in this area provide information sufficient to reconstruct spatial position in head-centered coordinates (Andersen, Essick, and Siegel, 1985). These neurons respond strongly only if the eyes are in a particular position in the orbit and a target occupies a particular retinal location, in a multiplicative interaction. Simulations showed that such a network of cells codes information sufficient to derive spatiotopic output (Zipser and Andersen, 1988). A parallel distributed processing network was trained to respond to targets at particular locations in a visual field. After training, the response properties of the nodes in the model resembled the receptive fields of neurons in area 7a.

Spatial processing may be too basic a function to be limited to the parietal cortex, a relatively high-order structure that is well differentiated only in primates. Some features of the midbrain superior colliculus, such as broad intermodal integration and close connection to oculomotor control, suggest a role in sensorimotor vision (Collicular Visuomotor Transformations for Gaze Control), reflecting the earlier midbrain/forebrain distinction.

## Clinical Evidence

Damage to part of the primary visual cortex in human patients results in functional blindness in the affected field—a scotoma. Patients have no visual experience in the scotoma, but when forced to point to targets located there, which they insist they cannot see, they point fairly accurately by using sensorimotor information unavailable to their perception. Visual information coexisting with a lack of visual experience is called blindsight (Weiskrantz et al., 1974); it is an example of visually guided behavior without the experience of perception. It may be made possible by an alternative pathway from the retina to nonstriate visual cortex through the superior colliculus or other subcortical structures. Recent work has shown surprisingly sophisticated processing without awareness, including orientation and color discriminations.

Another example of dissociation of sensoriomotor and cognitive function has been found in a patient with damage to lateral occipital and occipitoparietal cortex (Goodale and Milner, 1992). When asked to match line orientations, the patient could not reliably distinguish horizontal from vertical, though she had no scotoma in which visual experience was altogether absent. Asked to put a card through a slot at varying orientations, however, she oriented the card correctly even as she raised her hand from the start position. There was a dissociation between her inability to perceive object orientation and her ability to direct accurate reaching movements toward objects of varying orientations. Her cognitive representation of space was unavailable, while sensorimotor representation remained intact. The complementary dissociation, with retention of perception accompanied by loss of ability to use visual information to control movements of the limb and hand, is seen clinically under the label of optic ataxia.

Such examples demonstrate separate cognitive and sensorimotor representations, but only in patients with brain damage. When a human suffers brain damage with partial loss of visual function, there is always the possibility that the visual system will reorganize itself, isolating fragments of the machinery that normally function as a unit. The clinical examples, then, leave open the possibility that the system may function differently in intact humans. Any rigorous proof that normal visual function shows the cognitive/sensorimotor distinction must include psychophysical measures in intact humans.

## Psychophysics of Space

Some of the earliest evidence for a cognitive/sensorimotor distinction in normal subjects came from studies of rapid (saccadic) eye movements. Subjects are normally unaware of sizable displacements of the visual world if the displacements occur during saccadic eye movements. This implies that information about spatial location is degraded during saccades. There is a seeming paradox to this degradation, however, for people do not become disoriented after saccades, implying that spatial information is maintained. Experimental evidence supports this conclusion. For instance, the eyes can saccade accurately to a target that is flashed (and mislocalized) during an earlier saccade, and hand-eye coordination remains fairly accurate following saccades. How can perceptual information be lost while visually guided behavior is preserved?

To resolve this paradox, it should be noted that the conflicting observations use different response measures. The experiments on perception of displacement during saccades require a symbolic response, such as a nonspatial verbal report or a button press, with an arbitrary spatial relationship to the target. Orienting of the eye or hand, in contrast, requires quantitative spatial information, defined as requiring a 1:1 correspondence between a target position and a motor behavior, such as directing the hand or the eyes to the target. The conflict might be resolved if the two types of measure, which can be labeled as cognitive and sensorimotor, could be combined in a single experiment. If two visual pathways process different kinds of information, spatially oriented motor activities might have access to accurate position information even when that information is unavailable at a cognitive level.

The two conflicting observations (perceptual suppression on one hand and accurate motor behavior on the other) were combined by asking subjects to jab the position of a target that had been displaced and then extinguished (reviewed in Bridgeman, Peery, and Anand, 1997). On some trials the target jump was detected, while on others the jump went undetected due to a simultaneous eye movement (monitored photoelectrically). As one would expect, subjects could point accurately to the position of the now-extinguished target following a detected displacement. Pointing was equally good, however, following an undetected displacement. It appeared that updating information was available to the motor system but not to perception.

This result implied that quantitative control of motor activity was unaffected by the perceptual detectability of target position. One can also interpret the result in terms of signal detection theory as a high response criterion for the report of displacement. The first control for this possibility was a two-alternative forced-choice measure of saccadic suppression of displacement. This criterion-free measure showed an inability to perceive displacements under conditions where pointing was accurate even when the target had been displaced (Bridgeman and Stark, 1979). Information was available to a sensorimotor system controlling pointing, but not to a cognitive system informing visual perception.

Dissociation of cognitive and sensorimotor function has also been demonstrated by giving cognitive and sensorimotor systems opposite signals at the same time. This is a more rigorous way to separate cognitive and sensorimotor systems. A signal was inserted selectivity into the cognitive system with stroboscopic induced motion. In this illusion a surrounding frame was displaced, creating the illusion that a target jumps although it remains fixed relative to the subject. We know that induced motion affects the cognitive system, because we experience the effect and subjects can make verbal judgments of it. But the above saccadic suppression experiments (Bridgeman and Stark, 1979) implied that the information used for motor behavior might come from sources unavailable to perception.

In the experiment, a target spot jumped in the same direction as a frame, but not far enough to cancel the induced motion. The spot still appeared to jump in the direction opposite the frame. Saccadic eye movements followed the actual jump direction, even though subjects perceived stroboscopic motion in the opposite direction (Wong and Mack, 1981). If a delay in responding was required, however, eye movements followed the perceptual illusion. This implies that the sensorimotor system has no memory, but must rely on information from the cognitive system when responding to what was previously present rather than what is currently present.

All of these techniques involve motion or displacement, leaving open the possibility that the dissociations are associated in some way with motion systems, rather than with representation of visual location per se. Motion and location may be confounded in some kinds of visual coding schemes. A newer design allows the examination of visual context in a situation where there is no motion or displacement at any time (Bridgeman et al., 2000). The design is based on the Roelofs effect, a perceptual illusion seen when a static frame is offset to the left or the right of a subject's centerline. Objects that lie within the frame tend to be mislocalized in the direction opposite the offset of the frame. For example, in an otherwise featureless field, a rectangle is presented to the subject's left. Both the rectangle and stimuli within it tend to be localized too far to the right.

A Roelofs effect is seen with a perceptual measure, but subjects point without error. If a delay in responding causes subjects to switch from using sensorimotor information directly to using information imported from the cognitive representation, delaying the response should force them to switch to using cognitive information. By delaying the response cue long enough, all subjects showed a Roelofs effect in both pointing and judging. Thus, this design showed a switch from motor to cognitive information in directing the motor response; the cognitive illusion appears after a delay of about 2 s (Bridgeman et al., 2000; Rossetti, 2000). In the delay case, information flowed from the cognitive system, with the illusion, to the sensorimotor system and thence to behavior. However, the perception of the Roelofs effect shows that accurate sensorimotor information never corrects perception. Thus the arrow from cognitive to sensorimotor in Figure 1 extends in only one direction.

An even longer motor memory is seen for the slopes of hills, where veridical information endures for several minutes despite exaggerated perceptions of the slopes (Creem and Proffitt, 1998). The sensorimotor branch of the system seems to hold spatial information just long enough to direct current motor activity, but no longer. These authors have also shown that the sensorimotor system does not have access to top-down information about the conventional uses of an object. A group of objects is arrayed before a subject with their handles facing away. They will be grasped by their handles if the cognitive system is available to help organize the movement, but if the cognitive system is distracted by another, non-motoric task, the objects will be grasped skillfully but inappropriately by their closest parts. This result raises another issue, the extent of object coding in the sensorimotor system.

## Psychophysics of Objects

The cognitive system needs detailed information to identify top-down information about the meanings and uses of objects, while the sensorimotor system needs only information about size, location, and graspability.

Research on object properties has followed several methods. One method is based on the Ebbinghaus illusion, also called the Titchner circles illusion. A circle looks larger if it is surrounded by smaller circles than if it is surrounded by larger circles. Haffenden and Goodale (1998) measured the illusion by asking subjects either to indicate the apparent size of a circle or to pick it up. In both cases neither hand nor target could be seen during the movement. The illusion was larger for the size estimations than for the grasp, indicating that the sensorimotor system was relatively insensitive to the illusion.

A challenge to this line of research came from Franz et al. (2000), who analyzed the Ebbinghaus illusion into two half-illusions: comparing a circle surrounded by larger circles to a circle alone, and comparing a circle surrounded by smaller circles to a circle alone. When the small-circle context and the large-circle context are compared directly, a super-additivity occurs: the illusion is larger than the sum of the two half-illusions. Because grasp necessarily involves a circle alone, the differences between grasp and perception were explained. Goodale has recently clarified this issue by showing that it is the physical distance between the inducing circles and the target circle, not the size of the circles, that influences grasp aperture. Perception, in contrast, is based on the size difference between the inducing circles and the target circle.

## Discussion

Information about egocentric spatial location and some object properties is available at a motor level despite cognitive illusions of location. Egocentric localization information is available to the sensorimotor system even while the cognitive system, relying on relative motion and relative position information, holds unreliable information about location. Spatial information can flow from the cognitive to the sensorimotor representation if the sensorimotor information has degraded due to delay, but information cannot flow in the other direction. The two-visual-systems conception applies not only to the localization of objects, but also to their properties.

# Dopamine, Roles of

*Jean-Marc Fellous and Roland E. Suri*

## Introduction

Dopamine (DA) is a neuromodulator (see Neuromodulation in Invertebrate Nervous Systems) that originates from small groups of neurons in the mesencephalon [the ventral tegmental area (A10), the substantia nigra (A9) and A8], and the diencephalon (area A13, A14 and A15). Dopaminergic projections are in general very diffuse and reach large portions of the brain. The time scales of dopamine actions are diverse, from a few hundred milliseconds to several hours. This chapter will focus on the mesencephalic dopamine centers because they are the most studied, and because they are thought to be involved in diseases such as Tourette's syndrome, schizophrenia, Parkinson's disease, Huntington's disease, drug addiction, and depression (see Tzschentke, 2001). These centers are also involved in normal brain functions, such as working memory, reinforcement learning, and attention. This chapter briefly summarizes the main roles of dopamine with respect to recent modeling approaches.

## Biophysical Effects of Dopamine

The effects of dopamine on membrane currents and synaptic transmission are complex and depend on the nature and distribution of the postsynaptic receptors. At the single-cell level, in the in vitro rat preparation, DA has been found to either increase or decrease the excitability of neurons, through the modulation of specific sets of sodium, potassium, and calcium currents (see Gulledge and Jaffe, 1998, and Nicola, Surmeier, and Malenka, 2000, for reviews). Although the exact nature of the modulation is still debated, it is likely to depend on the opposing contributions of the D1/D5 and D2/D3 family of dopamine receptors that are respectively positively and negatively coupled with adenylate cyclase. Studies in monkey cortical tissue showed that the D1/D5 family of receptor was 20-fold more abundant than the D2/D3 family, and that these receptors were present distally in both pyramidal and nonpyramidal cells (Goldman-Rakic, Muly, and Williams, 2000).

Dopamine modulates excitatory and inhibitory synaptic transmission. Although the nature of neuromodulation of inhibitory transmission is still debated, it appears that in both the cortex and the striatum, D1 receptor activation selectively enhances NMDA but not AMPA synaptic transmission. Because of their voltage dependence, NMDA currents are smaller at rest than in a depolarized state when the postsynaptic cell is firing. Experimental and theoretical evidence suggest that the dopamine enhancement of NMDA currents may be used to induce working memory-like (see later discussion) bistable states in large networks of pyramidal neurons (Lisman, Fellous, and Wang, 1998).

In rats in vivo, stimulation of the ventral tegmental area or local application of dopamine decreases the spontaneous firing of the prefrontal cortex (Thierry et al., 1994), striatum, and nucleus accumbens (Nicola et al., 2000), suggesting that dopamine may be able to control the levels of noise, and hence signal-to-noise ratios.

Given that dopamine modulation strongly depends on the particular distribution of D1/D5 and D2/D3 receptors and on the particular pattern of incoming synaptic transmission, the biophysical effects of dopamine on the intrinsic and synaptic properties is likely to differ from one neuron to the next, raising the intriguing possibility of the existence of several subclasses of neurons that differ mainly by their responses to this neuromodulator.

## Dopamine Levels Influence Working Memory

*Working memory* refers to the ability to hold a few items in mind, with the explicit purpose of working with them to yield a behavior (Short-Term Memory). Typically, working memory tasks, such as spatial delayed match-to-sample tasks, consist of the brief presentation of a cue-stimulus (bright dot flashing once) in one of the four quadrants of a screen, followed by a delay period of several seconds, and by a test in which the subject has to respond only if the test stimulus appears the same quadrant as the cue-stimulus. Single-cell studies in monkeys revealed that some prefrontal cortical cells increased their firing rate during the delay period, when the stimulus is no longer present but when the animal has to remember its location in order to later perform the correct action. Both pyramidal cells and interneurons may present this property. The activity of these cells is stimulus dependent, so that only the cells that encode for the spatial location where the cue-stimulus occurred remain active during the delay period.

Local iontophoretic administrations of DA in the prefrontal cortex of monkeys performing a working memory task increase the cells' firing rate during the delay period, without increasing background noise, essentially increasing the signal-to-noise ratio during the task. There is, however, an optimal level of dopamine concentration above and below which working memory becomes impaired. Current theories propose that this effect is due to the enhancement by dopamine of excitatory inputs on pyramidal cells and interneurons. Because DA is more effective in facilitating excitatory transmission on pyramidal cells than on interneurons, intermediate levels of DA improve performance, while higher levels of DA recruit feedforward inhibition and decrease pyramidal cell output, thereby resulting in impairments in the task. Low levels of DA would not be sufficient to induce excitatory facilitation, yielding a poor pyramidal cell output, and hence an impairment (Figure 1 and Goldman-Rakic et al., 2000). There have been a few attempts at modeling the neural substrate of working memory, but very little has yet been done to account for the role of dopamine (Tanaka, 2001).

## Dopamine Responses Resemble Reward Prediction Signal of TD Model

A large body of experimental evidence led to the hypothesis that Pavlovian learning depends on the degree of the unpredictability of the reinforcer (Dickinson, 1980). According to this hypothesis, reinforcers become progressively less efficient for behavioral adaptation as their predictability grows during the course of learning. The difference between the actual occurrence and the prediction of the reinforcer is usually referred to as the "error" in the reinforcer prediction. This concept has been used in the temporal-difference model (TD model) of Pavlovian learning (Reinforcement Learning in Motor Control). If the reinforcer is a reward, the TD model uses a reward prediction error signal to learn a reward prediction signal. The error signal progressively decreases and shifts to the time of earlier stimuli that predict the reinforcer. The characteristics of the reward prediction signal are comparable to those of anticipatory responses such as salivation in Pavlov's experiment.

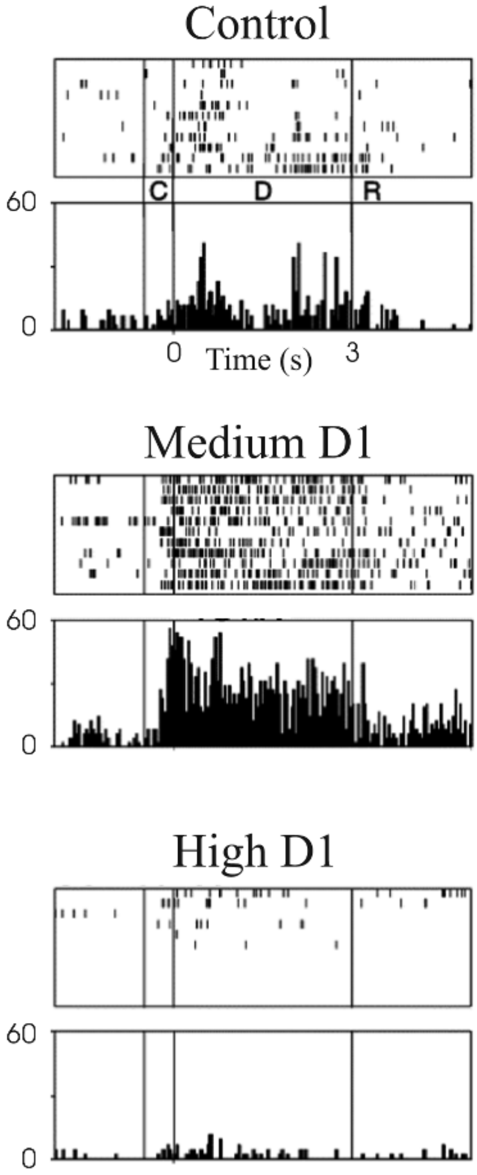

**Figure 1.** Biphasic effects of dopamine during a working memory task. The task consisted of the brief presentation of a cue (C), a delay of 3 seconds (D), and a response (R). Moderate levels of local application of SCH39166 (25 nA), a D1 receptor agonist, dramatically enhanced the activity of this cell, without significantly increasing its background activity (before cue). Higher levels of SCH39166 (75 nA) decreased the activity of this cell throughout the task. Histogram units are spikes/s. (Figure adapted from Goldman-Rakic, Muly, and Williams, 2000.)

The reward prediction error signal of the TD model remained a purely hypothetical signal until researchers discovered that the activity of midbrain dopamine neurons is strikingly similar to the reward prediction error of the TD model (Figure 2*A*) (Montague, Dayan, and Sejnowski, 1996; Schultz, 1998). Advances in reinforcement learning theories, as well as evidence for the involvement of dopamine in sensorimotor learning and in cognitive functions, led to the development of the Extended TD model. The reward prediction error signal of the TD model by Suri and Schultz (1999) reproduces dopamine neuron activity in several situations: (1) upon presentation of unpredicted rewards, (2) before, during,

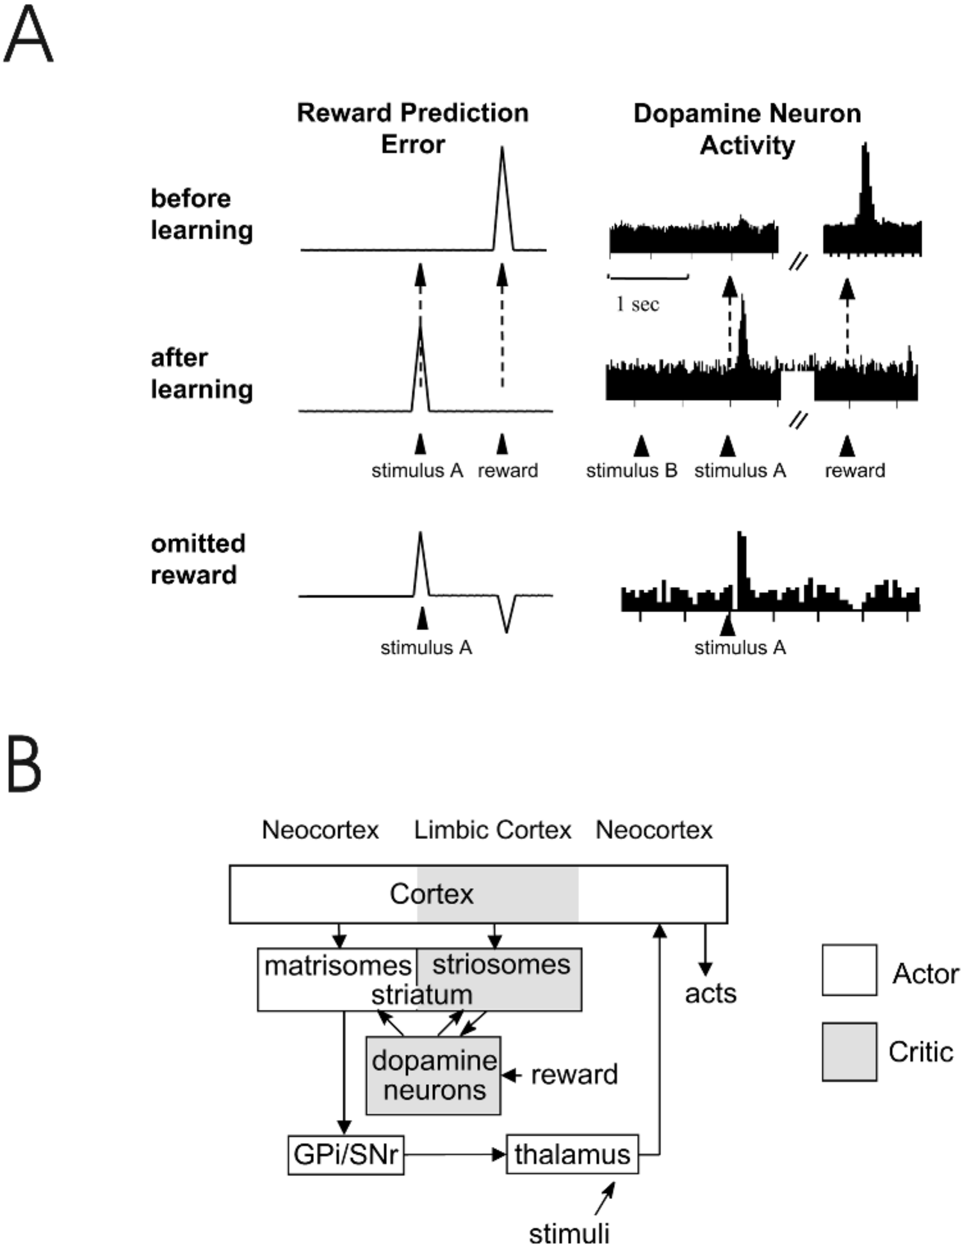

**Figure 2.** *A*, Prediction error signal of the TD model (left) similar to dopamine neuron activity (right). If a neutral stimulus A is paired with reward, prediction error signal and dopamine activity respond to the reward (before learning). After repeated pairings, the prediction error signal and dopamine activity are already increased by stimulus A and on baseline levels at the time of the reward (after learning). If the stimulus A is conditioned to a reward but is occasionally presented without reward, the prediction error signal and dopamine activity are decreased below baseline levels at the predicted time of reward (omitted reward). *B*, Interactions between cortex, basal ganglia, and midbrain dopamine neurons according to the Actor-Critic models. The limbic areas correspond to the Critic and the sensorimotor areas to the Actor. The striatum is divided into matrisomes (sensorimotor) and striosomes (limbic). Limbic cortical areas project to striosomes, whereas neocortical areas chiefly project to matrisomes. Midbrain dopamine neurons are contacted by medium spiny neurons in striosomes and project to both striatal compartments. They are proposed to influence sensorimotor learning in the matrisomes (instrumental learning) and learning of reward predictions in the striosomes (Pavlovian learning). Striatal matrisomes inhibit the basal ganglia output nuclei Gpi/SNr and can elicit actions due to their projections via thalamic nuclei to motor cortical areas. Several additional functions of this architecture were proposed in Suri, Bargas, and Arbib, 2001. (Figure adapted from Suri and Schultz, 1998.)

and after learning that a stimulus precedes a reward, (3) when two stimuli precede a reward with fixed time intervals, (4) when the interval between the two stimuli are varied, (5) when a reward is unexpectedly omitted, (6) when a reward is delayed, (7) when a reward occurs earlier than expected, (8) when a reward-predictive stimulus is unexpectedly omitted, (9) when there is a novel, physically salient stimulus that has never been associated with reward (see allocation of attention, discussed later in this chapter), (10) and when a blocking paradigm is used. To reach this close correspondence, three constants of the TD model were tuned to characteristics of dopamine neuron activity (learning rate, decay of eligibility trace, and temporal discount factor), some weights were initialized with positive values to achieve (9), and some ad hoc changes of the TD algorithm were introduced to reproduce (7) (see later discussion).

In Pavlov's experiment, the salivation response of the dog does not influence food delivery. The TD model is a model of Pavlovian learning and therefore computes predictive signals, corresponding to the salivation response, but does not select optimal actions. In contrast, instrumental learning paradigms, such as learning to press a lever for food delivery, demonstrate that animals are able to learn to perform actions that optimize reward. To model sensorimotor learning in such paradigms, a model component called the Actor is taught by the reward prediction error signal of the TD model. In such architectures, the TD model is also called the Critic. This approach is consistent with animal learning theory and was successfully applied to machine learning studies (Reinforcement Learning in Motor Control). Midbrain dopamine neurons project to the striatum and cortex and are characterized by rather uniform responses throughout the whole neuron population. Computational modeling studies with Actor-Critic models show that such a dopamine-like reward prediction error can serve as a powerful teaching signal for learning with delayed reward and for learning of motor sequences (Suri and Schultz, 1999). These models are also consistent with the role of dopamine in drug addiction and electrical self-stimulation (see later discussion). Comparison of the Actor-Critic architecture to biological structures suggests that the Critic may correspond to pathways from limbic cortex via limbic striatum (or striosomes) to dopamine neurons, whereas the Actor may correspond to pathways from neocortex via sensorimotor striatum (or matrisomes) to basal ganglia output nuclei (Basal Ganglia) (Figure 2*B*). Although this standard Actor-Critic model mimics learning of sensorimotor associations or habits, it does not imply that dopamine is involved in anhedonia.

## Allocation of Attention

Several lines of evidence suggest that dopamine is also involved in attention processes. Although the firing rates of dopamine neurons can be increased or decreased for aversive stimuli, dopamine concentration in striatal and cortical target areas are often increased (Schultz, 1998). Both findings are not necessarily inconsistent, since small differences in firing rates of dopamine neurons are hard to detect with single neuron recordings, and measurement methods for dopamine concentration usually have less temporal resolution than methods used to measure spiking activity. Furthermore, dopamine concentration is not only influenced by dopamine neuron activity but also by local regulatory processes. Slow changes in cortical or striatal dopamine concentration may signal information completely unrelated to reward. Also, relief following aversive situations may influence dopamine neuron activity as if it were a reward, which would be consistent with opponent processing theories (Conditioning). Allocation of attentional resources seems to determine dopamine neuron activity in situations when a reward is delivered earlier than usual. In contrast to any linear model, including the standard TD model, dopamine neuron activity is on baseline levels at the time of the expected reward in this situation. This suggests that delivery of the reward earlier than usual seems to reallocate attentional resources through competitive mechanisms (Suri and Schultz, 1999).

Dopamine neurons respond to a novel, physically salient stimulus even if the stimulus has never been associated with a reward (Schultz, 1998). In contrast to reward-predictive responses, for stimuli of equal physical salience, the increase due to novelty responses seems to be smaller and is followed by a pronounced decrease of neural activity below baseline levels. (Brief and less pronounced decreases of dopamine neuron activity sometimes also occur after a response to a reward.) In contrast to responses to conditioned stimuli, novelty responses extinguish for repeated stimulus presentations. The characteristics of this novelty response are consistent with the TD model if certain associative weights are initialized with positive values instead of using initial values of zero (Suri and Schultz, 1999). Such weights initialization with positive values was proposed in machine learning studies to stimulate exploration of novel actions. Simulation studies demonstrated that such a novelty bonus hardly influences slow movements of more than 100 msec duration because the effects of the two phases in the firing of dopamine neurons cancel out and the movement starts after the biphasic response. However, dopamine novelty responses may stimulate exploration for very brief actions, which may include saccades or allocation of attentional resources (Suri and Schultz, 1999).

Redgrave and collaborators (Redgrave, Prescott, and Gurney, 1999) argued that the latency of dopamine responses is too short to be consistent with the hypothesis that dopamine is a reward prediction signal. Onsets of dopamine novelty responses as well as reward responses seem to occur just before the start of the saccade or during the saccade. The dopamine response will likely occur after the superior colliculus has detected a visual target but prior to the triggering (by collicular neurons) of the saccadic movement required to bring the target to the fovea. If it is assumed that the animal must execute a saccade to a visually presented stimulus before it can adequately assess its predictive value, the latency of dopamine response would be too short to signal reward. We argue against this view. Neural activities in cortical and subcortical areas reflect the anticipated future visual image before a saccade is elicited (Ross et al., 2001). Therefore, the representations of future visual images may influence dopamine neuron activity as if the saccade has already been executed, and thus the dopamine response may start slightly before the saccade. The Extended TD model computes such predictive signals and uses them to select goal-directed actions in a cognitive task (Suri, Bargas, and Arbib, 2001). According to this Actor-Critic model, the interactions between dopamine neuron activities (computed by Critic) and activities that reflect the preparation for intended actions (in Actor) select the actions that maximize reward predictions. The model evaluates the expected values of future actions, without necessarily executing them, in order to select the action with the optimal predicted outcome. The model selects the optimal action from such "action ideas" or "imagined actions." This optimal action is selected by assuming that dopamine neuron activity increases the signal-to-noise-ratio in target neurons. According to this advanced Actor-Critic model, dopamine improves focusing of attention to intended actions and selects actions. Since some neural activities anticipate the retinal images that result in saccades before these saccades are executed (Ross et al., 2001), animals may indeed use such predictive mechanisms for the selection of intentional saccades. Furthermore, similar internal mechanisms may bias intentional switching capabilities of the basal ganglia to facilitate the allocation of behavioral and cognitive processing capacity toward unexpected events (see Basal Ganglia and Redgrave et al., 1999). If we assume similar functions of dopamine for short-term memory, this model suggests that dopamine may select the items that should be kept in short-term memory and may also help to sustain their representation over time.

## Conclusions

In vitro studies of the biophysical effects of dopamine demonstrate a wide range of dopamine effects on the intrinsic and synaptic properties of individual cells. In vivo studies suggest, however, that the main overall effect of dopamine may be to control noise levels and to selectively enhance the signal-to-noise-ratio of neural processing. This action may behaviorally lead to an improvement of working memory and to better selection of goal-directed actions. The TD model reproduces dopamine neuron activity in many behavioral situations and suggests that dopamine neuron activity codes for an error in reward prediction. This chapter described a TD model that solves cognitive tasks including goal-directed actions (also called planning or intentional actions) and that attempts to reproduce the function of dopamine in attention and preparation processes.

# Dynamic Link Architecture

*Christoph von der Malsburg*

## Introduction: The Architecture

The dynamic laws governing the brain's physical elements and their interaction enable it to fall into functionally useful states. The term neural architecture is taken here as referring to the shape of these dynamic laws. This article presents and discusses *dynamic link architecture* (DLA; von der Malsburg, 1981, 1985, 1986). There are various ways in which DLA has been couched in terms of equations (von der Malsburg, 1985; von der Malsburg and Schneider, 1986; von der Malsburg and Bienenstock, 1987; Bienenstock and von der Malsburg, 1987; Wiskott and von der Malsburg, 1996; Zhu and von der Malsburg, 2001). Because DLA has not yet received a canonical mathematical description, it is described here in abstract verbal terms. DLA is a construction site, and this article is an invitation to work at it.

According to DLA, the brain's data structure has the form of graphs composed of nodes (called units) connected by links. The graphs of DLA are dynamic: both units and links bear activity variables changing on the rapid functional time scale of fractions of a second. Graphs form a very versatile data format that is probably able to render the structure of any mental object. A particularly important feature is the ability of graphs to compose more complex data structures from simpler ones, an important requirement for the expression of cognitive structures (see COMPOSITIONALITY IN NEURAL SYSTEMS).

The units of DLA play the role of symbolic elements. This follows the tradition of associating neurons with elementary meaning (the identification of units with neurons is, however, not taken for granted here; see below). Units are endowed with structured signals changing in time. These signals can be evaluated under two aspects, intensity and correlation. Intensity measures the degree to which a unit is active in a given time interval, signifying the degree to which the meaning of the unit is alive in the mind of the animal. Correlations, on the other hand, quantify the degree to which the signal of one unit is related to that of others. The general idea is that identical signal patterns are strongly correlated, whereas statistically independent signal patterns have zero correlation. A correlation can be a binary relation, characterizing two units, or an $n$-ary relation, to be evaluated for $n$ units at a time.

The strength of links can change on two time scales, represented by two variables called *temporary weight* and *permanent weight*. The permanent weight corresponds to the usual synaptic weight, can change on the slow time scale of learning, and represents permanent memory. The temporary weight is constrained to the interval between zero and the permanent weight and can change on the same time scale as the unit activity (hence the name dynamic links).

Dynamic links constitute the glue by which higher data structures are built up from more elementary ones. Conversely, the absence of links (temporary or permanent) keeps mental objects separate from each other and prevents their direct interaction. In the simplest case, a link binds a descriptor to an object. For example, a link may bind a unit representing a color to another unit that stands for a specific object. More generally, mental objects are formed by binding together units representing constituent parts. The infinite richness and flexibility of the mind is thus made possible as a combinatorial game. The mental activity of familiar objects (like my grandmother, or a yellow Volkswagen) may be reliably correlated with the activity of specialized units, but these objects still acquire their substance—their imagined visual appearance, and so on—by the dynamical binding of appropriately structured arrays of other units. Units can be part of different functional contexts. They are integrated into a specific one by the activation of appropriate links. Dynamic links are the means by which the brain specializes its circuit diagram to the needs of the particular situation at hand.

### *Graph Dynamics*

Under the influence of signal exchange, graphs and their units and links are subject to dynamic change, constituting a game of network self-organization (see SELF-ORGANIZATION AND THE BRAIN). The dynamic links have a resting strength near the value of the permanent weight. When the units connected by a permanent link become active, there is rapid feedback between the units' signal correlations and the link's strength, with a strong link tending to increase signal correlation and a strong correlation controlling the link to grow in strength toward the maximum set by the permanent weight. This feedback can also lead to a downward spiral, with a weak correlation reducing a link's strength and a weak link losing its grip on signals, which, under the influence of other links, drift apart toward lower correlation. Thus, links between active units tend to be driven toward one of their extreme values, zero or the maximum set by the permanent weight.

Links are subject to divergent and convergent competition: links converging on one unit compete with each other for strength, as do links diverging from one unit. This competition drives graphs to sparsity. Links are also subject to cooperation. Several links carrying correlated signal structure cooperate in imposing that signal structure on a common target unit, helping them all to grow. Because the ultimate cause for all signal structure is random, correlations can only be generated on the basis of common origin of pathways. Thus, cooperation runs between pathways that start at one point and converge to another point. The common origin of converging pathways may, of course, be an event or a pattern in the environment.

Cooperation and competition conspire to favor certain graph structures. These are distinguished by being sparse (that is, activating relatively few of the permanent links in or out of units) and by having a large number of cooperative meshes—arrangements of alternative pathways from one source to one target unit. Beyond these statements, a general characterization of graph attractor states is an open issue. However, there are certain known graph structures that have been shown in simulations to be attractor states and that prove to be very useful (see the section on applications). All of these graph structures may be characterized as "topological graphs": if their units are mapped appropriately into a low-dimensional display space (one- or two-dimensional in the known examples), the links of those graphs all run between units that are neighbors in the display space.

### *Slow Plasticity*

In classical neural architectures, learning is modeled by *synaptic plasticity*, or the change of permanent synaptic weights under the control of neural signals. This general idea is also part of the dynamic link architecture. However, DLA imposes a further refinement in that a permanent weight grows only when the corresponding dynamic link has converged to its maximum strength, which happens only in the context of an organized graph structure. For a permanent link to grow, it is thus not sufficient for the two connected units to have high intensity in the same brain state; in addition, their signals must be correlated and their link must be active. This puts the extra condition on the growth of permanent connection weights that they be validated by indirect evidence, in the form of active indirect pathways between the units connected, and in the form of relative freedom from competition, the two conditions characterizing a well-structured dynamic graph. Thus, only the very few connections that are significant in this sense can grow.

## Neural Implementation of Dynamic Links

How can the units, links, and dynamical rules of DLA be identified with known neural structures? This is possible in several ways. It will turn out that to some extent, DLA can be seen as a fair interpretation of known structures, whereas some experimental predictions also flow from it.

### *Units Are Individual Neurons*

At the most fundamental level, units are to be identified with neurons, links with axons and synapses, signals with neural spike trains, and permanent weights with conventional synaptic strengths. Signal intensity is evaluated as firing rate, averaged over intervals of length $\Delta$, whereas the stochastic signal fine structure within that interval is evaluated in terms of correlations with a resolution time $\tau$, two spikes arriving within $\tau$ of each other being counted as simultaneous. The smallest reasonable choice for $\Delta$ is probably 100 ms or a little less; the smallest choice for $\tau$ may be 3 ms, as proposed in von der Malsburg (1981). Neural signals in the cerebral cortex have a very rich stochastic structure on all time scales, much of which is not correlated strongly with external stimuli in neurophysiological experiments (and is usually suppressed by averaging in a post-stimulus time histogram).

A point of contention at the present time is the precision with which nervous tissue can process temporal signal structure. Some authors (e.g., Shadlen and Movshon, 1999) believe that fine temporal structure cannot be transmitted by neurons, and that meaningful signal correlations cannot be extracted. The proposed argument is, however, circular, as it was assumed that neural input signals are random and independent. If this assumption is violated in the brain, the argument falls flat. Indeed, it has been shown (Mainen and Sejnowski, 1995) that spike timing of cortical neurons can be reliable with 1-ms precision if neural input is sufficiently structured, and similarly precise spike timing was found in response to temporally structured visual input seven synaptic generations behind the retina (Bair and Koch, 1995). The latter and other studies would encourage the assumption of a $\tau$ of 1 ms. A heated discussion has also sprung up around the status of the interpretation of signal correlations in terms of dynamic binding (SYNCHRONIZATION, BINDING AND EXPECTANCY) as proposed in von der Malsburg (1981; see also Shadlen and Movshon, 1999; Gray, 1999; Singer, 1999; von der Malsburg, 1999, and other articles in the same issue of *Neuron*). At the present time, the issue is the subject of intensive experimental study in many laboratories.

Dynamic links are realized at the single-neuron level as rapid reversible synaptic plasticity (RRP). Starting from a resting value, the temporary weight of a synapse is increased by correlations between the pre- and postsynaptic signals and is decreased if both signals are active in a given time period but are not correlated. The resting weight of a synapse is probably not too far from the maximum set by the permanent weight (so that RRP will manifest itself mainly in the form of rapid weight reduction). The interactions between temporary synaptic strength and signals is such as to constitute a positive feedback loop. Changes in temporary synaptic weights must take place on a fast time scale to be of functional significance, possibly as quickly as within 10 ms. In the prolonged absence of presynaptic or postsynaptic activity, the temporary weight rises or falls back toward its resting value, with a time scale that corresponds to short-term memory (perhaps a few dozen seconds), or it is reset by an active mechanism (for example, in the visual cortex during saccades). Convergent synaptic competition (competition between synapses at the same postsynaptic neuron) could be implemented by the signals arriving on one synapse or one set of synapses spoiling the postsynaptic activity for others. Divergent competition could be implemented with the help of inhibition between the target cells, making it difficult or impossible to synchronize them all with the same presynaptic signal.

The existence of rapid reversible changes in synaptic strength in cortex is a broadly documented experimental fact (see Hempel et al., 2000, for examples and a review of the experimental literature; see also TEMPORAL DYNAMICS OF BIOLOGICAL SYNAPSES). What has not been investigated experimentally in any detail is the dependence of rapid synaptic change on postsynaptic signals, and without such study the type of control postulated in RRP cannot be ascertained. There are many open details that must be determined experimentally. Among them is the identity of the relevant postsynaptic signal (membrane potential, some second messenger, e.g., $Ca^{2+}$, action potential, or other) and the precise definition of the dynamics of synaptic strength (which could require a delay between the presynaptic and postsynaptic signals, as described for long-term potentiation in Senn, Markram, and Tsodyks, 2001, and experimental work reviewed therein).

As was pointed out, implementation of DLA at the single-neuron level can be realized on a hierarchy of time scales $\Delta$ and the concomitant resolution time $\tau$. So far I have discussed the faster end of the hierarchy. If $\Delta$ is taken to be a large fraction of a second or longer, we are in the domain of overt attention and the well-studied phenomenon of the mind shifting context sequentially on smaller and larger time scales. There is no doubt that a very important function of attention is keeping topics separate if their simultaneous activation would lead to confusion, and thus to provide temporal binding. A proper understanding of the mechanisms of attention will have to provide an answer to the question of how the focus of attention is formed. Part of the answer will be, of course, that it must unite elements that have something to do with each other (as recorded by the links between them), and not to activate simultaneously what would lead to confusion. The conceptual framework of DLA and its network self-organization are therefore appropriate for the description of attention dynamics.

### *Multicellular Units*

Just as the DLA interpretation of neural dynamics can be applied at different temporal scales, it can also be applied at different spatial scales, either by identifying units with single neurons, as above, or by identifying units with groups of neurons. In this perspective, all individual neurons in a group, called a *multicellular unit* (MCU), are interpreted to have the same meaning. They differ, however, in the synaptic connections they have to neurons in other MCUs. The signal intensity of an MCU is the combined neural activity of all of its neurons. Signal correlations, however, are calculated by paying attention to the distribution of activity in MCUs and determining the combined synaptic weights of all connections between currently active cells in a pair of MCUs. By changing the distribution of activity over its neurons, an MCU can control the connectivity pattern it has to other MCUs. An important example of MCUs is constituted by the hypercolumns in visual cortex. All neurons in a hypercolumn have the same theme, subserving, by definition, one point in visual space. The neurons differ, however, in how they are connected with afferent neurons (which gives them different meaning on a more fine-grained level) and how they are connected to neurons in other hypercolumns.

MCU implementation of DLA differs in important points from the single-neuron implementation. The variables that constitute dynamic links are not temporary synaptic weights but neural spike activity, and correlations are not computed by time-consuming temporal integration over pairs of neural signals but by the instantaneous and parallel evaluation of the signals and connection weights of all active neurons in the MCUs involved. In consequence, with MCUs there is a much greater capacity to express highly structured graphs than in the single-cell implementation. The price for this greater power is much reduced flexibility, because appropriately specialized connectivity patterns within and between MCUs must first be installed.

Implementations of DLA on different temporal and spatial scales are not mutually exclusive and are probably realized concurrently in our brain. The single-cell version is indispensable because of its great flexibility and the absence of any need for specialized preexisting connectivity structures, but it is limited in its capacity to distinguish detailed link structures in limited time. The MCU version is very powerful and may be seen as just an unconventional view of networks in classic architecture, but it requires highly specialized connectivity structures and appropriately tuned activity dynamics.

## Applications

The aim of DLA is to serve as a framework for understanding brain functions. Conventional neural network architecture, lacking the equivalent of dynamic binding, may be a universal medium for realizing individual functions when they are defined ahead of time (such that appropriate combination-coding neurons and connectivity patterns can be defined and binding ambiguities avoided), but in decades of modeling attempts, this architecture has shown itself to be too narrow to go beyond elementary functions. DLA has the full functional repertoire of conventional neural network architecture but goes beyond it in being able to build up structured objects, have them interact in a structured way, or keep them from interfering. The full potential of DLA is far from realized, but some applications have already been modeled, as briefly reviewed in von der Malsburg (1999).

Figure-ground segmentation in visual scenes or other modalities is most naturally modeled by DLA (see VISUAL SCENE SEGMENTATION). So far, most concrete models have employed temporal signal correlations to bind all elements of a figure together and to keep them separate from elements belonging to the ground. For this type of model there is experimental evidence, as reviewed in Gray (1999) and Singer (1999). Also, MCU implementations have been realized in which each unit is subdivided into two subpopulations, one for figure, one for ground, and in a final state all units belonging to the figure restrict their activity to the "figure" neurons, all units in the ground just activate their "ground" neurons.

Many mental objects are met first as sensory arrays of local features. They are most naturally handled, stored, and recognized if the neighborhood relations between features are expressed as bindings and stored and retrieved as dynamic links. This has been realized as *dynamic link matching* for the purpose of invariant visual object recognition (reviewed in von der Malsburg, 1999, and FACE RECOGNITION: NEUROPHYSIOLOGY AND NEURAL TECHNOLOGY). Dynamic link matching, implemented in terms of temporal binding, has rightly been criticized as too slow to account for object recognition in adults. However, a recent implementation employing direct interaction between links (to be implemented with the help of MCUs, for instance) was shown to be very fast, requiring only one or a few iterations (Zhu and von der Malsburg, 2001).

As to the potential of DLA for modeling brain function and cognitive processes, the cited applications are but the tip of the iceberg. Processing and learning the syntactical structure of natural language on the basis of conventional neural architecture has proved very difficult to impossible. The reason is that the flexibility to analyze or to form novel sentences requires dynamic binding. It is particularly important here to realize the general process of instantiation, in which an abstract syntactical structure is applied to a concrete set of elements. Instantiation requires the manipulation of dynamic links between abstract roles and concrete role fillers, and requires the recognition of structural relations between abstract structures and concrete instances. Both of these functions are not part of the repertoire of conventional neural networks.

# Dynamic Remapping

*Alexandre Pouget and Terrence J. Sejnowski*

## Introduction

The term *dynamic remapping* has been used in many different ways, but one of the clearest formulations of this concept comes from the mental rotation studies by Georgopoulos et al. (1989) (see also Motor Cortex: Coding and Decoding of Directional Operations). In these experiments monkeys were trained to move a joystick in the direction of a visual stimulus or 90° counterclockwise from it. The brightness of the stimulus indicated which movement was required on a particular trial; a dim light corresponded to a 90° movement and a bright light to a direct movement. An analysis of reaction time suggested that, by default, the initial motor command always pointed straight at the target and then continuously rotated if the cue indicated a 90° rotation, an interpretation that was subsequently confirmed by single unit recordings.

The term *remapping* is also commonly used whenever a sensory input in one modality is transformed to a sensory representation in another modality. The best-known example in primates is the remapping of auditory space, from head-centered in the early stages of auditory processing to the retinotopic coordinates used in the superior colliculus (Jay and Sparks, 1987). This type of remapping, equivalent to a change of coordinates, is closely related to sensorimotor transformations. It does not have to be performed over time but could be accomplished by the neuronal circuitry connecting different representations.

This review is divided into three parts. In the first part, we briefly describe the types of cortical representations typically encountered in dynamic remapping. We then summarize the results from several physiological studies where it has been possible to characterize the responses of neurons involved in temporal and spatial remappings. Finally, in the third part, we review modeling efforts to account for these processes.

## Neural Representation of Vectors

A saccadic eye movement toward an object in space can be represented as a vector **S** whose components $S_x$ and $S_y$ correspond to the horizontal and vertical displacement of the eyes. Any sensory, or motor, variable can be represented by a similar vector. There are two major ways of representing a vector in a neural population—by a topographic map and by a nontopographic vectorial representation.

The encoding of saccadic eye movements in the superior colliculus is an example of a topographic map representation. A saccade is specified by the activity of a two-dimensional layer of neurons organized as a Euclidean manifold (see Collicular Visuomotor Transformations for Gaze Control). Before a saccade, a bump of activity appears on the map at a location corresponding to the horizontal and vertical displacement of the saccade.

Another example of a vectorial code is the code for the direction of hand movements in the primate motor cortex. Neurons in the primary motor cortex respond maximally for a particular direction of hand movement with a cosine tuning curve around this preferred direction (Georgopoulos et al., 1989). This suggests that each cell encodes the projection of the vector along its preferred direction. [Todorov (2000) questions this interpretation, but the precise identity of the vector being encoded in motor cortex is not critical to the issue of remapping.]

In both cases, the original vector can be recovered from the population activity pattern using statistical estimators. Various examples of such estimators are described in Population Codes.

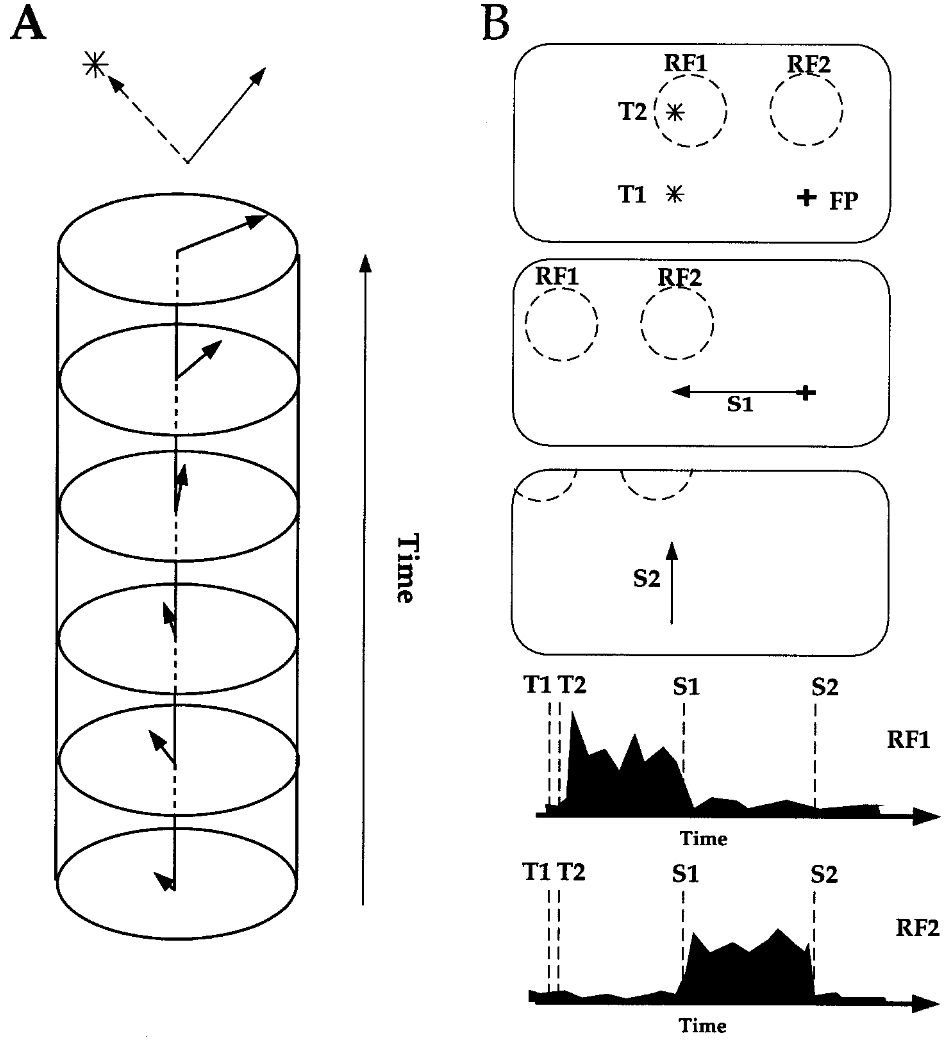
## Neurophysiological Correlates of Remapping

### Continuous Remappings

Georgopoulos et al. (1989) studied how the population vector varies over time in the mental rotation experiment described in the introduction. They found that for movement 90° counterclockwise from the target, the vector encoded in M1 initially pointed in the target direction and then continuously rotated 90° counterclockwise, at which point the monkey initiated a hand movement (Figure 1*A*). This is consistent with the interpretation of the reaction time experiments: The monkey had initially planned to move toward the stimulus, and then updated this command according to the task requirement.

Similar continuous remapping occurs in the postsubiculum of the rat, one of the cortical structures involved in navigation of space. Neurons in the postsubiculum provide an internal compass that encodes the direction of the head with respect to remembered visual landmarks. The neurons have bell-shaped tuning curves around their best direction, similar to the code for hand direction in the primary motor cortex. Electrophysiological recordings have revealed that this vector is continuously updated as the head of the

**Figure 1.** *A*, Rotation of population vector in the primary motor cortex when the brightness of the target (star) indicates a 90° clockwise movement. (Adapted from Georgopoulos et al., 1989.) *B*, Saccade remapping. The monkey makes a double saccade (S1 and S2) to the remembered positions of T1 and T2. *C*, Post-stimulus-time histograms showing the responses of two cells with receptive fields RF1 and RF2 illustrated in Figure 1*B*. The second cell (RF2) responds only after the first eye movement, encoding the new retinal location of T2, even though it is no longer present on the screen.



rat moves in space, even in complete darkness, suggesting that vestibular inputs are used for this updating (see Rodent Head Direction System).

Another example of continuous remappings has been reported in a double saccade task. In these experiments, two targets are briefly flashed in succession on the screen and the monkey makes successive saccades to their remembered locations (Figure 1*B*). Monkeys can perform this task with great accuracy, demonstrating that they do not simply keep a trace of the retinotopic location of the second target, since after the first eye movement this signal no longer corresponds to where the target was in space. Single unit recordings in the superior colliculus, frontal eye field, and parietal cortex have shown that the brain encodes the retinotopic location of the second target before the first saccade occurs. Then while the first eye movement is executed, this information is updated to represent where the second target would appear on the retina after the first saccade (Figure 1*C*; Mays and Sparks, 1980). In certain cases, this update is predictive; i.e., it starts prior to the eye movement (Duhamel, Colby, and Goldberg, 1992).

Graziano, Hu, and Gross (1997) have reported that the same mechanism appears to be at work in the premotor cortex. Bimodal, visuotactile neurons with receptive fields on the face remap the position of remembered visual stimuli after head movements. It is therefore becoming increasingly clear that continuous remappings are widespread throughout the brain and play a critical role in sensorimotor transformations.

Although all these examples clearly involve vector remappings, it is not entirely clear that the remappings are continuous. Hence, in the Georgopoulos et al. (1989) experiment, the population vector rotation could be a consequence of the simultaneous decay and growth of the initial planned hand direction and the final one, respectively, without ever activating intermediate directions. This is an example of one-shot remapping considered in the next section. Moreover, it is often difficult to determine whether a remapping in one particular area is computed in that area or is simply the reflection of a remapping in an upstream area.

### *One-Shot Sensory Remapping*

In the inferior colliculus and primary auditory cortex, neurons have bell-shaped auditory receptive fields in space whose positions are fixed with respect to the head. In contrast, in the multisensory layer of the superior colliculus, the positions of the auditory receptive fields are fixed in retinotopic coordinates, which implies that the auditory map must be combined with eye position (Jay and Sparks, 1987). Therefore, the auditory space is remapped in visual coordinates, presumably for the purpose of allowing auditory targets to be foveated by saccadic eye movements, a function mediated by the superior colliculus.

A similar transformation has been found in the striatum and the premotor cortex, where some of the cells have visual receptive fields in somatosensory coordinates (skin-centered; Graziano et al., 1997). In all cases, these remappings are thought to reflect an intermediate stage of processing in sensorimotor transformations.

These remappings can be considered as a change of coordinates, which correspond to a translation operation. For example, the auditory remapping in the superior colliculus requires the retinal location of the auditory stimulus, **R**, which, to a first approximation, can be computed by subtracting its head-centered location, **A**, from the current eye position, **E**:

$$\mathbf{R} = \mathbf{A} - \mathbf{E} \tag{1}$$

## Remapping Models

The remappings we have described so far fall into two categories: vector rotation with a vectorial code (e.g., mental rotation) and vector translation within a topographic map (e.g., auditory remapping in the superior colliculus). These transformations are similar, since rotating a vector within a vectorial representation consists of translating a pattern of activity around a circle. Therefore, in both cases the remapping involves translating a bell-shaped pattern of activity across a map. Most models perform this operation either dynamically through time or in one shot through the hidden layer of a feedforward network (Figure 2).

### *Dynamical Models*

Two kinds of mechanisms have been used in models of continuous remapping: the integration of a velocity signal or the relaxation of a recurrent network.

*Integrative model for remapping.* In the double saccade paradigm described above, the retinal coordinates of the second target were updated during the first saccade, a process that might involve moving a hill of activity within the parietal cortex. A model by Droulez and Berthoz (1991) shows how this bump of activity could be moved continuously across the map by integrating the eye velocities during the first saccade (Figure 1*A*). Their model is essentially a *forward* model of motion: Given a velocity signal, it generates the corresponding moving image. Interestingly, the equations are similar to those used for *inverse* models of motion processing. In both cases, the analysis relies on the assumption that the temporal derivative of a moving image is zero. In other words, the overall gray level profile in the image is unchanged; only the positions of the image features change. It is possible to design a recurrent network to implement this constraint (Droulez and Berthoz, 1991), and the resulting network moves arbitrary patterns of activity in response to an instantaneous velocity signal.

Several variations of this idea have been developed. Dominey and Arbib have shown that an approximation of eye velocity, obtained from the eye position modulated neurons found in the parietal cortex is sufficient for this architecture to work (Dominey and Arbib, 1992). Their simulations show patterns of activation very similar to the ones shown in Figure 1*B* in the part of their model corresponding to the parietal cortex, FEF, and superior colliculus. Zhang (1996) has used line attractor networks to model head direction cells in the postsubiculum of the rat. In this model, the hill is moved by using the velocity signal—in this case a head velocity signal—to temporarily modify the efficacy of the lateral connections.

*Recurrent networks.* Mental rotation of a population vector can be reproduced by training a neural network to follow a circular trajectory over time. In this case, the population vector rotates as a consequence of the network dynamics in the absence of any input signals. This approach has been used by Lukashin and Georgopou-

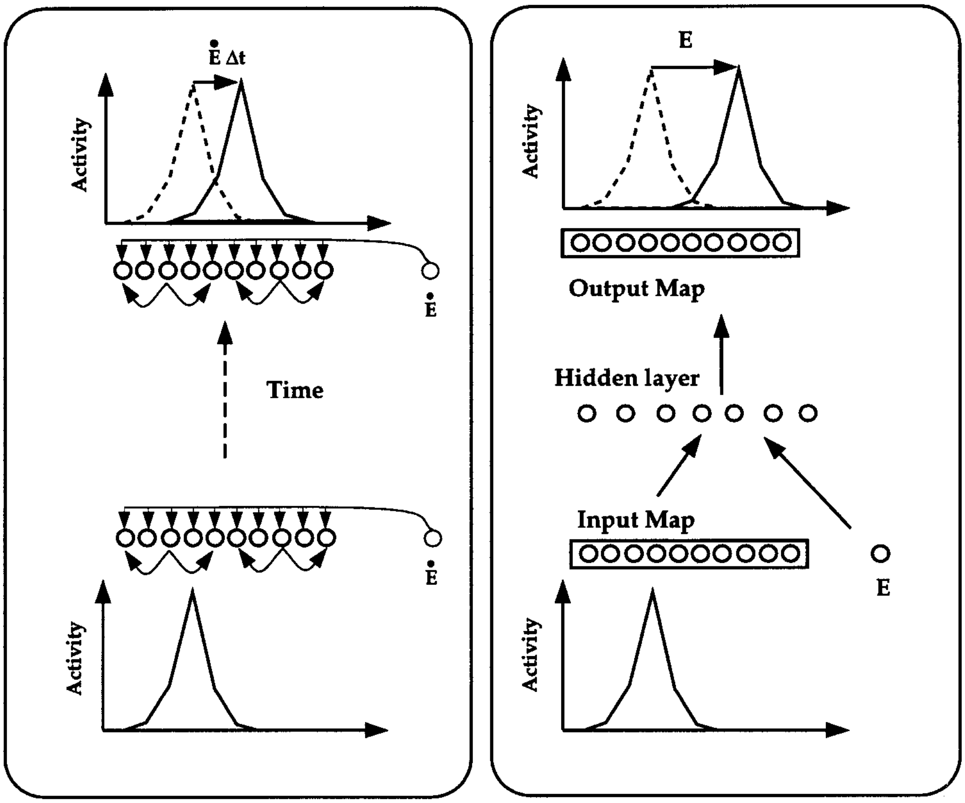


**Figure 2.** In a map representation, remappings involve moving hills of activity. These hills can be moved continuously in a recurrent network (*A*), or in one shot in a feedforward network (*B*). *A*, The recurrent network dynamically moves the hill of activity according to a velocity signal, $\dot{E}$. As described in the text, there are several ways to achieve this result. Droulez and Berthoz (1991) integrate the eye velocity signals through the lateral connections while Zhang (1996) uses the eye velocity signals to temporally bias the lateral connections. *B*, In feedforward remapping, the hill is moved in one shot by the full amount of the current displacement, *E*, via an intermediate stage of processing in the hidden layer. The weights can be adjusted with a learning algorithm such as backpropagation. Alternatively, one can use basis function units in the hidden layer and train the weights to the output units with a simple learning algorithm such as the delta rule.

los (1994) to model the generation of hand trajectories, but when the trajectory is a circle, mental rotation and a circular hand trajectory are equivalent. Although the model generates a rotating vector, additional mechanisms must be specified to stop the rotation.

### *Single-Shot Models*

Feedforward models have been used for vectorial as well as map representations. They are used whenever the amplitude of the shift is available to the brain beforehand, such as auditory remapping in the superior colliculus in which the shift is directly proportional to the current eye position (Equation 1). In contrast, for mental rotation, the amplitude of the shift is specified by an external stimulus.

*Shifter models.* As demonstrated by Touretzky, Redish, and Wan (1993), rotation within a vectorial representation can be performed by using a shifter circuit (for more details on shifter circuits, see Routing Networks in Visual Cortex in the First Edition). Their architecture uses $N$ independent circuits, each implementing a rotation through a particular angle. This mechanism is limited in resolution since it rotates only by multiples of $360/N$ degrees. Whether such shifter circuits actually exist in the brain remains to be demonstrated.

*Feedforward network models.* There are many examples of three-layer networks, and variations thereof, that have been trained or handcrafted to perform sensory remappings. Since these remappings perform vector addition, it might appear unnecessary to deploy a fully nonlinear network for such a task. However, with a map representation, vector addition requires moving a hill of activity in a map as illustrated in Figure 2*B*, an operation that is highly nonlinear.

Special-purpose nonlinear circuits can be designed to perform this operation (Groh and Sparks, 1992), but more biologically realistic solutions have been found with networks of sigmoidal units trained with backpropagation. Hence, the model of Zipser and Andersen (see Gaze Coding in the Posterior Parietal Cortex in the First Edition), which was trained to compute a head-centered map from a retinotopic input, uses hidden units with retinotopic receptive fields modulated by eye position, as in parietal neurons (see also Krommenhoek et al., 1993).

However, backpropagation networks are generally quite difficult to analyze, providing realistic models but little insight into the algorithm used by the network. Pouget and Sejnowski (2001) have explored a way to analyze such networks using the theory of basis functions.

*Basis functions.* The process of moving a hill of activity in a single shot can be better understood when considered within the larger framework of nonlinear function approximation. For example, consider the feedforward network shown in Figure 2*B*, applied to a remapping from retinotopic, $R_x$, to head-centered coordinates, $A_x$. Because of the map format used in the output later, the responses of the output units are nonlinear in the input variables, namely, the retinal position, $R_x$, and eye position, $E_x$.

Therefore, the actual goal of the network is to find an appropriate intermediate representation to approximate this output function. One possibility is to use basis functions of $R_x$ and $E_x$ in the hidden layer (Pouget and Sejnowski, 2001; Salinas and Abbot, 1995).

Perhaps the best-known set of basis functions is the set of cosine and sine functions used in the Fourier transform. Another example is the set of Gaussian or radially symmetric functions with local support (see Radial Basis Function Networks). A good model of the response of parietal neurons, which are believed to be involved in remapping, is a set of Gaussian functions of retinal position multiplied by sigmoid functions of eye position. The resulting response function is very similar to that of gain-modulated neurons in the posterior parietal cortex [see Gaze Coding in the Posterior Parietal Cortex in the First Edition, and Pouget and Snyder (2000) for a review].

## Conclusions

Remappings can be continuous and dynamic or a single shot through several layers of neurons. In both cases, the problem amounts to moving a hill of activity in neuronal maps. Whether some models are better than others is often difficult to establish simply because the neurophysiological data available are relatively sparse. Models can be further constrained by considering deficits that accompany localized lesions in humans (see Pouget and Sejnowski, 2001). These data not only provide valuable insights into the nature of remappings but also might help bridge the gap between behavior and single-cell responses.

# Dynamics and Bifurcation in Neural Nets

*Bard Ermentrout*

## Introduction

A *recurrent neural net*, whether it is continuous or discrete in space and time, defines a dynamical system. Thus, it is possible to apply the powerful qualitative and geometric tools of dynamical systems theory to understand the behavior of neural networks. These techniques are most useful when the behavior of interest is stationary in the sense that the inputs are at most time- or space-periodic. Thus, we can ask what kind of behavior we can expect over the long run for a given neural network. Such information is important both in artificial neural networks and biological neural nets. In the former, the final state of the neural network may represent the recognition of an input pattern, the segmentation of an image, or any number of machine computations. The stationary states of biological neural networks may correspond to cognitive decisions (e.g., binding via synchronous oscillations) or to pathological behavior such as seizures and hallucinations.

Another important issue that is addressed by dynamical systems theory is how the qualitative dynamics depends on parameters. The qualitative change in a dynamical system as a parameter is changed is the subject of *bifurcation theory*. The word *bifurcation* is derived from the Greek word for branching; we are concerned with the appearance and disappearance of branches of solutions to a given set of equations as some parameters vary. There are now a large number of very good general books on the mathematical theory behind dynamical systems and bifurcation. In this article we show how to use these techniques to understand the behavior of neural nets. A fundamental problem for both artificial and biologically motivated neural nets is to understand how the solutions depend on the parameters and the initial states of the network.

For excellent introductions to nonlinear dynamics and bifurcation theory, see Ermentrout (1998), Guckenheimer and Holmes (1983), Kuznetsov (1998), and Wiggins (1990).

## Some Basic Definitions

A *dynamical system* consists of a phase space, $X$, a time domain, $T$, and a function that describes the evolution of the phase space, $\phi(x, t)$. The function $\phi$ gives the value of an element in the phase space at time $t$, given that at $t = 0$ it was $x$. The two main motivating examples are differential equations and maps. In the former case, the time domain is the real line (continuous time); in the latter the time domain is the integers (discrete time). Consider the ordinary differential equation:

$$\frac{dx}{dt} = F(x) \qquad x \in X,\ t \in R \tag{1}$$

Then we define $\phi(x_0, t)$ to be the solution to Equation 1 with initial condition $x_0$. For example, if

$$\frac{dx}{dt} = x \qquad x(0) = x_0$$

then $x(t) = \phi(x_0, t) \equiv x_0 e^t$. (We have restricted our attention to *autonomous* systems in which there is no explicit time dependence.) Consider next the iteration:

$$x(n + 1) = F(x(n)) \qquad x \in X,\ n \in Z \tag{2}$$

Then $\phi(x_0, n)$ is defined as the solution to Equation 2 with initial conditions $x = x_0$. For example, if

$$x(n + 1) = 2x(n) \qquad x(0) = x_0$$

then $x(n) = \phi(x_0, n) = x_0 2^n$.

There is nothing that prevents us from considering infinite dimensional dynamical systems such as partial differential equations (see Pattern Formation, Biological) or neural networks distributed in space. The set of states $\Gamma(x_0) = \{\phi(x_0, t) : t \in T,\ \phi(x_0, t) \text{ defined}\}$ is called the *orbit* or *trajectory* through $x_0$. The orbit is a curve in state space for continuous systems and a sequence of points for discrete systems. If $\Gamma(x_0)$ consists of a single point in phase space, then we say that $x_0$ is a *fixed point* or *equilibrium* for the system. Fixed points are easily found by solving $F(x_0) = 0$ or $F(x_0) = x_0$ for continuous and discrete dynamical systems, respectively. If $\phi(x_0, t + P) = \phi(x_0, t)$ for some non-zero value $P$, then the orbit is called *periodic*, with period $P$. A set $S$ is *invariant* with respect to the dynamical system if $y \in S$ implies that $\phi(y, t) \in S$ for all $t \in T$. Thus, any orbit is an invariant set, as is any fixed point or periodic solution. The partitioning of the state space into orbits is called the *phase portrait* of the dynamical system and is one of the goals of dynamical systems.

Another key question in dynamical systems is the issue of stability. We say that an invariant set $S_0$ is *stable* if for any $y$ close to $S_0$, $\phi(y, t)$ stays close to $S_0$ for all $t \in T$. An invariant set is *asymptotically stable* if for any $y$ near $S_0$, the distance between $\phi(y, t)$ and $S_0$ tends to zero as $t \to \infty$. The stability of a fixed point in a discrete or continuous dynamical system is easily determined by studying the eigenvalues of an associated linear operator or matrix. Suppose that $x_0$ is a fixed point. Let $A = DF(x_0)$ be the matrix obtained by taking the partial derivatives of $F$ with respect to the state variables and evaluating it at the fixed point. The dynamical system obtained by replacing $F(x)$ with $Ax$ is called the *linearized system*. For Equation 1, if all of the eigenvalues of $A$ have strictly negative real parts, then the fixed point is asymptotically stable (and all solutions to the linearized system decay to 0). If any eigenvalue has a positive real part, then the fixed point is unstable. For Equation 2, if all of the eigenvalues of $A$ lie inside the unit circle, then the fixed point is asymptotically stable. If any eigenvalue lies outside the unit circle, then the fixed point is unstable. As long as none of the eigenvalues have zero real part (respectively, lie on the unit circle), we say the fixed point of the differential Equation 1 (respectively map, Equation 2) is *hyperbolic*. Eigenvalues that have negative real parts (lie in the unit circle) are called *stable eigenvalues*, those with positive real parts (lie outside the unit circle) are called *unstable eigenvalues*, and those that have zero real parts (lie on the unit circle) are called *neutral eigenvalues* for the continuous-time (discrete-time) fixed point. The invariant set $W^s(x_0) = \{y \in X : \phi(y, t) \to x_0 \text{ as } t \to \infty\}$ (respectively $W^u(x_0)\{y \in X : \phi(y, t) \to x_0 \text{ as } t \to -\infty\}$) is called the *stable manifold* (respectively *unstable manifold*) of the fixed point $x_0$. The stable (unstable) manifold is just the set of all points that tend to the fixed point as time increases (decreases) to infinity (negative infinity). The dimension of the stable (respectively, unstable) manifold is the number of stable (respectively unstable) eigenvalues of the linearized system. A fixed point that has both unstable and stable eigenvalues is called a *saddle point*. If the fixed point is asymptotically stable, then the stable manifold has the same dimension as the phase space and is then often called the *basin of attraction* for the fixed point. For neutral eigenvalues there is a *center manifold* that is invariant and has the same dimension as the number of neutral eigenvalues. The center manifold is extremely useful and important, as we shall see, since it allows one to study the behavior of high-dimensional systems in a lower-dimensional setting.

So far, the discussion of asymptotic behavior has been restricted to fixed points. A continuous dynamical system can often be re-

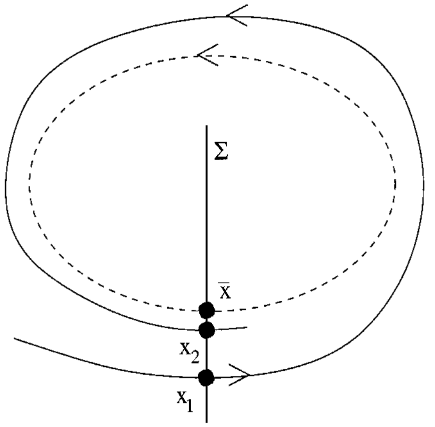

**Figure 1.** Construction of the Poincaré map for a two-dimensional system.

duced to a discrete one by introducing a *Poincaré map*. Suppose the system has a periodic orbit. A *cross-section* for an $n$-dimensional continuous dynamical system is an $n - 1$-dimensional hypersurface that is orthogonal to the tangent of the periodic orbit (Figure 1). A point on the surface that starts near the periodic orbit will be brought back to the surface at a later time. This produces a locally defined map from the surface back to itself, which is then a discrete dynamical system. From Figure 1, it is clear that a fixed point of the Poincaré map corresponds to a periodic solution of the original system. Thus, we can determine stability, stable, unstable, and center manifolds for periodic solutions just by studying the behavior of a Poincaré map defined in some local neighborhood of it. An isolated periodic solution is called a *limit cycle* and its stability is determined by studying the stability of the fixed point for the associated Poincaré map. A limit cycle solution is hyperbolic if the fixed point of the Poincaré map is hyperbolic.

Invariant sets are not all as simple as periodic solutions and fixed points. In fact, they can be quite complicated. A stable invariant set that has irregular behavior (e.g., it is not a simple curve or point) is called a *strange attractor*. Similarly, the behavior of an invariant set can be quite complex as well. We say that an invariant set is *chaotic* if it displays sensitive dependence on initial conditions; that is, the orbits through two arbitrarily close points on the set diverge from each other exponentially. (For examples of chaotic behavior in neurons, see Chaos in Neural Systems; Synaptic Noise and Chaos in Vertebrate Neurons; and Chaos in Biological Systems).

A dynamical system that has only hyperbolic fixed points and periodic orbits will maintain the same qualitative behavior if the parameters are varied slightly. Thus, qualitative changes are seen when the fixed points and periodic orbits become nonhyperbolic. This happens when eigenvalues cross the critical axis and thus a fixed point loses stability. This is one of the key ideas behind *bifurcation theory*. Roughly, we expect to see qualitative changes as a parameter varies when some of the fixed points or periodic orbits become nonhyperbolic. Bifurcation theory gives us a method of studying arbitrary dynamical systems near these critical values of parameters. The idea is that near a critical parameter value, there will be some neutral eigenvalues. This will imply that there is a nontrivial center manifold and in fact the local dynamics of the full system can be completely understood by studying the dynamics restricted to this center manifold. Bifurcation methods give a recipe for computing the form of the equations on this low-dimensional system. This means that one can study a possibly infinite-dimensional system by looking at the dynamics of a possibly one-dimensional system!

The simplified dynamical systems that one obtains near critical values of the parameters are called *normal forms*. Thus, the understanding of the local behavior of the full system comes from studying the behavior of the relevant normal form.

## Local Bifurcations

Local bifurcation theory allows one to study the behavior of discrete and continuous dynamical systems near fixed points. Since the behavior of periodic solutions to continuous systems reduces to the analysis of fixed points of the Poincaré map, local bifurcation of maps enables us to analyze bifurcations of limit cycles in continuous systems.

### *Continuous-Time Systems*

There are two ways in which a fixed point of a continuous-time dynamical system can become nonhyperbolic as a parameter varies: (1) an eigenvalue crosses zero or (2) a pair of complex eigenvalues crosses the imaginary axis. In the case of a zero eigenvalue, this signifies the appearance of new fixed points near the original one. In the most general setting, with no symmetries, a zero eigenvalue implies a *fold* or *turning point* bifurcation. In this bifurcation, the deviation from the fixed point obeys one-dimensional dynamics:

$$r' = ar^2 + c(\mu - \mu^*) \tag{3}$$

where $a$, $c$ are problem-dependent parameters, $r \in R$, and $\mu$ is the parameter that is varied. The fixed points of this simple system (called the normal form) correspond to fixed points of the full system even if it is infinite dimensional. In Figure 2*A*, steady-state solutions are shown for $a$, $c > 0$. As $\mu$ increases past $\mu^*$, two fixed points, a stable one and an unstable one, coalesce and disappear, leaving no nearby fixed point. (The picture is essentially the same

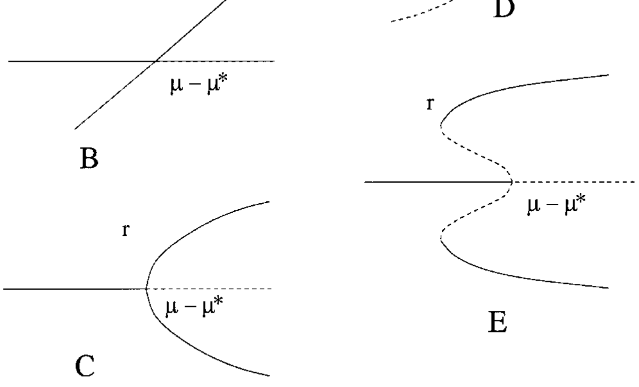

**Figure 2.** Bifurcation diagrams for fixed points of continuous-time dynamical systems. Solid lines are stable, dashed unstable. *A*, Steady-state solutions for a fold or turning point bifurcation. *B*, A transcritical or exchange-of-stability bifurcation. *C*, A supercritical bifurcation. *D*, A subcritical bifurcation. *E*, Subcritical pitchfork bifurcations turning around at a pair of fold points and restabilizing, leading to bistability.

for other choices of $c$, $a$.) In cases with additional symmetry (such as the requirement that there always be at least one fixed point or that the system have some symmetry), there are two additional common normal forms:

$$r' = ar^2 + cr(\mu - \mu^*) \quad (4)$$

$$r' = ar^3 + cr(\mu - \mu^*) \quad (5)$$

Equation 4 leads to the *transcritical* bifurcation shown in Figure 2*B*. This is also called an *exchange-of-stability* bifurcation since the stability of the two fixed points switches at the point of bifurcation. As in the fold, the signs of $a$, $c$ are irrelevant to the picture. With additional symmetry, Equation 5 occurs, and this is called the *pitchfork* bifurcation. In this case, the sign of $a$ is important. If $a < 0$, then the bifurcation is *supercritical*, and two new *stable* fixed points arise (Figure 2*C*). If $a > 0$, then two new *unstable* fixed points occur, and the bifurcation is called *subcritical* (Figure 2*D*). In many biological and physical systems, subcritical pitchfork bifurcations "turn around" at a pair of fold points and restabilize (as in Figure 2*E*). This leads to *bistability* between several fixed points and to hysteresis.

Suppose that stability is lost when a pair of complex eigenvalues crosses the imaginary axis. Then the system can undergo what is called a *Hopf* or *Andronov* bifurcation. The dynamics are locally determined by the simple complex differential equation:

$$z' = az^2\bar{z} + cz(\mu - \mu^*) + iwz \quad a, c, z \in C \quad (6)$$

If the real part of $a$ is negative, then a stable periodic orbit will bifurcate from the fixed point with amplitude that is proportional to $\sqrt{\mu - \mu^*}$. The bifurcation is called *supercritical*. If the real part of $a$ is positive, then an *unstable* periodic orbit bifurcates from the fixed point and the bifurcation is called *subcritical*. The bifurcation diagrams look like those of the pitchfork bifurcation (Figures 2*C* and 2*D*), where $r = |z|$. As with the pitchfork bifurcation, physical systems that have subcritical Hopf bifurcations often restabilize, as in Figure 2*E*. Thus, there will be a range of the parameter for which there is a stable limit cycle and a stable fixed point (analogous to Figure 2*E*.)

### *Discrete Dynamics*

For a discrete dynamical system to undergo a local bifurcation, eigenvalues must cross the unit circle. There are three ways in which this can happen: (1) an eigenvalue is +1, (2) an eigenvalue is −1, or (3) a complex pair of eigenvalues lies on the unit circle. The first case, an eigenvalue of 1, is completely analogous to the case of a zero eigenvalue for continuous systems. The third case is similar to the Hopf bifurcation for continuous systems and is called a *Neimark-Sacker* bifurcation. However, the dynamics of the bifurcating solution can be complicated, and all one can conclude is that there is a small invariant circle. The second case, $a - 1$ eigenvalue, is called a *flip* or *period-doubling* bifurcation. The dynamics is determined by the behavior of the simple one-dimensional map:

$$r_{n+1} = -r_n + c(\mu - \mu^*)r_n + ar_n^3 \quad (7)$$

If $a > 0$, then a stable period 2 fixed point appears; that is, every other iterate of the map is the same. If $a < 0$, then an unstable period 2 fixed point occurs. Period-doubling bifurcations are very important, as they often signal the onset of chaotic behavior. Indeed, often a period 2 point itself will become unstable through another period-doubling bifurcation to a period 4 point. This continues as the parameter is changed, and a whole *cascade* of period doublings occurs, terminating in chaotic behavior.

### *Periodic Orbits in Continuous Systems*

Periodic orbits undergo bifurcations similar to those of discrete dynamical systems since their local behavior is reducible to a discrete system. Folds of the Poincaré map correspond to the annihilation of a stable and unstable limit cycle; flips correspond to period doubling of the limit cycle; Neimark-Sacker bifurcations correspond to the appearance of an invariant 2-torus.

In addition to these local bifurcations, there are two common *global* bifurcations in which the period of the orbit tends to infinity. A *heteroclinic* orbit, $\gamma(t)$, is a nonconstant orbit satisfying

$$\lim_{t\to\pm\infty} \gamma(t) = x^{\pm}$$

where $x^{\pm}$ are fixed points. If $x^+ = x^-$, we call $\gamma(t)$ a *homoclinic* orbit. In general, one cannot expect to find a homoclinic orbit; rather, as some parameter $\mu$ changes, the homoclinic orbit appears at one value of that parameter, $\mu^*$ (Figure 3*A*). Thus, the appearance of a homoclinic is a bifurcation. If the fixed point $x^+ = x^-$ is a hyperbolic saddle, then, as the parameter moves away from criticality, a periodic orbit arises, and the period of this orbit goes to infinity as the homoclinic orbit is approached. The period is given by

$$T_{hom} \sim K \log \frac{1}{|\mu - \mu^*|}$$

If instead of a hyperbolic saddle point, the fixed point is a fold point, then a *saddle node on a limit cycle* occurs (Figure 3*B*). Limit cycles occur as the parameter is moved from criticality with a period

$$T_{sn} \sim \frac{K}{\sqrt{|\mu - \mu^*|}}$$

## Applications to Continuous-Time Neural Nets

So far, we have introduced definitions but not used them in the context of neural networks. Numerous papers have used bifurcation

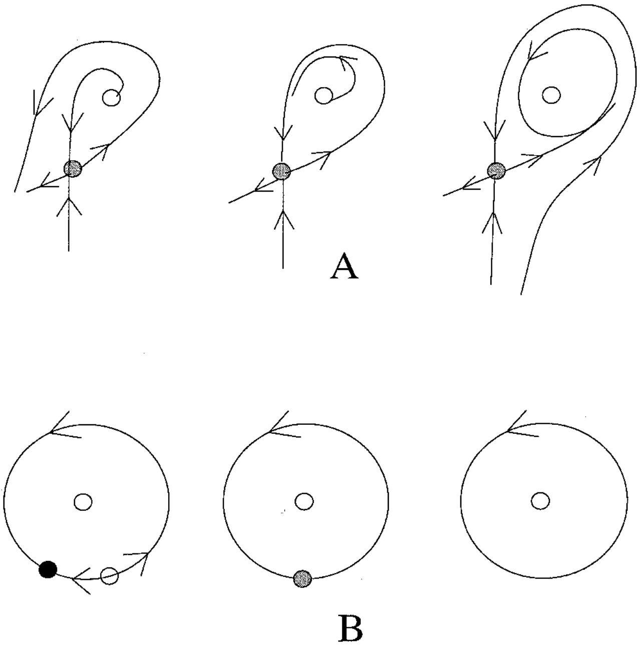

**Figure 3.** Two distinct types of homoclinic bifurcation. Bifurcation of (*A*) a homoclinic orbit from a hyperbolic saddle or (*B*) a saddle node on a limit cycle, leading to periodic orbits.

methods to analyze neural networks (see, e.g., Phase-Plane Analysis of Neural Nets; Cooperative Phenomena; Oscillatory and Bursting Properties of Neurons; and Pattern Formation, Neural; see also Izhikevich, 2000, for a long and well-illustrated review). The types of neural net models to which the theory has been applied generally have one of the following two forms:

$$\tau_j \frac{du_j}{dt} = -u_j + F_j\left(\sum_k W_{jk}u_k + I_j\right) \tag{8}$$

$$u_j(n + 1) = \mu_j u_j + F_j\left(\sum_k W_{jk}u_k(n) + I_j\right) \tag{9}$$

The functions $F_j$ are generally monotone and increasing, $W_{jk}$ are the weights, $I_j$ are the inputs, and $1/\tau_j$, $1 - \mu_j$ are decay rates. With proper limits, the sums in Equations 8 and 9 can go to integrals over space in order to represent a continuum model for neural nets. In this case the interaction takes the form

$$\int_\Omega W(x, y)u(y)dy$$

where $\Omega$ is the spatial domain, a one- or two-dimensional region in space. The behavior of these models is generally impossible to analyze completely except in certain simple cases. For example, Hopfield (1984) shows that if the weights $W_{jk}$ are symmetric, then all solutions to Equation 8 tend to be fixed points. In the case of one or two dimensions, Equation 8 can be completely analyzed (see Hoppensteadt and Izhikevich, 1997, chap. 2; Phase-Plane Analysis of Neural Nets). The discrete system in Equation 9 can be completely characterized only in one dimension.

## Local Bifurcations of Fixed Points

To see how bifurcation methods can be used in neural nets, consider a simple continuous neural network with no inputs and satisfying $\tau_j = 1$, $F_j(u) = F(u)$ with $F(0) = 0$, $F'(0) = \mu$, a gain parameter. Thus the trivial state of the network, $u_j = 0$, is a fixed point. To study stability and bifurcation, we linearize about $u_j = 0$ and obtain the matrix

$$M_{jk} = -\delta_{jk} + \mu W_{jk}$$

where $\delta_{jk}$ is the Kronecker delta function. If $\lambda$ is an eigenvalue of $W_{jk}$, then $-1 + \mu\lambda$ is an eigenvalue for $M$; thus, if the gain is sufficiently small, the trivial fixed point is stable. If some of the eigenvalues of the weight matrix $W$ have positive real parts, then, for sufficient gain, some of the eigenvalues of $M$ will cross the imaginary axis and the rest state will lose stability. In particular, let $\lambda_0$ be the eigenvalue with maximal real part and let $\Phi_0$ be the corresponding eigenvector. Since this is a continuous dynamical system, there are only two cases of interest. Suppose that $\lambda_0$ is real. Then if $\mu = \mu^* = 1/\lambda_0$, there will be a zero eigenvalue and a bifurcation to new fixed points. Since 0 is always a fixed point, the bifurcation will be transcritical, or a pitchfork. In any case, the new solution will have a non-zero amplitude and be proportional to $\Phi_0$. This is the essence of pattern formation. The trivial state $u_j = 0$ loses stability and a new state that is coded in the weight matrix bifurcates from rest. Analysis of pattern formation in neural networks (and for that matter, any pattern formation models) all comes down to this calculation (see Murray, 1989). If the weight matrix is symmetric, then the eigenvalues are real and the initial bifurcation from the rest state will always be through a zero eigenvalue. If the weight matrix is non-negative, then the eigenvalue with largest modulus will be real and positive and the first bifurcating mode will be proportional to the principal component of the weight matrix.

Suppose the weight matrix is not symmetric and not all the same sign; that is, there are "inhibitory" and "excitatory" interactions. Then the eigenvalue with maximal real part could be a complex eigenvalue. This means that the first instability is through a Hopf bifurcation and an oscillatory pattern of activities can bifurcate. In situations in which there is symmetry or in which the network has a particular geometry, this type of bifurcation can lead to periodic wave trains. Recently, Hoppensteadt and Izhikevich (1997) proposed a general theory of neural networks that exploits the kind of local analysis that we have only sketched here.

## Beyond Local Bifurcations

To go beyond the simple bifurcation analysis described above, it is necessary to turn to numerical methods. There are several numerical packages for the analysis of bifurcations in nonlinear dynamics. AUTO (Doedel et al., 1997) is among the best of them and works on many operating systems. To illustrate the concepts discussed in the previous sections, I present a global numerical diagram for a six-neuron model whose weight matrix was chosen randomly from a uniform distribution with mean 0 and a standard deviation of 0.5. (Note that this particular example was picked because of its rich behavior.) The function $F(x) = \tanh(\mu x)$ was chosen for simplicity. Once the weight matrix is chosen, there is only one parameter, the gain, $\mu$. Figure 4 shows the norm of the solutions that are computed numerically as the gain is increased. The eigenvalues for the weight matrix are approximately $-0.83$, $0.25 \pm 0.2i$, $-0.16$, $0.12$, $-0.47$. Thus, for positive gains, there will be a Hopf bifurcation at approximately $\mu = 4$ and a pitchfork bifurcation at approximately $\mu = 8.33$. Both of these branches are shown in the diagram (labeled H1 and P, respectively). The pitchfork is subcritical and undergoes a fold bifurcation (labeled F1) and stabilizes. A subcritical Hopf bifurcation (H3) occurs on this branch,

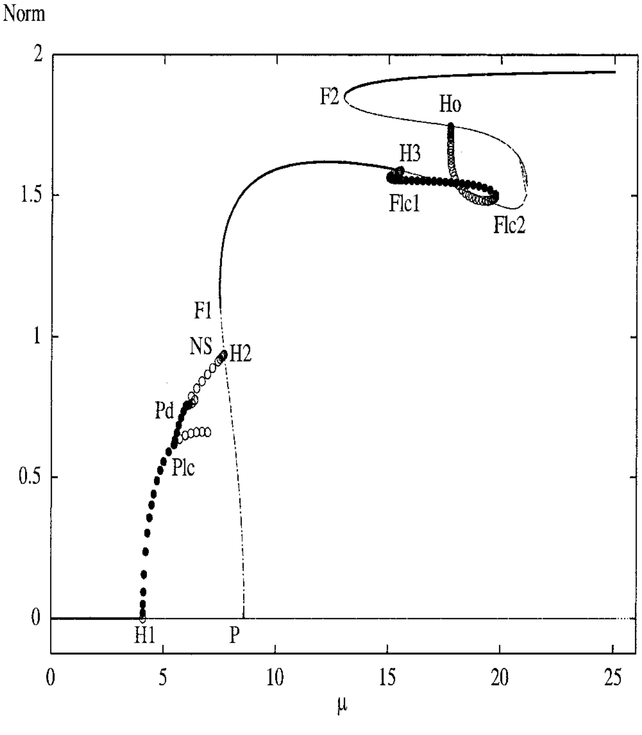

**Figure 4.** Numerically computed bifurcation diagram for a six-neuron network with random weights chosen between $-0.5$ and $0.5$.

which turns around at the limit-cycle fold bifurcation (Flc1), giving rise to a stable periodic orbit. This orbit turns around again at Flc2, and the resulting unstable limit cycle terminates at a homoclinic bifurcation (Ho). The curve of fixed points turns around at F2, leaving a stable fixed point that persists for all higher values of $\mu$.

The fate of the periodic orbit that arises at H1 is more interesting. This orbit is supercritical and leads to small-amplitude, stable periodic solutions. As $\mu$ increases, the periodic orbit (and hence the fixed point to the Poincaré map) loses stability as an eigenvalue crosses $+1$. This results in a pitchfork bifurcation at Plc. The unstable periodic orbit appears to persist for all values of $\mu$ beyond the bifurcation point, but never restabilizes. The pitchfork bifurcation of the Poincaré map is supercritical and results in a stable periodic orbit. This orbit becomes unstable at a flip or period-doubling bifurcation (Pd); the branch eventually terminates at a Hopf bifurcation (H2) on the branch of fixed points that bifurcated at P. The periodic branch also undergoes a Neimark-Sacker bifurcation (NS), resulting in an unstable torus. The flip bifurcation is supercritical and leads to a new branch of periodic solutions with twice the period. This branch in turn undergoes a flip bifurcation, and so on, producing a period-doubling cascade. The regimen between $\mu = 5.5$ and $\mu = 7.5$ is very complicated. There are many bifurcations, and the appearance of many stable and unstable periodic orbits as well as chaotic behavior, that are not described on this plot. In order to depict this behavior, we plot the Poincaré map whose cross-section is defined as the hyperplane where $u'_4 = 0$. The $u_2$ component of this map is shown in Figure 5 as a function of $\mu$. In this diagram, each dot represents an iteration of the Poincaré map, so that for a fixed value of $\mu$, a single dot implies a periodic solution, a pair is a period 2 orbit, and so on. The period-doubling cascades are clear. A period 3 orbit at about $\mu = 6.85$ is seen to undergo a period-doubling cascade as $\mu$ is decreased. Chaotic behavior terminates near a saddle point at $\mu \approx 7.57$ and disappears "instantly." This global bifurcation is called a *crisis* by Yorke.

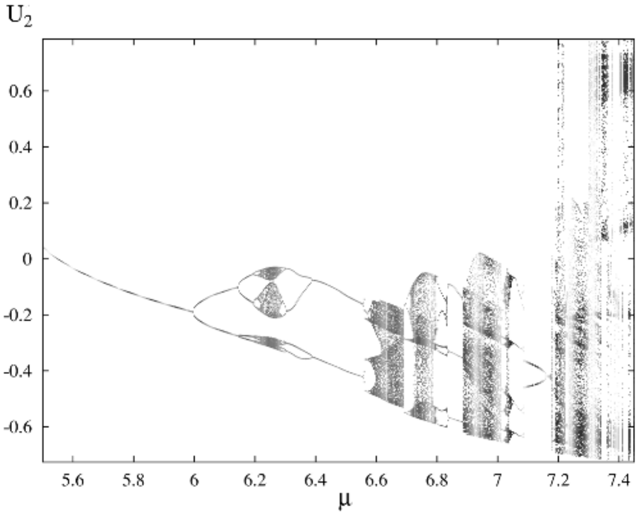

**Figure 5.** Poincaré map of a region from Figure 3 showing complex dynamics.

## Conclusion

The general behavior of recurrent neural networks as parameters vary remains an open problem. Dynamical systems methods and bifurcation theory provide a general approach to analyzing these interesting systems. Pattern formation, spatiotemporal behavior, and complex dynamics are all aspects of recurrent neural networks that can be understood by these useful mathematical tools. Analytical methods along with the careful use of numerical methods allow one to globally characterize complex biological and artificial neural networks.

## Appendix

The neural network used in Figures 3 and 4 has the form:

$$U'_j = -U_j + \tanh\left(\mu \sum_{k=1}^{6} W_{jk} U_k\right)$$

where

$$W = \begin{pmatrix} -0.42473 & 0.243325 & -0.267939 & 0.308063 & -0.0370201 & 0.394969 \\ -0.166832 & 0.474204 & -0.0151443 & 0.476774 & 0.211162 & 0.401305 \\ -0.427914 & 0.370044 & -0.0675567 & 0.276535 & 0.45988 & -0.457168 \\ -0.362131 & 0.033334 & -0.196538 & -0.037606 & -0.125548 & 0.143851 \\ 0.429334 & -0.306886 & 0.402954 & -0.166799 & -0.45518 & -0.0304156 \\ 0.294663 & -0.346348 & -0.138444 & 0.334973 & 0.13884 & -0.364227 \end{pmatrix}$$

# Dynamics of Association and Recall

*Ton Coolen*

## Introduction

The concept and relevance of associative memory in neural networks are discussed elsewhere in this *Handbook* (see, e.g., Associative Networks, Statistical Mechanics of Neural Networks, and Cortical Hebbian Modules). Associative memory networks are usually (but not always) recurrent, which implies that one cannot simply write down the values of successive neuron states (as with layered networks). The latter must be solved from coupled dynamic equations. Dynamical studies shed light on the pattern recall process and its relation to the choice of initial state, the properties of the stored patterns, the noise level, and the network architecture. In addition, for nonsymmetric networks (where the equilibrium statistics are not known), dynamical techniques are the *only* tools available. Since our interest is usually in large networks and in global recall processes, the common strategy of the theorist is to move away from the *microscopic* equations (i.e., equations at the level of individual neurons) and to derive dynamical laws at a *macroscopic* level (i.e., in terms of quantities that depend on many neuron states). One then faces the following questions:

- Which are the appropriate macroscopic quantities we should attempt to calculate?
- How do we extract the corresponding macroscopic equations from the microscopic ones?

All research in this field basically involves launching or elaborating proposals for dealing with these two issues, which are related in that the "natural" set of macroscopic quantities can be defined as the *smallest* set that will obey *closed deterministic* equations in the limit of an infinitely large network. Since the mid-1970s, many theoretical approaches to recall dynamics have been developed in parallel, while their relations were only understood later. To give an overview of the field I will therefore not always discuss papers in chronological order, but use the benefit of hindsight. In the absence of recent textbooks or reviews that deal with recall dynamics in a satisfactory manner (at least from the viewpoint of what we know today), most of the references will indeed be to research papers. In the interest of transparency, in this article I restrict myself mainly to simple Hopfield-type models, and discuss some variations and generalizations in a final section.

## The Core of the Problem

In Hopfield-type models one has $N$ binary neurons, with states $S_i \in \{-1, 1\}$. I will write $\boldsymbol{S} = (S_1, \ldots, S_N)$. The $S_i$ evolve stochastically, driven by postsynaptic potentials (or "local fields") $h_i$:

$$S_i(t + \Delta) = \text{sgn}[h_i(\boldsymbol{S}(t)) + \eta_i(t)] \qquad h_i(\boldsymbol{S}) = \sum_{j\neq i} J_{ij}S_j \tag{1}$$

The $\eta_i(t)$ are independent random variables, modeling threshold noise. The updates in Equation 1 can be executed in parallel or sequentially. Comparable time units result when choosing $\Delta = 1$ for parallel dynamics and $\Delta = 1/N$ for sequential dynamics. Hopfield networks are equipped with Hebbian-type synapses:

$$J_{ij} = \frac{c_{ij}}{c} \sum_{\mu=1}^{p} \xi_i^\mu \xi_j^\mu \tag{2}$$

These involve $p$ patterns $\boldsymbol{\xi}^\mu = (\xi_1^\mu, \ldots, \xi_N^\mu) \in \{-1, 1\}^N$. The $c_{ij} \in \{0, 1\}$ specify the network connectivity ($c_{ij} = 1$ if a connection $j \to i$ is present, $c_{ij} = 0$ if not), whereas the factor $c = \langle(1/N)\Sigma_{ij}c_{ij}\rangle$ (the average number of neurons contributing to a local field) ensures that the local fields remain finite as $N \to \infty$. One usually defines also the relative load factor $\alpha = p/c$ (the number of patterns stored per synapse). A fully connected network thus corresponds to $c_{ij} = 1$ for all $(i, j)$ and $c = N$. A so-called randomly extremely diluted network, on the other hand, would have $\lim_{N\to\infty}c^{-1} = 0$ and $\lim_{N\to\infty}c/N = 0$ (i.e., the number of synapses attached to a typical neuron diverges but remains small when compared to the total number of neurons). Theorists often choose to study these two connectivity types because they are found to simplify the analysis of the dynamics (e.g., one need not worry about spatial aspects).

The process of interest is that where, triggered by correlation between the initial state $\boldsymbol{S}(0)$ and a stored pattern $\boldsymbol{\xi}^\lambda$, the state vector $\boldsymbol{S}$ evolves toward $\boldsymbol{\xi}^\lambda$. If this happens, pattern $\boldsymbol{\xi}^\lambda$ is said to be recalled. Numerical simulations of a simple fully connected network (with randomly drawn patterns) already clearly illustrate the main features and complications of recall dynamics. Here the correlation between a state vector and the stored patterns is measured by so-called overlaps (or "directional cosines"):

$$m_\mu(\boldsymbol{S}) = \frac{1}{N} \sum_i \xi_i^\mu S_i \tag{3}$$

For large $N$ we distinguish structural overlaps, where $m_\mu(\boldsymbol{S}) = \mathbb{O}(1)$, from accidental ones, where $m_\mu(\boldsymbol{S}) = \mathbb{O}(N^{-1/2})$ (as for a randomly drawn $\boldsymbol{S}$). Figure 1 shows the result of measuring the quantities

$$m = m_1(\boldsymbol{S}) \qquad r = \alpha^{-1} \sum_{\mu>1} m_\mu^2(\boldsymbol{S}) \tag{4}$$

following initial states that are correlated with pattern $\boldsymbol{\xi}^1$ only. Overlaps with non-nominated patterns are seen to remain $\mathbb{O}(N^{-1/2})$, i.e., $r(t) = \mathbb{O}(1)$. We immediately observe competition between pattern recall ($m \to 1$) and interference of non-nominated patterns ($m \to 0$, with $r$ increasing). The initial overlap (the "cue") needed to trigger recall is found to increase with increasing $\alpha$ (the loading) and increasing $T$ (the noise), until beyond a critical value $\alpha_c(T)$ recall is no longer possible and all trajectories will ultimately lead to the $m = 0$ state (irrespective of the initial state). The competing forces are easily recognized when working out the local fields described by Equation 1, using Equation 2 with $c = N$:

$$h_i(\boldsymbol{S}) = \xi_i^1 m_1(\boldsymbol{S}) + \frac{1}{N} \sum_{\mu>1} \xi_i^\mu \sum_{j\neq i} \xi_j^\mu S_j + \mathbb{O}(N^{-1}) \tag{5}$$

The first term in Equation 5 drives $\boldsymbol{S}$ toward pattern $\boldsymbol{\xi}^1$ as soon as $m_1(\boldsymbol{S}) > 0$. The other terms represent interference caused by correlations between the state vector $\boldsymbol{S}$ and non-nominated patterns. One easily shows that for $N \to \infty$, the fluctuations in the values of the recall overlap $m$ must vanish at any time, and that for the present types of initial states and threshold noise, the overlap $m$ will obey

$$m(t + 1) = \int dz\; P_t(z) \tanh[\beta(m(t) + z)] \tag{6}$$

$$P_t(z) = \lim_{N\to\infty} \frac{1}{N} \sum_i \left\langle \delta\left[z - \frac{1}{N} \sum_{\mu>1} \xi_i^1 \xi_i^\mu \sum_{j\neq i} \xi_j^\mu S_j(t)\right]\right\rangle \tag{7}$$

(with $\beta = T^{-1}$). For general (symmetric) threshold noise distributions, one just substitutes $\tanh[\beta x] \to 2\int_0^x d\eta\; w(\eta)$. Note that Equation 6 can be interpreted as describing the dynamics of the average firing state $m(t) = \langle S(t)\rangle$ of a single "effective neuron" with an effective local field $h(t) = m(t) + z(t)$, where $z(t)$ (distrib-

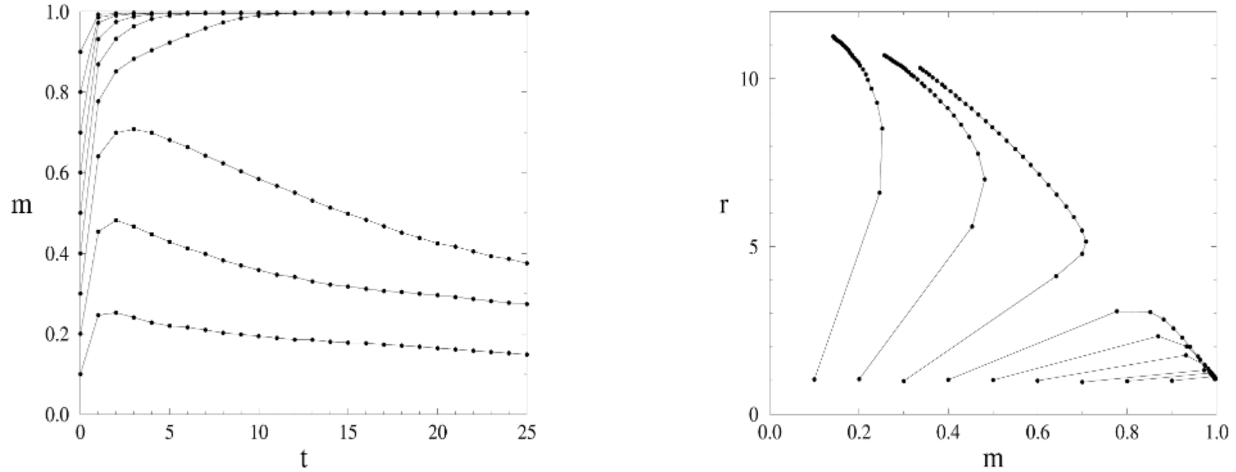

**Figure 1.** Simulations of a fully connected Hopfield model with $N = 30{,}000$, threshold noise distribution $w(\eta) = (1/2T)[1 - \tanh^2(\eta/T)]$, $\alpha = T = 0.1$, parallel dynamics, and randomly drawn pattern bits. *Left*, Overlap $m = m_1(\boldsymbol{S})$ with pattern 1 as functions of time, following initial states $\boldsymbol{S}(0)$ correlated with pattern 1 only, with $m_1(\boldsymbol{S}(0)) \in \{0.1, \ldots, 0.9\}$. *Right*, Corresponding trajectories in the $(m, r)$ plane, where the observable $r = \alpha^{-1}\Sigma_{\mu>1}m_\mu^2(\boldsymbol{S})$ measures the overlaps with non-nominated patterns.

uted according to $P_t(z)$) acts as an extra contribution to the threshold noise. If all $S_i(0)$ are drawn independently, $\text{Prob}[S_i(0) = \pm\xi_i^1] = (1/2)[1 \pm m(0)]$, the central limit theorem tells us that $P_0(z)$ is Gaussian. One easily derives $\langle z\rangle_0 = 0$ and $\langle z^2\rangle_0 = \alpha$, so that at $t = 0$, Equation 6 reduces to

$$m(1) = \int \frac{dz}{\sqrt{2\pi}}\, e^{-(1/2)z^2} \tanh[\beta(m(0) + z\sqrt{\alpha})] \qquad (8)$$

The above ideas, and Equation 8 in particular, go back to Amari (1977). For times $t > 0$, however, the independence of the states $S_i$ need no longer hold. Solving the recall dynamics thus boils down to calculating the (often nontrivial) interference noise distribution $P_t(z)$ in Equation 6 for non-zero times.

## Small Numbers of Patterns

The simplest way to avoid trouble is to study situations where the interference noise vanishes in the $N \to \infty$ limit, which happens, for example, in fully connected networks when $\alpha = \lim_{N\to\infty} p/N = 0$ (as with finite $p$). Equation 6 and its sequential dynamics counterpart now reduce to (with the integrated threshold noise distribution $f[x] = 2\int_0^x d\eta\ w(\eta)$)

$$\text{parallel: } m(t + 1) = f[m(t)]$$

$$\text{sequential: } \frac{d}{dt}\, m = f[m] - m$$

This situation was exploited by several authors (e.g., Buhmann and Schulten, 1987; Coolen and Ruijgrok, 1988; Riedel, Kühn, and van Hemmen, 1988), who, in view of the simplicity of the finite $p$ regime, were able to consider more complicated choices than Equation 2 for the synapses and arbitrary initial states $\boldsymbol{S}(0)$. If, for instance, we choose the more general form $J_{ij} = (1/N)\Sigma_{\mu\nu=1}^{p}\xi_i^\mu A_{\mu\nu}\xi_j^\nu$ (with $p$ finite) and if we put $\boldsymbol{m} = (m_1, \ldots, m_p)$, we find the above equations for a single overlap generalizing to coupled equations involving all $p$ overlaps:

$$\text{parallel: } \boldsymbol{m}(t + 1) = \langle \xi f[\xi \cdot \boldsymbol{A}\boldsymbol{m}(t)]\rangle_\xi$$

$$\text{sequential: } \frac{d}{dt}\, \boldsymbol{m} = \langle \xi f[\xi \cdot \boldsymbol{A}\boldsymbol{m}]\rangle_\xi - \boldsymbol{m}$$

with $\langle g[\xi]\rangle_\xi = 2^{-p}\Sigma_{\xi\in\{-1,1\}^p}\, g[\xi]$ and $\boldsymbol{A} = \{A_{\mu\nu}\}$. These equations, and more elaborate versions (with, e.g., neuronal transmission delays) have since been used extensively to study recall properties of models storing static patterns and of models storing pattern sequences (with nonsymmetric $J_{ij}$). It is even possible to generalize the allowed synapse types further to all matrices of the form $J_{ij} = (1/N)Q[\boldsymbol{\xi}_i; \boldsymbol{\xi}_j]$, with $\boldsymbol{\xi}_i = (\xi_i^1, \ldots, \xi_i^p)$, such as the "clipped Hebbian" synapses $J_{ij} = (1/N)\text{sgn}[\Sigma_\mu \xi_i^\mu \xi_j^\mu]$, by using a different (and larger) set of macroscopic quantities than the $p$ pattern overlaps.

## Gaussian Approximations

Let us now return to the nontrivial regime, where $\alpha > 0$ and the interference noise problem must be confronted. As a simple approximation one could just assume that the $S_i$ remain uncorrelated at all times, i.e., $\text{Prob}[S_i(t) = \pm\xi_i^1] = (1/2)[1 \pm m(t)]$ for all $t \geq 0$, such that the argument given earlier for $t = 0$ (leading to a Gaussian interference noise distribution $P(z)$) would hold generally, and where the mapping described by Equation 7 would describe the overlap evolution at all times:

$$m(t + 1) = \int \frac{dz}{\sqrt{2\pi}}\, e^{-(1/2)z^2} f[m(t) + z\sqrt{\alpha}] \qquad (9)$$

(again with $f[x] = 2\int_0^x d\eta\ w(\eta)$). This equation, however, must be generally incorrect: Figure 1 already shows that, at least for fully connected networks, knowledge of $m(t)$ *only* does not yet permit prediction of $m(t + 1)$. However, for extremely and asymmetrically diluted networks, which are constructed by drawing the synaptic wiring variables $c_{ij}$ in Equation 2 independently at random from $p(c_{ij}) = (c/N)\delta_{c_{ij},1} + (1 - (c/N))\delta_{c_{ij},0}$, with $\lim_{N\to\infty} c/N = 0$ and $c \to \infty$, Equation 8 is indeed found to be correct on finite times (Derrida, Gardner, and Zippelius, 1987). In these networks the time it takes for correlations between neuron states to build up diverges with $N$, so that correlations are simply not yet noticeable on finite times. For the common choice $f[x] = \tanh[x/T]$ (i.e., $w(\eta) = (1/2T)[1 - \tanh^2(\eta/T))$, Equation 9 predicts a critical noise level (at $\alpha = 0$) of $T_c = 1$, and a storage capacity (at $T = 0$) of $\alpha_c = 2/\pi \approx 0.637$.

Rather than taking all $S_i$ to be independent, a weaker assumption would be only to assume the interference noise distribution $P_t(z)$ to be a zero-average Gaussian one at any time (with statistically independent noise variables $z$ at different times): $P_t(z) =$

$[\sigma(t)\sqrt{2\pi}]^{-1}e^{-(1/2)z^2/\sigma^2(t)}$. One can then derive (for $N \to \infty$ and fully connected networks) an evolution equation for the width $\sigma(t)$, giving (Amari and Maginu, 1988; Nishimori and Ozeki, 1993):

$$m(t + 1) = \int \frac{dz}{\sqrt{2\pi}} e^{-(1/2)z^2} f[m(t) + z\sigma(t)]$$

$$\sigma^2(t+1) = \alpha + 2\alpha m(t + 1)m(t)h[m(t),\sigma(t)] + \sigma^2(t)h^2[m(t),\sigma(t)]$$

$$h[m, \sigma] = \int \frac{dz}{\sqrt{2\pi}} e^{-(1/2)z^2} f'[m + z\sigma]$$

These equations describe correctly the qualitative features of recall dynamics, and are found to work quite well when retrieval actually occurs. For nonretrieval trajectories, however, they appear to underestimate the impact of interference noise, and for $f[x] = \tanh[x/T]$, they predict $T_c = 1$ (at $\alpha = 0$) and a storage capacity (at $T = 0$) of $\alpha_c \approx 0.1597$ (whereas this should have been roughly 0.139). A final refinement of the Gaussian approach by Okada (1995) consisted in allowing for correlations between the noise variables $z$ at different times (while still describing them by Gaussian distributions). This then results in a hierarchy of macroscopic equations that improve upon the previous Gaussian theories and even predict the correct stationary state and phase diagrams, but still fail to be correct at intermediate times.

There is a fundamental problem with all Gaussian theories, however sophisticated: apart from special cases, the interference noise distribution is generally *not* of a Gaussian shape. This becomes clear when we follow Nishimori and Ozeki (1993) and return to the simulation experiments of Figure 1 to measure the distribution $P_t(z)$ of Equation 7, resulting in Figure 2. $P_t(z)$ is only (approximately) Gaussian when pattern recall occurs. Hence the successes of Gaussian theories in describing recall trajectories, and their perpetual problems in describing the nonrecall ones.

## Exact Results

The only exact procedure known at present is based on a philosophy different from those described so far. Rather than using the probability $p_t(\boldsymbol{S})$ of finding a microscopic state $\boldsymbol{S}$ at time $t$ in order to calculate the statistics of a macroscopic observable $m(\boldsymbol{S})$ at time $t$, one here turns to the probability Prob$[\boldsymbol{S}(0), \ldots, \boldsymbol{S}(t_m)]$ of finding a microscopic *path* $\boldsymbol{S}(0) \to \boldsymbol{S}(1) \to \ldots \to \boldsymbol{S}(t_m)$. One also adds time-dependent external sources (similar to injected currents) to the local fields, $h_i(\boldsymbol{S}) \to h_i(\boldsymbol{S}) + \theta_i(t)$, to probe the networks via small perturbations. The statistics of paths are fully captured by the following moment-generating function:

$$Z[\boldsymbol{\psi}] = \langle e^{-i\Sigma_i\Sigma_{t=0}^{t_m}\psi_i(t)S_i(t)}\rangle \tag{10}$$

It generates expectation values of most relevant observable quantities, including those involving neuron states at different times, such as correlation functions $C_{ij}(t, t') = \langle S_i(t)S_j(t')\rangle$ and response functions $G_{ij}(t, t') = \partial\langle S_i(t)\rangle/\partial\theta_j(t')$:

$$\langle S_i(t)\rangle = i \lim_{\boldsymbol{\psi}\to\mathbf{0}} \frac{\partial Z[\boldsymbol{\psi}]}{\partial\psi_i(t)} \qquad C_{ij}(t, t') = -\lim_{\boldsymbol{\psi}\to\mathbf{0}} \frac{\partial^2 Z[\boldsymbol{\psi}]}{\partial\psi_i(t)\partial\psi_j(t')}$$

$$G_{ij}(t, t') = i \lim_{\boldsymbol{\psi}\to\mathbf{0}} \frac{\partial^2 Z[\boldsymbol{\psi}]}{\partial\psi_i(t)\partial\theta_j(t')}$$

The idea is next to assume (correctly) that for $N \to \infty$, only the statistical properties of the stored patterns will influence the above macroscopic quantities, so that the generating function $Z[\boldsymbol{\psi}]$ can be averaged over all pattern realizations, i.e., $Z[\boldsymbol{\psi}] \to \overline{Z[\boldsymbol{\psi}]}$. After a certain amount of algebra to evaluate $\overline{Z[\boldsymbol{\psi}]}$ one finds that the recall dynamics can again be described in terms of a single "effective neuron" $S(t)$ with an effective local field. However, this effective local field will generally depend on past states of the neuron and on zero-average but temporally correlated Gaussian noise contributions $\phi(t)$:

$$h(t|\{S\}, \{\phi\}) = m(t) + \theta(t) + \alpha \sum_{t'<t} K(t, t')S(t') + \sqrt{\alpha}\phi(t) \tag{11}$$

The first comprehensive neural network studies along these lines, dealing with fully connected networks, were carried out by Rieger, Schreckenberg, and Zittartz (1988) and Horner et al. (1989), followed by applications to asymmetrically and symmetrically extremely diluted networks (Kree and Zippelius, 1991; Watkin and Sherrington, 1991) (in symmetrically diluted networks the dilution is subject to the constraint $c_{ij} = c_{ji}$ for all $(i, j)$). More recent applications include sequence processing networks (Düring, Coolen, and Sherrington, 1998), where the overlap $m$ is defined with respect to the "moving" target, i.e., $m(t) = (1/N)\Sigma_i S_i(t)\xi_i^t$. The differences between the results obtained for different models are mainly in the actual form taken by the effective local field in Equation 11, i.e., in the dependence of the "retarded self-interaction" kernel $\mathbf{K} = \{K(t, t')\}$ and the covariance matrix $\Phi = \{\Phi(t, t') = \langle\phi(t)\phi(t')\rangle\}$ of the interference-induced Gaussian noise on the macroscopic quantities $\boldsymbol{C} = \{C(s, s') = \lim_{N\to\infty}(1/N)\Sigma_i C_{ii}(s, s')\}$ and $\boldsymbol{G} = \{G(s, s') = \lim_{N\to\infty}(1/N)\Sigma_i G_{ii}(s, s')\}$. For instance:

| Model | Synapses $J_{\mathrm{ij}}$ | $K(t, t')$ | $\langle\phi(t)\phi(t')\rangle$ |
|---|---|---|---|
| *Fully connected, static patterns* | $\frac{1}{N}\sum_{\mu=1}^{\alpha N} \xi_i^\mu\xi_j^\mu$ | $(\mathbf{I} - \boldsymbol{G})^{-1}\boldsymbol{G}$ | $(\mathbf{I} - \boldsymbol{G})^{-1}\boldsymbol{C}(\mathbf{I} - \boldsymbol{G}^\dagger)^{-1}$ |
| *Fully connected, pattern sequence* | $\frac{1}{N}\sum_{\mu=1}^{\alpha N} \xi_i^{\mu+1}\xi_j^\mu$ | 0 | $\sum_{n\geq 0} (\boldsymbol{G}^\dagger)^n\boldsymbol{C}\boldsymbol{G}^n$ |
| *Symmetric extremely diluted, static patterns* | $\frac{c_{ij}}{c}\sum_{\mu=1}^{\alpha c} \xi_i^\mu\xi_j^\mu$ | $\boldsymbol{G}$ | $\boldsymbol{C}$ |
| *Asymmetric extremely diluted, static patterns* | $\frac{c_{ij}}{c}\sum_{\mu=1}^{\alpha c} \xi_i^\mu\xi_j^\mu$ | 0 | $\boldsymbol{C}$ |

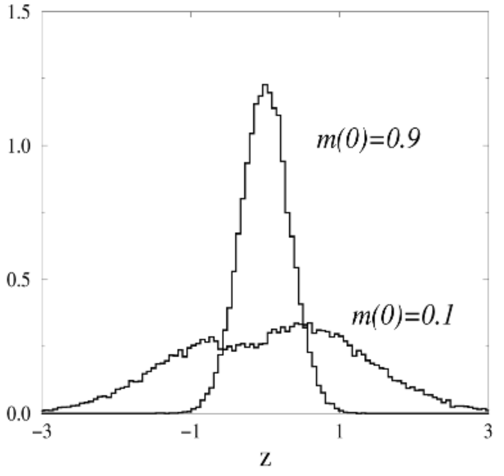

**Figure 2.** Distributions of interference noise variables $z_i = (1/N)\Sigma_{\mu>1}\xi_i^1\xi_i^\mu\Sigma_{j\neq i}\xi_j^\mu S_j$, as measured in the simulations of Figure 1, at $t = 10$. Unimodal histogram: noise distribution following $m(0) = 0.9$ (leading to recall). Bimodel histogram: noise distribution following $m(0) = 0.1$ (not leading to recall).

The correlation and response functions are to be solved self-consistently from the following (closed) equations, involving the statistics of the single effective neuron experiencing the field described by Equation 10:

$$C(t, t') = \langle S(t)S(t')\rangle \qquad G(t, t') = \frac{\partial}{\partial\theta(t')}\langle S(t)\rangle \tag{12}$$

In the case of sequential dynamics the picture is found to be very similar to the one above; instead of discrete time labels $t \in \{0, 1, \ldots, t_m\}$, path summations, and matrices, there one has a real-time variable $t \in [0, t_m]$, path integrals, and integral operators.

It is now clear what happens with Gaussian theories: they can at most produce exact results for asymmetric networks. Any degree of symmetry in the synapses is found to induce, via the kernel $K(t, t')$ a non-zero retarded self-interaction that constitutes a non-Gaussian contribution to the local fields. One also sees that it is not extreme dilution that is responsible for a drastic simplification of the dynamics, but synaptic asymmetry. This is underlined by Figure 3, which shows the phase diagrams of the asymmetrically and the symmetrically extremely diluted Hopfield model (both with $\lim_{N\to\infty} c/N = 0$ and $c \to \infty$), as derived from the above equations. The indirect effect on the dynamics of (even partial) synaptic symmetry is fundamental and can be understood as follows: such (partial) symmetry implies that an excitatory synapse $i \to j$ is more likely to be accompanied by an excitatory synapse $j \to i$ than an inhibitory one; conversely, an inhibitory synapse $i \to j$ is more likely to be accompanied by an inhibitory synapse $j \to i$. In both cases the net effect for an active (inactive) neuron $i$ is an effective self-excitation (self-inhibition); any degree of synaptic symmetry thus acts as a retarded "mirror," which complicates (and slows down) the dynamics.

## Non-Gaussian Approximations

Owing to the generally complicated nature of a rigorous treatment of recall dynamics, there is still a market for approximate theories. In view of the non-Gaussian shape of the interference noise distribution, several attempts have been made to construct non-Gaussian approximations. In all cases the aim is to arrive at a theory involving only macroscopic quantities with a *single* time argument. Henkel and Opper (1990) approximated the theory of a fully connected network with parallel dynamics by replacing the field in Equation 10 with the simpler expression

$$h(t) = m(t) + \theta(t) + d(t)S(t-1) + \sqrt{\alpha}\phi(t)$$

$$\langle \phi(t)\phi(t')\rangle = \sigma^2(t)\delta_{tt'}$$

(with independent zero-average Gaussian fields $\phi(t)$), followed by a self-consistent calculation of $d(t)$ (representing the retarded self-interaction) and of the width $\sigma(t)$ of the distribution of $\phi(t)$. This results in an interference noise distribution $P_t(z)$ (Equation 6), which is the sum of *two* Gaussians, which appears sensible in view of Figure 2, and a nice (but not perfect) agreement with numerical simulations.

A different philosophy was followed by Coolen and Sherrington (1994). Here (as yet exact) equations are derived for the evolution of the macroscopic quantities $m$ and $r$ in Equation 4 (for sequential dynamics), which both involve $P_t(z)$:

$$\frac{d}{dt} m = \int dz\ P_t(z)\ \tanh[\beta(m + z)]$$
$$\frac{d}{dt} r = \frac{1}{\alpha}\int dz\ P_t(z) z\ \tanh[\beta(m + z)] + 1 - r$$

Next one closes these equations *by hand*, using a maximum-entropy (or "Occam's razor") argument: Instead of calculating $P_t(z)$ with the (unknown) distribution $p_t(\boldsymbol{S})$, it is calculated upon assigning equal probabilities to all states $\boldsymbol{S}$ with $m(\boldsymbol{S}) = m$ and $r(\boldsymbol{S}) = r$, followed by averaging over all realizations of the stored patterns. This results in an explicit (non-Gaussian) expression for the noise distribution in terms of $(m, r)$ only, a theory that is exact for short times and in equilibrium, accurate predictions of the macroscopic flow in the $(m, r)$ plane, but (again) deviations in predicted time dependences at intermediate times. This theory, and its performance, was later improved by applying the same ideas to a derivation of a dynamic equation for the function $P_t(z)$ itself (rather than for $m$ and $r$ only).

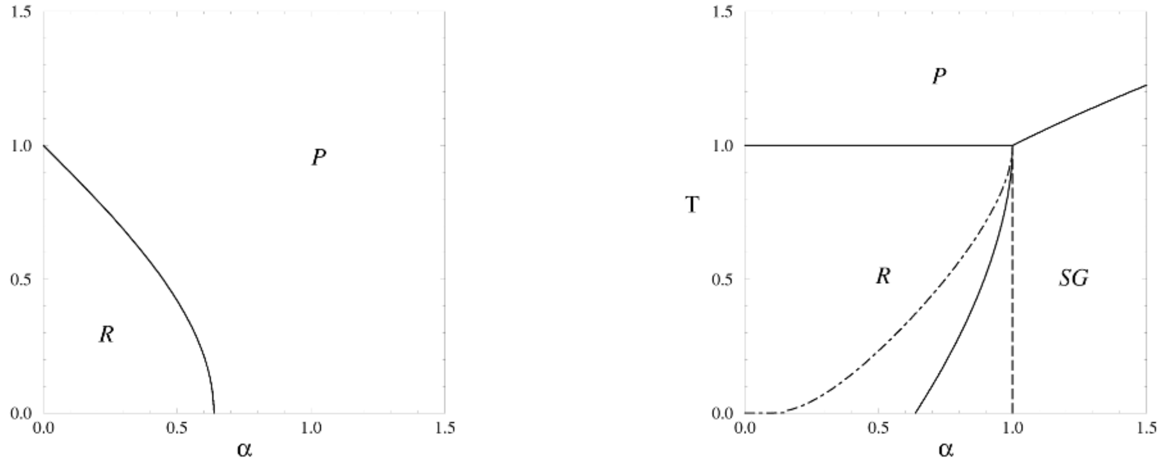

**Figure 3.** *Left*, Phase diagram of *asymmetrically* extremely diluted networks. Solid line traces continuous transition, separating a paramagnetic (P) region (with pseudo-random motion) from a recall (R) region, reaching the $T = 0$ axis at $\alpha_c = 2/\pi \approx 0.637$. *Right*, Phase diagram of *symmetrically* extremely diluted networks. Solid lines indicate continuous transitions, separating a paramagnetic region from a recall region ($\alpha < 1$) and from a spin-glass region (SG) ($\alpha > 1$) (SG describes the unwanted state where $m = 0$ and $r > 0$, in the language of Figure 1), and separating the recall region from a spin-glass region (calculated using the so-called replica symmetry assumption). Dashed-dotted line indicates the AT instability (where this assumption breaks down), reaching the $T = 0$ axis at $\alpha_c^{\mathrm{RS}} = 2/\pi \approx 0.637$; replica symmetry breaking displaces the solid line to a new (dashed) line, with a new storage capacity $\alpha_c^{\mathrm{RSB}} = 1$.

## Discussion

In this review I have attempted to explain the various theories that have been developed since the mid-1970s, in often disjunct communities, to understand the dynamics of pattern recall in recurrent neural networks. The methods and ideas described in this review can be, and indeed have been, extended and generalized in many ways. This includes networks with spatial structure, axonal or neuronal delays, nonbinary neurons such as graded-response or integrate-and-fire ones, correlated patterns, networks of coupled oscillators, and so on. Increased biological realism of a model is, as always, paid for by a proportionate reduction in how far one can push the mathematical analysis. However, remarkable progress has been made over the last two decades, with a wave of dynamical studies especially around 1990 (unfortunately, many popular textbooks on neural network theory were written in about 1989, and thus contain very little on recall dynamics), but with new ground being covered up to the present day. Recall dynamics is interesting and relevant in its own right (and a nice challenge for the theorist), yet one can hardly underestimate the importance, especially to those interested in understanding recurrent modules in real nervous tissue, of the other deliverable of dynamical studies: they open up for mathematical analysis the area of recurrent networks with *nonsymmetric* (i.e., biologically more realistic) synapses, which is not accessible with the more common equilibrium tools.

# Echolocation: Cochleotopic and Computational Maps

*Nobuo Suga*

## Introduction

The order *Chiroptera* (bats) accounts for one-fifth of mammalian species and has two suborders, Megachiroptera, with 154 species, and Microchiroptera, with about 800 species. All microchiropterans thus far studied echolocate, but only one megachiropteran, the genus *Rousettus*, does. The morphology and ecology of bats are so diverse that echolocation behavior and orientation sounds (biosonar pulses, or simply pulses) are quite different among different species of bats. Accordingly, the auditory system differs among species. Studies in the neuroscience of echolocation have been mainly performed with four different species of microchiropterans: *Pteronotus parnellii* (mustached bat), *Rhinolophus ferrumequinum* (horseshoe bat), *Myotis lucifugus* (little brown bat), and *Eptesicus fuscus* (big brown bat). Among them, the parallel/hierarchical processing of biosonar information was best explored in *Pteronotus*. Thus, the neurophysiology of the auditory system of *Pteronotus* is mainly described in this article.

## Properties of Biosonar Signals

For insect capture and orientation, certain microchiropterans emit constant-frequency (CF) and/or frequency-modulated (FM) sounds. The biosonar pulses of *Pteronotus* always consist of a long CF component followed by a short FM component. Since each biosonar pulse contains four harmonics ($H_{1-4}$), there are potentially eight major components ($CF_{1-4}$ and $FM_{1-4}$ in Figure 1*A*). The second harmonic ($H_2$) is always predominant, with $CF_2$ at about 61 kHz and $FM_2$ sweeping from 61 kHz to about 49 kHz. The $CF_2$ “resting” frequency differs among individual bats and is sexually dimorphic. In target-directed flight, a CF-FM pulse varies in duration and emission rate, but its spectrum changes little. Target echoes usually overlap with the emitted pulses (Figure 1*B*). *Rhinolophus* also emits CF-FM sounds with $H_2$ at about 83 kHz. In comparison, *Myotis* and *Eptesicus* emit FM pulses that sweep downward about one octave within a range between 100 and 15 kHz. The properties of FM pulses vary, depending on the species and situations in echolocation. Target echoes usually do not overlap with the emitted pulses (Figure 1*C* and 1*D*).

Different components or parameters of echoes carry different types of target information (Table 1). The long CF component is an ideal signal for target detection and measurement of target relative velocity (2.84 m/s/kHz Doppler shift for a 61-kHz carrier) and the velocity of an insect’s wing beat. *Pteronotus* optimizes the acquisition of velocity information by an acoustic behavior called Doppler-shift compensation, by which the frequency of the echo $CF_2$ is stabilized at approximately 61 kHz. The short FM component is more appropriate for ranging (17.3 cm/ms), localization, and characterization of a target. Since bats emit acoustic pulses at rates of 5–200/s, their auditory system creates stroboscopic acoustic images through enormous parallel processing of pulse-echo pairs in all aspects listed in Table 1.

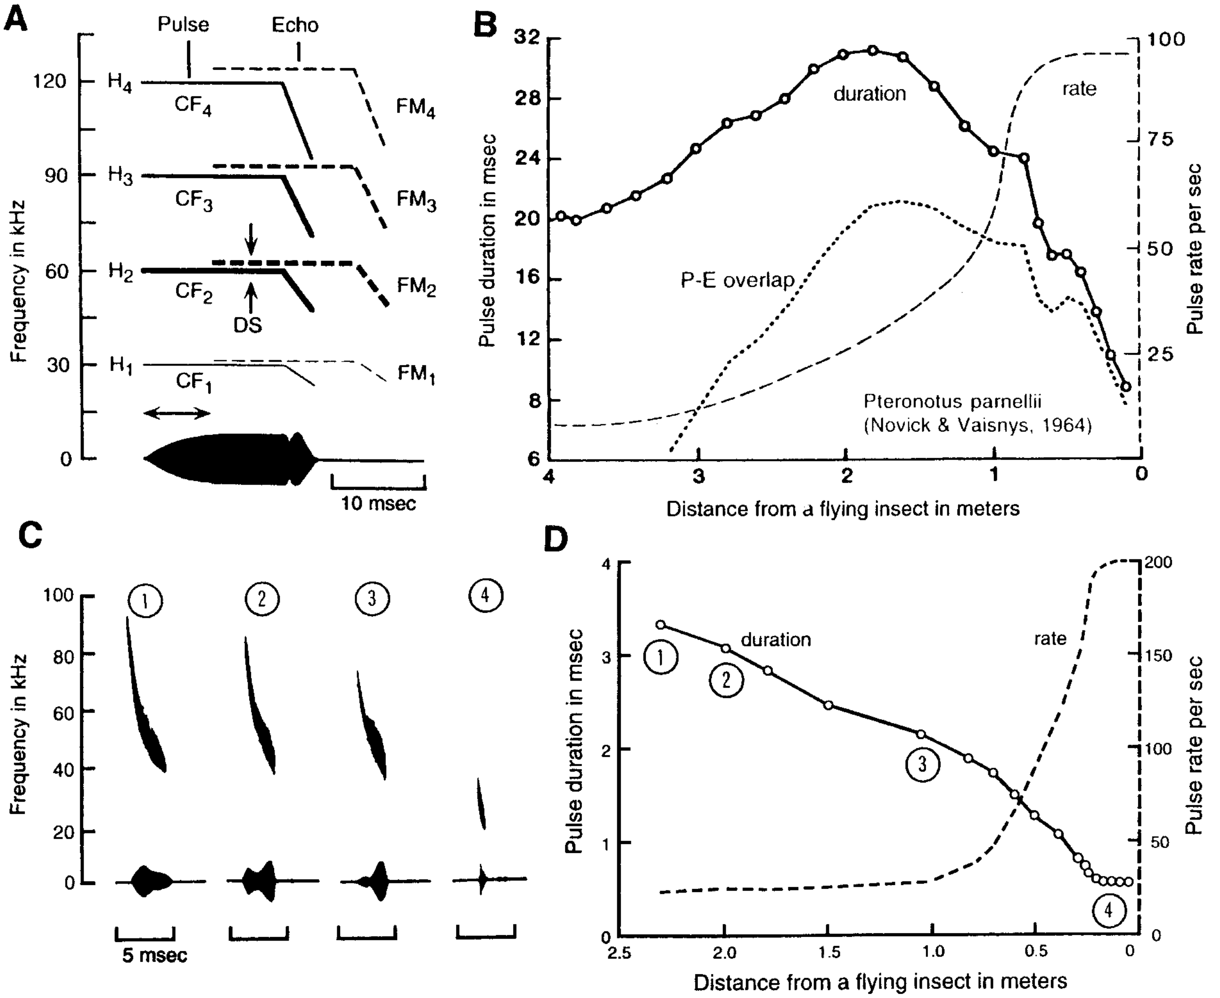

**Figure 1.** Biosonar "pulses" of the mustached bat, *Pteronotus parnellii* (*A*, *B*) and the little brown bat, *Myotis lucifugus* (*C*, *D*). *A*, The four harmonics ($H_{1-4}$) of a *Pteronotus* biosonar pulse each consist of a long CF component terminating in a short FM sweep, so that there are eight components, $CF_{1-4}$ and $FM_{1-4}$. Most of the sound energy is in the second harmonic ($H_2$), with $CF_2$ at approximately 61 kHz and $FM_2$ sweeping from approximately 61 kHz to approximately 49 kHz. As the bat approaches a target, a reflected echo is Doppler-shifted (DS) in frequency, and its delay from the pulse becomes shorter. *B*, During target-directed flight, *Pteronotus* increases the rate of its pulse emissions. The bat initially lengthens the duration of the pulse and then systematically shortens it. Pulse-echo overlap is maximal when the pulses emitted are longest in duration. *C*, *Myotis* emits a short, downward-sweeping FM pulse. *D*, During target-directed flight, *Myotis* increases the rate of pulse emissions, shortens pulse duration as to avoid pulse-echo overlap, and lowers the frequency sweep range of the pulse. Circled numbers 1–4 correspond to those in *C*. (*B* adapted from Novick, A., and Vaisnys, J. R., 1964, Echolocation of flying insects by the bat, Chilonycteris parnellii. *Biol. Bull.*, 127:478–488.)

**Table 1.** Different acoustic parameters of an echo relative to the biosonar pulse at the ear carry different types of target information

| Echo | Target |
|---|---|
| Doppler shift | Velocity |
| Steady component | Relative velocity |
| Periodic component | Insect wingbeat |
| Amplitude | Subtended angle |
| Steady component | Relative size |
| Periodic component | Insect wing beat |
| Delay | Range |
| Amplitude + delay | Absolute size |
| Amplitude spectrum | Fine characteristics |
| Envelope | Fine characteristics |
| Binaural cues | Azimuth |
| Pinna-tragus cue | Elevation |

## The Auditory System

The gross structure of the auditory system of *Pteronotus* is basically the same as that of other mammals, but it shows a unique functional organization reflecting the properties of its biosonar pulse and echolocation behavior. One of the most striking features is the extremely sharp tuning and the large population of neurons at the auditory periphery for fine frequency analysis of the $CF_2$ component at approximately 61 kHz. Because of this extremely sharp tuning, they can easily code the small frequency modulation of echoes that would be evoked by the wings of flying insects. The $CF_2$ processing channel is disproportionately large, from the cochlea through the auditory cortex. The other striking feature of the auditory system of *Pteronotus* is the parallel/hierarchical organization to extract certain types of biosonar information by "combination-sensitive" neurons, as described below.

All the CF and FM components of the biosonar pulse differ in frequency (Figure 1*A*), and hence they are separately analyzed in the cochlea and are sent in parallel into the brain by different auditory nerve fibers. At the auditory periphery, frequency is represented by the location along the basilar membrane in the cochlea and phase (or stimulus)-locked discharges of auditory nerve fibers. There are no anatomical axes for the representation of stimulus amplitude (intensity) and time (i.e., duration of stimuli and interval between the stimuli). In the central auditory system, divergent/convergent interactions repeatedly take place, and multiple frequency maps and neuronal response properties are formed that differ from those at the periphery. Inhibition (in particular, lateral inhibition), coincidence detectors (AND gates), and multipliers play important roles in the processing of auditory information in the frequency and amplitude domains, whereas delay lines, in addition to the above three, play key roles in time domain processing. For example, the response properties of neurons tuned to echo delays, durations, repetition rates, sequences of sounds, or interaural time differences are created with these four neural mechanisms. The length of delay lines is very short for the processing of interaural time differences, but it can be very long for the processing of other acoustic parameters. Long delay lines are created by inhibition that evokes rebound off-response.

In the CF$_{1-3}$ processing channels, the frequency-tuning curves of peripheral neurons are much sharper than those in other channels. However, they are still triangular in shape, so that the ambiguity in coding frequency by a single neuron is large at high-stimulus amplitudes. All these peripheral neurons respond not only to tone bursts, but also to FM sounds and noise bursts. They are not "combination sensitive." At higher levels, however, many neurons show sharp "level-tolerant" frequency tuning for further analysis of CF signals. A level-tolerant tuning curve has a very narrow bandwidth regardless of stimulus level (amplitude) and plays a role in level-tolerant fine-frequency analysis. Level-tolerant tuning is created by lateral inhibition, which occurs at different levels of the central auditory system (Figure 2). Sharpening of tuning by lateral inhibition is most dramatic in the CF$_2$ processing channel, and it is practically completed in the medial geniculate body. Inhibition also creates amplitude selectivity, so that some central auditory neurons are tuned not only in frequency but also in amplitude (Figure 2). The CF$_2$ processing channel mostly projects to the Doppler-shifted CF (DSCF) area of the primary auditory cortex (Figure 3). For the extraction of velocity information from biosonar pulse-echo pairs, the parts of the CF$_{1-3}$ processing channels are integrated in the inferior colliculus (IC), and perhaps in the medial geniculate body (MGB). (It is likely that this integration greatly depends on corticofugal feedback.) As a result, CF/CF combination-sensitive neurons are produced (Figure 4). These neurons project to the CF/CF and DIF areas in the auditory cortex (AC) (Figure 3).

In the FM$_{1-4}$ processing channels, some neurons at higher levels respond selectively to FM sounds because of neural circuits incorporating *disinhibition* and/or *facilitation*. The IC has frequency-versus-latency coordinates. Part of the latency axis is perhaps used as delay lines, as explained later. The parts of the FM$_{1-4}$ processing channels are integrated in the inferior colliculus to create FM-FM neurons, which are tuned to particular echo delays for the extraction of target-distance information from biosonar pulse-echo pairs. The neural mechanisms for creating FM-FM neurons consist of at least

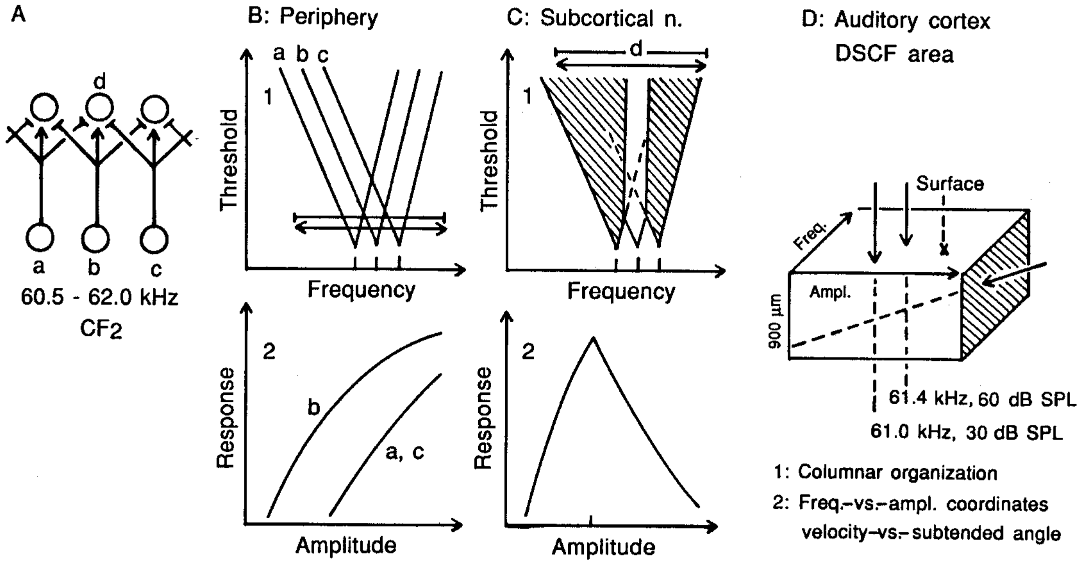

**Figure 2.** Sharpening of frequency-tuning curves and creation of amplitude tuning by inhibition. *A*, Neural circuit for lateral inhibition. The arrowheads and bar heads represent excitatory and inhibitory synapses, respectively. *B*, Frequency-tuning curves (*B*1) and impulse-count functions (*B*2) of three peripheral neurons: a, b, and c in *A*. The impulse-count functions are measured with a tone burst at a best frequency of neuron b. The double-headed arrow in *B*1 indicates that the neurons respond to upward as well as downward-sweeping FM sounds and that the threshold of the response is slightly higher than that to a CF tone at a neuron's best frequency. The horizontal bar in B1 indicates that these neurons respond to a noise burst and that the threshold of the response is slightly higher than those to the FM sounds. *C*, Subcortical neuron d in *A* has a sharp, level-tolerant frequency-tuning curve sandwiched between inhibitory tuning curves (shaded) as a result of lateral inhibition (*C*1). This subcortical neuron is tuned to a weak tone burst because of the inhibition. The impulse-count function measured with a tone burst at a best frequency of neuron d is highly nonmonotonic (*C*2). The double-headed arrow and horizontal bar in C1 indicate that neuron d does not respond to FM sounds and noise bursts. *D*, The functional organization of the DSCF area in the auditory cortex. The DSCF area shows columnar organization characterized by a particular combination of best frequency and best amplitude. It has the frequency-versus-amplitude coordinates. (Based on Suga, N., 1994, Processing of auditory information carried by complex species-specific sounds, in *Cognitive Neuroscience* (M. S. Gazzaniga, Ed.), Cambridge, MA: MIT Press, pp. 295–318; Suga and Manabe, 1982.)

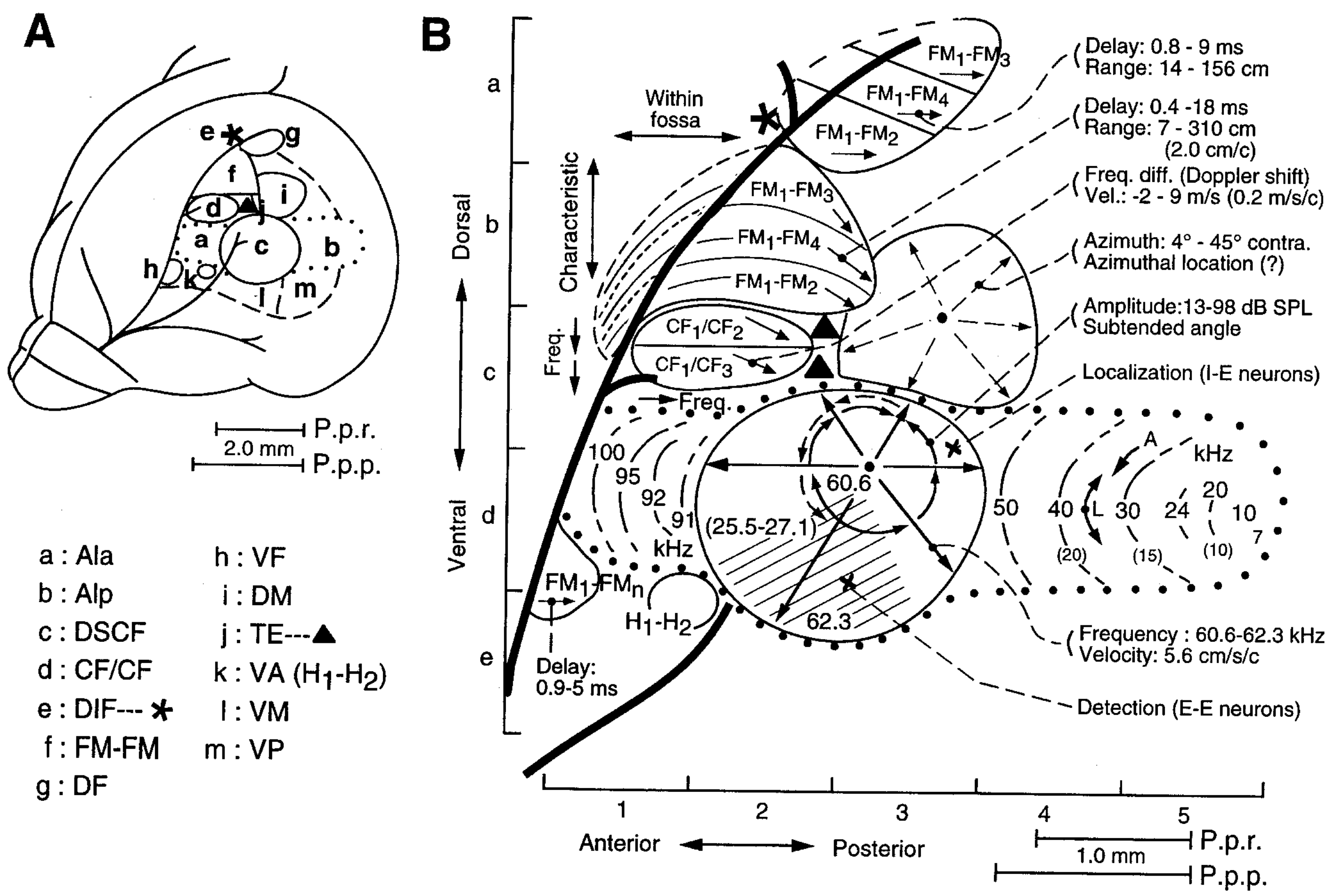

**Figure 3.** The auditory cortex of the mustached bat. *A*, Dorsolateral view of the left cerebral hemisphere and the branches of the median cerebral artery. The long branch is on the fossa. The auditory cortex consists of several areas (a–m), are called Ala, Alp, etc. The functional organization of certain areas has been electrophysiologically explored and is graphically summarized in *B*. *B*, The tonotopic representation of AI (Ala, DSCF, and Alp) and the functional organization of the other areas are indicated by lines and arrows. The DSCF area has axes representing target-velocity information (echo frequency: 60.6–62.3 kHz) or subtended target-angle information (echo amplitude: 13–98 dB SPL). It consists of two subdivisions suited for either target detection (shaded) or target localization (unshaded). These subdivisions are occupied mainly by E-E or I-E binaural neurons. The anterior and posterior halves of the DSCF area are hypothesized to be adapted for processing echoes from either fluttering or stationary targets. Neurons in the DSCF area are sensitive to an $FM_1$-$CF_2$ combination. The FM-FM area consists of three major types of FM-FM neurons ($FM_1$–$FM_2$, $FM_1$–$FM_3$, and $FM_1$–$FM_4$), which form separate clusters. Each cluster has an axis representing target ranges from 7 to 310 cm (echo delay: 0.4–18 ms). The dorsoventral axis of the FM-FM area probably represents fine target characteristics. The CF/CF area consists of two major types of CF/CF neurons ($CF_1/CF_2$ and $CF_1/CF_3$), which are also found in separate clusters. Each cluster has two frequency axes and represents a target velocity from −2 to +9 m/s (echo Doppler shift: −0.7 to +3.2 kHz for $CF_2$, and −1.1 to +4.8 kHz for $CF_3$). The DF area consists of the three clusters of FM-FM neurons and has an axis representing target ranges from 7 to 140 cm. The VF area also contains FM-FM neurons and represents target ranges up to 80 cm. The DM area has an axis representing the azimuthal location of the target on the contralateral side in front of the animal. This azimuthal representation is incorporated with tonotopic representation. In the VP area, azimuthal motion-sensitive neurons have been found. The functional organization of the VA and VP areas remains to be studied further. (Adapted from Suga, N., 1994, Processing of auditory information carried by complex species-specific sounds, in *Cognitive Neurosciences* (M. S. Gazzaniga, Ed.), Cambridge, MA: MIT Press, pp. 295–318.)

four physiological components: phasic/constant latency responding neurons, delay lines, coincidence detectors, and amplifiers. An FM sound sequentially stimulates an array of neurons tuned to different frequencies by sweeping across their frequency tuning curves. Phasic/constant latency responders are suited for coding that moment of the stimulus. They code the exact timing of the pulse and its echo, i.e., the echo delay. They are mostly created in the subcollicular nuclei. The other three components are now considered to be in the IC, although part of the delay lines are perhaps created in subcollicular nuclei. Delay lines shift the response to the pulse $FM_1$ in time. A coincidence detector (FM-FM neuron) has two inputs: one input carries activity evoked by the pulse $FM_1$ through a delay line, and the other input carries activity evoked by the echo $FM_n$ without delay lines. An echo always delays acoustically from the pulse emitted by the bat according to the distance to an echo source. At a coincidence detector whose neural delay is equal to an echo delay, the excitatory response to the echo $FM_n$ arrives at the same time as the delayed excitatory response evoked by the pulse $FM_1$. Then, the coincidence detector shows a strong facilitative response (Figure 5). This facilitation greatly depends on corticofugal feedback.

Collicular FM-FM combination-sensitive neurons produced in this way are tuned to particular echo delays, i.e., target distances. They project to thalamic FM-FM neurons, which show stronger facilitative responses to pulse-echo pairs and sharper delay tuning than the collicular FM-FM neurons. These thalamic FM-FM neurons project to the FM-FM, DF, and VF areas in the AC. The response of these thalamic neurons greatly depends on corticofugal

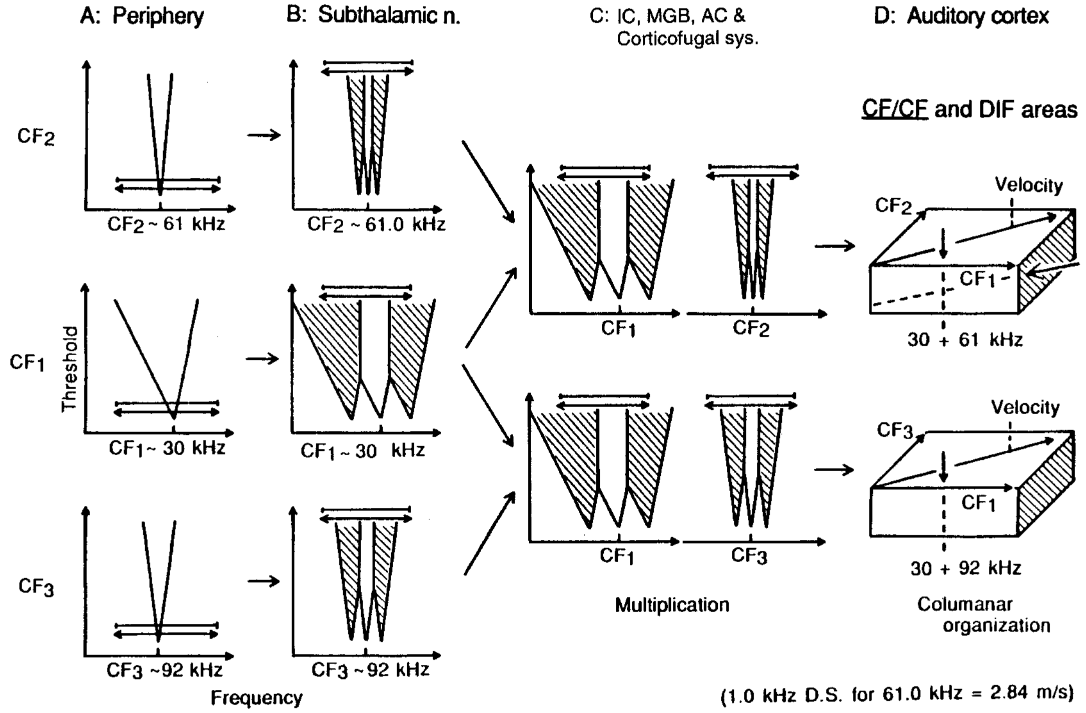

**Figure 4.** Neural mechanisms for creating frequency-versus-frequency coordinates. Triangular frequency-tuning curves of three channels ($CF_{1,2}$ and $CF_3$) at the periphery (*A*) are changed into level-tolerant frequency-tuning curves in the subthalamic auditory nuclei by lateral inhibition (*B*). Then, the $CF_1$ and $CF_2$ or $CF_3$ channels are integrated in the inferior colliculus (IC) and, perhaps, in the medial geniculate body (MGB) to create two types of velocity-tuned, CF/CF combination-sensitive neurons (*C*). These neurons project to the CF/CF area in the auditory cortex and form the $CF_1/CF_2$ and $CF_1/CF_3$ subdivisions. In each subdivision, a cortical minicolumn is characterized by a particular combination of two frequencies. Each subdivision has frequency-versus-frequency coordinates, in which relative velocities of targets are systematically mapped. CF/CF neurons also cluster in the DIF area. (Based on Suga and Tsuzuki, 1985.)

feedback. As a consequence of such parallel-hierarchical processing of complex sounds, there are many functional divisions in the auditory cortex (Figure 3).

## Cochleotopic (Frequency) Map in the Auditory Cortex

The central auditory system of *Pteronotus* processes different types of biosonar information and communication calls in a parallel/hierarchical way. As a result, its AC consists of many areas containing different types of combination-sensitive neurons. Therefore, each of these areas has more than one frequency axis. Accordingly, frequency maps based on best frequencies (BFs) of combination-sensitive neurons are much more complex than those based on BFs measured with single-tone stimuli, and indicate the following four important facts. (1) The frequency axes in the AC are not exact copies of the frequency axis along the basilar membrane in the cochlea. Certain portions of the peripheral frequency axis are reduced or enlarged in a cortical frequency axis. (2) Different portions of the peripheral frequency axis are superimposed in parallel or orthogonally across certain cortical areas. (3) An area where the frequency axis can hardly be demonstrated with single-tone stimuli has distinct frequency axes when studied with combination tones. (4) The complex multiple frequency representations in the AC are directly related to the representations of different types of biosonar information.

## Computational Maps in the Auditory Cortex

The response properties of certain types of combination-sensitive neurons can be easily related to the processing of particular types of biosonar information, because the CF and FM components of the biosonar signals are suited for the measurements of target velocities and distances, respectively.

Neurons in the DSCF processing area are tuned to particular frequencies and amplitudes of the $CF_2$ component and show a facilitative response to the echo $CF_2$ combined with the pulse $CF_1$ and/or $FM_1$. Most of them are sensitive to periodic frequency modulation. In the DSCF area, individual minicolumns, often called "cortical modules," are characterized by a particular combination of frequency and amplitude. They form frequency-versus-amplitude coordinates for the fine spatiotemporal representation of periodic changes of echoes in frequency and amplitude that would be evoked by insect wing beats (Figure 3*B*). Inactivation of the DSCF area disrupts frequency but not echo-delay discrimination.

Another cortical area (CF/CF) consists of two subdivisions: $CF_1/CF_2$ and $CF_1/CF_3$ (Figure 3*B*). The responses of $CF_1/CF_2$ and $CF_1/CF_3$ neurons to an echo $CF_2$ or $CF_3$ are facilitated by the pulse $CF_1$ emitted by the bat when the echo $CF_2$ or $CF_3$ returns from a target with a particular relative velocity and/or with beating wings. Their frequency-tuning curves are extremely sharp. They act as coincidence detectors tuned to particular combinations of CF sounds in the frequency (Doppler shift) domain. Since emitted pulses and Doppler-shifted echoes both vary independently in frequency from each other, the amount of a Doppler shift should be expressed with the frequency-versus-frequency coordinate system. In the CF/CF area, individual minicolumns are characterized by a particular combination of two frequencies. They form the frequency-versus-frequency coordinates by which the relationships between $CF_1$ and $CF_2$ or $CF_3$ (i.e., relative target velocities) are systematically mapped (Figures 3*B* and 4). Some CF/CF neurons are sensitive to

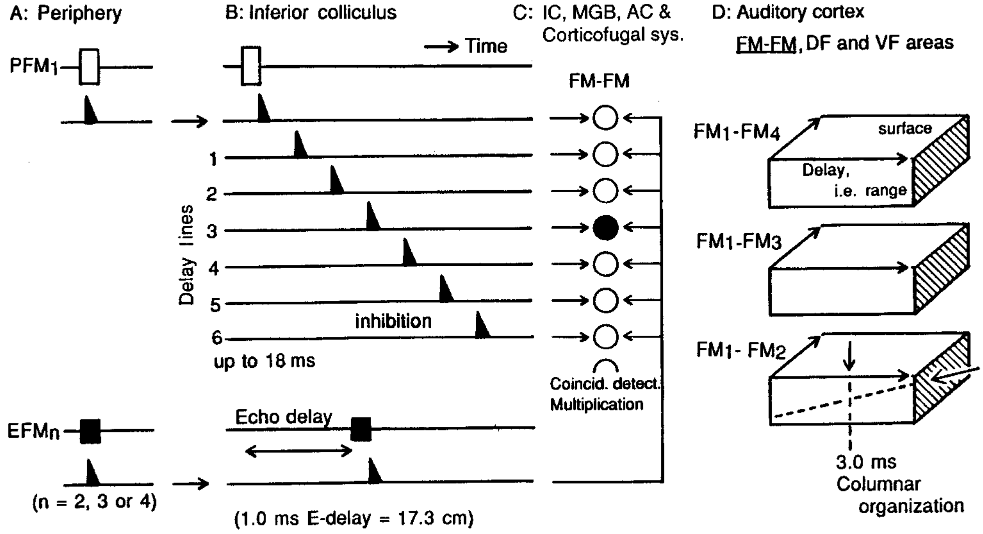

**Figure 5.** Neural mechanisms for creating delay-tuned neurons and a delay (range) axis. Delay-tuned neurons utilize delay lines (0.4–18 ms long) that are mostly created by inferior collicular neurons tuned to frequencies swept by the $FM_1$ (top portion of *A* and *B*). However, the delay-tuned neurons do not use delay lines created by neurons tuned to frequencies swept by $FM_n$ ($n = 2, 3$, or 4; bottom portion of *A* and *B*). An array of delay-tuned neurons in the inferior colliculus (IC) receives signals from both the $FM_1$ and $FM_n$ channels (*C*). In a delay-tuned neuron (filled circle), where an echo $FM_n$ delay from the pulse $FM_1$ is equal to the neural delay line associated with it, both the signals arrive at the same time. The amount of facilitative excitation of the neuron depends on the degree of coincidence. Three types of thalamic delay-tuned neurons separately project to the FM-FM area of the auditory cortex, forming three subdivisions within the FM-FM area (*D*). Each subdivision of the FM-FM area shows columnar organization characterized by a particular value of echo delay. It has an echo delay axis, i.e., target-range axis. Delay-tuned neurons also cluster in the DF and VF areas. For simplicity, phasic on-response (onset detector), amplitude tuning, and FM sensitivity are eliminated from the model. (Adapted from Suga, 1990, based on O'Neill and Suga, 1982.)

a combination of three CF signals: $CF_1$, $CF_2$, and $CF_3$. CF/CF neurons are also found in another cortical area (dorsal intrafossa, or DIF) (Figure 3*B*).

Another specialized area (FM-FM) consists of three subdivisions: $FM_1$-$FM_2$, $FM_1$-$FM_3$, and $FM_1$-$FM_4$ (Figure 3*B*). The responses of FM-FM neurons to an echo $FM_n$ ($n = 2, 3$, or 4) are facilitated by the pulse $FM_1$ emitted by the bat when the echo $FM_n$ returns from a target at a particular distance. They act as coincidence detectors tuned to particular combinations of FM sounds in the time (echo-delay) domain. In the FM-FM area, individual minicolumns are characterized by a particular echo delay. They form an echo-delay (range) map in each subdivision of the FM-FM area (Figures 3*B* and 5). Some FM-FM neurons are sensitive to a combination of three or even four FM signals. Inactivation of the FM-FM area disrupts delay but not frequency discrimination. FM-FM neurons are clustered not only in the FM-FM area, but also in the dorsal fringe (DF) and ventral fringe (VF) areas, which also have an echo delay map (Figure 3*B*). It is also important to note that most FM-FM neurons are more sensitive to the combinations of FM sounds than to the combinations of CF tones.

As explained above, velocity and distance information is extracted by combination-sensitive neurons comparing the fundamental of the emitted pulse ($CF_1$ or $FM_1$) with the higher harmonics of echo components ($CF_n$ or $FM_n$). This heteroharmonic sensitivity is one of seven possible mechanisms used to protect the echolocation system from the jamming effect of biosonar pulses produced by conspecifics.

There are many important topics and findings of echolocation that are not described in this short article. One of the important topics to be discussed is sound localization. As in other mammalian and avian species, the bat's auditory system creates binaural neurons tuned to particular interaural time or intensity differences in the subcollicular auditory nuclei and the auditory space map in the superior colliculus, which is an important nucleus for sensorimotor integration. In this nucleus, some neurons are tuned to a sound source at a combination of a particular azimuth, elevation, and depth. In the AC, however, the auditory space map has not yet been found in any animal, although it has been found that two types of binaural neurons (I-E and E-E) are separately clustered in the DSCF area and that the best azimuth to excite neurons varies systematically along the frequency axis of the AC.

Since the amplitude, velocity, and range maps do not exist in the periphery but are created centrally, these maps are called *computational maps*. The findings made in the AC of the mustached bat and in the visual cortex of the macaque monkey indicate that the auditory and visual systems share an identical principle for processing acoustic or visual scenes: different types of information-bearing elements and parameters are represented/processed in separate cortical areas in parallel. As visual information, auditory information is expressed by spatiotemporal patterns of neural activity in different cortical areas, and cortical neurons contributing to these patterns are quite different from peripheral neurons in response properties. (The cortical areas highly specialized for the processing of biosonar information are also involved in processing communication calls. Each cortical area apparently has multiple functions in auditory information processing.)

## Ascending and Descending (Corticofugal) Auditory Systems

Auditory information sent into the brain from the cochlea by the auditory nerve is sent up to the AC in the cerebrum through the brainstem auditory nuclei, the IC in the midbrain, and the MGB in the thalamus. This ascending system is incorporated with the descending (corticofugal) system. In the corticofugal system, neural signals originating from the AC are sent down to the MGB and IC, and then further down to the brainstem auditory nuclei and eventually to the cochlea. The corticofugal system forms feedback loops and plays an important role in adjusting and improving signal processing according to auditory experiences.

## Adjustment and Improvement of Cochleotopic and Computational Maps

Corticofugal feedback amplifies excitatory responses to single tones by 1.5 times in the IC and 2.5 times in the MGB, whereas it amplifies facilitative responses to paired sounds by 2.9 times in the IC and 5.6 times in the MGB. Therefore, the auditory responses of subcortical neurons would be very weak without corticofugal feedback. Detailed studies on the corticofugal modulation of subcortical signal processing indicate the following important facts. (1) Neurons in a cortical minicolumn increase the auditory responses of "physiologically matched" subcortical neurons and sharpen, but do not shift, their tuning curves. (2) Neurons in a cortical minicolumn decrease the auditory responses of "physiologically unmatched" subcortical neurons, and sharpen and shift their tuning curves away from the tuning curves of the cortical neurons. (3) As the tuning curves of adjacent neurons along a frequency or echo delay axis overlap each other, the direction of the shift in tuning curve depends on the relative contribution of positive feedback and lateral inhibition. (These cortical functions, mediated by a highly focused positive feedback associated with widespread lateral inhibition, are referred to as *egocentric selection.*) (4) Lateral inhibition spreads only in a given cortical functional area. (5) The effect of egocentric selection is larger on thalamic neurons than on collicular neurons, and is larger on the facilitative responses of combination-sensitive neurons than on the excitatory responses of neurons primarily responding to single tones. (6) Without egocentric selection, the auditory responses of subcortical neurons are significantly weaker than normal. (7) Egocentric selection evoked overrepresentation of a particular value of an acoustic parameter and underrepresentation of adjacent values. In other words, it increases the contrast in neural representation of acoustic signals. (8) Short tone bursts at moderate intensity delivered for 30 minutes can evoke a change (overrepresentation of these tone bursts) in the IC, MGB, and AC. (9) The change becomes larger when the tone bursts become behaviorally relevant. (10) Egocentric selection plays a role in self-organizing the central auditory system according to auditory experiences.

Both the cortical cochleotopic and computational maps are the result not only of divergent and convergent projections in the ascending auditory system, but also of corticofugal feedback. For echolocation, these maps and response properties of central auditory neurons are continuously adjusted and improved by corticofugal feedback according to auditory experience.

# EEG and MEG Analysis

*Fernando H. Lopes da Silva and Jan Pieter Pijn*

## Introduction

The electroencephalogram, or EEG, consists of the electrical activity of relatively large neuronal populations that can be recorded from the scalp. Along with the EEG, the magnetic fields generated by these populations can also be recorded as the magnetoencephalogram or MEG using very sensitive transducers. In this article we discuss these two types of activity jointly, since the same methods of analysis apply to both.

Over the course of time, EEG and MEG have became valuable tools in the diagnosis of functional brain disorders, and indispensable in sleep and epilepsy research. The related study of Event-Related Potentials (q.v.) became essential for studies of brain function in neurology and pathopsychology. This research field received a strong impetus with the development of whole-head MEG systems, since the latter produce data that are less ambiguous in their interpretation. In contrast to EEG, MEG does not need a reference point, and MEG data are more readily modeled in terms of localization of brain sources. These sources of EEG and MEG reflect the dynamics of populations of neurons that have the capacity to work in synchrony. Current understanding emphasizes that synchronous activity in neuronal populations is coupled to the emergence of "local field potentials" (LFPs), which may display oscillations over a wide range of frequencies (Salinas and Sejnowski, 2001).

In general, the same brain sources account for EEG and MEG, with the reservation that the orientation of the active neuronal populations with respect to the cortical surface affects these two modalities differently. MEG signals reflect magnetic fields perpendicular to the skull that are caused by tangential current dipolar fields, whereas EEG signals reflect both radial and tangential fields. This property can be used advantageously to disentangle radial sources lying in the convexity of cortical gyri from tangential sources lying in the sulci.

Over the past few decades, the tools available for functional studies of the brain have been enriched with brain imaging modalities that measure changes in hemodynamics and/or in brain metabolism (e.g., positron emission tomography [PET], functional magnetic resonance imaging [fMRI]). Although these imaging methods have a higher spatial resolution than EEG or MEG, the former have an insurmountable time resolution problem. By contrast, EEG and MEG signals can follow the dynamics of brain activities on a time scale of milliseconds, which corresponds well to the time span for cognitive processing.

A constant preoccupation of EEG research has been to develop techniques to extract information from EEG/MEG signals, recorded at the scalp, that may be relevant for the study of brain functional states and disorders. To this end, a large number of quantitative analytic methods applicable to EEG/MEG have been developed. In general, one can analyze EEG/MEG in time, in space, or both together (spatiotemporal analysis). Recently, the mathematical theory of dynamical nonlinear systems has started to influence the field of brain sciences, in particular by providing a framework that can lead to a better understanding of the dynamics of EEG/MEG signals in relation to brain functions.

In this article we briefly discuss the main aspects of EEG/MEG analysis, considering first, EEG/MEG as a spatiotemporal time series, second, EEG/MEG in terms of the corresponding brain sources, and third, EEG/MEG as a signal that provides information about the state of complex neuronal networks considered as nonlinear dynamical systems (reviewed in Nunez, 1995).

## Analysis of EEG/MEG Signals as Spatiotemporal Signals

EEG/MEG signals are complex *spatiotemporal signals*, the statistical properties of which depend on the state of the subject and on external factors. Even when the subject's behavioral state is almost constant, the duration of epochs that have the same statistical properties (i.e., that are *stationary*) is limited. Therefore, EEG/MEG signals present essential *nonstationary* properties. According to the interest of the researcher, emphasis may be placed on analysis of EEG/MEG signals during steady states or on the detection and characterization of transients, such as the paroxysmal patterns that commonly occur in epileptic patients, or alterations of the basic rhythmic activity that occur during changes of the state of alertness (Figure 1). A special type of EEG/MEG transients is formed by event-related, or event-evoked, potentials (see Event-Related Potentials).

In an analysis of ongoing EEG/MEG activity, it is customary to subdivide EEG/MEG signals into quasi-stationary epochs and to characterize them by a number of statistical parameters, such as probability distributions, correlation functions and frequency, or power spectra. EEG/MEG time series often present a certain degree of *interdependence. Correlation functions* have commonly been used to analyze this property. Here we must distinguish two main questions: the determination of whether within one EEG/MEG signal, a dependency between successive time samples exists, such as in the case of brain rhythmic activity, and the determination of the degree of relationship between two or more EEG/MEG signals. The former can be approached by computing the time average of the product of the signal and a replica of itself shifted by a given time interval—i.e., the *autocorrelation function* (for a more extensive and formal description, see Lopes da Silva, 1999). An important property of the autocorrelation function is that its Fourier transform is the power density spectrum, or simply the *power spectrum*. It gives the distribution of the (squared) amplitude of different frequency components. In general, power spectra represent steady-state variables, but there are also interesting applications to dynamic changes that may reveal how neuronal processes are correlated with specific behaviors. In the latter case, changes in ongoing EEG/MEG activity within given frequency bands, induced by some event (e.g., a sensory stimulus, a cognitive task, or a movement), can be adduced in evidence. Such changes may be characterized by a reduction in EEG/MEG power within a frequency band, usually called event-related desynchronization (ERD), or, in the opposite case, by an increase in power, or event-related synchronization (ERS) (Pfurtscheller and Lopes da Silva, 1999). This form of analysis has been applied to the assessment of cortical areas involved in different behaviors, with interesting results. An example is the planning of specific movements (Figure 2). This example shows that in preparation for a finger movement, the rhythmic activity at 10–12 Hz (i.e., the mu rhythm of the central region) desynchronizes, while a burst of gamma (36–40 Hz) oscillations emerges. The former reflects the focused arousal preparation of the movement, while the latter corresponds to the increase in coupling between clusters of neurons, oscillating within the gamma frequency range, that likely mediates the coordination of the movement. This may be the LFP that corresponds to the neuronal population vector encoding for particular finger movements (Georgopoulos et al., 1999). The postmovement ERS in the beta frequency range probably reflects a reset phenomenon of the dynamical state of the cortical networks engaged in this behavior.

The degree of relationship between two EEG/MEG signals can be estimated using the *cross-correlation function*. Similar to autocorrelation, cross-correlation is the time average of the product of two signals as a function of the time delay between both. The Fourier transform of this function yields the *cross-power spectrum*. The latter is a complex quantity that has magnitude and phase. To quantify the degree of relationship between pairs of EEG/MEG signals as a function of frequency, the magnitude of the cross-power spectrum is usually normalized by dividing it by the value of the autospectra at that frequency of the corresponding signals. This yields a normalized quantity called the *coherence function*. Coherence functions can be used to estimate the degree of the relationship, in the frequency domain, between pairs of EEG/MEG signals.

The counterpart of the coherence function is the *phase function*, which provides information about the time relationship between two signals as a function of frequency. The computation of phase functions has been used to estimate time delays between EEG/MEG signals, in order to obtain evidence for the propagation of EEG/MEG signals in the brain.

As indicated earlier, the correlated activity in neuronal populations (which may display oscillations over a wide range of fre-

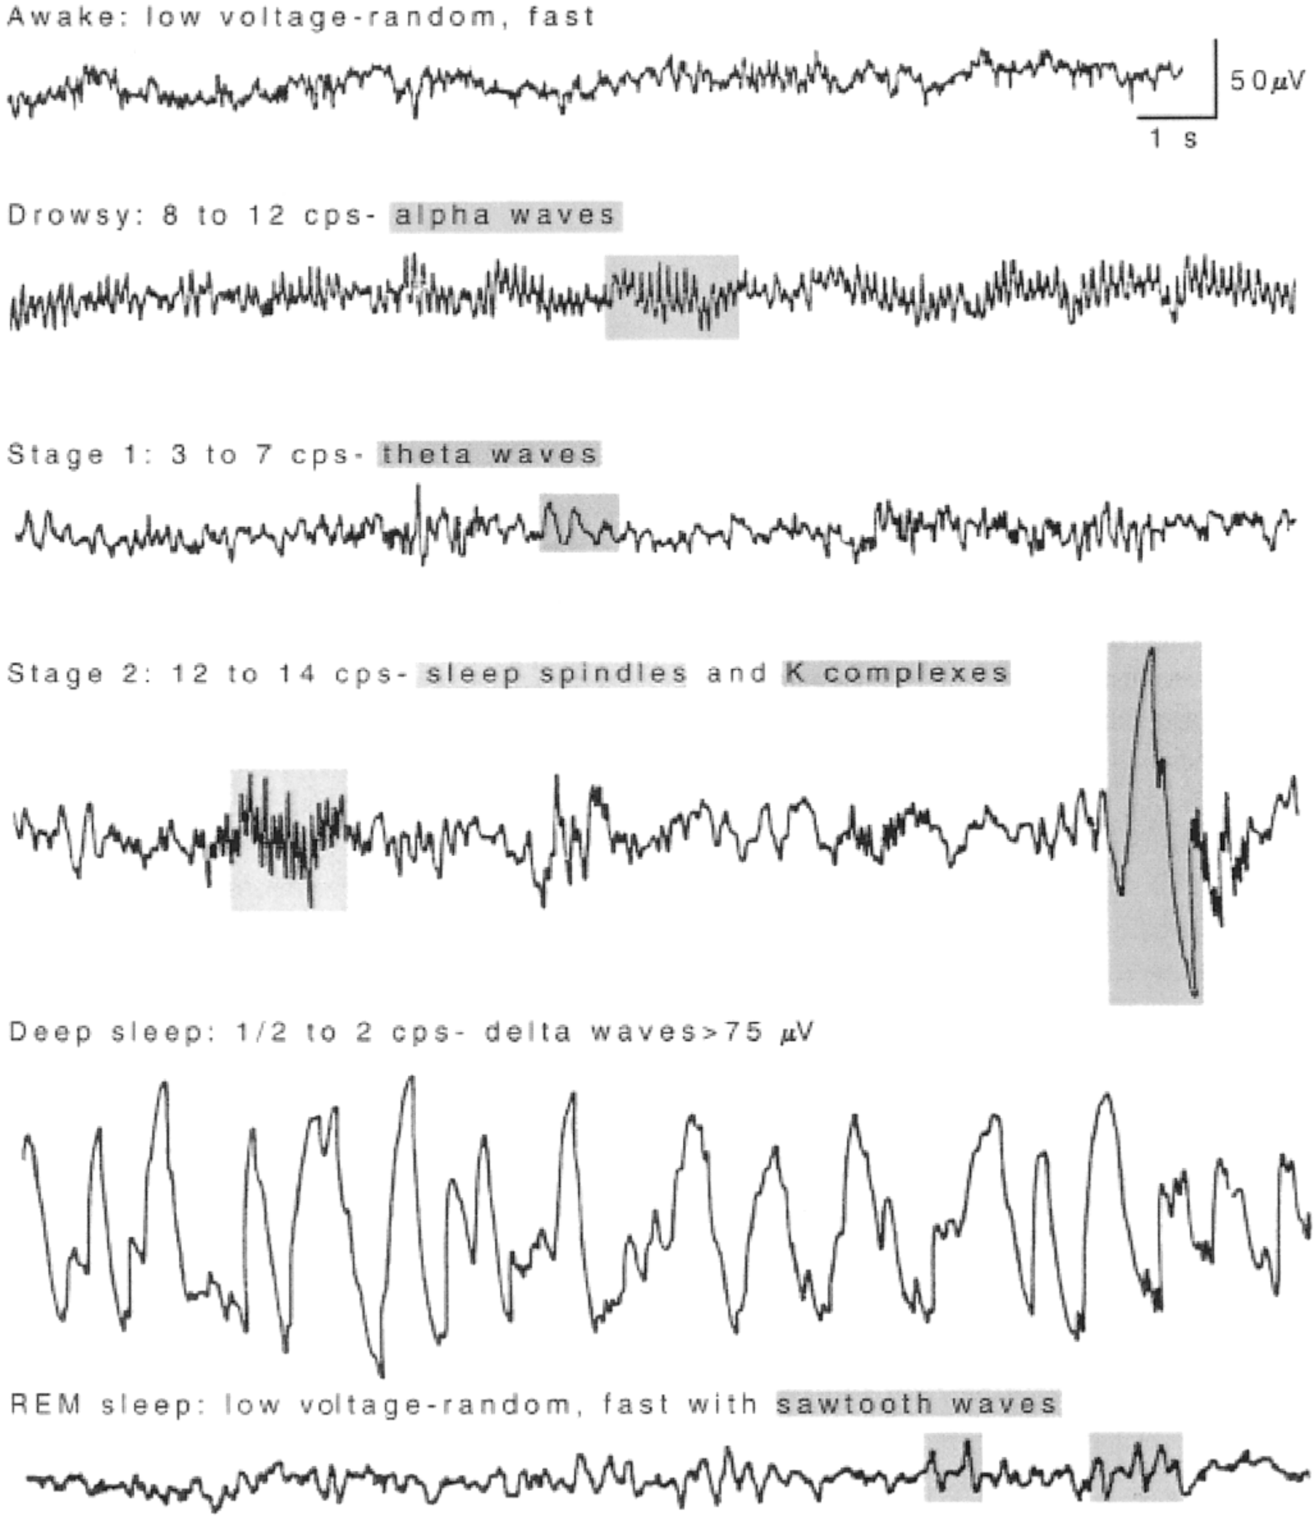

**Figure 1.** EEG/MEGs recorded during different behavioral stages: awake, drowsy, and sleep stages from superficial sleep (stages 1 and 2) to deep or slow-wave sleep. The last trace shows the EEG during rapid-eye-movement sleep (REM). Note that the awake state is characterized by a mixed pattern, dominated by low-voltage, fast-amplitude (beta/gamma) activities. In the relaxed, drowsy state with the eyes closed, the trace is dominated by oscillations within the alpha frequency range (8–12 Hz). As the subject falls asleep, systematic changes occur: deepening of drowsiness is associated with an increase in slow activitiy, with occasional bursts of 3–7 Hz (theta) waves (shaded area). As sleep deepens, sleep spindles, i.e., bursts of 11 or 12–14 Hz oscillations, and K-complexes (shaded areas), which are evoked responses to afferent stimuli, are the dominant features. During REM sleep the EEG is difficult to distinguish from that of the awake state: it is characterized by low-voltage polyrhythmic activity with occasional "sawtoothed waves" in the 2–6 Hz range (shaded area) that may ocur in conjunction with ocular movements (Modified with permission from Zigmond et al., *Fundamental Neuroscience*, San Diego: Academic Press, 1999.)

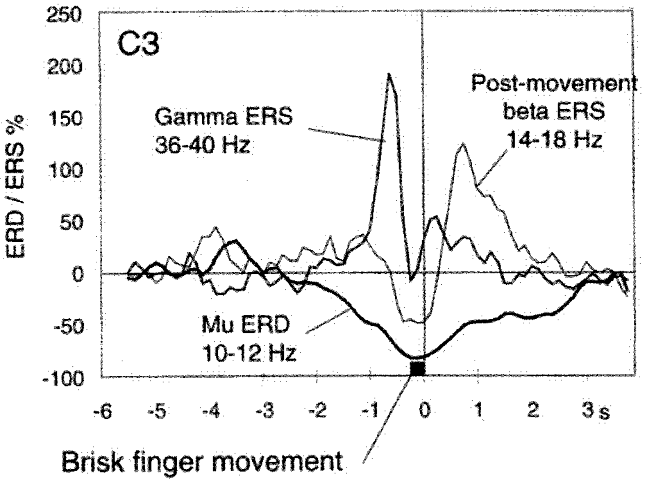

**Figure 2.** Running power spectra computed for three frequency bands of an EEG recording from electrode site C3, referenced to the left mastoid, and covering the rolandic cortical area, during a brisk right index finger movement. The latter lasted about 240 ms (black bar). The analysis is triggered with respect to movement offset and shows the average of 40 trials. ERD means event-related desynchronization: it consists of a significant power decrease with respect to baseline: ERS indicates the inverse: increase of power or of synchrony. Note that the rhythm in the alpha frequency range (10–12 Hz), called the mu rhythm of the central region, displays ERD starting about 2 s before the movement, while a burst of ERS of gamma frequency components (35–40 Hz) reaches a maximum just before the movement. After movement offset, a rebound ERS in the beta range (14–18 Hz) appears. (Modified with permission from Pfurtscheller, G., and Lopes da Silva, F. H., 1999, Event-related EEG/EMG synchronization and desynchronization: Basic principles, *Clin. Neurophysiol.*, 110:1842–1857.)

quencies as revealed in the EEG and MEG) forms the substrate for a variety of brain functions and associated cognitive processes. Namely transient periods of phase synchrony of oscillating neuronal discharges, particularly in the frequency range of 30–80 Hz (gamma oscillations), appear to act as an integrative mechanism that brings a widely distributed set of neurons together into a coherent ensemble that underlies a cognitive process or the preparation of a movement, as shown in the example of Figure 2. This implies that mechanisms of synchronization at various levels of brain organization, from individual pairs of neurons to LFPs to the much larger scale of EEG and MEG signals recorded from the scalp, are necessary for the coordination of neural activities distributed over distinct brain areas (Varela et al., 2001). Because phase synchrony in EEG/MEG signals must be detected and measured in order to investigate neurocognitive processes, ways of measuring synchrony are of increasing interest. This has led to the development of analytical tools that allow the phase component to be obtained separately from the amplitude component for a given frequency range (Le Van Quyen et al., 2001). With this methodology it was shown, for example, that the scalp EEG/MEG of subjects performing the perceptive task of recognizing human faces induces a long-distance pattern of phase synchronization that represents active coupling of the underlying neural populations. This coupling appears to be necessary for the realization of this cognitive task (Rodriguez et al., 1999).

## Estimation of Brain Sources from Scalp EEG/MEG Recordings

A most fundamental aspect of EEG/MEG analysis is to be able to estimate from multiple scalp EEG/MEG recordings the distribution of the corresponding sources within the brain. This implies solving the so-called *inverse problem* of volume conduction theory, i.e., determining the location within the brain tissue of the sources of electrical activity, taking into consideration the properties of both the brain and the conductive media surrounding the brain. This problem has no unique solution: it is not possible to determine a unique current source distribution in a volume conductor from measurements taken at the conductor surface. However, it is possible to solve this problem by putting constraints on the current source distributions, i.e., by defining a specific model of the source. A commonly assumed source model is the equivalent current dipole that represents an active patch of cortex. Therefore, two models are required, one of the source and another one of the volume conductor. Of course, it is necessary to have a sufficient number of measurement points at the scalp in order to obtain a satisfactory solution.

We consider, briefly, the main problems posed by the source and the volume conductor models. The problem of estimating the source is a nonlinear problem that has to be solved iteratively. De Munck (1990) has proposed a general approach that takes into account both the time functions of the activity of the sources and the corresponding spatial properties (positions and orientations). Regarding the volume conductor models, the most commonly used model is a set of concentric spheres that represent, from inside to outside, the brain, the cerebrospinal fluid (in some cases), the skull, and the scalp. However, the head deviates appreciably from a sphere. With the increasing availability of MRI, it is now possible to reconstruct the different head compartments in a more realistic way. This is important, since several simulation studies have shown that deviations from a realistic shape of the head can significantly influence the magnetic fields and the potential distributions (Hämäläinen et al., 1993).

In most applications of EEG/MEG spatial analysis, either in neurology or in psychophysiology, one does not attempt an estimation of the brain sources using the inverse approach, because of the inherent difficulties of this method and the uncertainties of the estimated localizations. Most researchers are satisfied with representing the sets of multiple EEG/MEG signals projected as a map at the surface of the scalp. This is called electric or magnetic *brain mapping*.

## EEG/MEG Signals as Expressions of Dynamical Nonlinear Systems

An overview of the basic concepts of nonlinear dynamics can be found in Chaos in Neural Systems. Here we briefly state that EEG/MEG signals may correspond to multiple kinds of dynamical states that are characterized by the corresponding attractors, depending on the network's parameters and input conditions. Thus, bifurcations between different modes of dynamics of the same network can take place. This nonlinear dynamical behavior can account for the fact that an epileptic seizure, with a typical paroxysmal EEG/MEG pattern, can emerge suddenly from an apparently normal state characterized by resting EEG/MEG activity.

Quantitative measures for identifying complex nonlinear dynamics have been applied to several kinds of EEG/MEG signals. The *correlation dimension* ($D_2$) (Grassberger and Procaccia, 1983) has been the most widely used. To interpret estimates of $D_2$, it is important to use *surrogate* signals (controls) obtained by randomizing the phase of the original EEG/MEG signals. The latter should yield a large $D_2$ value, since the transformed signal is not distinguishable from Gaussian noise (Theiler, 1990; Pijn et al., 1991). In most cases of ongoing EEG/MEGs, including those recorded during sleep, the difference between the real signals and the surrogate signals is very small, such that the hypothesis that the EEG/MEG signals are generated by a deterministic chaotic process cannot be supported in these cases. However, in the case of EEG/MEG signals recorded during epileptic seizures, the value of $D_2$ was shown to be much smaller than that of the corresponding surrogate signals. This finding led several groups to explore whether this kind of methodology could be used to unravel changes in EEG/MEG dynamics that may take place *before* an epileptic seizure becomes manifest (Elger and Lehnertz, 1998; Martinerie et al., 1998). Similar results were also obtained from the spatiotemporal evolution of other nonlinear parameters (reviewed by Lehnertz et al., 2001). Taken together, these results indicate that the dynamical properties of the interictal, preictal, ictal, and postictal states are clearly different and have different attractors. This opens the exciting possibility of using these nonlinear analysis methods to predict the occurrence of impending epileptic seizures in clinical practice, and of possibly avoiding their occurrence.

In conclusion, EEG/MEG recordings are complex signals that may provide valuable information about the underlying brain systems, since they have unsurpassed resolution in time, although their spatial resolution is rather limited. Therefore, mapping cortical activity using EEG/MEG signals combined with realistic models of the brain, extracted from MRI scans, may yield new possibilities for functional imaging of dynamical brain states.

# Electrolocation

*Joseph Bastian*

## Introduction

The electrosensory systems of weakly electric fishes are widely recognized as attractive model systems for studies of the neural bases of behavior. These animals are specialists, relying heavily on information acquired via this unique sensory system, and the importance of electroreception in the animals' life history is reflected in the hypertrophy of brain regions devoted to processing electrosensory information. Animals with active electrosensory systems generate an electric field around their body by means of an electric organ located in the trunk and tail, and measure this field via electroreceptors embedded in the skin. Distortions of the electric field due to animate or inanimate targets in the environment or signals generated by other fishes provide inputs to the system, and several distinct behaviors can be linked to simple patterns of electrosensory input. The ease with which behaviorally relevant stimuli can be identified and simulated, and the wealth of background anatomical and physiological information, are major advantages to studying this system.

Since publication of the first edition of the *Handbook*, advances have been made in understanding the electric organ discharge field of weakly electric fishes and its interaction with targets in the environment (Assad, Rasnow, and Stoddard, 1999). Studies of feeding behavior revealed the motor strategies used during prey capture and have determined detection limits for the system (Nelson and MacIver, 1999). A novel algorithm for determining fish-target distance (depth perception), using information acquired from a single two-dimensional (2D) receptor array, has also been discovered (von der Emde, 1999). Properties of the epidermal electroreceptors have been further defined; numerical models that accurately predict their responses are now available (Nelson, Xu, and Payne, 1997), and analyses of their information-encoding capabilities (see Rate Coding and Signal Processing) have been completed (Wessel, Koch, and Gabbiani, 1996; Gabbiani and Metzner, 1999). Studies of the primary electrosensory processing region, the electrosensory lateral line lobe (ELL), have revealed how the interaction between ascending sensory information and that descending from higher centers contributes to gain control, receptive field organization, and attentional mechanisms (Berman and Maler, 1999). In addition, these descending inputs participate in an adaptive filtering mechanism, enabling the system to reject predictable patterns of input while preserving sensitivity to novel stimuli (Bastian, 1999; Bell et al., 1997, 1999; Bodznick, Montgomery, and Carey, 1999).

This review focuses on recent progress made in understanding electrolocation behavior, and on the neural implementation of an adaptive filter that attenuates electrosensory stimuli resulting from the fish's own movements. Movement-caused signals can exceed those caused by small prey by more than two orders of magnitude; hence, without a reduction in this "noise," the animal may be unable to detect food efficiently. Reviews of recent progress made in areas ranging from electric fish taxonomy and behavior through the physiology and molecular biology of important neural circuits can be found in Turner, Maler, and Burrows (1999).

## Overview of Electroreception

Figure 1*A* illustrates a South American electric fish, *Apteronotus leptorhynchus. Apteronotus* produces a quasi-sinusoidal electric organ discharge, or EOD, that ranges in frequency from about 600 to 1,000 Hz, depending on the individual. The bold arrows in Figure 1*A* show the pattern of current flow due to the EOD, which results in a pattern of transdermal potential changes. Electroreceptors specialized to measure the amplitude and timing of this potential are found at high densities within the skin. Objects in the environment having an impedance different from that of the water distort the pattern of EOD current, resulting in a localized change in the transdermal potential or electric image. As the animal moves relative to an object, an EOD amplitude modulation (EOD AM) is produced that is encoded as a change in the firing pattern of electroreceptor afferents (Figure 1*B*). The electroreceptor afferents convey this information to the first processing region in the brain, the ELL. The pyramidal cells (Figure 1*C*) are the principal efferent neurons of the ELL; they receive massive descending or feedback inputs as well as receptor afferent input. Insofar as many of the higher-order neurons providing these feedback signals receive inputs from the pyramidal cells themselves, the ELL is positioned within an electrosensory processing loop, with the result that the functional characteristics of the pyramidal cells are subject to continuous feedback control.

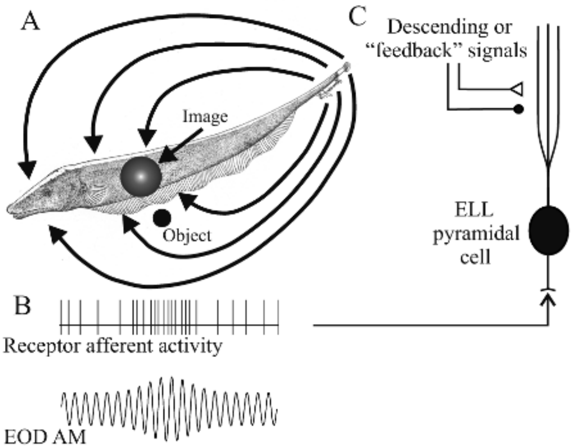

**Figure 1.** *A*, Pattern of current flow due to the electric organ discharge in *Apteronotus leptorhynchus*. The circle labeled "image" illustrates the pattern of electric organ discharge amplitude modulation (EOD AM) at the animal's body surface as a result of the presence of an object near the fish. *B*, The pattern of EOD AM expected to occur as the animal moves relative to the object, and the resulting change in electroreceptor afferent activity. *C*, Electrosensory lateral line lobe (ELL) pyramidal cell. These "principal cells" of the first-order central electrosensory processing station receive receptor afferent inputs along with feedback signals from higher centers.

## Electric Field Measurements and Electrolocation Behavior

Most of the early studies of electrolocation focused on the physiological properties of the receptor afferents and ELL pyramidal cells. Of necessity, these physiological studies used immobilized animals and relatively simple stimulus patterns. Although such studies provided important descriptions of electrosensory system function under well-defined conditions, they were also limited. Natural stimulus patterns such as living prey were not used, and, more important, the animals were not able to engage in normal exploratory behaviors. Recently, high-resolution measurements of the EODs of several species have been completed, and techniques for accurate 3D modeling of the EOD field and various object-caused EOD distortions have become available. These advances have allowed accurate predictions to be made of the spatiotemporal patterns of electrosensory input that occur as a fish encounters targets in its environment. Such studies have also suggested sensory processing algorithms that the animals might use to accomplish critical tasks (Rasnow, 1996; Assad et al., 1999). For example, prey capture based on electrosensory cues requires that the 3D location of the prey relative to the fish be determined. Because the prey or electrolocation target "casts" an electric image on the skin surface (see Figure 1*A*), the 2D position of a target relative to the animal's body surface can be determined from the pattern of activity over the 2D array of electroreceptors. However, estimation of the distance of an object lateral to the fish, or depth perception, is much more difficult. Unlike visual systems, in which depth information can be extracted from paired sensors that view the target from slightly different positions, electrosensory systems probably gauge distance using information from a single receptor array. The peak change in amplitude of the transdermal potential caused by a given object decreases rapidly with increasing lateral distance; hence, this cue could provide information related to target distance. However, the peak amplitude is also a function of object size, resulting in size-distance ambiguities: larger objects at greater distances can generate the same peak potential change as smaller objects closer to the fish. Empirical and modeling studies suggest that distance estimation could be achieved by simultaneous evaluation of multiple image characteristics. It was specifically proposed that measuring the *relative* dimensions of electrical images (e.g., the ratio of electric image width to its peak amplitude) would allow unambiguous distance determination (Rasnow, 1996; Assad et al., 1999).

A series of elegant behavioral experiments demonstrated that another weakly electric fish, *Gnathonemus petersii*, does determine electrolocation target distance using information received over a single 2D receptor array by simultaneously evaluating two electric image characteristics (von der Emde, 1999). Fish were trained to swim through one of two openings in a partition dividing an experimental tank contingent on the relative distances of electrolocation targets positioned behind the openings. Fishes had to choose the opening associated with the object further inside the partition. Not only could the fishes accurately determine the relative distances to identical objects, but, once trained, they could generalize, correctly discriminating relative distance even when objects of different sizes were presented. However, for this species, the maximum slope of the electrical image's spatial profile in combination with peak image amplitude was found to be the best combination of parameters. Von der Emde also found that, at a given distance, spherical objects always produced significantly smaller slopes relative to amplitude than did cubes of the same size. This observation led to the prediction that the animals could be fooled and should misjudge distances when spheres and cubes were compared. This prediction was fulfilled, and the fishes interpreted spherical objects as being farther away than cubes, even when the spheres were as much as 1.5 cm closer to the animal. Such responses to the predicted illusory position of spheres provide compelling evidence in support of the proposed mechanism for distance determination. Furthermore, identification of the sensory processing algorithm used for a given perceptual task provides physiologists with important clues that should greatly facilitate the search for neural correlates of this behavior.

Although it has long been assumed that weakly electric fishes rely heavily on the electrosensory system for prey capture, detailed descriptions of feeding behavior have only recently appeared. Nelson and MacIver (1999) used a video tracking and reconstruction technique to analyze the behavior of two related fishes, *Apteronotus albifrons* and *A. leptorhynchus*, as they fed on small aquatic crustaceans. Stereotyped changes in swimming direction and velocity were found to be associated with prey detection, and, based on the timing of these behavioral landmarks, prey distance at the time of detection was determined. Additionally, given the relationships between electrolocation target size and distance from a fish and the resulting electric image characteristics provided by Rasnow (1996), Nelson and MacIver reconstructed the temporal sequence of electrical images experienced by the fish during prey capture. Finally, given the sequence of electric images as input to a numerical model of electroreceptor afferent responsiveness, Nelson and MacIver arrived at predictions of the spatiotemporal patterns of electroreceptor afferent activity during prey capture. At a typical detection distance of 1 cm, the fishes would experience a peak electric image amplitude of approximately 3 $\mu$V, or about 0.3% of the transdermal potential. This translates into a change in receptor afferent firing of about 2.5%, or 7 spikes/s. More recent results also showed that maximum detection distance is dependent on water conductivity, which lends additional support to the idea that the animal's behavior is guided by electrosensory information instead of other cues, such as water turbulence caused by the prey (MacIver, Sharabash, and Nelson, 2001).

These fishes also often change posture during swimming and prey capture; the body is frequently bent into an arc-like posture like that shown in Figure 2. Because the electric organ is located in the trunk and tail, such changes in posture result in large transdermal potential modulations that cause changes in electroreceptor afferent activity 10- to 100-fold greater than changes due to a small prey. These large electrosensory signals resulting from locomotor activity are obviously problematic; they could easily mask small signals due to the presence of prey. However, an adaptive filter operating at the level of the ELL removes the predictable signals related to locomotion while preserving sensitivity to novel signals such as those generated by prey.

## Adaptive Plasticity in the Electrosensory Systems

Movements of the trunk and tail of *A. leptorhynchus* through an arc of less than ±20 degrees, which mimic changes in posture that commonly occur during swimming, cause transdermal potential changes in excess of 100 $\mu$V. It has long been recognized that mechanisms must exist that enable the animals to differentiate between such movement-related or reafferent inputs and prey-related signals. Studies in several lower vertebrate species have identified a general mechanism by which reafferent or other predictable and potentially disruptive stimulus patterns can be canceled without compromising sensitivity to relevant stimuli. Importantly, this cancellation process is adaptive; that is, the network mediating the cancellation learns, enabling the system to filter out reafferent inputs that change or evolve over time.

The operation of the ELL pyramidal cell filter is shown diagrammatically in Figure 2. During electrolocation, the fishes often make bending movements of the trunk and tail as they approach and orient to targets (Figure 2*A*). Consequently, the input to the receptor afferents consists of predictable, often cyclical EOD AMs due to changes in posture as well as unpredictable AMs due to the object. This AM pattern, shown by the lowest waveform in Figure 2*B*, leads to modulation of receptor afferent firing, with the possibility that responses to the cyclical postural changes mask responses to the object. The pattern of receptor afferent synaptic input received by the pyramidal cell is illustrated by the lower waveform, labeled *R.A. psps*. Descending electrosensory, proprioceptive, and corollary discharges of motor commands are received at the pyramidal cell's apical dendrites, and this constellation of excitatory and inhibitory inputs provides a signal that is approximately the inverse of the expected or predictable component of the receptor afferent input. Pyramidal cells sum this negative image input, *N.I. psps*, with the *R.A. psps*, canceling the predictable component of the afference while preserving sensitivity to the unpredictable stimulus (Figure 2*B**).

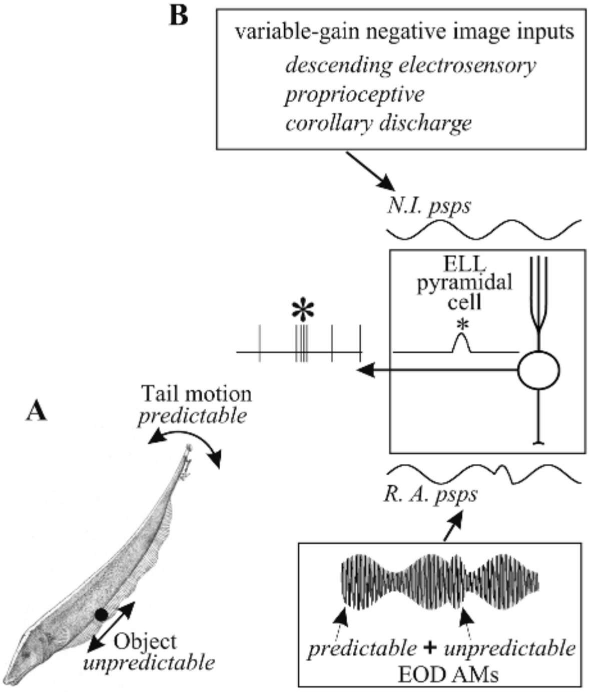

**Figure 2.** Adaptive filtering by ELL pyramidal cells. *A*, Changes in the fish's posture result in reafferent patterns of afferent input that are *predictable* and can be differentiated from *unpredictable* inputs due to the presence of an object. *B*, ELL pyramidal cells integrate receptor afferent psps (*R.A. psps*) with negative image inputs (*N.I. psps*), with the result that predictable afferent inputs are attenuated while unpredictable inputs are encoded without interference (*).

Very similar mechanisms have been described for four different groups of fishes; elasmobranches, mormyrid weakly electric fish, gymnotid weakly electric fish, and a nonelectric teleost (Bastian, 1999; Bell et al., 1997, 1999; Bodznick et al., 1999). In all cases the neural networks underlying the process are components of the octavolateral system; they process either electroreceptor or normal lateral line inputs and have a cerebellum-like organization. In each case a population of principal cells (e.g., the gymnotid ELL pyramidal cells) receives receptor afferent inputs as well as inputs from large numbers of cerebellar-like parallel fibers. The parallel fibers provide the predictive or negative image inputs. The adaptive characteristic of the cancellation is due to an anti-Hebbian form of synaptic plasticity (see Hebbian Synaptic Plasticity) at the parallel fiber to principal cell synapse, and a simple set of learning rules can account for the circuit's behavior (reviewed in Bodznick et al., 1999). First, coincident activity of parallel fibers and principal cells leads to a reduction in the strength of active excitatory dendritic synapses. Second, parallel fiber inputs active at times when the postsynaptic cell is inactive lead to increased excitatory synaptic strength. These rules are anti-Hebbian: rather than coincident pre- and postsynaptic activity leading to increased synaptic strength, the opposite occurs. Although these two rules governing plasticity at excitatory synapses are sufficient to account for the adjustment of negative image inputs as described in Figure 2, it is very likely that the strength of inhibitory synapses can also be adjusted, and a complementary pair of rules should govern inhibitory plasticity (Bodznick et al., 1999).

Parallel studies of the cancellation mechanism in these different species have verified that plasticity is associated with parallel fiber to apical dendritic synapses (reviewed in Bastian, 1999; Bell et al., 1999; Bodznick et al., 1999). The plasticity can be blocked by glutamate antagonists applied at these synapses, and it can be evoked by pairing direct electrical stimulation of the parallel fibers with depolarization of the principal cells via intracellular current injection. The depression of excitatory synaptic strength that results is similar to the long-term depression (see Cerebellum: Neural Plasticity) that occurs at cerebellar parallel fiber to Purkinje cell synapses. As in the cerebellum, the depression requires a postsynaptic $Ca^{2+}$ influx; however, unlike in the cerebellum, the depression can be blocked by NMDA receptor antagonists, suggesting that the $Ca^{2+}$ influx may occur via activation of these channels (see NMDA Receptors: Synaptic, Cellular, and Network Models). Second-messenger systems operating within the ELL pyramidal cells have also been implicated, and it has been suggested that protein kinase A (PKA) and $Ca^{2+}$/calmodulin-dependent kinase (CaMK2$\beta$) may be involved in pre- and postsynaptic mechanisms underlying the anti-Hebbian plasticity (see Berman and Maler, 1999). Most recently, Han, Grant, and Bell (2000), using an in vitro preparation of the mormyrid ELL, demonstrated that the anti-Hebbian depression at excitatory synapses occurs at the same locus as a nonassociative potentiation. Having both depression and potentiation operative at the same locus has long been recognized as critical to ensuring true reversibility of plastic changes and preventing saturation of potentiation or depression mechanisms. This is the first demonstration of potentiation and depression occurring at the same locus in a cerebellum-like structure.

## Discussion

Although electrosensory organisms are highly specialized, they face the same problems and constraints as most other animals do. They must find prey, avoid predators, communicate with conspecifics, and reproduce. Although many of these critical behaviors rely heavily on information acquired via this single sensory system, the properties of the neural circuits involved are likely to reflect general principles operating in many other systems. For example, a widespread but poorly understood characteristic of sensory processing circuits is the presence of massive descending or feedback connections by which higher centers presumably modulate the operation of lower centers. Studies of the ELL of these fishes have shown not only that fundamental properties such as response gain and receptive field organization are controlled by these descending connections, but also that elegant adaptive filtering mechanisms exist that enable the rejection of stimuli that otherwise might mask critical functions. Understanding the cellular mechanisms underlying the synaptic plasticity that forms the basis for this filter should contribute to our understanding of closely related neural circuits such as those found in the cochlear nuclei and the cerebellum. In addition, defining general principles of operation, such as the use of stored sensory expectations for the cancellation or perhaps the identification of specific input patterns, may lead to increased understanding of more diverse neural circuits.

# Embodied Cognition

*Olaf Sporns*

## Introduction

The central tenet of embodied cognition is that cognitive processes emerge from the interactions between neural, bodily, and environmental factors (Varela, Thompson, and Rosch, 1991). Brain, body, and environment are seen as reciprocally and dynamically coupled, with neural and behavioral processes exerting specific effects across the boundaries of brain and body and over different time scales. Clark (1997) has called this complex interplay "continuous reciprocal causation," the coupling of distinct subsystems leading to the emergence of qualitatively new structures. Embodied cognition places strong emphasis on perception-action loops, in which internal and external processes are intricately and cyclically interwoven. The distributed nature of neural, bodily, and environmental interactions has led many authors to deemphasize or, in radical formulations, even abandon some fundamental concepts of cognitive science such as internal representations and the computational nature of mind. They claim that embodied systems generate their cognitive power through real-world interaction, not by manipulating an internal world model, organized in a predominantly sequential (sense-think-act) processing scheme. Whether all internal models (symbolic or neurally based) should be abandoned is a matter of much debate. More balanced theories of embodied cognition would place emphasis on the dynamic coupling between brain and body while allowing for the existence and use of internal models in motor control, planning, and linguistic and symbolic behavior.

Not only has embodied cognition sparked much philosophical and foundational discussion within cognitive science, it has also inspired numerous attempts to build embodied systems as working models of cognitive processes. This article briefly examines embodied models that focus on real-time perception-action coupling, developmental processes, the role of sensorimotor activity in category formation, and value systems. Before we discuss examples of embodied models, we briefly examine some of the underlying design principles.

## Design Principles of Embodied Models

While embodied cognitive models show great diversity across different task domains and physical instantiations, most of them fall into distinct classes using different sets of design principles. Roughly, these classes comprise connectionist, dynamic, and neurocomputational (synthetic) models.

Most formal symbolic models rely heavily on computation and representation and do not address neural implementations, learning mechanisms, or the coupling between brain and body. Not surprisingly, embodied cognition eschews such models as appropriate means for implementation. Connectionist models seem more appropriate because they attempt to embed cognitive processes in a neural context. Typical connectionist architectures operate by converting encoded inputs into outputs via intermediate layers, with an emphasis on learning as the search for optimal configurations of synaptic weights. At first glance, however, some basic design principles of connectionist networks appear inconsistent with the philosophy of embodied cognition. Connectionist models employ internal representations in the form of distributed activity patterns that encode higher-order statistical properties of inputs. Motor action is usually not an explicit part of the model and thus rarely contributes to the generation or selection of input patterns. Learning is limited to the optimization of synaptic weights and does not include active exploration or real-world interaction. Although these design principles apply to many classical connectionist architectures (consisting of three layers with hidden units and backpropagation), a number of connectionist approaches have evolved that aim at constructing internal models while taking interactions with the real world into account (see Sensorimotor Learning). In addition, numerous connectionist models make explicit reference to neural architectures and dynamics and employ realistic rules of synaptic change. Such neurocomputational models can be embedded in behaving autonomous systems and yield interesting behavior.

A distinct class of models of embodied cognition is based on concepts of dynamical systems theory (Thelen and Smith, 1994; Kelso, 1995). Here the emphasis is less on the mechanistic implementation of neural structures and more on the interplay between the internal dynamics of the agent and the external dynamics of the body and environment. Some central concepts of dynamical systems theory are those of *attractor* and *phase space*. Any point in phase space corresponds to a particular set of values of the system's state variables (which form the dimensions of the space). Over time, the system goes through a trajectory within this phase space, a set of points that are occupied as time progresses. The temporal evolution of the system's trajectory is described by a set of dynamic equations (usually nonlinear differential equations). An attractor is that portion of the state space that the system's trajectory converges upon over time; attractors can be points (stable steady state), limit cycles (periodic states), quasi-periodic, or chaotic. When this formal approach is applied to modeling embodied cognition, cognitive processes (perceiving, planning, deciding, remembering) are described using the language and tools of dynamical systems theory. This has the advantage of unifying the formal treatment of internal and external processes within a common (dynamical) framework. The basic building blocks of dynamical embodied models are state variables, realized as spatially continuous activation fields and usually defined in a behavioral or task-dependent context (e.g., "movement planning field," "decision field"). The temporal evolution of these fields is governed by sets of dynamical equations that ultimately determine behavior.

Another class of models attempts to create autonomous and embodied systems by synthetically assembling such systems from simple components. This approach, also called "synthetic modeling," incorporates explicit mechanisms at all levels and studies their emergent dynamic behavior (Edelman et al., 1992; Pfeifer and Scheier, 1999; Sporns, Almassy, and Edelman, 2000; see also Braitenberg, 1986). In synthetic models, the neural system is defined in terms of a specific physiology and anatomy. When combined with a matching body structure, this approach produces models that often closely resemble particular animal species; examples in the literature include robotic ants, bees, crickets, lobsters, frogs, and primates (see also Neuroethology, Computational). Real and simulated neural systems often attain specific (input- and state-dependent) dynamic states as a result of neuronal interactions. Thus, in synthetic models, large-scale dynamics are the emergent product of low-level components (neurons and connections) and their specific structural and functional properties (e.g., spike dynamics, neuronal morphology, excitatory and inhibitory effects, synaptic plasticity, and connectivity patterns). The synthetic approach allows us to use established principles of computational neuroscience and to relate results obtained with embodied models to the empirical findings of neurobiology. However, the computational expense of simulating realistic neural architectures still places serious limits on the size and complexity of such models, given that they must function in real time as part of a behaving creature.

The emphasis on body structure and environment as causal elements in the emergence of organized behavior requires their explicit inclusion in models of embodied cognition. Although some researchers use simulated environments, more often they use actual robots as physical analogues of real organisms. Robot sensors and effectors are interfaced with a computational model (a neural or dynamic simulation). The robot moves or acts within an environment, either an unconstrained real-world setting (office, lab) or an enclosure containing various kinds of objects. When designing embodied models, it is important to include the relevant physical, dynamic, and kinematic properties of the robot body (Beer et al., 1998), as well as to match the sensorimotor capabilities of the robot and the complexity of its task environment (the principle of "ecological balance"; Pfeifer and Scheier, 1999). Finally, embodied cognitive models must function without human intervention and without the use of supervised learning strategies. A truly autonomous system not only must be embodied, it should also be able to seek out and gather its own sensory inputs ("situatedness") and generate its own experiential and behavioral history. Autonomous systems may exist in a social context. A full account of their behavior and development should include their social interactions and socially mediated processes such as observational or imitation learning.

## Real-Time Coupling Between Brain and World

Embodied models of active vision and motor coordination show that several computationally hard problems of information extraction and control are more naturally addressed when the real-time coupling between neural and bodily structures is taken into account. Rather than relying on explicit internal representations or internal world models in computing appropriate outputs, such systems use "the world as its own model."

For example, for many years researchers in machine vision believed that the purpose of vision is to generate an accurate and comprehensive internal representation of the surrounding three-dimensional (3D) world by extracting information from 2D images. According to this view, given an image, the visual system computes a solution, and ultimately issues appropriate motor commands. Movement implements the outcome of perceptual decision making but does not participate in the perceptual process as a source or generator of useful information. About 10 years ago, several authors, among them Dana Ballard and Ruzena Bajcsy (see review in Clark, 1997), proposed an alternative strategy called active or animate vision. According to this approach, vision is best understood in the context of visual behaviors. Organisms use vision to guide motor action in real time, and motor action serves to seek out sources of perceptual information in the environment, for example by orienting sensory surfaces during gaze control. For example, visuomotor behaviors greatly facilitate efficient sampling of sensory environments by autonomous sensorimotor agents. Active vision simplifies several problems of standard machine vision, such as invariant recognition, by using sensorimotor strategies such as foveation to reduce variance across multiple views of the same object. In addition, visual agents can utilize and continually reference objects in the outside world during the generation of behavior instead of relying exclusively on internal models and representations to guide action. Active vision strategies provide only one set of examples of how agent-environment interactions can be exploited in perception; other examples include the use of haptic exploration strategies in active touch.

Another set of examples demonstrating how coupling to the real world can simplify classical control problems comes from embodied models of coordinated movement (see LOCOMOTION, INVERTEBRATE). Several researchers (e.g., Brooks, 1991; Beer et al., 1998) have studied locomotion in insect-like hexapod robots. In these models, walking and other behaviors were not preprogrammed or controlled by a central processor; rather coordination emerged from the interactions between individual leg dynamics, layered control architectures, and the physics of the real world. Real-time coupling to an environment has also been exploited in robotic models of swimming in fish and flying in insects.

## Motor Development and the Embodied Perspective

Many theories of human cognitive development primarily rely on the gradual maturation of an internal representation-based processing architecture as an explanatory basis for developmental change. Thelen and Smith (1994) proposed an alternative account focusing on the intimate linkage between brain, body, and environment. These authors claim that, in the course of development, structured action and perception result from dynamic interactions between all these domains, without the necessity for the prior construction of underlying internal representations.

Recently, Thelen and colleagues have investigated the development of Jean Piaget's classic "A-not-B" error in infants. The basic phenomenon involves infants reaching for and retrieving an object from one of two identical containers (labeled A and B) after the object was hidden in full view of the infants. First, the object is repeatedly hidden at and retrieved from location A. If the object is then hidden in container B, the infants, after a brief delay, continue to reach for container A, even though they viewed the object being hidden in B. Numerous contextual effects on the A-not-B task have been demonstrated, including the visual appearance of the containers, timing effects, and infant posture. Several cognitive theories have been proposed to account for the A-not-B error, some suggesting an immature concept of object permanence as the principal cause, others focusing on a dissociation or modular segregation between "knowing" and "acting." Thelen and colleagues (2001) designed a detailed dynamical model to account for the A-not-B error and its context dependency. Important components of the model include a "movement planning field" whose dynamics determine the goal location of the reaching movement. This field receives activation from sensory input fields and from a "memory field" that maintains a memory of recent reaching locations. The A-not-B error emerges dynamically if acute or specific sensory inputs cuing target location B decay (for example, during a brief temporal delay) while inputs from the memory field (with high activity at location A and a slow time course) continue to dominate. Thus, in the model, the A-not-B error is not due to immature or weak internal representations or to a separation between "knowing" and "acting" but is the result of the internal dynamics of the reaching system, specifically the interaction between the effects of memory (long time course) and those of acute sensory inputs (short time course). The model was tested in numerous other contexts and for different sets of task parameters and produced results that were consistent with empirical findings.

A major advance of the dynamical perspective has been to unify processes of neural, bodily, and environmental change within a common dynamical framework. According to this approach, for example, "knowing" and "acting" do not constitute neatly separable modules or domains within the human cognitive architecture. Rather, in the course of human cognitive development, "knowing" and "acting" are intricately coupled and manifest themselves in different contexts of embodied, situated action and individual experience.

## Sensorimotor Processes in Category Formation

Perceptual categorization is one of the most fundamental cognitive processes. The formation of new categories is crucial for an organism's ability to continually adapt within a changing and unpredictable environment (Edelman, 1987). A large number of computational and connectionist models of categorization have been proposed (see Pfeifer and Scheier, 1999). The majority of these models work by constructing an optimal mapping between representations of the stimulus (input) and discrete category representations (output). Synaptic weights linking input and output representations are adjusted by using supervised (backpropagation) or unsupervised learning schemes.

Embodied cognition offers a different perspective on category learning. An embodied system is not passively exposed to sensory "data" or to coded feature vectors. Rather, embodied systems exploit movement and interactions with the environment to actively seek out sensory stimulation. In the process, they not only sample but also may generate "good" sensory information, for example by introducing temporal correlations due to bodily movement that help in constructing perceptual invariants. To test this hypothesis, Sporns and colleagues designed an embodied neural model of the development of translation invariance and object selectivity in the primate inferior temporal cortex (Almassy, Edelman, and Sporns, 1998). The model demonstrated that smooth lateral displacement of visual objects due to visual scanning movements are essential for constructing large homogeneous receptive fields of inferior temporal cortical neurons. When such movements were disrupted, translation-invariant and object-selective cells failed to emerge. Even after the initial developmental phase was completed, ongoing synaptic changes within the visual neural maps produced representational experience-dependent plasticity. Groups of neuronal units continued to compete for neural inputs and showed differential increases and decreases reflecting the behavioral history of the model. In another model of category learning, Pfeifer and Scheier (1999) showed that an embodied system can construct sensorimotor categories by generating consistent spatiotemporal correlations across sensor readings while interacting with objects. A simple circling behavior was sufficient to learn the distinction between large and small objects, encountered as a mobile robot navigates its environment.

Both of these models show how embodied systems can actively generate information about objects that is not contained in individual sensor "snapshots." The categorization of objects requires bodily movement and real-world interaction to generate temporally correlated sensory inputs. Correlations can be generated within one sensory modality across time, which may lead to a disambiguation of sensory input through a reduction of the dimensionality of sensory space. In addition, correlations across different sensory channels can be exploited to form cross-modal associations, which are a prerequisite for concept formation. In the context of category and concept formation, embodiment may be viewed as an essential principle that supports the ability of autonomous systems to extract statistical regularities ("knowledge") from an environment. In order to accomplish this function, the temporal dynamics of the nervous system, the morphology of the body (the spatial arrangement and characteristics of its sensors and effectors), and the movement repertoire act together in ways that are not encompassed by pure information-processing approaches.

## Value and Embodied Cognition

Embodied cognition requires that neural, bodily, and environmental domains attain dynamically coupled states. Embodied systems need to function coherently within a given environment or task domain. If behavior is to be adaptive, mechanisms must exist by which global functional goals can shape the elementary (neural and bodily) components of the organism, enabling adaptive dynamic states consistently to emerge. In other words, the global performance or adaptiveness of the system must be able to influence its local (internal) structure such that the propensity of the system to behave adaptively is increased. For the system to be truly autonomous, the mechanisms that mold local structure to yield global function must reside wholly within the system itself.

Supervised learning is clearly inconsistent with this requirement. Reinforcement learning (see Reinforcement Learning) and in particular temporal difference learning provide a promising set of computational principles, although generally they do not specify the neural mechanisms by which consequences of behavior are sensed by an organism. In mammals, several neuromodulatory systems (including the dopaminergic and noradrenergic systems) are known to project diffusely and widely throughout the cerebral cortex (see Dopamine, Roles of; Neuromodulation in Mammalian Nervous Systems). They are responsive to salient events in the environment (e.g., reward stimuli) and exert physiological effects on cortical neural activity and plasticity. Sporns and colleagues have implemented such "value systems" in embodied synthetic models (Almassy et al., 1998; Sporns et al., 2000) to study their role in adaptive behavior. Computationally, value acts to gate plasticity during brief episodes of high behavioral saliency. Through synaptic plasticity in sensory afferents to value systems, previously neutral sensory stimuli or modalities can acquire the ability to trigger value and thus become salient to the organism. Sporns et al. (2000) showed how innate and acquired response characteristics can shape the behavioral history of an autonomous robot and provide a neural basis for avoidance and secondary conditioning.

## Discussion

Embodied cognition presents a stark contrast to classical views of cognition. The theoretical challenge of embodied cognition has provoked numerous philosophical discussions of core principles of cognition such as representation and the internal world model. It is unclear whether internal models, explicitly symbolic or based on neural representations, should be fully abandoned. Modern neuroscience provides abundant evidence for neural coding in all sensory and motor domains, as well as neural activity underlying internally generated states related to attention, memory, prediction, and planning. Embodied cognition needs to strive for a conceptual synthesis between such internal processes and coupled sensorimotor and behavioral interactions across brain and body. Perhaps it is fair to say that the ultimate success of embodied cognition will depend on whether empirical findings in developmental, cognitive, and neural science buttress its far-reaching theoretical claims and whether implementations of embodied models will compare favorably with those based on other approaches.

In the future we may expect to see a fruitful convergence between the methods and concepts from dynamical systems theory and neuroscience. For example, the large-scale dynamics of an extended network such as the cerebral cortex can be characterized by global interactions between locally specialized (segregated) areas, leading to the emergence of functionally integrated cognitive and perceptual states (Tononi, Edelman, and Sporns, 1998). Thus, in a sense, perceptual and cognitive states are characterized not only by the activity of certain brain regions, but also by their dynamic coand interactivity. In the future, as we continue to explore the important connection between neural dynamics and cognition (Arbib, Érdi, and Szentágothai, 1998), more advanced synthetic approaches will begin to study neurodynamical processes of increasing complexity within the embodied systems of organisms and robots.

# Emotional Circuits

*Jean-Marc Fellous, Jorge L. Armony, and Joseph E. LeDoux*

## Introduction

Emotion is clearly an important aspect of the mind; yet it has been largely ignored by the "brain and mind (cognitive) sciences" in modern times. However, there are signs that this is beginning to change. This chapter surveys some issues about the nature of emotion, describes what is known about the neural basis of emotion, and considers some efforts that have been made to develop computer-based models of different aspects of emotion.

## What Is Emotion?

The nature of emotion has been debated within psychology for the past century. The formal debate goes back to William James's famous question: Do we run from the bear because we are afraid, or are we afraid because we run? James suggested that we are afraid because we run. Subsequently, the psychological debate over emotion has centered on the question of what gives rise to the subjective states of awareness that we call feelings, or emotional experiences. Theories of emotional experience typically seek to account for how different emotional states come about, and can be grouped into several broad categories: feedback, central, arousal, and cognitive theories (for review, see LeDoux, 1996). Though very different in some ways, each of these theories proposes that emotional experiences are the result of prior emotional processes. Feedback and arousal theories require that the brain detect emotionally significant events and produce responses appropriate to the stimulus; these responses then serve as a signal that determines the content of emotional experience. Central and cognitive appraisal theories, which are in some ways different levels of description of similar processes, assume that emotional experience is based on prior evaluations of situations; these evaluations then determine the content of experience. Interestingly, the evaluative processes that constitute central and appraisal theories are also implicitly necessary for the elicitation of the peripheral responses and arousal states of feedback and arousal theories.

The disparate theories of emotional experience thus all point to a common mechanism—an evaluative system that determines whether a given situation is potentially harmful or beneficial to the individual. Since these evaluations are the precursors to conscious emotional experiences, they must, by definition, be unconscious processes. Such processes are the essence of the ignored half of James's question. That is, we run from a bear because our brain determines that bears are dangerous. Many emotional reactions are likely to be of this type: unconscious information processing of stimulus significance, with the experience of "emotion" (the subjective feeling of fear) coming after the fact.

Although the manner in which conscious experiences emerge from prior processing is poorly understood, progress has nevertheless been made in understanding how brain circuits process emotion. Just as vision researchers have achieved considerable understanding of the neural mechanisms underlying the processing of color while still knowing little about how color experience emerges from color processing (COLOR PERCEPTION), it is possible to study how the brain processes the emotional significance of situations without first solving the problem of how those situations are experienced as conscious content.

## The Neural Basis of Emotional Processing

Traditionally, emotion has been ascribed to the brain's limbic system, which is presumed to be an evolutionarily old part of the brain involved in the survival of the individual and species (LeDoux, 2000). Some of the areas usually included in the limbic system are the hippocampal formation, septum, cingulate cortex, anterior thalamus, mammillary bodies, orbital frontal cortex, amygdala, hypothalamus, and certain parts of the basal ganglia. However, the limbic system anatomical concept and the limbic system theory of emotion are both problematic (LeDoux, 2000). The survival of the limbic system theory of emotion is due in large part to the fact that the amygdala, a small region in the temporal lobe, was included in the concept.

The amygdala has been consistently implicated in emotional functions (LeDoux, 1996; Rolls, 1998; Damasio, 1999; various chapters in Aggleton, 2000). Lesions of this region interfere with both positive and negative emotional reactions. Moreover, unit-recording studies show that cells in the amygdala are sensitive to the rewarding and punishing features of stimuli and to the social implications of stimuli. Other limbic areas have been less consistently implicated in emotion, and when they have been implicated, it has been difficult to separate out the contribution of the region to emotion per se as opposed to some of the cognitive prerequisites of emotion. The amygdala therefore serves as an experimentally accessible entry point into the distributed network of brain regions that mediate complex emotional evaluations.

The contribution of the amygdala to emotion results in large part from its anatomical connectivity (reviewed in LeDoux, 2000). The amygdala receives inputs from each of the major sensory systems and from higher-order association areas of the cortex. The sensory inputs arise from both the thalamic and cortical levels. These various inputs allow a variety of levels of information representation (from raw sensory features processed in the thalamus to whole objects processed in sensory cortex to complex scenes or contexts processed in the hippocampus) to impact on the amygdala and thereby activate emotional reactions. Most of these sensory inputs converge in the lateral nucleus of the amygdala, and the higher order information in the basal nucleus (Figure 1). These can be viewed as the sensory and cognitive gateways, respectively, into the amygdala's emotional functions. At the same time, the amygdala sends output projections to a variety of brainstem systems involved in controlling emotional responses, such as species-typical behavioral responses (including facial expressions and whole-body responses such as freezing), autonomic nervous system responses, and endocrine responses. Most of these outputs originate from the central nucleus of the amygdala. Recent anatomical and physiological work has, however, shown that the amygdala consists of several interacting subnuclei that may have specific individual contribution to the overall emotional computation performed (see the following discussion and Figure 1). If the amygdala is consistently found to contribute to the evaluation of the emotional significance of a stimulus, are there systems that control the processing of the amygdala? Recent work suggests that the amygdaloid complex can be modulated by neurochemical systems, such as serotonergic or dopaminergic, that are activated in relation to the overall behavioral state of the organism.

Much of the anatomical circuitry of emotion described previously has been elucidated through studies of fear conditioning, a procedure whereby an emotionally neutral stimulus, such as a tone or light, is associated with an aversive event, such as a mild shock to the foot (LeDoux and Phelps, in Lewis and Haviland-Jones, 2000; Davis, 1998). After such pairings, the tone or light comes to elicit emotional reactions that are characteristically expressed when members of the species in question are threatened. Although there are other procedures for studying emotion, none has been as successfully applied to the problem of identifying stimulus-response connections in emotion. The fear conditioning model is at this point particularly attractive since it has laid out pathways from the sensory input stage to the motor output stage of processing, showing how simple stimulus features, stimulus discriminations, and contexts control the expression of behavioral, autonomic, and endocrine responses in threatening situations (Figure 2).

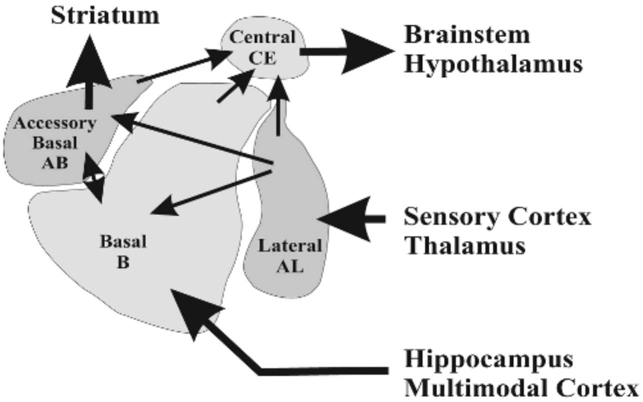

**Figure 1.** Simplified diagram of the amygdala intrinsic connections. The two main inputs to the amygdala are from the sensory/thalamic structures to AL, providing low level sensory information, and from polymodal and multimodal cortical association areas to B, providing more processed sensory information. The central nucleus receives convergent information from many other amygdaloid nuclei, and generate behavioral outputs (low level motor, autonomic, endocrine responses) that are a reflection of the intrinsic computations performed by the amygdala as a whole. Higher order motor control outputs are generated by the AB. See LeDoux and Pitkanen's chapter and Aggleton's chapter in Aggleton (2000) for more details.

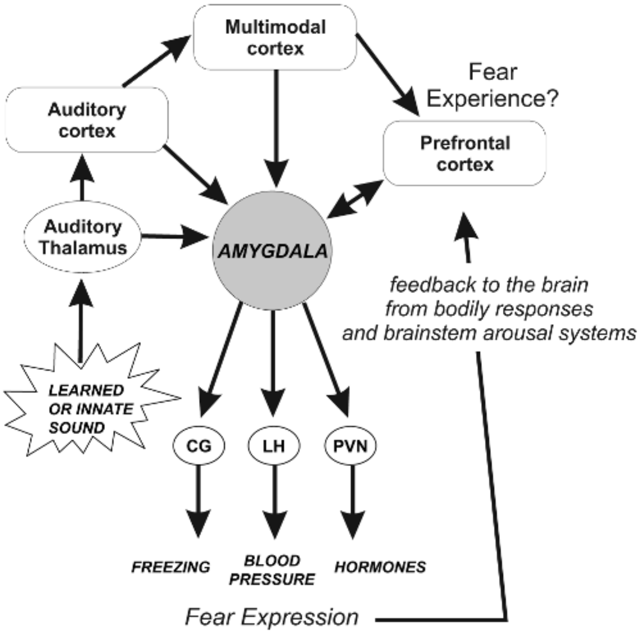

**Figure 2.** Emotional expression and emotional experience of auditory fear. Fearful stimuli (learned or innate) follow two main routes. The fast route involves the thalamo-amygdala pathway and responds best to simple stimulus features (such as a tone), the slow route involves the thalamo-cortical-amygdala pathway and carries more complex features (such as context). The expression of fear is mediated by the outputs of the amygdala to lower brain centers (brainstem, hypothalamus), while the experience of fear involves the prefrontal cortex circuitry.

Although many emotional response patterns are hardwired in the brain's circuitry, the particular stimulus conditions that activate these are mostly learned by association through classical conditioning. The amygdala appears to contribute significantly to this aspect of learning and memory and may be a crucial site of synaptic plasticity in emotional learning (LeDoux, 2000). This form of memory is quite different from what has come to be called *declarative memory*, the ability to consciously recall some experience from the past (CORTICAL MEMORY; SHORT-TERM MEMORY). Declarative memory, in contrast to *emotional memory*, crucially requires the hippocampus and related areas of the cortex. When we encounter some stimulus that in the past had aversive consequences, we recall the details of who we were with and where we were and even that it was a bad experience. However, in order to give the declarative memory an emotional flavor, it may be necessary for the stimulus, simultaneously and in parallel, to activate the emotional memory system of the amygdala. It is likely to be this dual activation of memory systems that gives our ongoing declarative memories their emotional coloration. Emotional memories are formed by the amygdala, in the same manner as declarative memories are formed in the hippocampus. The actual site of storage of emotional and declarative memories is still a matter of debate (Cahill et al., 1999), but may involve distant cortical and subcortical areas in addition to the amygdala and hippocampus (LeDoux, 2000).

In the last several years, the basic findings regarding fear conditioning in animals have been confirmed and extended by studies of brain-damaged patients and functional imaging studies. This work has shown that the human amygdala is also involved in fear learning and other emotional processes (for reviews see Damasio, 1999; LeDoux, 2000; and Dolan's chapter in Aggleton, 2000).

At this point, we have mentioned "emotional experience" a number of times, and it may be worth speculating on just what an emotional experience is and how it might emerge. The emotion of fear will be used as an example. All animals, regardless of their stage of evolutionary development, must have the ability to detect and escape from or avoid danger. The widespread distribution of these behaviors in the animal kingdom makes it unlikely that the subjective experience of fear is at the heart of this ability. It may well be the case that subjective, consciously experienced fear is a mental state that occurs when the defense system of the brain (the system that detects threats and organizes appropriate responses) is activated, but only if that brain also has the capacity for consciousness. That is, by this reasoning, fear and other emotions reflect the representation of the activity of neural systems shaped by evolution and the responses they produce as conscious content. If this is true, then it is important that we focus our research efforts on these stimulus-detection and response-organizing systems, as these are the systems that generate the conscious content we call emotions. Although emotional behaviors may be triggered by sensory inputs that bypass or pass through the neocortex, the experience of emotion is likely to involve the cortical representation of the emotional episode. Although our understanding of the cortical representation of emotion episodes (or other conscious experiences) is poor at present, considerable evidence suggests that working memory circuits involving the frontal lobe may play a key role (LeDoux, 2000, and Figure 2). For a different view of the neural basis of emotional experience, see Damasio, 1999.

## Computational Models of Emotion

Using computers to understand emotions has always been a challenge. Popular beliefs define computing devices as inherently incapable of exhibiting and experiencing any emotions and, at present, no definite claims have been made that computers may be suitable for such a task. Nevertheless, consistent with the notion put forth in the introduction, computers are used as tools for modeling certain aspects of emotional processing.

## Models of Emotional Learning and Memory

As proposed by most central theories, many emotional responses are hardwired in brain circuitry. Nevertheless, in humans and animals, the environmental events that trigger these responses are often learned through experiences in which emotionally neutral stimuli come to be associated with emotionally charged stimuli. One important aspect of emotional processing, therefore, involves the manner in which the brain forms, stores, and uses associations between meaningless and meaningful stimuli.

Grossberg developed models of conditioned affective states based on the notion that conditioned reinforcement involves pairs of antagonistic neural processes, such as fear and relief. The model suggests a mechanism by which neutral events are charged with a reinforcing value (either positive or negative) depending on the previous activity of the model. The simulated neural circuits are suggestive of the role of brain structures involved in the processing of certain emotions, such as the hippocampo-amygdaloid system (described as a zone of convergence of conditioned (CS) and unconditioned (US) stimulus pathways), the septum (described as a zone in which the opposition of the processes is represented), the hypothalamus, the nucleus of the solitary tract, and the reticular formation (described as zones of visceral and somatosensory inputs). These models have been used to explain some aspects of the dysfunctional behaviors seen in diseases such as schizophrenia (see Grossberg, 2000, for a review).

Armony and co-workers have implemented another connectionist model of emotional learning and memory that, like the previous model, also focuses on zones of convergence of US and CS pathways (Armony et al., 1997). This model is anatomically constrained by the known data of the fear conditioning circuitry. It examines processing in two parallel sensory (CS) transmission pathways to the amygdala from the auditory thalamus and the auditory cortex in a learning situation involving an auditory CS paired with a footshock US. The model is initially trained using a modified Hebb-type learning rule and, under testing conditions, reproduces data related to frequency-specific changes of the receptive fields known to exist in the auditory thalamus and amygdala. The model predicted that lesions of the cortical auditory route would not affect the specificity of the behavioral response to a range of frequencies centered on the training (aversively meaningful) frequency. This prediction has been verified experimentally. Because cortical representations are subject to attentional focus, this modeling study, like the previous one, suggests a close link between the amygdala and the attentional system of the midbrain. A separate connectionist-like model proposed that the amygdala might work in concert with the perirhinal cortex to generate conditioned responses to fear in cases in which the CS-US interval lasts several seconds (Tieu et al., 1999).

Recent anatomical studies coupled to physiological experiments in vivo and in vitro have provided invaluable data that can be used to build biophysically realistic computational models of amygdala circuits. Such models explore the interactions between converging thalamic and cortical inputs onto neurones in the lateral nucleus of the amygdala (Armony and LeDoux, 1997), as well as the role of local feedforward and feedback inhibition in stimulus processing (reviewed in Armony et al., 1997).

## Computational Models of Cognitive-Emotion Interactions and Appraisal

Researchers in experimental psychology, artificial intelligence (AI), and cognitive science have long recognized the mutual influences of emotion and cognition. However, these interactions are still not clearly understood. We still do not have adequate theories defining each of these components of human mentation (emotion and cognition), much less a full understanding of how cognition and emotion might relate (EMOTION-COGNITION INTERACTIONS in the First Edition).

As described previously, most theories of emotion recognize the importance of evaluative or appraisal processes. Although there is considerable disagreement as to how these processes should best be viewed, most workers nevertheless see evaluative or appraisal processes as functioning by comparing sensed characteristics of the world to internal goals, standards, and attitude structures, deducing the emotional significance of the stimulus, guiding the expression of emotional behavior and other physiological responses, and influencing other modules pertaining to behavioral decisions.

In principle, it is possible to model appraisal processes using classical symbolic AI techniques (see Picard, 1997, for a review). It is possible, for example, using a vector space approach, to find a plausible mapping between appraisal features (e.g., novelty, urgency, intrinsic pleasantness) and emotion categories (e.g., fear, joy, pride). Relying on a posteriori verbal reports and a predefined set of emotions, one could then derive a limited set of appraisal criteria, sufficient for emotion prediction and differentiation. Other AI approaches, such as decision trees, pattern matching, and production rules (expert systems), are also possible, although each of these methods encounters theoretical difficulties. These types of systems, however, do not generally account for neurophysiological data.

One criticism often made of cognitive models of emotion is related to the complexity of processing involved and to the time they consequently require. From an AI point of view, the criticism has been addressed by introducing reactivity to "classical" cognitive models. Classical AI approaches assume that systems possess a well-defined representation of their environment, state, actions, and goals. In contrast, reactive systems do not make such assumptions; they are mostly based on real-time, incomplete evaluations, their performance being based more on the properties of the evaluative mechanisms than on the quality and quantity of their internal representations (Reactive Robotic Systems).

It is interesting to note that, as we mentioned earlier, appraisal of sensory information might be one of the most prominent functions of the amygdala, placing this structure in a key position to actually perform the mapping of the emotional value of the stimuli. In this view, the relation between amygdala activity and emotion is a computational one (in the broad sense of the term) rather than a subjective one. The existence of multiple pathways to the amygdala from input processing systems of various levels of complexity (see previous discussion) provides a biological resolution to some of the concerns that have been raised about the importance of cognition in driving emotion. The involvement of cognition can be minimal or maximal, depending on the situation.

## Models of Facial Expressions of Emotion

Of interest to feedback and arousal theories, the expression of emotion in the face is an important biological aspect of emotion that has significant implications for how emotion is communicated in social situations. Face recognition and analysis of facial expression has only recently been an active field of research in the computer vision community (for review, see Bartlett, 2001). Face analysis can be computationally divided into three subproblems: detecting the face in a scene; identifying the face; and analyzing its expression. At present, each of these tasks uses different features of the face, and different computational approaches. These approaches are based on psychophysical observations and are not yet explicitly based on neurophysiological data. However, a number of neurophysiological studies have been conducted (for review, see Rolls's chapter in Aggleton, 2000). These studies have shown cells selectively responsive to particular faces in areas of the temporal neocortex and in the amygdala. Functional imaging studies of humans have led to similar results (see Dolan's chapter in Aggleton, 2000). Other studies have shown that there might be an influence of facial expressions on the actual neural correlates of the emotional states experienced, through modifications of blood flow characteristics (for review, see Ekman, 1992). Other approaches are more physicomathematical, relying on image processing techniques. These implementations address exclusively the problem of emotional expression (and, possibly, communication of emotions) without relying on any theory of emotional experience (Bartlett, 2001).

## Conclusions

It is important to distinguish between emotional experiences and the underlying processes that lead to emotional experiences. One of the stumbling blocks to an adequate scientific approach to emotion has been the focus of the field on constructing theories of the subjective aspects of emotion. Studies of the neural basis of emotion and emotional learning have instead focused on how the brain detects and evaluates emotional stimuli and how, on the basis of such evaluations, emotional responses are produced. The amygdala was found to play a major role in the evaluation process. It is likely that the processing that underlies the expression of emotional responses also underlies emotional experiences, and that progress can be made by treating emotion as a function that allows the organism to respond in an adaptive manner to challenges in the environment rather than to a subjective state. Although computational approaches to subjective experiences of the emotional or nonemotional kind are not likely to be easily achieved, computational approaches to emotional processing are both possible and practical. Although relatively few models currently exist, this situation is likely to change as researchers begin to realize the opportunities that are present in this long-neglected area.

# Energy Functionals for Neural Networks

*Eric Goles*

## Introduction

In this article we survey some of the most common neural network models for which an *energy* can be defined, where an energy is a quantity $E(x(t))$, depending on the current configuration of the network, $x(t)$, that does not increase when the network is updated, i.e., $E(x(t + \tau)) \leq E(x(t))$, and that is constant in steady state. Classically, these quantities appeared in the dynamical study of ordinary differential equations as what is called a Lyapunov function. In fact, the Lyapunov function approach consists in determining a positive quantity that decreases when the differential system approaches the equilibrium points. In such a case, it is possible to study the stability of the solutions (see Grossberg, 1988, and Hirsch, 1989, in the neural networks context). From the physical point of view, the possibility of associating an energy with neural networks arose from the deep analogy between them and the spin-glass magnetic model (Little and Shaw, 1975; Hopfield, 1984; see also OPTIMIZATION, NEURAL). The interest in determining when such quantities exist arises from the fact that their existence allows study of the convergence rate, for specific update modes of the network, to stable or short-period configurations. Moreover, the attractors are local minima of the energy $E$, so this kind of network can be used to model associative memories (Hopfield, 1982) and hill-climbing optimization strategies.

Energies have been developed for discrete and continuous networks. There are three principal models: discrete transition–discrete time, continuous transition–discrete time, and continuous transition–continuous time. The first model was made famous by Hopfield (1982) for associative memories with Hebb interactions updated asynchronously. It was later extended to sequential and parallel update (Fogelman-Soulié, Goles, and Weisbuch, 1983; Goles, Fogelman-Soulié, and Pellegrin, 1985). The discrete time–continuous function appears in the context of the brain-state-in-a-box model (Golden, 1986). A survey of the energy approach can be found in Goles and Martinez (1990). Finally, the continuous time–continuous transition model has been studied first by Cohen and Grossberg (1983; see COMPUTING WITH ATTRACTORS) and in a particular case by Hopfield (1984). It is important to point out that Hopfield's energy approach was based on a spin-glass analogy of symmetric neural networks. This analogy and some preliminary results were presented in Little (1974) and Little and Shaw (1975).

In this article, we present first the linear argument model for discrete time and continuous transition. We determine, under symmetric assumptions about interconnections, the associated energy. Moreover, we extend the approach to the related class of quasi-symmetric interconnections. In a similar way, we present the discrete time–continuous transition model by taking as a local function a real, bounded, increasing function. It is important to point out that in this case symmetry is also the key hypothesis in determining the energy. Further, we extend the analysis to any increasing function.

For continuous time–continuous transition, we present the general model studied by Grossberg (1988), and we illustrate the energy determination for the particular case developed in Hopfield (1984).

## The Binary State–Discrete Time Model

Suppose the neurons take values in a binary set, usually $\{0, 1\}$ or $\{1, 1\}$. We present here the threshold case, i.e., $y_i = \mathbb{1}(\sum_{i=1}^n w_{ij}x_j - b_i)$, for $x \in \{0, 1\}^n$ and $\mathbb{1}(u) = 1$ iff $u \geq 0$ (0 otherwise). Throughout this paragraph we will assume, without loss of generality, that for any $x \in \{0, 1\}^n$ and $i \in \{1, \ldots, n\}$, $\sum_{j=1}^n w_{ij}x_j - b_i \neq 0$. (Otherwise, it suffices to make a small change in threshold $b_i$ without changing the dynamics; Goles and Martínez, 1990.) The threshold model is the classical one. Other binary models, such as states in the set $\{-1, 1\}$ with the sign transition function, can be reduced to the threshold model, with similar expressions for the energies.

### *Asynchronous Update*

Let us consider the foregoing model with asynchronous update, i.e., the neurons are updated one by one in random order. In this context, we have the following result.

*Theorem 1.* (Hopfield, 1982; Fogelman-Soulié et al., 1983.) Let $W = (w_{ij})$ be a symmetric $n \times n$ matrix with non-negative diagonal entries (i.e., $\mathrm{diag}(W) \geq 0$). Then the quantity $E(x) = -\tfrac{1}{2}\sum_{i,j=1}^n w_{ij}x_ix_j + \sum_{i=1}^n b_ix_i$ is an energy associated with the asynchronous iteration of the network.

*Proof.* Let $x = (x_1, \ldots, x_n) \in \{0, 1\}^n$ be the current configuration. Suppose we update the $k$th neuron, obtaining the new configuration $\tilde{x} = (x_1, \ldots, x_{k-1}, \tilde{x}_k, \ldots, x_n)$, where $\tilde{x}_k = \mathbb{1}(\sum_{j=1}^n w_{kj}x_j - b_k)$. Let $\Delta_k E = E(\tilde{x}) - E(x)$. Since $W$ is symmetric, we get:

$$\Delta_k E = -(\tilde{x}_k - x_k)\left(\sum_{j=1}^{n} w_{kj}x_j - b_k\right) - \tfrac{1}{2} w_{kk}(\tilde{x}_k - x_k)^2 \qquad (1)$$

By definition of the threshold function, the first term is negative when $\tilde{x}_k \neq x_k$. Since $w_{kk} \geq 0$, we conclude that $\Delta_k E \leq 0$, with $\Delta_k E < 0$ iff $\tilde{x}_k \neq x_k$. □

The first determination of this energy for a particular symmetric threshold model was done by Hopfield (1982) for associative memories and interactions $w_{ij}$ defined by Hebb's rule, i.e., $w_{ij} = \sum_{k=1}^p x_i^{(k)}x_j^{(k)}$, $(w_{ij} = 0)$, where $x = \{x^{(1)}, \ldots, x^{(p)}\}$ is the set of prototypes to be memorized. This rule was used before Hopfield in a neural model proposed by Anderson (see ASSOCIATIVE NETWORKS).

As a corollary to the previous theorem, we can state that the only stable states of the network are fixed points, i.e., configurations remaining invariant by the application of the threshold rule. In fact, it suffices to remark that between two successive different configurations, the energy decreases. Furthermore, since the energy is bounded on the set $\{0, 1\}^n$, the network converges in a finite number of steps to a fixed point. We will come back to this aspect in the next section. On the other hand, when $\mathrm{diag}(W) = 0$ (as in Hopfield, 1982), it is easy to verify that the fixed points of the network are local minima of $E$. In fact, consider a fixed point $x \in \{0, 1\}^n$ and its $k$th neighborhood in the hypercube, $\tilde{x} = (x_1, \ldots, 1 - x_k, \ldots, x_n)$. Since $x$ is a fixed point and $\mathrm{diag}(W) = 0$, one gets $x_k = \mathbb{1}(\sum_{j \neq k} w_{kj}x_j - b_k)$ and $\Delta_k E = E(\tilde{x}) - E(x) = -(1 - 2x_k)(\sum_{j \neq k} w_{kj}x_j - b_k) > 0$, so $x$ is a local minimum of $E$. The previous aspect is important for modeling, by hill-climbing neural strategies, some hard combinatorial optimization problems (see OPTIMIZATION, NEURAL)

### *Periodic Update*

Assume now that the neurons are updated one by one in a periodic order: $\{1 \rightarrow 2 \rightarrow \ldots \rightarrow n \rightarrow 1\}$. Clearly, this update strategy is a particular case of the asynchronous one, but the periodicity permits us to obtain bounds on the transient time. It is obvious that the network has the same energy, $E$, as the asynchronous iteration. Given a matrix $W$ and a threshold vector $b$, we define $\tau(W, b)$ as the maximum number of steps taken by the network, for any initial condition, to reach a stable configuration.

*Theorem 2.* (Fogelman-Soulié et al., 1983.) Let $W$ be an $n \times n$ symmetric matrix with non-negative diagonal. Then the transient time $\tau(W, b)$ for periodic update is bounded by

$$\tau(W, b) \leq \frac{\|W\|_1 + 2\|b\|_1}{2\left(e + \min_i w_{ij}\right)} \tag{2}$$

where $e = \min\{|\Sigma_{j=1}^n w_{ij}x_j - b_i| : i \in \{1, \ldots, n\}, x \in \{0, 1\}^n\}$, $\|W\|_1 = \Sigma_{i,j=1}^n |w_{ij}|$, and $\|b\|_1 = \Sigma_{i=1}^n |b_i|$.

*Proof.* From the proof of Theorem 1, one gets, for any $k \in \{1, \ldots, n\}$, $|\Delta_k E| \geq e + ½ \min_i w_{ii}$. On the other hand, $|E(x)| \leq ½ \Sigma_{i,j=1}^n |w_{ij}| + \Sigma_{i=1}^n |b_i|$. From previous inequalities we obtain the bound directly. □

Better bounds can be obtained with a finer analysis of $|\Delta_k E|$ and $|E(x)|$. See, for instance, Kamp and Hasler (1990) and Goles and Martínez (1990).

## *Parallel Update*

Suppose we update the network synchronously:

$$x_i(t + 1) = \mathbb{1}\left(\sum_{j=1}^n w_{ij}x_j(t) - b_i\right) \quad 1 \leq i \leq n, x(0) \in \{0, 1\}^n \tag{3}$$

In this context we have the following result.

*Theorem 3.* (Goles et al., 1985.) Let $W$ be an $n \times n$ symmetric matrix. Then the expression

$$E(t) = -\sum_{i=j=1}^n w_{ij}x_i(t)x_j(t - 1) + \sum_{i=1}^n b_i(x_i(t) + x_i(t - 1))$$

is an energy associated with the parallel update.

*Proof.* Let $\Delta E = E(t) - E(t - 1)$. Since $W$ is symmetric, one gets

$$\Delta E = -\sum_{i=1}^n (x_i(t) - x_i(t - 2))\left(\sum_{j=1}^n w_{ij}x_j(t - 1) - b_i\right) \tag{4}$$

By definition of the threshold function, $\Delta E \leq 0$ and it is strictly negative when $x(t) \neq x(t - 2)$. □

This energy can also be obtained in the framework of the statistical mechanics model proposed by Little (1974). In fact, the energy $E(t)$ with threshold $b = 0$ is the zero temperature limit of the Hamiltonian: $H(x) = -\beta^{-1}\Sigma_{i=1}^n \log_2 \cosh(\beta n^{-1}\Sigma_{j\neq i} w_{ij}x_i)$, where $\beta = 1/kT$, $k$ being the Boltzmann constant (Peretto, 1984). More information about the physical approach can be found in Statistical Mechanics of Neural Networks (q.v.).

*Corollary 1.* For a symmetric matrix $W$, the parallel iteration converges to fixed points or two-periodic configurations.

*Proof.* Suppose that $\{x(0), \ldots, x(T - 1), x(T) = x(0)\}$ is a cycle of period $T$. From Theorem 3 it follows that $E(t)$ is necessarily constant on the cycle. If $T > 2$, we have $x(0) \neq x(2)$, so $E(2) < E(0)$, which is a contradiction. □

*Corollary 2.* For a positive-definite matrix $W$, the parallel update converges to fixed points.

*Proof.* From Corollary 1 it is enough to prove that there are no two-cycles. Suppose $\{x(0), x(1)\}$ is a two-cycle, i.e., $x(2) = x(0)$. Since $W$ is positive definite, $\alpha = (x(1) - x(0))^T(Wx(1) - x(0)) \geq 0$, with equality only if $x(1) = x(0)$. Further, by Equation 4,

$$\begin{aligned}\alpha &= (x(0) - x(1))^T(Wx(1) - b) - (x(1) - x(0))^T(Wx(0) - b)\\ &= \Delta_2 E + \Delta_1 E\end{aligned}$$

From the proof of Theorem 3, we know that $\Delta_2 E \leq 0$ and $\Delta_1 E \leq 0$, so $\alpha = 0$. Hence, $x(1) = x(0)$, i.e., two-cycles do not exist. □

The application of the foregoing result to associative memory models is straightforward. Consider the Hopfield model with generalized Hebb interconnections on the prototype set $\{x^{(1)}, \ldots, x^{(p)}\} \subseteq \{0, 1\}^n$, with interconnection matrix $W = (1/p)X^TX$, where $X = (x^{(1)}, \ldots, x^{(p)})$. Consider also the projection or pseudo-inverse interconnection model, i.e., $W = (X^TX)^{-1}X^T$. Since in both cases $W$ is positive definite, the parallel updates of previous models converge only to fixed points (Kamp and Hasler, 1990).

From the energy given in Theorem 3, one may determine that the transient time for the parallel update is bounded by $\tau(W, b) \leq (1/e)(\|W\|_1 + 3\|2b - W\bar{1}\|_1 - 2\Sigma_{i=1}^n e_i)$ if $e > 0$ (0 if $e = 0$), where $e = \min\{-E^*(2) - E^*(1): x(0) \neq x(2)\}$, $e_i = \min\{|\Sigma_{j=1}^n w_{ij}u_j - b_i| : u \in \{0, 1\}^n\}$, and $\bar{1} = (1, \ldots, 1)$. Clearly, if all the vectors belong to a two-cycle, then $e = 0$ and $\tau(W, b) = 0$.

It is important to remark that this bound is not necessarily polynomial. In fact, it is possible to build symmetric neural networks of size $n$ with exponential transient time (recall that $n$ neurons corresponds to $2^n$ states). When the matrix $W$ takes values on the integers, the quantities $e_i$, $e$ can be controlled and an explicit bound on $\tau(W, b)$ can be given in terms of $W$, $b$. Further, there exist symmetric neural networks where the bound is attained. More information about these topics can be found in Goles and Martínez (1990).

Another model that can be studied by using the energy approach is the bidirectional associative memory (BAM) model proposed by Kosko (1988). Roughly, it consists of a two-layer bidirectional network that achieves heteroassociations with a smaller correlation matrix. Given its correlation matrix $W$ and a pair of vectors $(x, y) \in \{0, 1\}^{2n}$, the energy is $E = -x^TWy$ (Wang, Cruz, and Mulligan, 1991).

## *Energies for Nonsymmetric Models*

When the matrix $W$ is no longer symmetric, it is difficult, for general classes of matrices with other nontrivial regularities, to determine energies that ensure convergence to fixed points (in the asynchronous and sequential update) and to fixed points and two-cycles (for the parallel update). That fact is not surprising, since if we permit arbitrary interconnections and enough neurons we can model arbitrary automata (see Neural Automata and Analog Computational Complexity).

Furthermore, the dynamics (sequential or parallel) is very dependent on symmetry. In fact, arbitrarily small variations in a symmetric matrix can generate long cycles. A similar situation occurs for the sequential iteration and the non-negativity diagonal hypothesis: a negative diagonal also generates long cycles (Goles and Martínez, 1990). So one may say that the existence of energies relies very much on the hypothesis of symmetric interconnections. Of course, one may find nonsymmetric matrices that accept an energy, but one could not find a nontrivial class, really different from the symmetric one, with the energy property. However, minor variation on symmetry are possible.

One can generalize the foregoing results to the quasi-symmetric class of matrices. We say that a matrix $W = (w_{ij})$ is quasi-symmetric if there exists a positive vector $(u_1, \ldots, u_n)$ such that for any $i, j \in \{1, \ldots, n\}$, $u_i w_{ij} = u_j w_{ji}$. We have the following result.

*Theorem 4.* (Goles and Martinez, 1990.) Let $W$ be a quasi-symmetric matrix. Then the quantity $E(x) = -\frac{1}{2}\sum_{i,j} u_i w_{ij} x_i x_j + \sum_{i=1}^{n} u_i b_i x_i$, is an energy for the asynchronous and sequential update.

The quantity $E(t) = -\frac{1}{2}\sum_{i,j=1}^{n} u_i w_{ij} x_i(t) x_j(t-1) + \sum_{i=1}^{n} u_i b_i(x_i(t) + x_i(t-1))$ is an energy for the parallel update.

## The Continuous Transition–Discrete Time Model

Let us now consider a real transition function, $f: \mathbb{R} \to \mathbb{R}$, continuous, strictly increasing on an interval $S = (-a, a)$, $f(0) = 0$, and constant outside $S$, i.e., $f(x) = f(-a)$ for $x \leq -a$ and $f(x) = f(a)$ for $x \geq a$. As an example, $f$ could be a truncated "sigmoidal" similar to those used by Hopfield (1984) and classically empoloyed in multilayered networks. Another example is the BSB model (Golden, 1986) where $f$ is linear in $S$. In the previous context, the update function is as follows:

$$y_i = f(\arg_i(x)) \quad 1 \leq i \leq n,\ x \in S^n \tag{5}$$

where $\arg_i(x) = \sum_{j=1}^{n} w_{ij} x_j - b_i$. For this model and the iterations defined in previous paragraphs we have the following result.

*Theorem 5.* (Goles and Martínez, 1990.) Suppose $W$ is an $n \times n$ symmetric matrix. Then when $\operatorname{diag}(W) \geq 0$ the asynchronous or periodic update admits the energy

$$E(x) = -\frac{1}{2} \sum_{i,j=1}^{n} w_{ij} x_i x_j + \sum_{i=1}^{n} \left( \int_0^{x_i} f^{-1}(s)ds + b_i x_i \right) \tag{6}$$

Furthermore, the quantity

$$\begin{aligned} E(t) = &-\sum_{i,j=1}^{n} w_{ij} x_i(t) x_j(t-1) \\ &+ \sum_{i=1}^{n} \left[ \int_0^{x_i(t)} f^{-1}(s)ds + \int_0^{x_i(t-1)} f^{-1}(s)ds \right] \\ &+ \sum_{i=1}^{n} b_i(x_i(t) + x_i(t-1)) \end{aligned} \tag{7}$$

is an energy associated with the parallel update.

*Proof.* We first give the proof for the asynchronous (analogous to the periodic) update. Suppose we update the $k$th neuron, so that $\tilde{x} = (x_1, \ldots, \tilde{x}_k, \ldots, x_n)$, where $\tilde{x}_k = f(\arg_k(x))$. Suppose also that each neuron has been updated at least one time, so $x_k = f(\arg_k(z))$, where $z \in S^n$. Since $W$ is symmetric, one gets

$$\begin{aligned} \Delta_k E = &-(\tilde{x}_k - x_k) \arg_k(x) - \tfrac{1}{2} w_{kk}(\tilde{x}_k - x_k)^2 \\ &+ \int_0^{\tilde{x}_k} f^{-1}(s)ds - \int_0^{x_k} f^{-1}(s)ds \end{aligned}$$

Since $w_{kk} \geq 0$, the quadratic term is clearly negative. For the other two terms, let $u = \arg_k(x)$ and $v = \arg_k(z)$. Then $\Delta_k E = -(f(u) - f(v))u + \int_0^{f(u)} f^{-1}(s)ds - \int_0^{f(v)} f^{-1}(s)ds$.

From the definition of $f$, we have easily

$$\int_0^{f(\alpha)} f^{-1}(s)ds = \alpha f(\alpha) - \int_0^{\alpha} f(s)ds \tag{8}$$

so $\Delta_k E = (u - v)f(v) + \int_0^{v} f(s)ds - \int_0^{u} f(s)ds$. Since $f$ is an increasing function, one concludes that $\Delta_k E \leq 0$. For the parallel update the proof is similar. □

One may also prove that the only finite orbits are fixed points for the asynchronous and periodic update, while fixed points and/or two-cycles are possible for the parallel update.

The generalization to a nonsymmetric interval, and functions such that $f(0) \neq 0$, can be studied in a similar way. A more general approach would suppose that local update functions act in a high-dimensional space. In this framework, by considering $f: \mathbb{R}^p \to \mathbb{R}^p$, it has been proved that when $f$ is positive (i.e., $\langle f(x) - f(y), x \rangle \geq 0$ for all $x, y \in \mathbb{R}^p$, where $\langle\ ,\ \rangle$ is a scalar product) the sequential and parallel update for symmetric interconnections admits an energy (Goles, 1985).

Further, if $f$ is a subgradient of a convex function $g$ (i.e., $g(y) \geq g(x) + \langle f(x), y - x \rangle$ for all $x, y \in \mathbb{R}^p$), it can be proved that, under the symmetry hypothesis, the parallel iteration also admits an energy (Goles and Martínez, 1990).

## Continuous Transition–Continuous Time Models

Several authors have introduced differential models of neural networks such that the transition function and the time steps are continuous. In this context Cohen and Grossberg (1983) proposed the nonlinear update

$$\frac{dx_i}{dt} = a_i(x_i)\left[ b_i(x_i) - \sum_{j=1}^{n} w_{ij} d_j(x_j) \right] \quad 1 \leq i \leq n \tag{9}$$

To study the dynamics of Equation 9, the authors assume that $a_i(x) \geq 0$, $d_j'(x) \geq 0$, and the matrix $W$ is symmetric. Then they determine the following energy function:

$$E(x) = -\sum_{i=1}^{n} \int^{x_i} b_i d_i'(x)dx + \frac{1}{2} \sum_{i,j=1}^{n} w_{ij} d_i(x_i) d_j(x_j) \tag{10}$$

A particular case of this model was studied by Hopfield (1984):

$$c_i\left(\frac{dy_i}{dt}\right) = \sum_{j=1}^{n} w_{ij} x_j - \frac{y_i}{R_i} + I_i \tag{11}$$

where $y_i = g_i^{-1}(x_i)$.

*Theorem 6.* (Hopfield, 1984.) Let $W$ be a symmetric matrix and $g_i$ a sigmoid. Then

$$E(x) = -\frac{1}{2} \sum_{i,j=1}^{n} w_{ij} x_i x_j + \sum_{i=1}^{n} \left(\frac{1}{R_i}\right) \int_0^{x_i} g_i^{-1}(s)ds + \sum_{i=1}^{n} I_i x_i \tag{12}$$

is an energy function associated with Equation 11.

*Proof.* Since $W$ is symmetric, one gets

$$\frac{dE}{dt} = -\sum_{i=1}^{n} \frac{dx_i}{dt} \left( \sum_{j=1}^{n} w_{ij} x_j - \frac{y_i}{R_i} + I_i \right)$$

From Equation 11 we have

$$\frac{dE}{dt} = -\sum_{i=1}^{n} c_i \frac{dx_i}{dt} \frac{dy_i}{dt} = -\sum_{i=1}^{n} c_i (g_i^{-1})'(x_i) \left( \frac{dx_i}{dt} \right)^2$$

Since $g_i^{-1}$ is increasing, one concludes that $dE/dt \leq 0$. □

Good surveys of differential models of neural networks are provided by Grossberg (1988) and Hirsch (1989).

## Discussion

In this article we have reviewed the principal neural models that accept an energy function. In all cases, the existence of such operators depends strongly on regularities of interconnections: symmetry and quasi-symmetry. One may also determine an energy for a class of antisymmetric matrices (Goles and Martínez, 1990), but it seems difficult to find other nontrivial classes of matrices that accept energy functions. In fact, arbitrarily small perturbation of the matrices discussed in this article can induce long cycles in the network dynamics. Necessary and sufficient conditions for the existence of an energy function have been formally studied by Kobuchi (1991) under a plausible decomposition hypothesis of $\Delta E$. But, in practice, the authors recover only the quasi-symmetry class.

Further, some of the results can be extended to high-order networks, i.e., neural networks with polynomial interactions. In this context, under a generalization of the symmetry hypothesis, one may find an energy function for the periodic update (Xu and Tsai, 1990; Kamp and Hasler, 1990).

# Ensemble Learning

*Thomas G. Dietterich*

## Introduction

*Learning* describes many different activities, ranging from Concept Learning (q.v.) to Reinforcement Learning (q.v.). The best understood form of statistical learning is known as *supervised learning* (see Learning and Statistical Inference). In this setting, each data point consists of a vector of features (denoted $\mathbf{x}$) and a class label $y$, and it is assumed that there is some underlying function $f$ such that $y = f(\mathbf{x})$ for each training data point $(\mathbf{x}, y)$. The goal of the learning algorithm is to find a good approximation $h$ to $f$ that can be applied to assign labels to new $\mathbf{x}$ values. The function $h$ is called a *classifier*, because it assigns class labels $y$ to input data points $\mathbf{x}$. Supervised learning can be applied to many problems, including handwriting recognition, medical diagnosis, and part-of-speech tagging in language processing.

Ordinary machine learning algorithms work by searching through a space of possible functions, called *hypotheses*, to find the one function, $h$, that is the best approximation to the unknown function $f$. To determine which hypothesis $h$ is best, a learning algorithm can measure how well $h$ matches $f$ on the training data points, and it can also assess how consistent $h$ is with any available prior knowledge about the problem.

As an example, consider the problem of learning to pronounce the letter $k$ in English. Consider the words *desk*, *think*, and *hook*, where the $k$ is pronounced, and the words *back*, *quack*, and *knave*, where the $k$ is silent (in *back* and *quack*, we will suppose that the $c$ is responsible for the $k$ sound). Suppose we define a vector of features that consists of the two letters prior to the $k$ and the two letters that follow the $k$. Then each of these words can be represented by the following data points:

| $x_1$ | $x_2$ | $x_3$ | $x_4$ | $y$ |
|---|---|---|---|---|
| e | s | _ | _ | +1 |
| i | n | _ | _ | +1 |
| o | o | _ | _ | +1 |
| a | c | _ | _ | −1 |
| a | c | _ | _ | −1 |
| _ | _ | n | a | −1 |

where $y = +1$ if $k$ is pronounced and $-1$ if $k$ is silent, and where "_" denotes positions beyond the ends of the word.

One of the most efficient and widely applied learning algorithms searches the hypothesis space consisting of decision trees. Figure 1 shows a decision tree that explains the data points given above. This tree can be used to classify a new data point as follows. Starting at the so-called root (i.e., top) of the tree, we first check whether $x_2 = c$. If so, then we follow the left ("yes") branch to the $y = -1$ "leaf," which predicts that $k$ will be silent. If not, we follow the right ("no") branch to another test: Is $x_3 = n$? If so, we follow

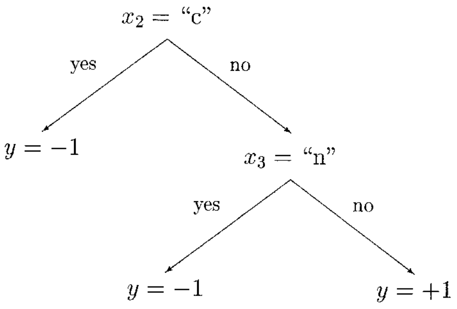

**Figure 1.** A decision tree for pronouncing the letter *k*. First, feature $x_2$ is tested to see if it is the letter *c*. If not, the feature $x_3$ is tested to see if it is the letter *n*. *K* is pronounced only if $x_2$ is not *c* and $x_3$ is not *n*.

the left branch to another $y = -1$ leaf. If not, we follow the right branch to the $y = +1$ leaf, where the tree indicates that *k* should be pronounced.

A decision tree learning algorithm searches the space of such trees by first considering trees that test only one feature (in this case $x_2$ was chosen) and making an immediate classification. Then they consider expanding the tree by replacing one of the leaves by a test of a second feature (in this case, the right leaf was replaced with a test of $x_3$). Various heuristics are applied to choose which test to include in each iteration and when to stop growing the tree. For a good discussion of decision trees, see the books by Quinlan (1993) and Breiman et al. (1984).

In addition to decision trees, there are many other representations for hypotheses that have been studied, including PERCEPTRONS, ADALINES, AND BACKPROPAGATION (q.v.), RADIAL BASIS FUNCTION NETWORKS (q.v.), GAUSSIAN PROCESSES (q.v.), graphical models, Helmholtz machines, and SUPPORT VECTOR MACHINES (q.v.). In all cases, these algorithms find one best hypothesis *h* and output it as the "solution" to the learning problem.

Ensemble learning algorithms take a different approach. Rather than finding one best hypothesis to explain the data, they construct a *set* of hypotheses (sometimes called a *committee* or *ensemble*) and then have those hypotheses "vote" in some fashion to predict the label of new data points. More precisely, an ensemble method constructs a set of hypotheses $\{h_1, \ldots, h_K\}$, chooses a set of weights $\{w_1, \ldots, w_K\}$, and constructs the "voted" classifier $H(\mathbf{x}) = w_1h_1(\mathbf{x}) + \cdots + w_Kh_K(\mathbf{x})$. The classification decision of the combined classifier $H$ is $+1$ if $H(\mathbf{x}) \geq 0$ and $-1$ otherwise.

Experimental evidence has shown that ensemble methods are often much more accurate than any single hypothesis. Freund and Schapire (1996) showed improved performance on 22 benchmark problems, equal performance on one problem, and worse performance on four problems. These and other studies are summarized in Dietterich (1997).

## Why Ensemble Methods Work

Learning algorithms that output only a single hypothesis suffer from three problems that can be partly overcome by ensemble methods: the statistical problem, the computational problem, and the representation problem.

The statistical problem arises when the learning algorithm is searching a space of hypotheses that is too large for the amount of available training data. In such cases, there may be several different hypotheses that all give the same accuracy on the training data, and the learning algorithm must choose one of these to output. There is a risk that the chosen hypothesis will not predict future data points well. A simple vote of all of these equally good classifiers can reduce this risk.

The computational problem arises when the learning algorithm cannot guarantee finding the best hypothesis within the hypothesis space. In neural network and decision tree algorithms, for example, the task of finding the hypothesis that best fits the training data is computationally intractable, so heuristic methods must be employed. These heuristics (such as gradient descent) can get stuck in local minima and hence fail to find the best hypothesis. As with the statistical problem, a weighted combination of several different local minima can reduce the risk of choosing the wrong local minimum to output.

Finally, the representational problem arises when the hypothesis space does not contain any hypotheses that are good approximations to the true function *f*. In some cases, a weighted sum of hypotheses expands the space of functions that can be represented. Hence, by taking a weighted vote of hypotheses, the learning algorithm may be able to form a more accurate approximation to *f*.

A learning algorithm that suffers from the statistical problem is said to have high *variance*. An algorithm that exhibits the computational problem is sometimes described has having *computational variance*. And a learning algorithm that suffers from the representational problem is said to have high *bias*. Hence, ensemble methods can reduce both the bias and the variance of learning algorithms. Experimental measurements of bias and variance have confirmed this.

## Review of Ensemble Algorithms

Ensemble learning algorithms work by running a base learning algorithm multiple times, and forming a vote out of the resulting hypotheses. There are two main approaches to designing ensemble learning algorithms.

The first approach is to construct each hypothesis independently in such a way that the resulting set of hypotheses is accurate and diverse, that is, each individual hypothesis has a reasonably low error rate for making new predictions and yet the hypotheses disagree with each other in many of their predictions. If such an ensemble of hypotheses can be constructed, it is easy to see that it will be more accurate than any of its component classifiers, because the disagreements will cancel out. Such ensembles can overcome both the statistical and computational problems discussed above.

The second approach to designing ensembles is to construct the hypotheses in a coupled fashion so that the weighted vote of the hypotheses gives a good fit to the data. This approach directly addresses the representational problem discussed above.

We will discuss each of these two approaches in turn.

### *Methods for Independently Constructing Ensembles*

One way to force a learning algorithm to construct multiple hypotheses is to run the algorithm several times and provide it with somewhat different training data in each run. For example, Breiman (1996) introduced the bagging (*b*ootstrap *agg*regat*ing*) method, which works as follows. Given a set of *m* training data points, bagging chooses in each iteration a set of data points of size *m* by sampling uniformly with replacement from the original data points. This creates a resampled data set in which some data points appear multiple times and other data points do not appear at all. If the learning algorithm is *unstable*—that is, if small changes in the training data lead to large changes in the resulting hypothesis—then bagging will produce a diverse ensemble of hypotheses.

A second way to force diversity is to provide a different subset of the input features in each call to the learning algorithm. For example, in a project to identify volcanoes on Venus, Cherkauer (1996) trained an ensemble of 32 neural networks. The 32 networks were based on eight different subsets of the 119 available input features and four different network sizes. The input feature subsets were selected (by hand) to group together features that were based on different image processing operations (such as principal component analysis and the fast Fourier transform). The resulting ensemble classifier was significantly more accurate than any of the individual neural networks.

A third way to force diversity is to manipulate the output labels of the training data. Dietterich and Bakiri (1995) describe a technique called error-correcting output coding. Suppose that the number of classes, $C$, is large. Then new learning problems can be constructed by randomly partitioning the $C$ classes into two subsets, $A_k$ and $B_k$. The input data can then be relabeled so that any of the original classes in set $A_k$ are given the derived label $-1$ and the original classes in set $B_k$ are given the derived label $+1$. This relabeled data is then given to the learning algorithm, which constructs a classifier $h_k$. By repeating this process $K$ times (generating different subsets $A_k$ and $B_k$), an ensemble of $K$ classifiers $h_1, \ldots, h_K$ is obtained.

Now, given a new data point $\mathbf{x}$, how should it be classified? The answer is to have each $h_k$ classify $\mathbf{x}$. If $h_k(\mathbf{x}) = -1$, then each class in $A_k$ receives a vote. If $h_k(\mathbf{x}) = +1$, then each class in $B_k$ receives a vote. After each of the $K$ classifiers has voted, the class with the highest number of votes is selected as the prediction of the ensemble.

An equivalent way of thinking about this method is that each class $j$ is encoded as a $K$-bit codeword $C_j$, where bit $k$ is 1 if $j \in B_k$ and 0 otherwise. The $k$th learned classifier attempts to predict bit $k$ of these codewords (a prediction of $-1$ is treated as a binary value of 0). When the $L$ classifiers are applied to classify a new point $\mathbf{x}$, their predictions are combined into a $K$-bit binary string. The ensemble's prediction is the class $j$ whose codeword $C_j$ is closest (measured by the number of bits that agree) to the $K$-bit output string. Methods for designing good error-correcting codes can be applied to choose the codewords $C_j$ (or, equivalently, subsets $A_k$ and $B_k$). Dietterich and Bakiri (1995) report that this technique improves the performance of both decision-tree and backpropagation learning algorithms on a variety of difficult classification problems.

A fourth way of generating accurate and diverse ensembles is to inject randomness into the learning algorithm. For example, the backpropagation algorithm can be run many times, starting each time from a different random setting of the weights. Decision tree algorithms can be randomized by adding randomness to the process of choosing which feature and threshold to split on. Dietterich (2000) showed that randomized trees gave significantly improved performance on 14 out of 33 benchmark tasks (and no change on the remaining 19 tasks).

Ho (1998) introduced the random subspace method for growing collections of decision trees ("decision forests"). This method chooses a random subset of the features at each node of the tree, and constrains the tree-growing algorithm to choose its splitting rule from among this subset. She reports improved performance on 16 benchmark data sets. Breiman (2001) combines bagging with the random subspace method to grow random decision forests that give excellent performance.

### *Methods for Coordinated Construction of Ensembles*

In all of the methods described above, each hypothesis $h_k$ in the ensemble is constructed independently of the others by manipulating the inputs, the outputs, or the features, or by injecting randomness. Then an unweighted vote of the hypotheses determines the final classification of a data point.

A contrasting view of an ensemble is that it is an *additive model*, that is, it predicts the class of a new data point by taking a weighted sum of a set of component models. This view suggests developing algorithms that choose the component models and the weights so that the weighted sum fits the data well. In this approach, the choice of one component hypothesis influences the choice of other hypotheses and of the weights assigned to them. In statistics, such ensembles are known as *generalized additive models* (Hastie and Tibshirani, 1990).

The Adaboost algorithm, introduced by Freund and Schapire (1996, 1997), is an extremely effective method for constructing an additive model. It works by incrementally adding one hypothesis at a time to an ensemble. Each new hypothesis is constructed by a learning algorithm that seeks to minimize the classification error on a *weighted* training data set. The goal is to construct a weighted sum of hypotheses such that $H(\mathbf{x}_i) = \Sigma_k w_k h_k(\mathbf{x}_i)$ has the same sign as $y_i$, the correct label of $\mathbf{x}_i$.

The algorithm operates as follows. Let $d_k(\mathbf{x}_i)$ be the weight on data point $\mathbf{x}_i$ during iteration $k$ of the algorithm. Initially, all training data points $i$ are given a weight $d_1(\mathbf{x}_i) = 1/m$, where $m$ is the number of data points. In iteration $k$, the underlying learning algorithm constructs hypothesis $h_k$ to minimize the weighted training error. The resulting weighted error is $r = \Sigma_i d(\mathbf{x}_i) y_i h_k(\mathbf{x}_i)$, where $h_k(\mathbf{x}_i)$ is the label predicted by hypothesis $h_k$. The weight assigned to this hypothesis is computed by

$$w_k = \frac{1}{2} \ln\left(\frac{1 + r}{1 - r}\right)$$

To compute the weights for the next iteration, the weight of training data point $i$ is set to

$$d_{k+1}(\mathbf{x}_i) = d_k(\mathbf{x}_i) \frac{\exp(-w_k y_i h_k(\mathbf{x}_i))}{Z_k}$$

where $Z_k$ is chosen to make $d_{k+1}$ sum to 1.

Breiman (1997) showed that this algorithm is a form of gradient optimization in function space with the goal of minimizing the objective function

$$J(H) = \sum_i \exp(-y_i H(\mathbf{x}_i))$$

The quantity $y_i H(\mathbf{x}_i)$ is called the *margin*, because it is the amount by which $\mathbf{x}_i$ is correctly classified. If the margin is positive, then the sign of $H(\mathbf{x}_i)$ agrees with the sign of $y_i$. Minimizing $J$ causes the margin to be maximized. Friedman, Hastie, and Tibshirani (2000) expand on Breiman's analysis from a statistical perspective.

In most experimental studies (Freund and Schapire, 1996; Bauer and Kohavi, 1999; Dietterich, 2000), Adaboost (and algorithms based on it) gives the best performance on the vast majority of data sets. The primary exception are data sets in which there is a high level of mislabeled training data points. In such cases, Adaboost will put very high weights on the noisy data points and learn very poor classifiers. Current research is focusing on methods for extending Adaboost to work in high noise settings.

The exact reasons for Adaboost's success are not fully understood. One line of explanation is based on the margin analysis developed by Vapnik (1995) and extended by Schapire et al. (1998). This work shows that the error of an ensemble on new data points is bounded by the fraction of training data points for which the margin is less than some quantity $\Theta > 0$ plus a term that grows as

$$\sqrt{\frac{d}{m}} \frac{\log(m/d)}{\Theta}$$

ignoring constant factors and some log terms. In this formula, $m$ is the number of training data points, and $d$ is a measure of the expressive power of the hypothesis space from which the individual classifiers are drawn, known as the VC-dimension. The value of $\Theta$ can be chosen to minimize the value of this expression.

Intuitively, this formula says that if the ensemble learning algorithm can achieve a large "margin of safety" on each training data point while using only a weighted sum of simple classifiers, then the resulting voted classifier is likely to be very accurate. Experimentally, Adaboost has been shown to be very effective at increasing the margins on the training data points; this result suggests that Adaboost will make few errors on new data points.

There are three ways in which this analysis has been criticized. First, the bound is not tight, so it may be hiding the real explanation for Adaboost's success. Second, even when Adaboost is applied to large decision trees and neural networks, it is observed to work very well even though these representations have high VC-dimension. Third, it is possible to design algorithms that are more effective than Adaboost at increasing the margin on the training data, but these algorithms exhibit worse performance than Adaboost when applied to classify new data points.

### *Related Nonensemble Learning Methods*

In addition to the ensemble methods described here, there are other nonensemble learning algorithms that are similar. For example, any method for constructing a classifier as a weighted sum of basis functions (see, e.g., RADIAL BASIS FUNCTION NETWORKS) can be viewed as an additive ensemble where each individual basis function forms one of the hypotheses.

Another closely related learning algorithm is the hierarchical mixture-of-experts method (see MODULAR AND HIERARCHICAL LEARNING SYSTEMS). In a hierarchical mixture, individual hypotheses are combined by a gating network that decides, based on the features of the data point, what weights should be employed. This differs from Adaboost and other additive ensembles, where the weights are determined once during training and then held constant thereafter.

## Discussion

The majority of research into ensemble methods has focused on constructing ensembles of decision trees. Decision tree learning algorithms are known to suffer from high variance, because they make a cascade of choices (of which variable and value to test at each internal node in the decision tree) such that one incorrect choice has an impact on all subsequent decisions. In addition, because the internal nodes of the tree test only a single variable, this creates axis-parallel rectangular decision regions that can have high bias. Consequently, ensembles of decision tree classifiers perform much better than individual decision trees. Recent experiments suggest that Breiman's combination of bagging and the random subspace method is the method of choice for decision trees: it gives excellent accuracy and works well even when there is substantial noise in the training data.

If the base learning algorithm produces less expressive hypotheses than decision trees, then the Adaboost method is recommended. Many experiments have employed so-called decision stumps, which are decision trees with only one internal node. In order to learn complex functions with decision stumps, it is important to exploit Adaboost's ability to directly construct an additive model. This usually gives better results than bagging and other accuracy/diversity methods. Similar recommendations apply to ensembles constructed using the naive Bayes and Fisher's linear discriminant algorithms. Both of these learn a single linear discrimination rule. The algorithms are very stable, which means that even substantial (random) changes to the training data do not cause the learned discrimination rule to change very much. Hence, methods like bagging that rely on instability do not produce diverse ensembles.

Because the generalization ability of a single feedforward neural network is usually very good, neural networks benefit less from ensemble methods. Adaboost is probably the best method to apply, but favorable results have been obtained just by training several networks from different random starting weight values, and bagging is also quite effective.

For multiclass problems, the error-correcting output coding algorithm can produce good ensembles. However, because the output coding can create difficult two-class learning problems, it is important that the base learner be very expressive. The best experimental results have been obtained with very large decision trees and neural networks. In addition, the base learning algorithm must be sensitive to the encoding of the output values. The nearest neighbor algorithm does not satisfy this constraint, because it merely identifies the training data point $\mathbf{x}_i$ nearest to the new point $\mathbf{x}$ and outputs the corresponding value $y_i$ as the prediction for $h(\mathbf{x})$, regardless of how $y_i$ is encoded. Current research is exploring ways of integrating error-correcting output codes directly into the Adaboost algorithm.

# Equilibrium Point Hypothesis

*Reza Shadmehr*

## Introduction

If one were to take a robot arm and replace each of its motors with a pair of opposing rubber bands, the arm would tend to settle to the same configuration, regardless of where it was released. That configuration is the *equilibrium point* of the system. If we now change the length-tension properties of the rubber bands, such as by changing the resting lengths or stiffnesses, the equilibrium point of the system will change. Our muscles share a property with rubber bands in that the static force they generate depends on length: the greater the length, the greater the force (see MUSCLE MODELS). The activations received by motor neurons, whether from direct descending commands from the brain or from the spinal reflex circuitry, can change the force-length relation for each muscle, resulting in a change in the equilibrium position of the system. When we reach for an object, is the smooth, stable motion a consequence of a simple trajectory of equilibrium points? Are our muscles and the associated spinal reflex circuitry designed in a way that makes control of motion particularly simple for the brain?

If the answer is yes, then it implies that many of the problems inherent to control of a multijoint limb, such as nonlinear state-dependent dynamics, might be simplified by a well-designed low-level control system. In this article I review the evidence regarding this hypothesis.

## Mathematical Basis of the Hypothesis

*Equilibrium* refers to a state of a system in which the forces acting on it are zero. For example, if the dynamics of the system are

$$\dot{q} = h(q, u) \tag{1}$$

where $q$ is the state of the system and $u(t)$ is a control input, then the equilibrium points $q^*$ satisfy the following condition:

$$0 = h(q^*, u) \text{ for all } t \geq t_0$$

In short, if the system reaches an equilibrium position, it will remain there.

For a mechanical system, the state is an ordered pair $q = \{\theta, \dot{\theta}\}$, where $\theta$ and $\dot{\theta}$ are the position and velocity of the system. A change in the state occurs when there are forces acting on it. This can be written in the framework of Equation 1 as

$$\ddot{\theta} = I(\theta)^{-1}(f_c(\dot{\theta}, \theta, u(t)) - f_m(\dot{\theta}, \theta)) \tag{2}$$

where $I$ is the system's inertia, $f_c$ is the external force field imposed on the system due to the controller with control input $u(t)$, and $f_m$ is the force field produced by the motion of the inertial coordinate frames (Coriolis and centripetal) and other forces. It follows that the system is at equilibrium at any state $\{\theta = 0, \dot{\theta} = 0\}$ where the force in the net field $f_c - f_m$ is zero. Any such position $\theta^*$ is an equilibrium point for the system.

We call each state where a field has zero force a *null point* of that field. The equilibrium points for the system, however, are a subset of these null points: the equilibrium point exists only at those null points of the force field $f_c - f_m$ where the state has zero velocity.

Let us consider how we could go about controlling the system of Equation 2. Our objective may be to select the input $u$ in such a way that the system follows a desired trajectory $\theta_d(t)$. For this to occur, we might select $u$ at any time $t$ in such a way that if we were at state $\{\theta_d, \dot{\theta}_d\}$, our controller would produce a force $f_c = \hat{f}_m + \hat{I}\ddot{\theta}_d(t)$, where $\hat{x}$ is the controller's estimate of $x$. Since there may be uncertainties in the environment, it is a good idea to also have a mechanism to push us toward where we should be if the need arises:

$$f_c = \hat{f}_m + \hat{I}\ddot{\theta}_d - B(\dot{\theta} - \dot{\theta}_d) - K(\theta - \theta_d) \tag{3}$$

where $B$ and $K$ should be positive definite matrices. We can think of the estimates as a feedforward component of the controller and the remainder as the feedback component of the controller. If the estimates were perfect, substitution of Equation 3 into Equation 2 would give:

$$\ddot{e} + c_1\dot{e} + c_2 e = 0$$

where $e = \theta - \theta_d$ is the error in tracking our desired trajectory, and $c_1$ and $c_2$ are positive definite (because the inertia matrix $I$ is also positive definite for a mechanical system). Therefore, the tracking error would exponentially decline with time and the system would be stable about the desired trajectory.

Equation 3 makes plain the notion that the forces produced by the controller must take into account the system's mass if it is to move the system along the desired trajectory. The estimates are *internal models* that the brain would presumably have to know (see MOTOR CONTROL, BIOLOGICAL AND THEORETICAL for a discussion of how these models might be learned). However, the equilibrium point hypothesis suggests that the feedback system in Equation 3 is designed in a way that largely eliminates the need for the estimates of the dynamics of the limb. In this hypothesis, the muscles and the spinal reflexes function as the feedback system about the desired trajectory, i.e., the stiffness and viscosity of the system. The main question is the extent to which the mechanical behavior of muscles and the reflex system can compensate for the dynamics of the limb.

## Biomechanical Behavior at Rest

In a seminal paper by Feldman (1966), it was observed that the spinal control system acting on the elbow joint of the human arm (composed of muscles and the local feedback circuitry) had static characteristics similar to those of a nonlinear spring. When the elbow was displaced from its equilibrium position, muscles produced monotonically increasing force (as measured at the hand):

$$f = a(\exp[b(x(t) - x_\lambda(t))] - 1) \tag{4}$$

where $f$ is muscle force, $t$ is time, $x(t)$ is length of a muscle, and $x_\lambda(t)$ is the threshold length beyond which the muscle will produce force. Feldman's thesis was that the signals sent from the brain to the spinal reflexes and muscles could be interpreted as setting the threshold length $x_\lambda(t)$ for each muscle. Feldman and Orlovsky (1972) later showed that stimulation of a motor center in the brainstem (of cats), resembling what might happen in a voluntary change in the brain's input to the spinal cord, did result in force-length changes in the muscles. These changes appeared as changes in $x_\lambda(t)$ in the above system.

For a constant input $x_\lambda(t)$ in Equation 4, muscle force reflects both the mechanical properties of the isolated muscles (increased production of force when muscle is lengthened) and the effect of local neural feedback (recruitment of more motor neurons if length exceeds a set threshold). There is now independent support for the formulation in Equation 4. Hoffer and Andreassen (1981) measured the rate of change in stiffness with respect to force in muscles of a cat's hindlimb. They found the relation between force and stiffness to be independent of muscle length, and of the form:

$$\frac{df}{dx} = k(1 - \exp[-\alpha f]) \qquad (5)$$

where $df/dx$ is muscle stiffness. Shadmehr and Arbib (1992) noted that the solution to the above differential equation has the form:

$$f = \frac{1}{\alpha} \ln(\exp[\alpha k(x - \lambda)] + 1) \qquad (6)$$

In the above, $\lambda$ is the constant of integration and depends on the initial conditions for Equation 5. This result demonstrated that an intact muscle reflex system has a static behavior that resembles that of a nonlinear spring with an adjustable threshold.

If a single-joint limb is controlled by a pair of muscles, then setting $\lambda$ for each muscle sets the equilibrium point of the system and describes a force field about this equilibrium. Hogan (1985) showed that in a multijoint system, this field will be conservative. This means that if the nervous system produces a force field $f_c$ in Equation 3 through setting of threshold lengths for the muscles of the limb, then when $\ddot{\theta}$ and $\dot{\theta}$ are zero, curl of the field $f_c$ should be zero. Mussa-Ivaldi, Hogan, and Bizzi (1985) measured the static component of $f_c$ in humans. The procedure was to have subjects hold on to the handle of a robotic arm. The robot produced force perturbations at various directions and measured the steady-state force response of the subject's arm as a function of position. It was found that the resulting force field was essentially curl-free. Taken together, static behavior of muscles and the spinal control circuitry appeared to be well described as a nonlinear spring with an adjustable threshold length.

## Movements as a Shift in Equilibrium Position

When threshold lengths are set for each muscle, the result is a corresponding equilibrium position $\theta^*$ for the limb. The major contribution of the equilibrium point hypothesis has been to suggest that motion is generated by the CNS through a gradual transition of equilibrium points along the desired trajectory without an explicit compensation for dynamics. The evidence for this initially came from a simulation study by Flash. She suggested that in the case of human reaching movements in the horizontal plane, it was possible to predict the hand's motion accurately by smoothly shifting the equilibrium point along a straight line from the start point to a target location. Interestingly, she showed that in the simulation, because the controller was not attempting to compensate for the limb's dynamics, the hand's trajectory slightly deviated from a straight line. However, it turns out that the trajectories recorded in human subjects also show similar deviations, matching her simulations. In this model, the controller was composed of a linear spring-dashpot system with adjustable threshold:

$$f_c = K(\theta - \theta^*(t)) + B\dot{\theta}$$

The field had the property that its static behavior about equilibrium was defined by a stiffness matrix $K$. This matrix was measured about the equilibrium position of a resting arm by Mussa-Ivaldi et al. (1985).

Taking a different approach, Shadmehr, Mussa-Ivaldi, and Bizzi (1993) suggested that if a movement was generated through a gradual shift of the equilibrium position toward the target, then from measurements of the force field about the hand at rest, one should be able to predict the direction and magnitude of forces that should be produced by the muscles during the initiation of the reaching movement (Figure 1). Because the field at rest is not isotropic and depends on the position of the hand, the forces measured during the initiation of a movement should not point toward the target and be position dependent. These movement initiation forces were measured, and it was found that the pattern of forces from measurements at rest agreed with the measured forces during initiation of movement. In other words, during the start of movements, the equilibrium point of the field had shifted toward the target.

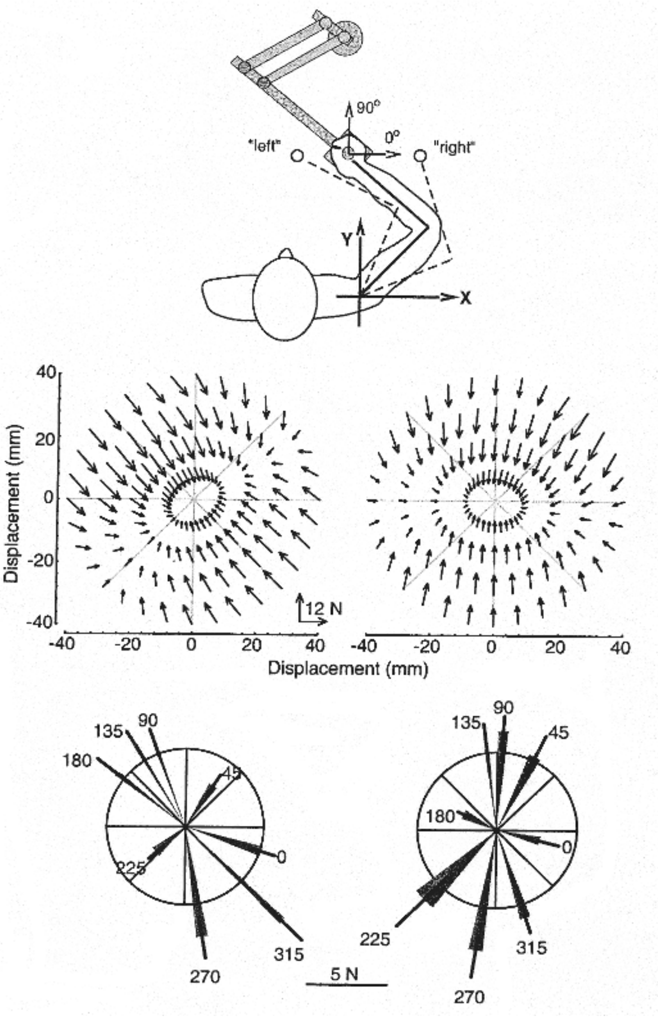

**Figure 1.** Subject was seated in front of a robotic arm and instructed to hold the handle at either the *right* or *left* configuration. Robot slowly displaced the hand from the origin and measured restoring forces. These forces represent the static component of the force field produced by the muscles, i.e., the postural field. Note the anisotropic shape. Now the subject is told to reach to a target. For randomly selected targets, the robot prevents initiation of the movement (applies a break) and measures the force that the subject is generating in order to make the movement. The magnitude and standard deviations of the movement-related forces are plotted for targets at 0°, 45°, . . . , 315°. The magnitude and direction of movement-related forces are in agreement with the hypothesis that movement is generated through a shift of the equilibrium position of the postural force field toward the target. (From Shadmehr, R., Mussa-Ivaldi, F. A., and Bizzi, R., 1993, Postural force fields of the human arm and their role in generating multijoint movements, *J. Neurosci.*, 13:45–62. Reprinted with permission.)

Won and Hogan (1995) went a step further and suggested that during the entire movement, the static component of the field $f_c$ should be similar to that measured when the hand was at rest; i.e., it should converge to an equilibrium position. In their experiment, the hand was displaced from its intended trajectory via a rigid mechanical constraint. It was shown that as the arm was being displaced, it produced forces directed toward the intended trajectory.

The notion of stability about a trajectory (Equation 3) was clearly demonstrated in the data as the controller's output during movement was a force field with an equilibrium point moving roughly along the path connecting the start to the target position.

## Dynamics of the Muscle-Reflex System During Movement

Katayama and Kawato (1993) noted that the simulations by Flash used a magnitude of stiffness $K$ that was approximately three times that measured when the arm was at rest. This correctly highlighted the fact that a very stiff system has no need to take into account dynamics of the system in generating its motor output. Although the actual stiffness of the arm was a crucial factor in the simulations, its actual value during movement was unknown, and its estimation had been difficult. Bennett et al. (1992) had found that stiffness during a highly practiced movement was significantly less than that measured when the hand was at rest, while Milner (1993) had found a value that was near the rest levels. It seemed clear that accurate measures of the arm's stiffness during motion were required.

Gomi and Kawato (1996) designed a high-performance robotic manipulandum and measured the arm's stiffness during motion. They found that the stiffness of the arm was near those measured at rest but was temporally modulated about this level during motion. They used measures of local stiffness to estimate the point of convergence of the static component of field $f_c$ by assuming that the static muscle forces were linearly related to distance from equilibrium. Gomi and Kawato concluded that motion of the arm could not be due to a simple shift of the equilibrium point along the desired trajectory. This suggested that ultimately, control of motion required explicit compensation for dynamics of the limb.

The crucial question in the work of Gomi and Kawato (1996) was how to estimate the null point of a force field from local measures of stiffness. Most if not all of the experimental data on intact muscle reflex systems describe only the static behavior, as in Equations 4 and 6. Gomi and Kawato showed that if the dynamic behavior of the muscle reflex system is dominated by its static properties, then it is unlikely that the brain can produce a desired movement via a simple shift of the equilibrium point of the system. But what about the dynamic properties of the muscle reflex system? How do they contribute to control?

Gribble et al. (1998) approached this question by modifying Equation 4 to include the effect of delayed sensory feedback on recruitment of motor neurons, and dependence of muscle force on velocity of contraction and temporal summation of activations. The result was a muscle reflex model that, as before, was controlled via a threshold muscle length, and had a static behavior that remained similar to Equation 4, but was now a complex dynamical system. Remarkably, it was found that if the threshold lengths of the muscles acting on a simulated two-joint arm were shifted along a smooth desired trajectory to the target, the resulting motion was also a smooth trajectory. Furthermore, the local stiffness of the system about the actual trajectory was very similar to that reported by Gomi and Kawato (1996). This suggested that the dynamical behavior of the muscle reflex system was a crucial element in compensating for the arm's dynamic, and that the input to the system might change rather simply from a starting location to a desired end point in order to produce a smooth hand trajectory.

Hodgson and Hogan (2000) performed an elegant experiment that appears to resolve this issue. Rather than estimating a limb's equilibrium position from local stiffness properties and extrapolating to its null point, they perturbed the limb until its equilibrium point was found. Their results (Figure 2) clearly demonstrated that for simple reaching movements, the attractor trajectory was not along the actual trajectory but led it considerably. Therefore, this demonstrates that while the limb has simple reflex mechanisms that stabilize it in the case of perturbation, the system is not stiff enough that its input can simply ignore dynamics.

## Learning and Modulation in Stiffness Properties of the Limb

The motor commands that act on muscles produce not only force but also an attractor that stabilizes the limb about a trajectory. This is a fundamental property that is crucial for control of our movements because there exists a significant delay in tranmission of sensory information from the limbs to our brain. The delay results in multiple levels of feedback: muscles respond with almost no delay with increased force as they are stretched; muscle spindles sense this stretch and activate spinal reflex pathways that enhance this force production with a delay of approximately 30 ms (termed "short-loop" reflexes); the afferent information is conveyed to the thalamus and then to the motor cortex, and the brain responds to the muscle stretch by altering the descending commands, affecting the muscle in approximately 100 ms (termed "long-loop" reflexes). Therefore, the stiffness of the limb and the behavior of the attractor have a time-dependent component. The brain has the ability to modulate the attractor (force response to a displacement) at a time scale of about 100 ms.

Two recent experiments demonstrate that the brain can modulate the long-loop reflexes so as to match the properties of the task. Burdet et al. (2001) asked subjects to make reaching movements while holding a robot that produced a field that was zero along a straight line connecting the start point to end point, but pushed the hand away if the hand strayed from the straight line. Effectively, the hand was traveling along a knife's edge. They domonstrated that the stiffness of the arm increased only along the dimension where the forces were acting (perpendicular to the direction of motion). The results of Wang, Dordevic, and Shadmehr (2001) in subjects who also learned to reach in force fields suggest that this modulation is limited to the long-latency component of the reflex. Therefore, not only do stiffness properties of the limb produce an attractor trajectory that stabilizes the limb during movements, but the brain can also modulate the shape of the restoring forces about the attractor to match the properties of the task.

## Summary

Biological muscles are spring-like systems. It was thought that because of their elastic behavior, the CNS might simply describe motor commands in terms of the resting lengths of these springs, effectively producing trajectories in terms of equilibrium points of the system. These commands would ignore the inertial dynamics

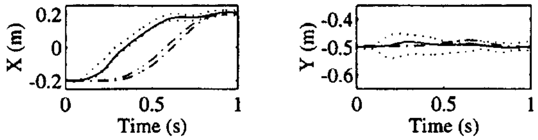

**Figure 2.** The hand is making a reaching movement while holding a robotic arm. In some cases, the movement is perturbed so that the robot takes the arm along the current estimate of the equilibrium trajectory. The process is repeated until the equilibrium trajectory is found. The bounds for the actual movement are shown by the dash-dot lines. The bounds for the equilibrium trajectory are shown by the dotted lines. The estimate for the equilibrium trajectory is shown by the solid line. Note the large distance by which the equilibrium trajectory leads the actual trajectory. (From Hodgson, A. J., and Hogan, N., 2000, A model-independent definition of attractor behavior applicable to interactive tasks, *IEEE Trans. Syst. Man Cybern.*, 30:105–118. Reprinted with permission.)

of the limb, simplifying the process of control. However, there is now convincing evidence that in programming motor commands to the muscles, the brain does take into account the dynamics of the task (see SENSORIMOTOR LEARNING). The motor commands result in an attractor trajectory that leads the hand in simple reaching movements. It would be expected that both the trajectory of the attractor and the shape of the restoring field about the attractor would change as the dynamics of the task change. Although it is quite possible that biological motor commands can be described in terms of changes in the equilibrium position of the limb, the hypothesis that control of movements by the brain is explicitly performed through this manipulation because it somehow simplifies the process of control appears to be inconsistent with the current data.

# Event-Related Potentials

*Steven L. Bressler*

## Introduction

It is commonly believed that cognition intimately depends on the functioning of the cerebral cortex. Understanding the neural basis of cognition therefore will likely require knowledge of cortical operations at all organizational levels, which may usefully be grouped as microscopic, mesoscopic, and macroscopic. The cellular mechanisms of cortical neurons operate at the microscopic scale and are measured by a host of techniques targeted at that level. Individual cortical neurons contribute to cognitive function, however, by joining in the cooperative actions of neural networks, which operate at the mesoscopic and macroscopic scales. At the microscopic scale, the cooperative fraction of any single neuron's total activity may be exceedingly small, but the cooperative activity of the network exerts effects that are relevant for cognition. The mesoscopic level concerns the cooperative activity of neurons locally in ensembles and area networks, and the macroscopic level concerns the cooperative activity of neurons globally in large-scale networks and entire systems. Thus, many important cortical functions reside in the operations of neural networks and are measured by specialized techniques targeted at the mesoscopic and macroscopic levels.

The event-related potential (ERP) is a neural signal that reflects coordinated neural network activity. The cortical ERP provides a window onto the dynamics of network activity in relation to a variety of different cognitive processes at both mesoscopic and macroscopic levels on a time scale comparable to that of single-neuron activity. Cortical ERPs arise from synchronous interactions among large numbers of participating neurons. These include dense local interactions involving excitatory pyramidal neurons and inhibitory interneurons, as well as long-range interactions mediated by axonal pathways in the white matter. (See NEUROANATOMY IN A COMPUTATIONAL PERSPECTIVE.) Multiple feedback loops involving both excitatory and inhibitory interactions typically cause ERPs to be oscillatory, meaning that they fluctuate within bounds around a central value. Depending on the types of interaction that occur in a specific behavioral condition, cortical networks may display different states of synchrony, causing their ERPs to oscillate in different frequency bands, designated delta (0–4 Hz), theta (5–8 Hz), alpha (9–12 Hz), beta (13–30 Hz), and gamma (31–100 Hz).

The physiological basis of the cortical ERP lies in fields of potential generated by interacting neurons (Lopes da Silva, 1991). Field potentials are largely dendritic in origin, resulting from the summed extracellular currents generated by electromotive forces (EMFs) in the dendrites of synchronously active cortical neurons, primarily pyramidal cells. The EMFs, arising from synaptic activation of postsynaptic ion channels, circulate current in closed loops across the cell membrane and through the intracellular and extracellular spaces. Summed closed-loop currents generated by an ensemble of neighboring neurons flow across the external resistance to form the local ensemble mean field potential (Freeman, 2000).

Depending on the location and size of the recording and reference electrodes, recorded cortical field potentials integrate neural activity over a range of spatial scales: from the intracortical local field potential (LFP) to the intracranial electrocorticogram (ECoG) to the extracranial electroencephalogram (EEG). The LFP (Figure 1) is the most spatially localized signal, integrating the field potential on a submillimeter scale; the ECoG integrates on a submillimeter to millimeter scale; and the EEG integrates over centimeters. The term "field potential" will be used here in reference to the general class of signal subsuming the LFP, ECoG, and EEG. (The intracellular components of the same closed-loop currents that give rise to field potentials are responsible for the closely related magnetic fields, recorded extracranially as the magnetoencephalogram, or MEG.)

A general problem in the investigation of ERPs is that field potential recordings most often contain a combination of potentials, in unknown proportions, from multiple sources. Thus, in addition to the ERP, which is derived from specific networks associated with a behavioral event, the field potential typically also contains potentials derived from the more general field activity of large neural populations. Owing to their fortuitous geometric arrangements and synchronous behavior, these later potentials are mixed with the ERP waveform. Thus, a primary task of all ERP studies is to extract the event-related portion of the recorded field potential. The next section deals with some basic methodology by which this is accomplished for different kinds of ERP.

## ERP Varieties and Their Analysis

Whether reflecting mesoscopic or macroscopic activity, the cortical ERP is an electrical signal generated by neuronal networks in relation to a behaviorally significant event. (The corresponding event-related magnetic field has many of the same dynamic and functional properties as the ERP.) Two general classes of ERP are distinguished by whether the relevant event is discrete or continuous. In the case of discrete events, the associated transient ERP is analyzed in short epochs that are time-locked to the event. In the case of continuous events, which usually are periodically modulated sensory stimuli such as a visual flicker, the concurrent steady-state ERP is analyzed in a relatively long time segment.

The traditional approach to the analysis of transient ERPs is to consider the ERP as a characteristic waveform that occurs in relation to the behaviorally significant discrete event. As a simplifying assumption, the ERP waveform is usually treated as if it possesses the same amplitude and phase each time that the event is repeated on multiple trials, although recent analysis shows that this assumption may not always be valid (Truccolo et al., 2002). Nonetheless, as was discussed above, the recorded single-trial field potential contains contributions from network activity that are both associated (ERP signal) and not associated (noise) with the event. Therefore, averaging of the single-trial field potential time series, time-locked to the event, is commonly employed to extract the ERP from the non-event-related noise. When the relevant event is a sensory stimulus, such phase-locked ERPs are called "evoked." Averaged evoked potentials (Figure 2) are most commonly described in terms of the succession of waveform components that follow stimulus presentation. These components are typically identified according to their polarity (positive or negative) and their time latency following stimulus onset. (Note that the time latency is equivalent to phase in this context.)

Transient ERP waveform components having variable phase may also reliably occur in relation to the repeated event. In this case, time series averaging does not reveal the ERP but instead is destructive, since components of opposite polarity on successive trials tend to be canceled. Non-phase-locked ERPs are referred to as "induced" when they occur following a stimulus and "spontaneous" in the period prior to a stimulus or motor response. This type of ERP may be effectively analyzed by averaging the frequency content of single-trial time series rather than the time series themselves.

Non-phase-locked transient event-related phenomena are detected as frequency-specific changes in the ERP time series. These phenomena may consist of either an event-related increase or decrease of power in one or more of the aforementioned frequency bands. Since the level of ERP power is typically considered to reflect the degree of synchrony within local neuronal populations, a power increase is called event-related synchronization, and a power decrease is called event-related desynchronization (Pfurtscheller and Lopez da Silva, 1999). Frequency analysis has the further advantage of allowing measurement of event-related phase synchronization of ERPs from different cortical sites (Varela et al., 2001). ERP phase synchronization in different frequency ranges has been identified as a fundamental neural correlate of basic sensory and motor processes, as well as higher cognitive processes such as perception and recall of semantic entities. (See SYNCHRONIZATION, BINDING AND EXPECTANCY.)

The study of steady-state ERPs also depends on a variant of frequency analysis. Field potentials recorded during periodically modulated sensory stimulation are narrow-bandpass filtered around the frequency of the driving periodicity to derive the steady-state (periodic) ERPs. Variations in the amplitude and phase of the steady-state ERP are interpreted in terms of driving frequency, spatial location, and behavioral state.

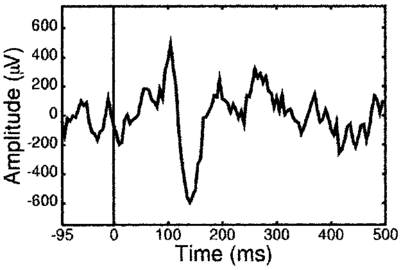

**Figure 1.** A local field potential (LFP) recorded from the posterior parietal cortex of a macaque monkey in relation to a visual stimulus presented on a display screen for 100 ms, starting at time 0. The LFP was recorded from a chronically implanted bipolar transcortical electrode consisting of 51-$\mu$m-diameter Teflon-coated platinum wires with 2.5-mm tip separation.

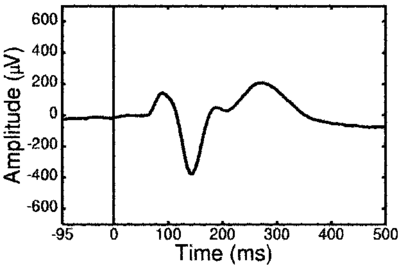

**Figure 2.** The averaged event-related potential from the same posterior parietal cortex site as in Figure 1, computed from an ensemble of 888 trials. Note the flat prestimulus baseline as compared to the single trial in Figure 1. This illustrates the fact that rhythmic prestimulus activity that is not phase-locked to the stimulus is canceled out by the averaging process.

## The Theory of Large-Scale Cortical Networks

Evidence from a variety of sources indicates that neural networks in the cerebral cortex are organized both locally in anatomically segregated areas and on a large scale encompassing multiple distributed areas (Bressler, 2002). Although research on cortical network properties is still in its infancy, a rough depiction of some basic operational features is now possible. Local-area networks process and store information related to specialized sensory, motor, and executive functions, and local synaptic interactions lead to the manifestation of coherent spatial ERP patterns in these specialized informational domains. These interactions also modify the local synaptic matrix with learning. The modified synaptic matrix exerts an essential control on pattern formation in the local-area network by attracting its dynamics to learned (attractor) patterns. In this regard, artificial neural networks that operate according to attractor dynamics bear a resemblance to cortical networks at the local level. (See COMPUTING WITH ATTRACTORS.)

An essential element of overall cortical network function, however, is missing from most artificial network models. Following training on pattern recognition problems, traditional artificial neural networks converge to fixed solutions for a given class of input patterns. Although this behavior has well-known advantages for pattern recognition, it represents an excessive processing rigidity, since these networks lack the ability to adapt to changing external constraints such as are found in real-world situations. Adaptability, in this sense, is a distinguishing feature of normal cortical function.

Theoretical considerations suggest that processing adaptability in the cerebral cortex derives from an essential property of large-scale network dynamics called *metastability*. Cortical metastability refers to a state of dynamic balance among multiply interacting local networks in which the tendency for independent local expression is offset by the tendency for large-scale entrainment (Bressler and Kelso, 2001). The property of metastability permits local networks that are interconnected within the large-scale network architecture of the cortex to coordinate their activities without becoming locked in a fixed pattern of coordination from which they cannot escape.

The ability of local-area networks to form transient coordination relations may represent a basic cortical mechanism for the rapid and flexible association of information from different informational domains. (See ASSOCIATIVE NETWORKS.) It is to be expected that the concurrent coordination of multiple local-area networks imposes conjoint constraints on the spatiotemporal patterning of activity in each local network. The imposition of such constraints may have the important effect of creating associations between activity patterns in different informational domains during the learning process, through the modification of synapses of axons that project from one local network to another. These learned associations would then act during recall on the attractor dynamics of multiple interacting local area networks, causing them to reach a conjunction of consensual patterns that represents an integration of their information. (See COMPUTING WITH ATTRACTORS.)

## ERP Evidence for Large-Scale Cortical Network Organization

The theoretical considerations presented in the previous section lead to predictions about the large-scale cortical network organization underlying cognition. One straightforward prediction is that cognitive states should be characterized by unique configurations of interdependent cortical areas in large-scale networks. A confirmation of this prediction is found in the spatial patterning of coactivated cortical areas seen with functional brain imaging techniques such as PET and fMRI. (See COVARIANCE STRUCTURAL EQUATION MODELING.) Like these neuroimaging procedures, ERPs can provide information about the spatial distribution of large-scale network activity underlying a cognitive function. Moreover, because ERPs reflect neurodynamics on a fast time scale (that is inaccessible to current brain imaging technologies), ERPs can also reveal elementary neural subprocesses that subserve that cognitive function. This section uses working memory to illustrate how ERP results can relate large-scale network activity to different subprocesses of a cognitive function.

Working memory consists of several subprocesses for which prominent averaged ERP waveform components have revealed distinct underlying large-scale networks (McEvoy et al., 1998). The mismatch negativity is an early poststimulus ERP component that reflects the maintenance of sensory working memory in the auditory modality. It is elicited by auditory stimuli having physical acoustic properties that deviate from prior (standard) stimuli registered in auditory memory. Occurring between 80 and 200 ms after presentation of deviant auditory stimuli, thus overlapping the N1 and P2 components, the mismatch negativity is isolated by computing the difference wave between averaged ERPs evoked by deviant and standard stimuli. The mismatch negativity is subserved by a large-scale network that includes, in addition to auditory cortical areas, dorsolateral prefrontal cortex, which may serve to control the maintenance of sensory memory in the auditory cortex following one stimulus for comparison with subsequent stimuli (Alain et al., 1998).

A second ERP component, the P3b, occurring roughly 300 ms poststimulus, also results from the comparison of target stimuli with the content of working memory. However, rather than being tuned to the physical characteristics of stimuli, the widely distributed cortical network underlying the P3b is involved in the categorization of stimuli as significant events. Network strength has been found to reflect the degree of consonance resulting from comparison of stimulus attributes with a maintained "expectation" (Kok, 2001).

A third ERP component, related to semantic memory, is the negative-going N400. It occurs between 200 and 500 ms after presentation of a potentially meaningful information-bearing stimulus and varies systematically according to the preexisting context that is established by semantic and long-term memory influences. Specifically, N400 amplitude is reduced as a function of associative, semantic, and repetition priming within or across sensory modalities (Kutas and Federmeier, 2000). Variation of its scalp-recorded topographic distribution with task and stimulus type suggests that the N400 reflects the construction of meaning by cross-modal interactions in a widely distributed neural network. This view is supported by intracranial evidence that the N400 arises from similar waves of activity in multiple brain areas, particularly in the temporal and prefrontal cortices, during the retrieval of information from semantic memory.

Deeper insight into the dynamic organization of large-scale networks underlying working memory comes from studies of the phase synchronization between ERPs from distributed cortical areas. For example, long-range ERP phase synchronization has been reported in the theta frequency range between prefrontal and posterior association areas when subjects retain verbal and spatial items for short periods of time (Sarnthein et al., 1998) and in the beta frequency range between extrastriate areas when they retain visual object representations (Tallon-Baudry et al., 2001). These studies suggest that large-scale cortical network function is based not just on the co-activation of distributed neuronal ensembles, but also on the active coordination of ensemble activity, observable as ERP phase synchronization.

Finally, other ERP types have been used to examine the neural correlates of working memory load. In one investigation, the steady-state visual ERP elicited by a diffuse 13-Hz visual flicker was used to study memory load during the retention period of an object working memory task (Silberstein et al., 2001). The steady-state visual ERP exhibited a load-dependent increase in amplitude at frontal and occipitoparietal sites. By comparison, in a study of event-related synchronization and desynchronization, significant effects of memory load were found in the frontal lobe during a visual sequential letter task (Krause et al., 2000). Event-related synchronization was found at theta frequencies during the initial stages of stimulus processing, whereas event-related desynchronization was observed at alpha frequencies.

## Discussion

The cortical ERP reflects the coordinated behavior of large numbers of neurons in relation to a meaningful externally or internally generated event. Single neurons are actively coordinated in the operations of ensembles, local-area networks, and large-scale networks. ERP studies provide a unique avenue of approach to the dynamics of coordination in the cortex at the mesoscopic and macroscopic levels of organization. ERP analysis is an indispensable complement to single-cell neurophysiology and whole-head neuroimaging techniques and can supply a rich source of criteria for neural network modeling efforts.

ERP studies have shown that local cortical area networks are able to synchronize and desynchronize their activity rapidly with changes in cognitive state. These synchronization changes occur between neurons located both within individual local networks and in different local networks. The ability of local area networks to repeatedly reconfigure their activity patterns under constraint of large-scale coordinating influences may allow them to increase the degree of consensus of those local patterns in a short period of time, thereby causing the cortical system as a whole to evolve toward the solution of computational problems. Since it normally operates in a metastable dynamic regime, the cortex is able to balance the coordinated and independent behavior of local networks to maintain the flexibility of this process. When incorporated into artificial neural network designs, a similar computational process could prove useful in avoiding the processing rigidity of many current network models. A metastable large-scale neural network design that recruits and excludes subnetworks according to their ability to reach consensual local patterns has the potential to implement behavioral schema and adapt to changing environmental conditions. Such a system would represent an important advance in machine cognition.

# Evolution and Learning in Neural Networks

*Stefano Nolfi*

## Introduction

Evolution and learning are two forms of adaptation that operate on different time scales. Evolution is capable of capturing relatively slow environmental changes that might encompass several generations. Learning allows an individual to adapt to environmental changes that are unpredictable at the generational level. Moreover, evolution operates on the genotype, but learning affects the phenotype and phenotypic changes cannot directly modify the genotype. Recently, the study of artificial neural networks subjected both to an evolutionary (see Evolution of Artificial Neural Networks) and a lifetime learning process has received increasing attention. These studies (see also Nolfi and Floreano, 1999) have been conducted with two different purposes: (1) looking at the advantages, in terms of performance, of combining two different adaptation techniques; (2) understanding the role of the interaction between learning and evolution in natural organisms. The general picture emerging from this body of research suggests that, within an evolutionary perspective, learning has several different adaptive functions:

- It might help and guide evolution by channeling the evolutionary search toward promising directions. For example, learning might significantly speed up the evolutionary search.
- It might supplement evolution by allowing individuals to adapt to environmental changes that cannot be tracked by evolution because they occur during the lifetime of the individual or within few generations.
- It might allow evolution to find more effective solutions and facilitate the ability to scale up to problems that involve large search space.

Learning also has costs. In particular, it might increase the unreliability of evolved individuals (Mayley, 1997). Because learned abilities are also determined by learning experiences, learning individuals might fail to acquire necessary abilities in unfavorable conditions.

## How Learning Might Help and Guide Evolution

Hinton and Nowlan (1987) provided a clear and simple demonstration of how learning might influence evolution even if the learned characteristics are not communicated to the genotype. The authors considered a simple case in which (1) the genotype of the evolving individuals consists of 20 genes that encode the architecture of the corresponding neural networks and (2) just a single architecture (i.e., a single combination of gene values) confers added reproductive fitness. Individuals have a genotype with 20 genes that can assume two alternative values (0 or 1). The only combination of genes that provides a fitness value above 0 consists of all 1s. In this extreme case, the probability of finding the good combination of genes is very small, given that the fitness surface looks like a flat area with a spike corresponding to the good combination. Indeed, on such a surface, artificial evolution does not perform better than random search—finding the right combination is akin to discovering a needle in a haystack. The fitness surface metaphor is often used to visualize the search space on an evolutionary algorithm. Any point on the search space corresponds to one of the possible combinations of genetic traits, and the height of each point on the fitness surface corresponds to the fitness of the individual with the corresponding genetic traits.

The addition of learning simplifies the evolutionary search significantly. One simple way to introduce learning is to assume that, in the learning individual, genes can have three alternative values [0, 1, and ?], where question marks indicate modifiable genes whose value is randomly selected within [0, 1], each time step of the individual's lifetime. By comparing learning and nonlearning individuals, one can see that performance increases throughout generations much faster in the former. The addition of learning, in fact, enlarges and smoothes the fitness surface area around the good combination, which can be discovered much more easily in this case by the genetic algorithm. This is because not only the right combination of alleles but also combinations having in part the right alleles and in part unspecified (learnable) alleles might report an average fitness greater than 0. (Fitness increases monotonically with the number of fixed right values because the time needed to find the right combination is inversely proportional, on average, to the number of learnable alleles.) According to Hinton and Nowlan (1987, p. 496), "It is like searching for a needle in a haystack when someone tells you when you are getting close." (On this point, see also Basal Ganglia; Reinforcement Learning.) A variation of this model has been used to study the interaction between evolution, learning, and culture (Hutchins and Hazlehurst, 1991).

The Hinton-Nowlan model is an extremely simplified case that can be analyzed easily, but it makes several unrealistic assumptions: (1) There is no distinction between genotype and phenotype; (2) learning is modeled as a random process that does not have any directionality; (3) there is no distinction between the learning task (i.e., the learning functions that individuals try to maximize during their lifetimes) and the evolutionary task (i.e., the selection criteria that determine which individuals are allowed to reproduce). Nolfi, Elman, and Parisi (1994) conducted further research that showed how learning and evolution display other forms of mutually beneficial interactions when these limitations are released.

Nolfi et al. (1994) studied the case of artificial neural networks that "live" in a grid world containing food elements. Networks evolve (to become fitter at one task) at the population level and learn (a different task) at the individual level. In particular, individuals are selected on the basis of the number of food elements they are able to collect (evolutionary task) and their capacity to predict the sensory consequences of their motor actions during their lifetime (learning task).

The genotype of the evolving individuals encoded the initial weights of a feedforward neural network which, at each time step, receives sensory information from the environment (the angle and the distance of the nearest food element and the last planned motor action), determines a given motor action selected within four options (move forward, turn left, turn right, or stay still), and predicts the next sensory state (the state of the sensors after the planned action is executed). Sensory information is used both as input and as teaching input for the output units encoding the predicted state of the sensors—the new sensory state is compared with the predicted state, and the difference (error) is used to modify the connection weights through backpropagation. As in the case of the Hinton-Nowlan model, modifications due to learning are not transferred back into the genotype.

The experimental results showed that (1) after a few generations, by learning to predict, individuals increased their performance not only with respect to their ability to predict but also with respect to their ability to find food (i.e., learning produced a positive effect on evolution even if the learning and the evolutionary tasks were different), and (2) the ability to find food increased faster and achieved better results in the case of learning populations than in the case of control experiments in which individuals were not allowed to learn during their lifetime. Further analysis demonstrated that the first observation can be explained by considering that evolution tends to select individuals that are located in regions of the search space where the learning and evolutionary task are dynamically correlated (i.e., where learning-induced changes that produce an increase in performance with respect to the learning task also produce positive effects, on average, with respect to the evolutionary task). And the second observation can be explained by considering that, once learning channels evolution toward solutions in which the learning task and the evolutionary task are dynamically correlated, it allows individuals to recover from deleterious mutations (Nolfi, 1999).

Consider, for example, two individuals, *a* and *b*, that are located in two distant locations in weight space but have the same fitness at birth; i.e., the two locations correspond to the same height on the fitness surface (Figure 1). However, individual *a* is located in a region where the fitness surface and the learning surface are dynamically correlated—a region in which movements that result in an increase in height with respect to the learning surface cause an increase with respect to the fitness surface on average. Individual *b*, on the other hand, is located in a region where the two surfaces are not dynamically correlated. If individual *b* moves in weight space, it will go up in the learning surface but not necessarily in the fitness surface. Because of learning, the two individuals will move during their lifetime in a direction that improves their learning performance, i.e., a direction in which their height on the learning surface tends to increase. This implies that individual *a*, which is located in a dynamically correlated region, will end up with a higher fitness than individual *b* and will therefore have a better chance to be selected. The final result is that evolution will have a

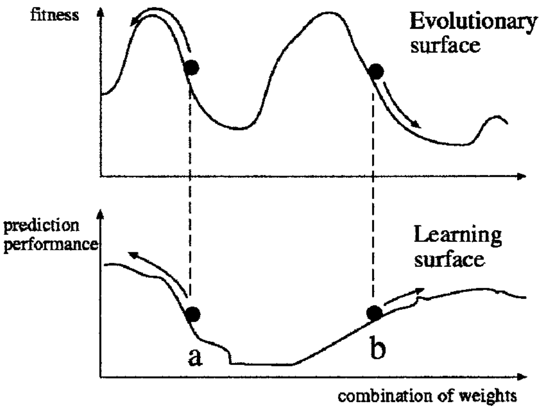

**Figure 1.** Fitness surface for the evolutionary task and performance surface for the learning task (sensory prediction) for all possible weight matrices. Movements due to learning are represented as arrows.

tendency to progressively select individuals that are located in dynamically correlated regions. In other words, learning forces evolution to select individuals that improve their performance with respect to both the learning and the evolutionary task.

## Adapting to Changing Conditions on the Fly

As claimed above, learning might complement evolution by providing a means to master changes that occur too fast to be tracked by the evolutionary process. However, the combination of learning and evolution deeply alters both processes; thus, in individuals that evolve and learn, adaptive characteristics emerge as the result of the interaction between evolutionary and lifetime adaptation and cannot be traced to just one of the two processes.

Nolfi and Parisi (1997) evolved neural controllers for a small mobile robot that was asked to explore an arena (60 × 20 cm) surrounded by walls. The robot was provided with eight infrared sensors that could detect walls up to a distance of about 4 cm and two motors that controlled the two corresponding wheels. The colors of the walls switched from black to white and vice versa each generation because the activity of the infrared sensors is highly affected by the color of the reflecting surface (white walls reflect much more than black walls). Thus, to maximize their exploration behavior, evolved robots should modify their behavior on the fly. In the dark-walled environment, in fact, robots need to move very carefully whenever their sensors are activated; this is because dark walls are detected only when they are very close. In the white-walled environment, robots must begin to avoid walls only when their sensors are strongly activated; this facilitates exploration of the area close to the walls.

Individuals learn during their lifetime by means of self-generated teaching signals. The genotype of the evolving individuals encodes the connection strengths of two neural modules: (1) a teaching module that, each time step, receives the state of the sensors as input and produces a teaching signal as output; (2) an action module that receives the state of the sensors as input and produces motor actions as output. The self-generated teaching signal is used to modify the connection strengths of the action module (for a similar architecture, see Ackley and Littman, 1991). This implies that both the initial behavior produced by the evolving individuals and what the individuals learn are results of the evolutionary process, and neither is determined by the experimenter.

Evolved robots displayed an ability to discriminate between the two types of environments and to modify their behavior accordingly, thereby maximizing their exploration capability. The analysis of the results revealed that this ability arose from a complex interaction between the evolutionary and learning process. For example, evolved individuals displad an inherited ability to behave so as to enhance the perceived differences between the two environments. This in turns allows the learning process to progressively modify the behavior of the robots so as to adapt to the different environmental conditions.

More generally, this research and that of others has shown that evolution, in the case of individuals able to change during their lifetime as a result of learning, does not tend to directly develop an ability to solve a problem; rather, it tends to develop a predisposition to acquire such ability through learning.

Other experiments conducted by coevolving two competing populations of predator and prey robots (Nolfi and Floreano, 1998) emphasized how lifetime learning might allow evolving individuals to achieve generality, i.e., the ability to produce effective behavior in a variety of circumstances. In these experiments, predators consisted of small mobile robots provided with infrared sensors and a linear camera with a view angle of 36°, which allowed them to detect prey. Prey consisted of mobile robots of the same size; these robots had only infrared sensors, but their maximum available speed was set to twice that of the predators. Each individual was tested against different competitors for ten trials. Predators scored one point for each trial in which they caught prey while prey scored one point for each trial in which they escaped predators.

In this experimental situation, both populations change through the generations as predators and prey face ever-changing, progressively more complex challenges. Interestingly, the authors observed that, in this situation, evolution alone displayed severe limitations; progressively more effective solutions could be developed only by allowing evolving individuals to adapt on the fly through a form of lifetime learning. Indeed, any fixed strategy could master only a limited number of different types of competitors; therefore, only by combining evolution and learning were the authors able to synthesize individuals capable of dealing with competitors adopting qualitatively different strategies. Indeed, by evolving learning individuals, the authors observed the emergence of predators able to detect the current strategy adopted by the prey and to modify their behavior accordingly.

## Evolving the Learning Rules

Floreano and Urzelai (2000) conducted a set of experiments in which the genotype of the evolving individuals encoded the learning properties of the neurons of the corresponding neural network. These properties included one of four possible Hebbian learning rules, the learning rate, and the sign of all the incoming synapses of the corresponding neuron. When the genotype is decoded into a neural controller, the connection strengths were set to small random values. After some generations, the genetically specified configuration of learning rules tended to produce changes in the synaptic strengths that allow individuals to acquire the required competencies through lifetime learning. By comparing the results obtained with this method with a control experiment in which the strength of the synapses was directly encoded into the genotype, the authors observed that evolved controllers able to adapt during lifetime can solve certain tasks faster and better than standard nonadaptive controllers. Moreover, they demonstrated that their method scales up well to large neural architectures.

The authors applied this method to evolve neural controllers for mobile robots. Interestingly, the analysis of the synaptic activity of the evolved controllers showed that several synapses did not reach a stable state but kept changing all the time. In particular, synapses continued to change even when the behavior of the robot became rather stable.

Similar advantages have been reported by Husband et al. (1999), who evolved a type of neural network in which neurons, which were distributed over a 2D surface, emitted "gases" that diffused through the network and modulated the transfer function of the neurons in a concentration-dependent fashion, thus providing a form of plasticity.

Finally, the experiments performed by Di Paolo (2000) showed how learning could play the role of a homeostatic process whereby evolved neural networks adapt in order to remain stable in the presence of external perturbations.

## Discussion

The interaction between learning and evolution deeply alters both the evolutionary and the learning processes. Evolution in interaction with learning displays dynamics very different from those observed in evolution alone. While in nonlearning individuals the characters that are selected through evolution directly incorporate an ability to produce successful behaviors, in learning individuals they incorporate a predisposition to learn, i.e., a predisposition to acquire necessary abilities through learning. This predisposition to learn may consist of the following:

1. The presence of starting conditions that canalize learning in the right direction. Evolution may select initial weight matrices or network architectures that cause a better and/or a faster learning (Belew, McInerney, and Schraudolph, 1992). This happens either when the learning task and the evolutionary task are the same or when they differ. In the latter case, evolution selects not only individuals that have a predisposition to learn better, but also individuals that, by learning a given task, improve their performance with respect to the evolutionary task.
2. An inherited tendency to behave in such a way that the individual is exposed to the appropriate learning experiences. Evolution tends to select characters that produce initial behaviors that enhance the possibility of learning and/or increase the probability of acquiring adaptive characters through learning. In other words, evolution tends to select individuals whose initial behavior is suitable for learning and not necessarily for solving the evolutionary task.

Similarly, learning within an evolutionary perspective has quite different characteristics from learning studied in isolation, as in "traditional" connectionist research. In individuals that learn but are not subjected to an evolutionary process (e.g., neural networks trained with supervised methods), learning is usually accomplished by ignoring the characters of the individual prior to learning (which are typically generated at random); but in evolving plastic individuals, learning exploits such starting conditions. Moreover, when the learning process itself (i.e., what it is learned during lifetime) is subjected to evolution and not determined in advance, learning does not necessarily tend to incorporate the right solution to the problem; rather, it tends to pull the learning individual in a direction that, given the initial state of the individual, maximizes the chances of adapting to the current environment.

The study of learning within an evolutionary perspective is still in its infancy. But in forthcoming years, it might have an enormous impact on our understanding of how learning and evolution operate in nature. In particular, this type of research might shed light on the ability to learn from others, and more generally on the co-evolution between brain structure and cultural processes such as natural language (for initial explorations of such issue, see Cangelosi, 2001).

## Introduction

Artificial neural networks may be either computational models of biological nervous systems or computational systems inspired, perhaps loosely, by neurobiology. Natural organisms, however, possess not only nervous systems but also genetic information stored in the nucleus of their cells (genotype). The nervous system is part of the phenotype derived from this genotype through a process called development. The information specified in the genotype determines aspects of the nervous system that are expressed as innate behavioral tendencies and predispositions to learn. When neural networks are viewed in the broader biological context of artificial life (i.e., the attempt to synthesize life-like phenomena within computer and other artificial media), they tend to be accompanied by genotypes and to become members of evolving populations of networks in which genotypes are inherited from parents to offspring (Parisi, 1997).

Artificial neural networks can be evolved by using evolutionary algorithms (Holland, 1975; Koza, 1992). An initial population of different artificial genotypes, each encoding the free parameters (e.g., the connection strengths, the architecture of the network, the learning rules, or some combination thereof) of a corresponding neural network, is created randomly. The population of networks is evaluated in order to determine the performance (fitness) of each individual network. The fittest networks are allowed to reproduce by generating copies of their genotypes with the addition of changes introduced by genetic operators such as mutations (random changes of a few genes that are selected randomly) or crossover (the combination of parts of the genotype derived from two reproducing networks). This process is repeated for a number of generations until a network that satisfies the performance criterion set by the experimenter is obtained (for a review of methodological issues, see Yao, 1993).

The genotype might encode all the free parameters of the corresponding neural network or only the initial values of the parameters and/or other parameters that affect development and learning. In the former case, networks are entirely specified in the genotype and change only phylogenetically as a result of the modifications introduced by genetic operators during reproduction. In the latter case, networks also change ontogenetically (i.e., during the period in which they are evaluated) as a result of both genetic and environmental factors. In this article we review examples of networks that undergo developmental processes such as neural growth. For an analysis of networks that are able to adapt to the environment as a result of a form of lifetime learning see Evolution and Learning in Neural Networks.

## Evolution and Development

A cornerstone of biology is the distinction between the inherited genetic code (genotype) and the corresponding organism (phenotype). What is inherited from the parents is the genotype. The phenotype is the complete individual that is formed according to the instructions specified in the genotype.

Evolution is critically dependent on the distinction between genotype and phenotype, and on their relation, i.e., the genotype-to-phenotype mapping. The fitness of an individual, which affects selective reproduction, is based on the phenotype; but what is inherited is the genotype, not the phenotype. Furthermore, while the genotype of an individual is a single entity, the organism is a continuum of different phenotypes taking form during the genotype-to-phenotype mapping process, each derived from the previous one under genetic and environmental influences.

When the genotype-to-phenotype mapping process takes place during an individual's lifetime, we speak of development. In this case, each successive phenotype corresponding to a given stage of development has a distinct fitness. The fitness of a developing individual is a complex function of these developmental phases. Evolution must ensure that all these successive forms are viable and, at the same time, that they comprise a well-formed sequence in which each form leads to the next until a mostly stable (adult) form is reached. This puts various constraints on evolution, but it also offers new means for exploring novelty. Small changes in the developmental rates of different components of the phenotype, for example, can have huge effects on the resulting phenotype. Indeed, it has been hypothesized that in natural evolution changes affecting regulatory genes that control the rates of development played a more important role than other forms of change such as point mutations (Gould, 1977; see also Evolution of Genetic Networks).

Although the role of genotype-to-phenotype mapping and development has been ignored in most experiments involving artificial evolution, awareness of its importance is now increasing. According to Wagner and Altenberg (1996, p. 967), "In evolutionary computer science it was found that the Darwinian process of mutation, recombination and selection is not universally effective in improving complex systems like computer programs or chip designs. For adaptation to occur, these systems must possess *evolvability*, i.e., the ability of random variations to sometimes produce improvement. It was found that evolvability critically depends on the way genetic variation maps onto phenotypic variation, an issue known as the representation problem."

## Genetic Encoding

To evolve neural networks one should decide how to encode the network in the genotype in a manner suitable for the application of genetic operators. In most cases, phenotypic characteristics such as synaptic weights are coded in a uniform manner so that the description of an individual at the level of the genotype assumes the form of a string of identical elements (such as binary or floating point numbers). The transformation of the genotype into the phenotypic network is called genotype-to-phenotype mapping.

In direct encoding schemes there is a one-to-one correspondence between genes and the phenotypic characters subjected to the evolutionary process (Yao, 1993). Aside from its biological implausibility (see Evolution of the Ancestral Vertebrate Brain), simple one-to-one mapping has several drawbacks. One problem, for example, is scalability. Since the length of the genotype is proportional to the complexity of the corresponding phenotype, the space to be searched by the evolutionary process increases quadratically with the size of the network (Kitano, 1990).

Another problem of direct encoding schemes is the impossibility of encoding repeated structures (such as network composed of several subnetworks with similar local connectivity) in a compact way. In one-to-one mappings, in fact, elements that are repeated at the level of the phenotype must be repeated at the level of the genotype as well. This affects not only the length of the genotype and the corresponding search space, but also the evolvability of individuals. A full genetic specification of a phenotype with repeated structures, in fact, implies that adaptive changes affecting repeated structures should be independently rediscovered through changes introduced by the genetic operators.

## Growing Methods

The genotype-to-phenotype process in nature is not just an abstract mapping of information from genotype to phenotype; it is also a process of physical growth (both in size and in physical structure). Thus, taking inspiration from biology, one may decide to encode in the genotype growing instructions. The phenotype is progressively built by executing the inherited growing instructions.

Nolfi, Miglino, and Parisi (1994) used a growing encoding scheme to evolve the architecture and the connection strengths of neural networks that controlled a small mobile robot. These controllers consisted of a collection of artificial neurons distributed over a 2D space with growing and branching axons (Figure 1, *Top*). Inherited genetic material specified instructions that controlled the axonal growth and the branching process of neurons. During the growth process, when a growing axonal branch of a particular neuron reaches another neuron, a connection is established between the two neurons. The bottom of Figure 1 shows the network re-

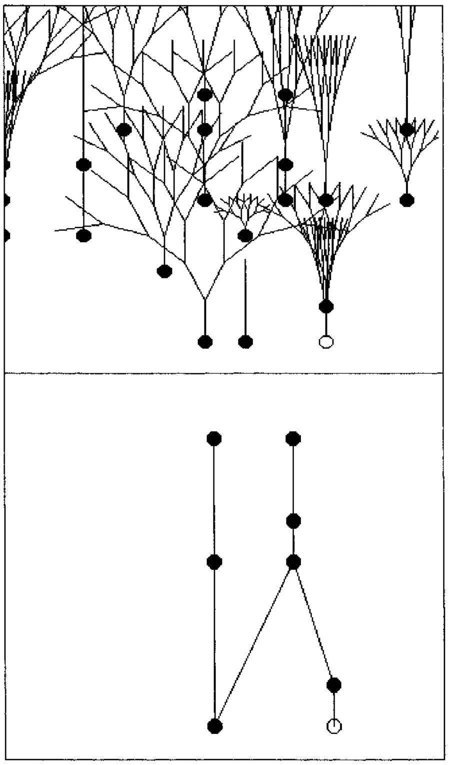

**Figure 1.** Development of an evolved neural network. *Top*, The growing and branching process of the axons. *Bottom*, The resulting neural network after removal of nonconnecting branches and the elimination of isolated neurons and groups of interconnected neurons.

sulting from this growth process after the elimination of isolated and nonfunctional neurons. Axons grew and branched only if the activation variability of the corresponding neurons was larger than a genetically specified threshold. This simple mechanism is based on the idea that sensory information coming from the environment has a critical role in the maturation of the connectivity of the biological nervous system and, more specifically, that the maturation process is sensitive to the activity of single neurons (Purves, 1994). Therefore, both genetic and environmental factors influenced the developmental process; i.e., the actual sequence of sensory states experienced by the network influenced the process of neural growth.

This method allows the evolutionary process to select neural network topologies that are suited to the task chosen (see LEARNING NETWORK TOPOLOGY). Indeed, analysis of the evolutionary process shows how improvements are due to changes affecting both the neural architecture and the connection weights. Moreover, if some aspects of the task are allowed to vary during the evolutionary process, evolved genotypes display an ability to develop into different final phenotypic structures that are adapted to current conditions.

## Cellular Encodings

In natural organisms the development of the nervous system begins with an in-folding of the ectodermic tissue to forms the neural crest. This structure gives rise to the mature nervous system through three phases: the genesis and proliferation of different classes of neurons by cellular duplication and differentiation, the migration of the neurons toward their final destination, and the growth of neurites (axons, dendrites). The growing process described in the previous section therefore characterizes very roughly only the last of these phases. A number of attempts inspired by the seminal work of Lindenmayer (1971) have been made to include other aspects of this process in artificial evolutionary experiments.

Cangelosi, Nolfi, and Parisi (1994), for example, extended the model described in the previous section by adding a cell division and migration stage to the already existing stage of axonal growth. The genotype is a collection of rules governing the process of cell division (a single cell is replaced by two daughter cells) and migration (the new cells can move in the 2D space). The genotype-to-phenotype process therefore starts with a single cell which, by undergoing a number of duplication and migration processes, produces a collection of neurons arranged in a 2D space. These neurons grow their axons and establish connections until a neural controller is formed.

Gruau (1994) proposed a genetic encoding scheme for neural networks based on a cellular duplication and differentiation process. The genotype-to-phenotype mapping starts with a single cell that undergoes a number of duplication and transformation processes, ending up in a complete neural network. In this scheme the genotype is a collection of rules governing the process of cell divisions (a single cell is replaced by two daughter cells) and transformations (new connections can be added and the strengths of the connections departing from a cell can be modified). In this model, therefore, connection links are established during the cellular duplication process.

The instructions contained in the genotype are represented as a binary-tree structure as in genetic programming (Koza, 1992). During the genotype-to-phenotype mapping process, the genotype tree is scanned starting from the top node of the tree, then following each ramification. The top node represents the initial cell that undergoes a set of duplication processes to produce the final neural network. Each node of the genotype tree encodes the operations that should be applied to the corresponding cell, and the two subtrees of a node specify the operations that should be applied to the two daughter cells. The neural network is progressively built by following the tree and applying the corresponding duplication instructions. Terminal nodes of the tree (i.e., nodes that have no subtrees) represent terminal cells that will not undergo further duplications. Gruau also considered the case of genotypes formed by many trees where the terminal nodes of a tree may point to other trees. This mechanism allows the genotype-to-phenotype process to produce repeated phenotypic structures (e.g., repeated neural subnetworks) by re-using the same genetic information. Trees that are pointed to more than once, in fact, will be executed more times. This encoding method has two advantages: (1) Compact genotypes can produce complex phenotypic networks; (2) evolution may exploit phenotypes in which repeated substructures are encoded in a single part of the genotype. By evolving neural controllers for a simulated hexapod robot able to walk, the author showed that the problem could be solved only by using a genetic encoding that allows for the possibility of re-using the same genetic information to encode repeated substructures (i.e., similar subnetworks controlling the legs) or by using incremental evolution (i.e., by first evolving oscillator networks to control a single limb, then evolving the coordinating circuitry to yield walking [see also Lewis et al., 1992]).

## Discussion

Artificial evolution can be seen as a learning algorithm for training artificial neural networks. From this point of view, one distinctive feature is the limited amount of feedback required. Supervised learning algorithms require immediate and detailed desired answers as feedback. Reinforcement learning algorithms require less—only a judgment of right or wrong, which need not be immediate. Viewed as a learning algorithm, artificial evolution requires still less—only an overall evaluation of the performance of the network over the entire evaluation period. A second distinctive feature is that any parameter of the neural network (e.g., the connection strengths, the network topology, the learning rules, the transfer function of the neurons) can be subjected to the evolutionary process.

Although systematic comparison between artificial evolution and other algorithms has not yet been done, it is reasonable to claim that artificial evolution tend to produce better results when detailed feedback is not available. This is the case, for example, for neural networks that should control mobile robots (Nolfi and Floreano, 2000). In this case, in fact, although the experimenter can provide a general evaluation of how much the behavior of a robot approximates the desired behavior, he or she usually cannot indicate what the robot should do at each time step to produce a desired behavior. Moreover, artificial evolution might prove more effective when certain features of the network (such as the network topology or the transfer functions) that cannot be properly set by hand are crucial. Artificial evolution, in fact, provides a way to co-adapt different types of parameters. Artificial evolution also has drawbacks, such as the time needed to conduct the evolutionary process and the lack of formal criteria for designing effective fitness functions.

The analogy with natural evolution, however, can also be considered more strictly. In this case, the evolutionary process is not seen as an abstract training algorithm but as a process that mimics some of the key aspects of the evolutionary process in nature. From this perspective, neural networks tend to be viewed as a part of a population of artificial organisms that adapt autonomously by interacting with the external environment.

This body of research might contribute to the understanding of natural systems by identifying the key characteristics of natural evolution that make it so successful in producing the extraordinary variety of highly adapted life forms present on the planet. Examples include a better understanding of the role of incremental or staged evolution (i.e., how evolution of animals adapted to one biological niche then provides the basis for further evolution into other niches [Harvey, 1993; Lewis et al., 1992]); the role of competitive co-evolution (i.e., how the evolution of two competing populations with coupled fitness may reciprocally drive each other to increasing levels of complexity [Nolfi and Floreano, 2000]); the importance of pre-adaptation (i.e., the possibility of evolving a predisposition to acquire an ability to solve a given problem during lifetime rather than, directly, an ability to solve such a problem [see EVOLUTION AND LEARNING IN NEURAL NETWORKS]).

## Introduction

With the completion of an initial draft of the more than 30,000 genes of the human genome we can now establish all the information to make a human from the coded sequences, which are based on a four-nucleotide alphabet. Man has achieved a significant catalog useful for understanding the basis of all evolution through the comparisons of whole genomes ranging from yeast and worms to mice and humans. At present, we can read those four letters and are, to some extent, able to understand words (genes) or phrases (known gene networks). However, most of our current higher level of understanding of the meaning of the DNA sequences and their subsequent organization into gene networks is comparable to an understanding of a poem by Goethe read by a six-year-old. Like the poem, the meta-language of information coding in the human genome needs to be understood above and beyond our current limited insight (Venter et al., 2001). Herein, we offer an outline that specifies some of the computational problems in modeling genetic networks, which can direct the establishment of a diversity of neuronal networks in the brain. Since these neuronal networks are composed of a wide variety of cell types, the final fate or end stage of each cell type represents the outcome of a dynamic amalgamation of gene networks. Genetic networks not only determine the cell fate acquisition from the original stem cell, but also govern the contact formation between the cell populations of a given neuronal network.

In many respects there are numerous intriguing parallels between the establishment and functioning of genetic networks with those of neuronal networks, which can range from simple (on and off switch) to extremely complex (computer logic gate). To appreciate the full complexity of organismic development we outline below how intracellular and cell-cell interactions modify the complexity of gene interactions involved in genetic networks. Such interactions will achieve an altered status of cell function and, ultimately, the connection alterations in the formation of neuronal networks.

## Evolving from Operons to Promoters with Enhancers and Suppressors

When Jacob and Monod published their now famous lac operon model of the regulation of the bacterial gene transcription, they initiated what has now become the main problem of developmental biology: unraveling the proximate causes for gene activation and silencing (repression) at the appropriate level. As such, a full understanding of this regulatory process is essential for any higher-level understanding of the information decoding process that unfolds the genome information to form a human being. Simply said, if a muscle cell precursor activates the wrong genetic network, it will form bone around it, like bone cells. The effect of such a developmental "error" would be catastrophic for the organism.

The lac operon (Figure 1) is a gene that consists of two regions. One contains the DNA elements responsible for regulation of gene transcription, and the other encodes for the transcribed protein(s). Regulation of gene transcription to form messenger RNA (mRNA), which is in turn the basis for translating the information coded in the DNA into a protein, is the way the cell regulates the availability of information coded in the genome. The regulatory region is composed of DNA elements, which can be categorized as operator (enhancer/silencer) and promoter sites. Promoters are regions in which RNA transcription is initiated. The operator sites, containing enhancer and silencer elements, are DNA sequences that require proper binding of regulatory proteins to either stimulate or inhibit the promoter region. Initiating transcription requires utilization of regulatory elements within a gene's genomic structure. In the case of the lac operon system, this is achieved by having an operator strand of DNA that initiates gene transcription, controlled by a repressor protein (lacI), which in turn is controlled by an inducer (lactose). The lacI and lactose have specific affinities for each other, such that in the presence of the inducer, the repressor changes its configuration and cannot bind to the operator DNA. This allows transcription of the gene. The product of the gene is an enzyme that metabolizes the inducer (lactose), thus freeing the repressor (lacI) to block transcription. Once all lactose is metabolized, the repressor binds to the operator, preventing the latter from initiating transcription of an enzyme that is no longer needed. In general terms, both negative (repression) and positive (activation) controlling elements exist for gene transcription.

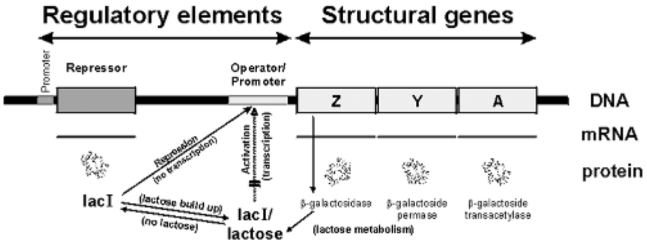

**Figure 1.** The lac operon model, which shows the regulation of transcription of the Z (*β*-galactosidase), Y (*β*-galactoside permase), and A (*β*-galactoside transacetylase) genes. The promoter regions for the repressor protein and the three structural genes are shown. If no lactose is present, the repressor protein (lacI) will bind with the operator/promoter sites and prevent transcription. If lactose is present, transcript occurs, since lactose binds with lacI and prevents lacI binding with the operator/promoter site. *β*-Galactosidase will metabolize lactose and thus allows lacI to bind to the promoter to prevent further transcription (negative feedback).

This basic system of bacterial gene expression regulation has evolved into a much more complicated regulatory process that involves genetic networks rather than single genes. This increase in complexity is further complicated by the evolution of interrupted DNA sequences in multicellular organisms that form exons (parts of the DNA that, when transcribed, are exported from the nucleus and subsequently translated into a protein) and introns (parts of DNA between the exons, which are not translated). This situation does not allow a simple specification of units of information as continuous strands of DNA that specify unique proteins. In general, a single gene specifies each protein, even if this gene is transcribed into a variety of mRNA species through differential splicing of various exons that gives rise to various proteins. It must be recognized that not all genes encode for proteins.

We next have to look at the level of transcription initiation in multicellular organisms, which can have greater complexity compared with that demonstrated by the lac operon. The promoter region requires a basic set of DNA binding proteins to initiate transcription, which is common for all promoter regions. However, for this complex to function, it requires association with one or more specific transcription factors. This transcription factor complex also targets to specific promoter sites. The presence of such transcription factors is therefore essential for the activity mediated by the enhancer and silencer sites on the promoter region of a gene. Such transcription factors regulate the temporal and tissue specific expression of any differentially regulated gene. However, a given enhancer may activate a number of genes, whereas several enhancer sites may be linked to a given promoter region. In addition, the same enhancer may activate transcription of some genes while simultaneously suppressing that of other genes. Most transcription factors can bind to specific DNA sequences, have an activation domain that acts on gene transcription, and also interact with the basic transcription complex as well as other transcription factors. In essence, the promoter region of a gene computes the overall expression of all enhancer/silencer sites that can modify its activity and regulates how much and for how long transcription of a gene occurs. In conclusion, most gene activation/suppression is not on a single gene level, but rather affects multiple genes simultaneously. We propose to use the term *genetic network* for those interactively regulated genes. Essentially, these genetic networks and their complex, spatiotemporally restricted interactions with the DNA provide the basis of the nonlinear relationship of genotype to phenotype.

## Modeling Genetic Networks and Their Evolution

In single-celled organisms many of the biochemical pathways represent a hierarchal pathway and as such may represent an intracellular genetic network in its most simplistic form. As organisms evolved, more complex genetic networks formed to control and modify cell-cell interactions and functions. Such networks allowed cells to evolve beyond simple substrate interactions in a continuously active cell and permitted the formation of different cell types, each specialized for specific tasks. Instead of evolving distinct sets of genes for each specific cell type, networks consisting of variable mixes of genetic modules evolved to allow rapid evolution of multiple cell types by rearranging those modules. The establishment of genetic networks was possible only through the evolution of multiple regulatory elements to control gene expression. Once established, a genetic network can be duplicated, then modified to form repeated modules or cassettes.

Beyond modularity of genetic networks, developing organisms and the brain also consist of repeated modules. For example, the cerebellum consists of such repetitive modules and has long been viewed as a paradigm for neuronal information processing. Likewise, reiterative development in terms of segmentation and segment transformation has appealed to developmental biologists. This mechanism has allowed us to understand how evolution works by gradually transforming developmental sequences in different segments to generate individuality from commonality. Because of this general interest, we know a great deal of the molecular development of segments and how the basic machinery is altered in various segmented animals as well as how modifiers of development can alter segmental fate (Robert, 2001).

Several models have been developed to theoretically examine genetic networks and how they can impact cellular patterning. Two basic approaches are the standard Boolean network model and the continuous models that approximate neural-like connectionist architectures or biochemical networks of interacting molecules. Salazar-Ciudad and colleagues (Salazar-Ciudad, Newman, and Sole, 2001a; Salazar-Ciudad, Sole, and Newman, 2001b) recently provided a mathematical model for some of those interactions. Building on a previous model to describe the formation of stripes in the fly embryo, Salazar-Ciudad et al. (2001a, b) analyzed properties of various gene networks to form patterns. The basic idea is a reaction-diffusion system that factors in the concentration of a gene product, the interactions of genes (both positive and negative), thresholds of gene responses, and diffusion between cells. Both qualitative and quantitative effects can be mathematically represented so that proximal and distal cell-cell interactions and the resulting effects on the ensuing cellular patterning can be predicted. Salazar-Ciudad et al. (2001a, b) showed that many properties of these larger networks of up to 30 interacting gene products can be broken down into subsets of a genetic network that can form basic patterns such as stripes. Moreover, many of those subsets, called modules, can be combined in various ways to form more complex patterns. Interestingly, this model is close to some models for information processing in neural networks (Salazar-Ciudad et al., 2001a, b).

Building on these properties, they generate two model networks based on the interactions of two diffusible factors that have been identified in setting up segments in insects (Salazar-Ciudad et al., 2001a, 2001b). In one case they assume that one of these diffusible factors increases expression of both factors whereas the other factor inhibits expression of both factors (emergent network). In the second (hierarchic) network, there are no direct or indirect reciprocal relationships between the gene products (Figure 2). Based on these two network properties, they show how either a hierarchic network or an emergent network can represent a realistic model of segmentation. The strength of the emergent network lies in its resilience against change and can result in complex repetitive patterns (three or more stripes). In contrast, the hierarchic network provides a closer relationship between genotype and phenotype and this allows for a more rapid implementation of variation. In addition, hierarchic networks form less complicated repetitive patterns (three or fewer stripes). Moreover, switching between those two networks during developmental steps can provide flexibility in cell fate acquisition and pattern formation. Other patterning processes that lead to the formation of checkerboard patterns can most easily be simulated by employing the lateral inhibition of cell fate assignment provided by the ubiquitous Delta-Notch system of lateral inhibition, again largely simulating network properties well known in computational neurobiology. The genetic networks discussed thus far are essentially suited for simple strings of cells or two-dimensional (2D) sheets of cells and can at best roughly approximate the complexity of three-dimensional organs such as the brain.

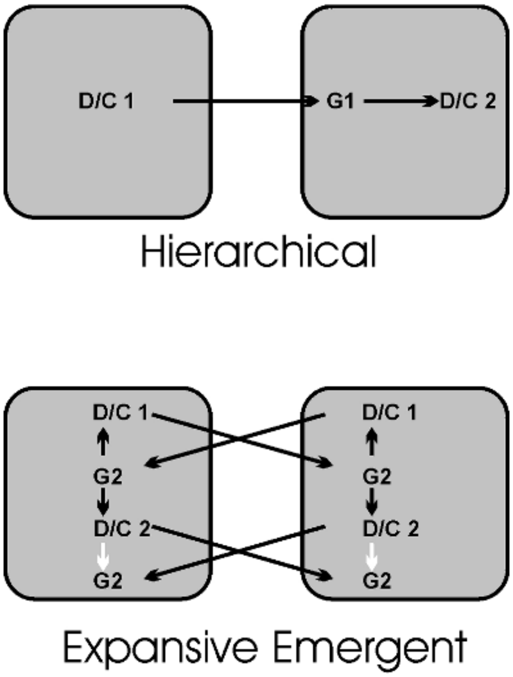

**Figure 2.** Two interactive modules, which show the interactions between two cells or cell clusters. Diffusible or surface contacting genes (D/C1; D/C2) and nondiffusible gene products (G1; G2) have both activating (black arrows) and inhibiting (white arrows) interactions in the emergent network.

## Transcription Factors Belong to a Number of Families

Transcription factors are characterized by a DNA binding domain and by a domain that permits protein-protein interactions to interact with other transcription factors and the transcription activation complex. Many transcription factors can be grouped into larger families depending on certain conserved DNA binding motifs. Perhaps the best-known transcription factors are the homeodomain (Helix-Turn-Helix) proteins, which contain a highly conserved sequence of 60 amino acids. This gene family is present in most eukaryotic organisms and plays a prominent role in controlling the genetic determination of development and implementation of the genetic body plan. Some of the other more famous DNA binding domains are the basic Helix-Loop-Helix (bHLH) domain, the basic Leucine zipper and the Zinc finger domain. Advances in comparative analysis of human, fly, worm, and yeast genomes suggest that, as expected, many transcription factor families have been greatly enlarged in the course of human evolution. For example, while the overall human genome is only about twice as large as the fly genome, and five times as large as the yeast genome, a specific Zinc finger transcription factor family has expanded almost 20 times that of yeast (Venter et al., 2001). Others, like the Forkhead domain, the bHLH domain, and the homeobox domain, have expanded from yeast to humans 10 to 25 times.

In addition to these transcription factors, an expansion of secreted factors that regulate transcription via their specific receptors has played a major role in the evolution of multicellular organisms. Outside of hormones, those secreted factors can be grouped into four families: the Fibroblast Growth Factor (*FGF*) family, the Hedgehog (*Hh*) family, the Wingless (*Wnt*) family, and the Transforming Growth Factor-$\beta$ (*TGF-b*) superfamily. As is to be expected, these families have been disproportionately enlarged in humans compared to flies (24:1 *FGF*s; 3:1 *Hh*; 18:6 *Wnt*; 29:6

*TGF-b*). This signifies that expansion of the human genome is not so much a simple duplication of all genes, but rather, an expansion of modulating capacity of gene expression to generate unique contexts in which genes are activated.

A number of researchers consider that some of these contexts involve what has been dubbed "master control genes." Such genes produce transcription factors that, if expressed in areas where they are normally not expressed, can turn those areas into an organ comparable to that in which the normal expression pattern of that gene is apparently involved. A classic example is the *Pax6* gene (reviewed in Pichaud and Desplan, 2002). *Pax6*, together with other genes, is essential for eye formation and forms an interactive gene network. If the mammalian *Pax6* gene is expressed instead of its fly homolog in flies, it can direct fly eye development. Moreover, if it is overexpressed, it can turn areas, like skin at joints, into eye-like structures. It must be noted that eyes form in flies from ectoderm. Thus, only the fly's ectoderm is competent to respond to the enhanced presence of *Pax6*. In analogy to the "grandmother" neuron concept in neurobiology, some people have adopted the view that a single gene can switch on and govern development of an entire organ—in this case, a fly's eye. Most recent research has already modified those initial claims; it has shown that a number of genes [e.g., eyeless1 (*Eya1*) and sine oculis homeobox (*Drosophila*) homolog 3 (*Six3*)], if disrupted by targeted deletion of essential parts of their protein coding regions (knockout), can also cause loss of eyes. Although *Pax6, Eya1*, and *Six3* are expressed in a number of organs, they are able to form eyes only if co-expressed in distinct areas. Thus, the genetic context in which a gene is expressed is undeniably important. By changing the context in which a transcription factor is expressed, it can be utilized in a variety of genetic networks and result in the development of a wide range of cell types. This cellular context can also be extended to the spatial and temporal patterning of precursor cells. This is exemplified by the generation of distinct *Drosophila* neuroblast cell lineages, which depend on the timing of the sequential expression of the transcription factors from a common neural precursor (Isshiki et al., 2001).

We have now established that context-dependent gene activation and developmental regulation of dynamically interacting networks of transcription factors are the likely causes for development to take a given pathway. Clearly, if *Pax6* were overexpressed in the endodermal lining of the gut, it would be unable to establish eye formation. The endoderm of the gut is not competent to develop an eye because it lacks the context in which *Pax6* gene activation can govern eye formation. In the following section we explore an example of those networks and their transcriptional regulation.

## Cochlea of the Inner Ear: A Paradigm for 2D Developmental Networks Utilizing Boundary Formation

A realistic application of such models would be for the development of an organ with two dimensions conveying crucial structural differences that are functionally meaningful. One such model would be the developmental network that generates the limbs and hands. Here we focus on another, clearly two-dimensionally organized organ—the mammalian cochlea—which converts sound energy into electric signals that convey frequency- and intensity-specific sound information. The mammalian cochlea is a spiral organ in which a functional longitudinal, tonotopic gradient is the basis for frequency-specific sound analysis. The cytoarchitecture of the cochlea is significantly altered across the longitudinal axis, where changes in specific cell types are quite dramatic. The cochlea can also be subdivided radially into the spiral ganglion, organ of Corti (with one row of inner and three rows of outer hair cells), and the lateral wall, which includes the stria vascularis. In essence, the cochlea represents a 2D organ with concentric and longitudinal differences in cell types. The adult cochlear structure requires at least two concurrent and overlapping developmental networks: one for generating the elongation of the cochlea and another for engendering the radial changes in cell types. In addition, given the existence of functionally distinct rows of single cells (one row of inner hair cells, three rows of outer hair cells), some of the reaction-diffusion models computed by Salazar-Ciudad et al. (2001b), which involve the presence of sharp boundaries, could well apply for cochlear development (Figure 3).

On the molecular side, a number of factors that are crucial for distinct steps in cochlear development have been identified. Several bHLH genes are known to control cell fate determination in the cochlea. The first of these factors to appear in development, *ngn1*, is essential for all sensory neuron formation. *Math1* is essential for all hair cell formation. *Hes1* and *Hes5* are specific for supporting cell formation out of pluripotent supporting cell/hair cell precursors (Zine et al., 2001). Expression of *Math1* drives, through the *Delta/Notch* system for lateral inhibition, the upregulation of *Hes1/5* in supporting cells. Expression of *Hes1/5* is essential to suppress *Math1*; in *Hes1/5* null mutants, some supporting cells assume a hair cell fate, as evidenced by additional hair cell rows (Zine et al., 2001). The exact mechanism(s) for the formation of the spiral ganglion, hair cells, and the supporting cells in their specific topology are still relatively unknown. However, there is evidence for molecular and possibly cellular interactions in assigning distinct cell lines to neuronal and hair cell phenotypes. The mechanisms for upregulation of a specific bHLH gene are tied into those that suppress upregulation of others. Thus, once a cell has upregulated, say, *Math1*, it cannot simultaneously upregulate *Hes1* or *ngn1*. In other words, once upregulated, one of the bHLH factors will activate the genetic network that ultimately leads to the specific cell differentiation.

A gradient exists with respect to the last mitosis of hair cells (first in the apex, last in the base), whereas the process of proliferation and differentiation of spiral ganglion cells starts in the base and finishes in the apex. Interestingly, this apical to basal hair cell proliferation gradient differs from almost all other developmental gradients, which always run from base to apex (e.g., Fariñas et al., 2001). These two complementary developmental genetic networks could be the foundation for the establishment of countergradients of gene expression. The resulting countergradient could lead to a

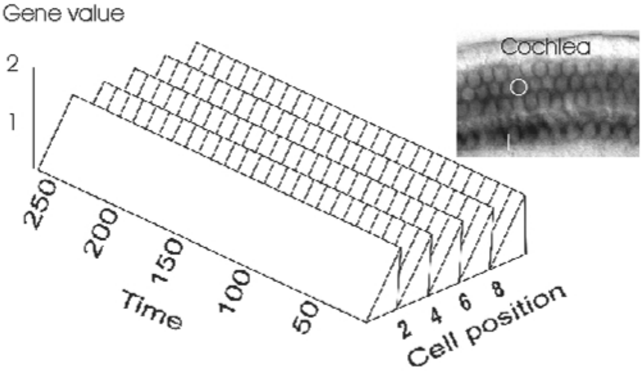

**Figure 3.** The outcome of a simulation using the nonexpansive emergent module is compared to the arrangement of four sensory hair cells in the cochlea (I, one row of inner hair cells; O, three rows of outer hair cells) as revealed by BDNF expression. It is possible that as few as four different genes and their interactions determine the pattern of the hair cell distribution in the cochlea. (Modified from Salazar-Ciudad et al., 2001a, and Fariñas et al., 2001.)

greater disparity of gene expression between the base and apex of the cochlea. A number of regulatory proteins and/or their receptors are expressed in the inner ear during embryonic and postnatal development and could influence the basal to apical longitudinal developmental expression patterns. These are the diffusible factors and their receptors, *BDNF/trkB* and *NT3/trkC*, *Jag2/Notch*, and *FGF8/FGFR-2(IIIb)* and the transcription factor *GATA3*. For example, in the course of hair cell differentiation the acetylcholine receptor channel $\alpha 9$ gene is upregulated in a basal to apical sweep starting at approximately embryonic day 15.5. In general, ion channel expression patterns in the inner ear follow the general developmental sweep from base to apex first in IHC, then in OHCs. Furthermore, this apparently expansive network may have quantitative effects on downstream gene expression, which could be displayed by differential continuous and discontinuous longitudinal gradients (Beisel et al., 2000).

In many respects, the longitudinal gradient in the cochlea parallels the dorsal-ventral network of bHLH expression in spinal cord and brain. In the brain, a *Mash1* expression domain is ventral to an *ngn* expression domain, which is capped by a *Math1* expression domain. These domains are mutually inhibitory (Gowan et al., 2001) and are directly involved in linking pathways of neurogenesis and regional specification to the formation of distinct functional longitudinal zones (Bermingham et al., 2001). One likely possibility for pattern formation in the cochlea is that the inner ear builds on these developmental regulatory networks. Thus, *ngn1* is expressed in spiral sensory neurons prior to *Math1* expression and inhibits its cellular upregulation, which would specify hair cell formation. Instead of forming longitudinal stripes, as in the brain, the interaction between those genes and the cells carrying them is now forming radially distinct, concentric columns of sensory neurons (more medial, *ngn1* dependent) and hair cells (more lateral, *Math1* dependent). Temporal extension of this interaction by repetitive utilization of this patterning network will result in the longitudinal extension of the cochlea as exemplified in its spiraling growth. Superimposing on this module other developmental modules for finer organization of the existing macropattern will organize the large disparities between the cochlear cell types and the cytoarchitecture.

Beyond these basically 2D models of cellular developmental organization, we next need to investigate 3D pattern formation, which is the real hallmark of brain development.

## Realistic Developmental Networks and Their Evolution Involved in the Central Nervous System

The brain can be broken down into longitudinal and transverse compartments. We have already introduced some of the molecular mechanisms for longitudinal functional column formation. Transverse boundaries are in the form of neuromeres, which coincide with specific gene expression domains such as Hox genes. One such transverse boundary has been identified as a major organizing center of molecular and cellular interactions, the midbrain/hindbrain boundary (MHB; Liu and Joyner, 2001). This area is crucial for a number of specific neuronal aspects of the vertebrate brain, notably the cerebellum, the area of the brain that contains the most neurons (Wang and Zoghbi, 2001). This MHB is induced by a negative feedback loop involving two transcription factors, *Otx2* and *Gbx2*, which are expressed in adjacent domains (Figure 4). Absence of *Otx2* reduces the entire forebrain/midbrain formation to the level of the otocyst; absence of *Gbx2* eliminates the MHB and expands the midbrain toward the level of the otic vesicle. Within the expression domain of *Gbx2* an upregulation of *FGF8* occurs, which is inhibited by *Otx2*. But while *FGF8* inhibits *Otx2*, it promotes *Wnt1, Engrailed*, and *Pax2/5* expression. Despite all this information, critical steps in this reasonably complicated interactive network are not yet understood. One obstacle hindering a precise model for the data is that the expression of other genes is eventually lost in a specific knockout (null) mutant (e.g., the *Gbx2* null). The associated genes appear to be upregulated initially in the proper spatiotemporal pattern, suggesting that the underlying patterns specifying the upregulation of these genes are not yet known. However, it is clear that the above outlined genes are essential for the continued expression of the other genes, as indicated in Figure 4.

Previously, we introduced the context dependence of gene expression and its regulation. It is noteworthy that none of the MHB genes, either alone or in combination, can induce formation of a posterior midbrain or a cerebellum in areas such as the caudal hindbrain or the forebrain. This suggests that another set of as yet undiscovered transcription factors must be expressed in the cells of the MHB area to render them competent to respond to the transcription factors outlined above. Those very genes may also be the ones that upregulate the initial expression of *Otx2* and *Gbx2*.

Evolution of the MHB seems to have occurred in steps. An *Otx2* homolog is expressed in the anterior part of the brain vesicle in most chordate species that have been analyzed (Hullond et al., 2000). However, neither spatial nor temporal expressions of all the molecular members necessary to form the mammalian MHB seem to be in place. Specifically, although a homolog of *Wnt1* exists in all chordates, it is not expressed in the typical vertebrate pattern in each chordate (Holland, Holland, and Schubert, 2000). Moreover, the evolution of crucial members of this boundary, such as *FGF8*, is unlikely to be conserved across phyla, as flies have only one *FGF* compared to the 24 *FGFs* known for man (Venter et al., 2001). In addition, formation of the cerebellum and many associated structures further requires the presence of *Math1* (Bermingham et al., 2001). Thus, although certain chordates do have some of the genes that regulate the MHB formation and these genes are expressed in a topologically comparable pattern, even the presence of all those players requires additional implementations of other genes to generate the cellular basis to build a cerebellum. In other words, if fully analyzed, the MHB example may elucidate how an existing expression genetic network implements more genes and expands its regulatory basis to transform midbrain and hindbrain neuronal tissue into a cerebellum.

## Discussion

Patterning is an evolving process that can generate new patterns by modifying existing genetic networks (Davidson et al., 2002). Thus, cell fate within those genetic networks can be further modified from existing patterning processes by merging other patterning modules

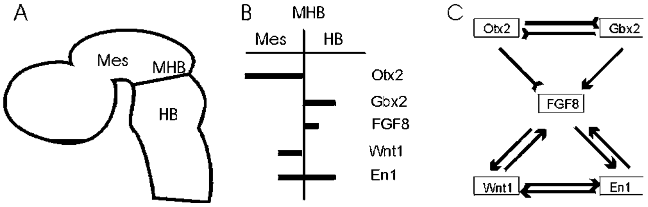

**Figure 4.** The midbrain/hindbrain boundary (*A*) is one of the best-understood boundaries in brain development. At least five genes (*B*) are interacting to form this boundary in both positive (arrows) and negative interactions (arrow tail; *C*). Each gene is expressed in specific stripes at or across the boundary (*B*). En1, engrailed 1; FGF8, fibroblast growth factor 8; Gbx2, gastrulation brain homeobox 2; Otx2, orthodenticle homolog 2; Wnt1, wingless related MMTV integration site 1. (Adapted from Wang and Zoghbi, 2001, and Liu and Joyner, 2001.)

into an existing genetic network as well as by implementing new downstream players. Currently, the increasing use of knockout (null mutant) mice has greatly facilitated our understanding of genetic networks in development of the central and peripheral neural systems. In many cases these studies demonstrated that knocking out a single gene can affect the expression of hundreds of genes, confirming that genes do not work in isolation. In other null mutants, however, no overt effects are observed, suggesting that biological redundancy may be playing a role. The use of transgenic mice, involving gene dosage or in other cases dominant-negative mutations, may provide additional approaches to elucidate the role of genetic networks in formation and function of neuronal networks. However, these models must be interpreted with caution. Genes, which affect development to yield a variety of CNS deformations, provide limited insights into "how the brain works" because many of these mutations are early lethal and hence cannot be studied. The anticipated extensive use of conditional mutations, in which a gene is deleted in a limited area of the brain only, will likely change this picture dramatically in the near future.

# Evolution of the Ancestral Vertebrate Brain

*Bernd Fritzsch*

## Introduction

Earlier work on the evolution of the vertebrate brain centered on the description and functional analysis of adult brains, with limited attempts to project the origin of various nuclei back to the ventricular surface, thereby generating flat, two-dimensional maps (Nieuwenhuys, ten Donkelaar, and Nicholson, 1997). The remarkable variations in size and shape of parts of the brain were often viewed as evidence of a progressive increase in complexity. The usual implication drawn was that information processing between the sensory input and the motor output became more sophisticated as the number of neurons increased. However, mere size is a tricky issue, as humans and dolphins share both absolute and relative size ratios, but we have no objective way to show which brain is more complex.

In this context it is important to understand that fairly little is known with respect to variations in connections between neurons from topologically comparable areas in different animals. This is unfortunate since altered connections between neurons are crucial functionally relevant aspects of brain variation.

In part this is so because there are always several ways to implement a certain function within existing connections using molecular and cellular mechanisms. These mechanisms are only partly understood (Koch and Laurent, 1999). It would therefore be naive to work out all connections of every neuron assuming that this alone will help to understand the function of the system in question. Ideally, one would need to have this information and record simultaneously from all neurons involved in a given behavior to unravel the computational properties of even small neuronal networks. Such networks might be those formed by the 302 neurons in the worm *Caenorhabditis elegans*, or the 30 cells of the stomatogastric ganglion. The next best thing is recording from individual neurons under situations of stable behavior, and using these data to simulate a network that can perform the same task using the measured parameters. An excellent example is the fictive swimming in lampreys. Another example is the use of cortical activity to govern robotic movements. For obvious reasons, achieving this in the ancestral vertebrate brain is impossible, and we have to find other ways to gain insights into the origin of the nervous system that evolved into the vertebrate brain.

In this overview I discuss the possible origin of the vertebrate brain, then present a possible ontogenetic way through which the problem of homology/homoplasy may be minimized. In addition, possible mechanisms to diversify the ancestral vertebrate brain are suggested, and data concerning structural changes whose functional implications are as yet unclear are presented

## When and How Did the Vertebrate Brain Form?

The origin of the vertebrate brain is tightly coupled to the origin of the vertebrate head, which likely happened around 600 million years ago (Knoll and Carroll, 1999). Next to nothing is known about the central nervous system of these ancestral, bilaterally symmetric animals. We can only assume that it consisted of a simple, dorsally located tube of nerve cells with a barely recognizable specialization of what would become the vertebrate brain at its anterior end.

However, the emerging synthesis of comparative morphology, development, and paleontology offers a new approach to understanding vertebrate brain evolution. Adult diversity is now viewed as the outcome of divergent genetic developmental mechanisms. Thus, resolving brain evolution through comparison of adult structures can be aided by comparative neuroembryology, that is, by comparing adult structures with their specific development and the genes that guide such development. Such comparative embryological data in conjunction with gene expression patterns have aided in clarifying major issues of brain development (Holland and Holland, 1999).

The vertebrate brain forms through invagination of ectoderm (the embryonic "skin") to form a neural tube. During further development the central nervous tissue becomes polarized and then subdivides into compartments, each characterized by a specific pattern of gene expression (Figure 1). It is this latter aspect that may eventually allow us to obtain a map of expression of homologous genes (based on nucleotide sequence identity) to identify topologically comparable and thereby homologous parts of the developing vertebrate brain, irrespective to their structural similarities. Thus far, only rudiments of this map are known, and the relationship of gene expression patterns to the structural evolution of topologically comparable areas is largely unknown (Bermingham et al., 2001). In a few years we will have the molecular delineation of identical subdivisions of the vertebrate brain based on the nested expression of homologous genes. This is a prerequisite to sorting out how identical areas of the brain (defined by their gene expression patterns) have evolved structural differences that serve specific adaptations unique to a specific animal. However, it also appears that molecular identification of major subdivisions of the vertebrate brain, such as forebrain, midbrain, and hindbrain, is possible in all chordates, based on the nested expression of certain homologous genes (Holland and Holland, 1999). Other genes, while conserved in their sequence, appear to have altered their developmental expression patterns in various groups of animals. For example, the left-right asymmetry determination in mice and chickens uses the same molecules but in a different pattern. Moreover, there is ample evidence that developmental genes can be co-opted into novel developmental pathways, either alone or in addition to their original task, (see Evolution of Genetic Networks). Moreover, a specific gene can be of conserved importance for forebrain development and evolution but also essential for specific aspects of ear development (Fritzsch, Signore, and Simeone, 2001).

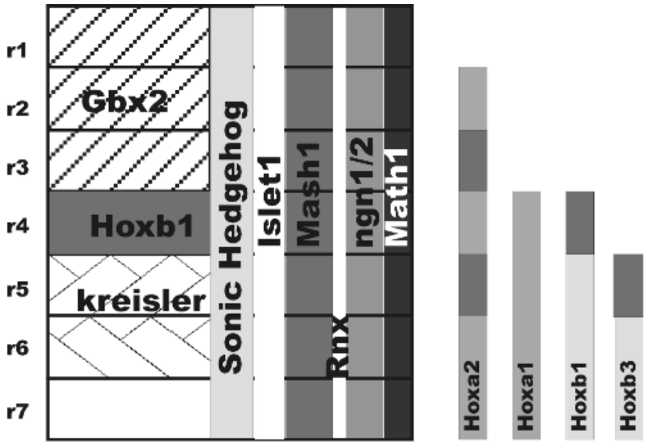

**Figure 1.** The expression of some longitudinal (Mash1, ngn1/2, Math1, Rnx) and transverse transcription factors (Gbx2, Hoxb1, kreisler) is shown. These expression domains produce an orthogonal grid in which brainstem neuronal phenotypes are uniquely specified. On the left is an idealized flat mounted embryonic day 11 mouse hindbrain. r1–r7 indicate rhombomeres. Note that homeobox genes (Hox) end at different levels with varying expression intensity. Sonic hedgehog defines the floor plate between the two halves of the brain. (Genes and their expression are adapted from Cordes, 2001, and Qian et al., 2001.)

The essence of these findings is that the developmental patterning of the vertebrate brain evolved over 600 million years ago and has been rather stable in many aspects of developmental gene expression. Nevertheless, compartments of the forming brain, once specified in their relative position through conserved gene expression, have diverged to form the unique anatomy of a given species.

The vertebrate head (and brain) evolved in part owing to novel embryonic material, neural crest and placodes, which contribute to all sensory systems of the head. Neural crest is embryonic neuronal material that emerges from the forming neural tube and undergoes extensive migration to form branchial arches, bones, teeth, and peripheral ganglia. Placodes are cake-like epidermal thickenings that contribute sensory neurons to cranial ganglia. Most recently, specific molecules have been identified that are associated with neural crest development. Interestingly, these molecules have also been identified in vertebrate relatives that lack neural crest. This provides molecular evidence that neural crest precursors may exist in the brain and spinal cord of these animals (Corbo et al., 1997). What is important here is that molecular markers may delineate identical populations of neurons that can evolve a novel morphology and function.

The view proposed here is that the evolution of the brain is a sequence of developmental variations leading to modified adult structures. These modified structures serve somewhat different functions that, in turn, are chosen in the process of natural selection (Raff, 1996). Thus the role of mutation in the selection of novel structures and functions is rather indirect (Fritzsch, 1998a). Arguably, the motor system, the common output of the brain, is the best understood part of the brain, as we can clearly define the output in terms of measuring the generated movement and can actually simulate the movement. In addition, we know more about its evolution (Fritzsch, 1998a) and the molecular governance of its compartmentalization (Cordes, 2001) than in any other part of the brain. In the following section I will focus on the evolution of some cranial motor neurons.

## Evolution of the Brainstem Oculomotor System

Recent research has shown that developmental selector genes (transcription regulation factors: see Evolution of Genetic Networks) play an important role in the differentiating vertebrate brain. These networks appear to form a space map that possibly orchestrates the activation of topologically appropriate structural genes in longitudinal columns and their rostrocaudal subdivisions. Some of these transcription regulators, known as basic helix-loop-helix genes (bHLH genes), may play a role in the dorsoventral patterning of the differentiating brain and spinal cord (Bermingham et al., 2001), while others, known as homeotic genes, play a role in rostrocaudal subdivisions (Cordes, 2001). These genes were identified first in the fruit fly, where they are related, for example, to homeotic transformation (changes in the developmental fate of compartments). Subsequently, homeotic and other selector genes, such as bHLH genes were identified in vertebrates, nonvertebrates, and plants. In vertebrates, these genes apparently govern (1) the formation of longitudinal columns of, for example, taste-related nuclei (Qian et al., 2001), and (2) the regionalization of these columns into domains destined to serve a specific cranial nerve (Cordes, 2001). Thus, a developing neuron will undergo activation of a different set from the 30,000+ genes available to differentiate according to its position within this spacemap. This differentiation leads to formation of classes of neurons that will have a characteristic morphology and set of afferents and efferents. However, the detailed connectivity of individual neurons varies as a result of both the regularities and happenstance of development.

The following discussion highlights what is known about the variable organization of a simple system composed of three neuron populations that constitute the vestibulo-ocular pathway, the oculomotor system. The oculomotor system is a unique model because both the input (gravistatic and angular acceleration from the ear) and the output (movement of the eyes) can be quantified and put in the appropriate behavioral context. In its basic pattern, the system has six eye muscles to move the eye and three sets of motor neurons to drive these muscles. A series of bilaterally projecting interneurons (named vestibular nucleus neurons) mediates the input from the ear to the motor neurons. Sensory input from the ear travels via the semicircular canal (for angular acceleration) and two or more gravistatic sensors (for linear acceleration, including earth gravity). Four of the six eye muscles in jawed vertebrates are innervated by the oculomotor motor neurons, but only three out of six eye muscles in lampreys are so innervated (Fritzsch, 1998b). The abducens innervates only one of the six eye muscles (but sometimes an additional muscle, see later discussion) in jawed vertebrates, but it innervates two eye muscles in lampreys (Figure 2). The remaining muscle is innervated by the trochlear motor neurons in all vertebrates. In the ear, jawless vertebrates, such as lampreys, have no horizontal canal, which is one of the major inputs into the oculomotor system of jawed vertebrates that drives compensatory horizontal eye movement.

Thus, the oculomotor system shows two major evolutionary changes in vertebrates: one is related to changes in the eye muscles and their innervation and the other is related to the ear and its additional formation of a semicircular canal. Interestingly, the connections within the brainstem from the inner ear projection to the oculomotor neurons seem to be fairly constant among all vertebrates (Fritzsch, 1998b; Baker, 1998). This common feature apparently provides enough built-in plasticity to accommodate changes on the input and output side without major reorganization of the interconnections.

It is unknown how computation of horizontal acceleration is performed and then transformed into the different coordinates of ocular muscles in lampreys. This vertebrate lacks a horizontal canal but obviously has a functional oculomotor system (Figure 2). If we are to understand the selective advantage (if any) of this reorganization in jawed vertebrates, we have to unravel the structural/functional relationship in this likely primitive pattern of the three-neuron vestibulo-ocular arch in lampreys, then compare this system with the two functionally equivalent vestibulo-ocular systems of jawed vertebrates (Figure 2). Such a comparison could provide exemplary insight into the functional constraints that may accompany the structural transformation of homologous systems. Interestingly, this system has retained its basic function, vestibular governance of eye movement, while at the same time modifying some of its properties.

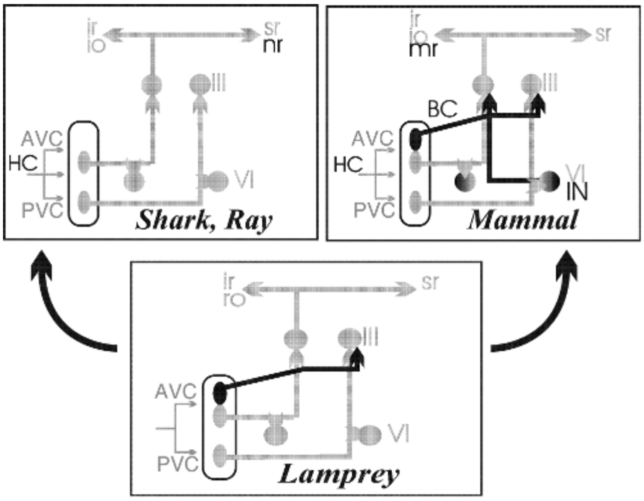

**Figure 2.** Reorganization of the oculomotor system among vertebrates. Lampreys have three eye muscles (inferior rectus [ir], rostral oblique [ro], and superior rectus [sr]), jawed vertebrates have four eye muscles innervated by cranial nerve III. However, in sharks and rays the nasal rectus (nr) receives a crossed innervation, whereas the functionally equivalent medial rectus (mr) of mammals receives an uncrossed innervation. All vertebrates have a rostral population in the vestibular nuclei that projects uncrossed and a caudal population that projects crossed to oculomotor neurons. Lampreys and mammals have an additional rostral population that projects through the brachium conjunctivum (BC) to the cranial nerve III nucleus. Note that lampreys have no horizontal canal (HC), and that only mammals have internuclear neurons (IN) from cranial nerve VI to III that provide the basis for conjugated horizontal eye movements. This task must be performed differently in lampreys and sharks. AVC, anterior vertical canal; PVC, posterior vertical canal; io. inferior oblique muscle. Dashed line indicates the midline. (Modified from Fritzsch, 1998b.)

The major driving force behind this eye muscle reorganization may not have been the need of the system to achieve a different function. Rather, “accidental” developmental changes may have led to a subdivision of eye muscles and their nerves (Fritzsch, 1998b). Alternatively, variation in the inner ear (Fritzsch et al., 2001) may have been the force driving eye muscle reorganization. Once such changes were in place, the entire oculomotor system implemented the computational alterations generated by this “new” sensory structure into the preexisting connection pattern. This change was nevertheless enough to achieve implementation of horizontal gaze control. Understanding the adaptive implications of these changes would require a detailed comparison of neuroanatomical, physiological, and behavioral data to gain insights into the ecophysiological context of adaptation of this system.

## How Does the Brain Change Its Pattern?

Thus far I have largely dealt with factors that keep neuronal development constant. However, despite the overall similarity in the regional subdivisions, it is clear that specific neuronal connections differ between species and perform different and sometimes novel functions. Logically, there are only three possible ways in which neurons can be made available to perform new functions:

1. Through increased proliferation of an existing population that forms redundant and therefore potentially uncommitted neurons.
2. Through loss of an old input and/or target, which frees neurons from their previous functional constraints and allows them to adopt a new commitment, thus adapting their function to changes in the sensory or motor system to which they are linked.
3. Through de novo formation of a novel set of neurons.

The last possibility requires that neurons somehow escape the pattern of gene activation normally mediated through the spatially restricted expression of developmental selector genes (i.e., they were set aside) (Knoll and Carroll, 1999). This could happen in three ways: (1) by alteration of selector gene expression through, for example, upstream changes in regulatory factor gradients that activate these genes, (2) by mutation of selector genes, resulting in changes in the expression pattern and thereby changes in the pattern of activation of downstream genes (see EVOLUTION OF GENETIC NETWORKS), or (3) by mutation of downstream genes to respond differently to selector genes. There is growing evidence that among chordates many selector genes may have a rather stable pattern of expression (Holland and Holland, 1999). Thus, differences in the activation of downstream genes or mutations in downstream genes may be a major mechanism by which nervous system organization is varied.

Increased proliferation and formation of more neurons clearly happened in the evolution of vertebrates, as exemplified by the relatively (brain to body weight) and absolutely larger-sized brains of humans compared to bony fishes. Moreover, specific areas may in some vertebrates become the largest part of the entire brain, while other species may entirely lack these areas. For example, the valvulae cerebelli are unique to bony fishes and can become the largest part of the bony fish brain, much as the forebrain has become the largest part of the human brain (Nieuwenhuys et al., 1997). It is thought that this growth of the valvulae cerebelli is related to the unique electroreceptive sense of these bony fishes, a sense all land vertebrates have lost. In contrast, the growth of the cerebellum in four-legged vertebrates is in part related to the growth of the forebrain (which provides a major input through the pontine nuclei).

This increased proliferation could come about through a simple mutation in genes regulating the proliferation of precursor cells. For example, if four divisions occur in a precursor cell population of ancestors, adding one round of mitosis could double the total number of neurons. Subsequently, some neurons of this initially identical population could develop a different identity. How this new identity could be achieved is still unclear, but one possibility might be that the enlarged population of postmitotic neurons could see a slightly different gradient of selector gene products and could therefore achieve their different phenotypes (Raff, 1996). Thus, neurons were developmentally set aside (Knoll and Carroll, 1999). The differences in function would be obtained by (1) reaching a different target and/or (2) segregation of their perikarya and dendrites (and thus input) through differential migration.

A second possible scenario for the formation of uncommitted neurons may be the loss of either the target or the input. Such a loss would eliminate the constraints normally acting on these neurons and thus would allow them to evolve a new function. A well-known example of this scenario is the evolution of the middle ear ossicles of land vertebrates. There is good comparative and developmental evidence suggesting that these ossicles are derived from former jaw-supporting ossicles. Once their original functional constraint, supporting the jaws, was lost, they underwent a radical change in function.

Experimental reorganization of input changes the function of existing neuronal networks and entire sensory systems. The mechanosensory lateral-line and the electroreceptive system of ampullary organs of fishes and many amphibians is lost in most land vertebrates. Although there is evidence for evolutionary loss of both inputs and targets, it is not yet proven that the neurons freed by such a process from their previous functional constraints are in fact modified to perform a novel, different function. However, it is clear that experimental changes of inputs change the function of existing neuronal networks (Pallas, 2001). Thus, while experimental evidence tends to support the notion of functional changes in existing neuronal networks, there is little evolutionary evidence to support it, and the effect of such a process for brain evolution has not yet been worked out.

## From New Neurons to New Functions

Irrespective of how new neurons evolved, they have to achieve new input/output relations to mediate any new function. Clearly, migration of neurons into a new position is a widespread phenomenon in the developing brain. It is widely agreed that neuronal migration correlates with the formation of novel input to this differently positioned subset of neurons. Migration can bring neurons from a dorsal part of the brain to the ventral part, or from one side to the other (Fritzsch, 1998a). One likely scenario is that homologous neurons with comparable function can differ in their position, as occurs in the cases of the laminar nucleus of birds and the medial superior olive in mammals. Both are relay neurons for the auditory pathway, but in birds (and reptiles) they are dorsal, next to the primary auditory nuclei, whereas in mammals they are ventral, near the base of the hindbrain. These differences in position can be reconciled with the assumed homology of these populations by showing that indeed, both nuclei arise dorsally but migrate ventrad in mammals, and that their initial formation is under the control of homologous genes. This change in position of neurons will affect the computation only if the input or output is changed.

In contrast to the well-accepted role of migration in achieving a novel input, how a novel target is reached by the axon is much more controversial. Some ideas have emanated from the undeniable fact of widespread, exuberant projection to different targets during development in birds and mammals. Out of these many targets a single or few targets will be selected by neuronal cell death and axonal pruning. In their ultimate version, such ideas require that no new connections ever form in the brain, arguing that differences are achieved exclusively through the differential loss of connections present in ancestral forms (Ebbesson, 1984). Although appealing, this idea fails to integrate the available data on the development of the peripheral and central nervous system, which show a rather precise selection of pathway choices by a navigating axon with limited developmental "error." Certain molecules have been identified that guide commissural systems in vertebrates and invertebrates alike. Other molecules specify the topology of the retinal projection onto the midbrain. Thus, beyond specifying the identity of topologically restricted populations of neurons, molecules also specify topologically restricted connections within the brain. However, maps generated by different sensors of the world around us form in the brain based on different principles. In the visual system, mapping of the eye onto the midbrain is achieved molecularly by using matching gradients of molecules that provide positional identity of neurons in the retina and target them toward specific areas in the tectum of the midbrain. In contrast, the space map of the hearing system is generated by computing time and intensity differences between both ears into an auditory space map. Thus, there likely will not be a uniform molecular principle for brain map formation in the various sensory modalities. However, the various maps, once established, can be brought into register with each other in certain areas of the brain, such as the roof of the midbrain.

One of the most striking examples of novel pathway selection is the growth of axons from the mammalian cortex to the spinal cord to form the corticospinal tract. The pyramidal neurons are the only cortical neurons in vertebrates that do project to the lumbar spinal cord and thus are considered by most researchers to be a novel tract. Any other interpretation would require the assumption that this tract is ancestral to vertebrates and was lost in all lineages except mammals. Even more compelling evidence for the de novo formation of pathways comes from fiber outgrowth into the periphery. Although these mechanisms were rejected for almost a century, it is now clear that motor neuron axons do not pass through the "ventral roots" of certain chordates. Instead of nerve fibers leaving the spinal cord, muscle fibers project with noncontractile processes to the "ventral roots" of the spinal cord of these small marine animals. One of the major steps in the evolution of the vertebrate brain and spinal cord was then to have motor neurons, which themselves project through the ventral root to reach their target muscles (Fritzsch, 1998a). Although it is still unclear when and how this novel invasion of axons into the periphery happened, those motor neurons had to find a pathway where they had never been before. Moreover, the addition of novel tissue, such as the ear, may have caused redirection of growing fibers.

In the hindbrain of chickens, motor neurons initially form two paramedian strips (Cordes, 2001). Motor neurons within a restricted region project their axons to the facial root to exit the brain (Figure 1). Within the facial nerve some axons reroute to reach the developing ear and function as stato-acoustic efferents. Instead of innervating striated muscle fibers as the facial motor neurons do, they innervate hair cells of the ear (Karis et al., 2001). Moreover, this pathway of efferent fibers to the ear differs among vertebrates. This rerouting within the nerve occurs in chickens and frogs, but not in mammals, where it happens within the brain. In addition, the initially overlapping populations of efferent neurons segregate into different positions within the hindbrain through differential migration.

It is unclear how much the reorganization of the facial motor neurons to the ear to form the stato-acoustic efferents depended on the formation of the ear itself and a concomitant suppression of differentiation of parts of branchial arch–derived muscle fibers. Such losses of target muscles could conceivably have forced a subset of facial motor neurons either to innervate a new target and become the efferents to the ear or to disappear entirely. This highlights but one possibility of how connections within the brain can be changed and the resulting function of the network altered. More detailed connectional data are needed to show how often such changes have happened in the brain.

In conclusion, there is both evidence for ongoing invasion of certain fibers into novel territories and evidence for rather precise pathway selection. This precludes the idea that evolution picked from a completely randomized network. Certain areas, like the forebrain, may in fact benefit from a less constrained development that enables them to form a wider array of initial connections from which only certain connections will be selected in a later developmental step.

## Variation in Functionally Relevant Details

Nervous tissue not only undergoes modifications in its long-range connections and formation of new cells, it also shows numerous cellular reorganizations. Such reorganization could manifest as changes in the degree of branching of dendrites, neurotransmitter(s), postsynaptic receptors, and stratification into distinct laminae, or as the absence of these structures in topologically comparable areas of the brain (Nieuwenhuys et al., 1997). For example, the gustatory nuclei in closely related species of bony fishes may be laminated or not. Or the neurons of the cerebellar nuclei, which are all assembled in the white matter in mammals, may become stratified with Purkinje cells into a single cortical layer in bony fishes. What (if any) functional implications these differences in cellular assembly may offer is still unclear, and the variations may represent nothing more than alternative designs to compute the same information. More physiology is needed to distinguish what each network is good for. This is particularly obvious in the stratification of the midbrain tectum of many vertebrates, which apparently can be secondarily reduced without appreciable functional deficits (Nieuwenhuys et al., 1997). Thus, salamanders may have a much less stratified midbrain tectum and yet are fully able to govern the protrusion of their tongue, as accurately as a reptile or a frog, which have a more stratified midbrain. In other words, we may be looking at structural organizations that do little for the underlying function but keep us baffled at how they vary.

Another example is provided by the differences in organization but similarities in function and long-range connections in the forebrain of birds and mammals. Obviously, comparable functions can be accomplished with either a laminar, cortical organization or with a set of interconnected groups of neurons. It has been suggested that "laminar organization of populations is an alternative means of organizing populations of neurons" (Nieuwenhuys et al., 1997). It appears, then, that some of the highly appreciated, laminar networks are but one way in which the brain can implement a specific functional circuit. It is entirely possible that the morphological differences in the forebrain organization of birds and mammals are not driven by their physiology and adaptivity to behavioral tasks but rather reflect alternative developmental strategies that were implemented simply because the outcome is a viable organism.

## Discussion

This brief overview has stressed some of the emerging developmental principles presumed to govern the remarkably stable overall pattern of the vertebrate brain throughout its evolution while providing enough room for plasticity in both local interactions as well as long-range connections. The developmental analysis has not yet reached a level that can causally explain how local neuronal assemblies, such as cortical columns, come about during development and how the connections between those neurons are organized to adapt the organism to various tasks.

However, it is proposed that complex interactive genetic networks not only guide overall development but offer room for self-organization of these neuronal assemblies within a set of limitations imposed by the developmental selector genes. Thus, whereas some behavior, such as a reflex, is directly translated from the genes through development into a specific set of connections forming the reflex arc, other connections have enough redundancy to be modified in their response by experience and are able to learn. Evolution not only selects modifications in specific connections that allow for a more adapted response, it also selects neuronal networks that allow for learning and thus adaptation during the life of an organism within the genetic limitations in which the brain and its connections developed.

Looking at the evolution of the brain as the evolution of a system that has both genetically and behaviorally hardwired components and other components that can change their response properties allows us to understand the "adaptiveness" of the brain from a less restricted, more dynamic perspective. Adaptation may be viewed as a compromise between change and development in a system that struggles to stay on top of its changing adaptive landscape (Raff, 1996) by balancing both components in various ways. Clearly, hardwiring a response provides superior response speed but restricts adaptation to change during an organism's lifetime. In contrast, learned responses, while initially slower, allow adaptation over the lifetime of an organism. Modeling such systems must take into account that optimization is constrained by at least these two facts, and thus may never be achieved in any living system to the extent that it can be achieved in artificial systems. Although there have been interesting models of the Evolution of Artificial Neural Networks (q.v.), their biological relevance has been somewhat limited by the use of selection on features, such as individual synaptic weighs, that are not necessarily regulated by separate genes in biological nervous systems. Thus, an interesting challenge will be to develop a new generation of models in which evolution occurs within genetically plausible parameters, such as numbers of neurons, variation in long-range output connections, and variation in inputs into the dendrites.

# Eye-Hand Coordination in Reaching Movements

*Valérie Gaveau, Phillipe Vindras, Claude Prablanc, Denis Pélisson, and Michel Desmurget*

## Introduction

Despite a century of research, the neural mechanisms involved in eye-hand coordination during reaching movements are still largely unknown. This article addresses this question and describes the mechanisms whereby a visual input is transformed into a motor command. To this end, we consider the different problems that the nervous system has to solve to generate a movement, namely, localizing the target, creating a motor plan, and correcting the ongoing movement if necessary.

## Representation of Target Position

Reaching toward a visual target requires transformation of visual information about target position with respect to the line of sight into a frame of reference suitable for the planning of hand movement. This problem is classically decomposed in analytic steps that provide target position information in an eye, head, and ultimately bodily frame of reference. For the sake of clarity, we follow this progression to describe the mechanisms encoding retinal information and extraretinal signals of eye-in-orbit and head-on-trunk positions.

Visual information initially signals the angle separating the target and the line of sight. The reliability of this retinal signal is constrained by the spatial anisotropy of the retina and visual system. Because of the gradient of visual acuity, the encoding of a target location with respect to the line of sight degrades when the stimulus falls in the peripheral visual field. This relative inaccuracy of signals from the peripheral retina can be illustrated by hand-pointing errors observed when the movement is performed while the foveating saccade is prevented. Despite this limitation, it is the peripheral part of the retina that is most often involved in the initial localization of a visual target.

In addition to the retinal signal, the position of the eye in the orbit is necessary to encode the location of the target in a body-centered frame of reference. Paradoxically, without a retinal signal, orbital eye position appears to be only coarsely encoded by extraocular signals. Indeed, when subjects are required to point in darkness in the direction of their eyes, the final hand position correlates with eye position, but the scatter is much higher than when the target is a luminous spot (Bock, 1986). Thus, it appears that retinal and extraretinal signals do not simply add but also interact with each other, and that accurate encoding of target location requires concomitant foveal and extraretinal signals. Compatible with this hypothesis are recent studies suggesting that gaze position could influence the encoding of target location for limb motions (Soechting, Engel, and Flanders, 2001).

At the neurophysiological level, the search for interactions between retinal and extraretinal information has stimulated many studies on the neural code of target internal representations. Two different conceptions have emerged: single-unit coding and distributed coding. The single-unit coding concept of integration hypothesizes the existence of individual neurons encoding information about target position, irrespective of eye position. In support of this hypothesis, individual neurons representing symbolic parameters, such as target location in a body-centered reference system, have been described in several studies. For instance, the neuronal activities described by Duhamel et al. (1997) have been shown to encode the position of a visual target respectively in a head-centered frame of reference. This latter coding might hypothetically result from an ultimate stage of coordinate transformation necessary to direct the hand toward a target.

In contrast to the single-unit concept, the distributed coding hypothesis assumes a statistical combination of elementary information about retinal eccentricity and eye position within large neuronal populations. A growing body of evidence of population-based interactions between retinal and extraretinal information supports this concept. Thus, electrophysiological recordings in the parietal cortex of awake monkeys have shown that the activity of the reach-related cells was influenced by eye position information (Batista et al., 1999). With the aid of neural network modeling, Andersen and colleagues (1997) showed that these characteristics of individual neuron discharges are compatible with the existence in the parietal cortex of a distributed code for egocentric target localization.

It may be worth mentioning at this point that the single-unit and distributed concepts are not mutually exclusive. Indeed, symbolic information generated by distributed neuronal populations may ultimately converge at the output level to provide a single-unit representation. For example, the distributed model of Andersen and colleagues yields an output signal of target position relative to the head that is represented at a single-unit level. In addition, a recent electrophysiological study of ventral intraparietal neurons in the monkey showed that the visual response of single units reveals a continuum between head-centered coding and retinotopic coding, leading to the hypothesis that "space may be represented in the cortex both at the population level and at the single cell level" (Duhamel et al., 1997).

How head position signals are integrated with retinal and eye position signals has stimulated less neurophysiological investigation. In 1995, Brotchie et al. reported that the visual response of parietal cortex neurons is modulated by the direction of gaze (integrating both eye and head components). This result suggests that the distributed coding hypothesis of target relative to the head can be generalized to visual target encoding in trunk-centered coordinates. Thus, target-related information in a body reference system seems to be distributed in large neuronal populations.

## Planning Movement Trajectory

It is generally admitted that spatiotemporal invariances can give insight into how visually directed movements are planned and controlled by the nervous system. As an example, consider the task of pointing, from a given initial position, toward visual targets distributed within the workspace. In such a situation, two types of regularities can be expected: (1) *extrinsic regularities*, such that the movement displays invariant features in the Cartesian space (e.g., a straight-line path irrespective of the movement direction or amplitude), and (2) *intrinsic regularities*, such that the movement displays invariant features in one of the intrinsic spaces (e.g., a linear relation between joint angle variations). Interestingly, because the relationships between the extrinsic and intrinsic variables are complex and nonlinear, these two potential types of invariances generally cannot occur at the same time. That is, when the hand trajectory is invariant in the extrinsic space, it displays a consistent variability in the intrinsic space, and vice versa.

The task of pointing from a given starting position toward visual targets distributed within the workspace was initially studied by Morasso (1981). Morasso found that joint covariation patterns varied systematically as a function of movement direction, whereas Cartesian hand paths were always roughly straight. Based on this extrinsic stability, he concluded that (1) the hand trajectory in Cartesian space was the primary variable computed during movement planning, and (2) the joint covariation pattern constituted a dependent variable defined secondarily in order to allow the hand to move along the planned trajectory. Futher evidence supporting this view was found in the demonstration that motor planning was a parametric process involving an independent specification of the Cartesian amplitude and Cartesian direction of the upcoming movement (Vindras and Viviani, 1998), as would be expected if these two components were planned separately.

The hypothesis that the hand always follows a straight line path in external space during visually directed reaching has recently been challenged in several studies showing that hand movements can be significantly curved and that the amount of curvature can vary with the movement direction. For instance, Osu et al. (1997) investigated visually directed movements under two conditions: no path instruction (NI), and instruction to move the hand along a straight line (SI). They found that subjects generated much straighter movements in SI than in NI. As indicated by electromyographic activity (EMG), this difference could not be related to an increase in arm stiffness, which suggested that path curvature was really reflective of the movement planning process. A similar conclusion was reached by Desmurget et al. (1999), who showed, however, that the results reported by Osu et al. were valid only for unconstrained three-dimensional movements. No difference was observed between NI and SI for planar movements. This result might suggest that unconstrained movements, unlike planar movements, are not programmed to follow a straight-line path in the extrinsic space. With respect to this conclusion, several hypotheses have been proposed to explain how unconstrained movements are planned by the central nervous system (CNS). The most popular of these hypotheses suggests that hand trajectory is specified as a vector in the joint space (Flanders, Helms-Tillery, and Soechting, 1992). According to this view, the spatial characteristics of the target are initially converted into a set of arm and forearm orientations. The movement from the starting posture to the target posture is then implemented on the basis of an "angular error vector" whose components represent the difference between the starting and target angles for each joint. During the movement, joint angle variations are not controlled independently, but in a synergic way (temporal coupling). The movement curved path observed in the task space results directly from this temporal coupling.

## Eye-Hand Coordination and the Need for On-Line Trajectory Control

For an external observer, the relative coordination of eye, head, and hand during goal-directed reaching appears sequential. When a subject points to a visual target in peripheral space, the eyes move first, followed by the head and ultimately the hand. Because eye movement duration is brief, the gaze generally arrives at the target before or around the time of hand movement onset. Although this sequential organization was initially thought to have a functional foundation, it was subsequently shown to result primarily from inertial factors (Desmurget and Grafton, 2000). Indeed, the EMG discharge is generally synchronized for the eye, head, and arm during fast reaching movements, indicating that the motor command is sent to these different effectors in parallel (the arm moves last simply because it has the greatest inertia). It follows that the motor command initially sent to the arm is based on an extrafoveal visual signal that has been shown to be inaccurate (see first section). At the end of the ocular saccade, which roughly corresponds to the onset of hand movement, the target location can be recomputed on the basis of foveal information. As shown by Prablanc and Martin (1992), this updated visual signal is used by the nervous system to adjust the ongoing trajectory. To demonstrate this point, the authors used a double-step pointing paradigm in which the target location was slightly modified during the course of the ocular saccade when there was saccadic suppression (i.e., the target jump was not perceived consciously by the subject). Results showed that the hand path, which was initially directed to the first target, diverged smoothly toward the second target. Interestingly, corrections were detectable about 110 ms after hand movement onset, showing that hand trajectory was amended very early. As shown by Prablanc and Martin, these corrections were similar whether or not the moving limb was visible to the subject. This suggests that nonvisual feedback loops represent the main process through which extrinsic errors are corrected.

Because of the existence of consistent delays in sensorimotor loops, the rapid path corrections observed during reaching movements cannot be attributed to sensory information only. They can only rely on a "forward model" of the arm dynamics. The idea behind this concept is that the motor system can progressively learn to estimate its own behavior in response to a given command. By integrating information related to the initial movement conditions, the motor outflow, and the sensory inflow, the forward model can determine, and even predict in advance, the probable position and

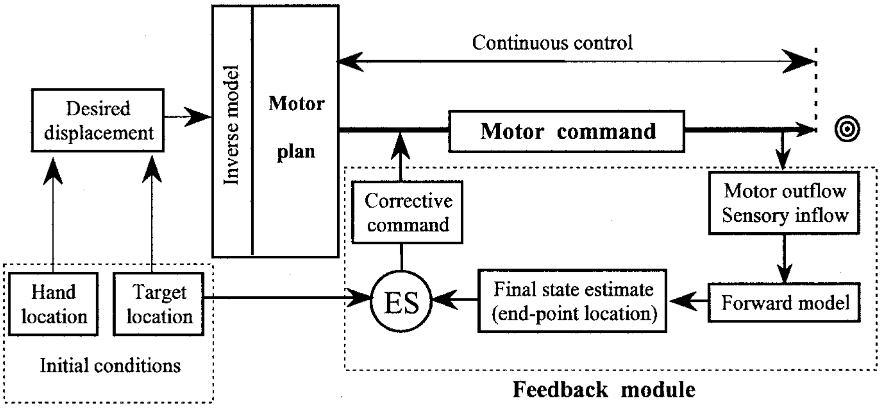

**Figure 1.** Forward model of arm dynamics for controlling hand movements. To reach a target, the nervous system has to elaborate a motor plan based on initial conditions (locations of the hand and target). During the execution of the motor command, a forward model of the dynamics of the arm is generated by integration of a copy of motor outflow and sensory inflow. This model then generates an estimation of the movement end-point location. Discrepancies between estimation and target location cause an error signal, which triggers a modulation of the motor command. (From Desmurget, M., and Gafton, S., 2000, Forward modeling allows feedback control for fast reaching movements, *Trends Cognit. Sci.*, 4:423–431. © Elsevier Publishing Co.; reproduced with permission.)

velocity of the effector, thus making feedback strategies possible for fast reaching movements.

This idea was recently operationalized by Desmurget and Grafton (2000), who proposed a simple model through which fast feedback control might be achieved (Figure 1). According to these authors, the forward model of the arm's dynamics generated during a movement is used to predict the movement's end point. By comparing this prediction with the actual target location, the motor system can directly estimate the movement's final accuracy. When a discrepancy is detected between the movement's predicted final location and the target location, an error signal is generated and a corrective command is issued.

The past two decades have been dominated by the hypothesis that reaching movements are primarily under preprogrammed control and that sensory feedback loops exert only a limited influence at the very end of the trajectory. As a consequence, functional investigations have focused primarily on the cerebral structures participating in motor preparation and execution, yielding few insights into the functional anatomy of on-line movement guidance. This latter issue was recently investigated by our group using positron emission tomography (PET) (Desmurget et al., 2001). Seven subjects were required to look at (Eye) or look and point to (EyeArm) visual targets whose location either remained stationary or changed undetectably during the ocular saccade. The latter condition allowed us to increase the amount of correction to be generated during the movement. The functional anatomy of nonvisual feedback loops was identified by comparing the reaching condition involving large corrections (Jump) with the reaching condition involving small corrections (Stationary), after subtracting the activations associated with saccadic movements and hand movement planning [(EyeArm-Jumping minus Eye-Jumping) minus (EyeArm-Stationary minus Eye-Stationary)]. In agreement with earlier observations (Prablanc and Martin, 1992), behavioral recordings indicated that the subjects were both accurate at reaching toward the stationary targets and able to update their movement smoothly and early in response to the target jump. PET difference images showed that these corrections were mediated by a restricted network involving the posterior parietal cortex (PPC), the cerebellum, and the primary motor cortex (M1). As shown in Figure 2, the parietal activation was located in the left intraparietal sulcus, in a region that is generally considered the rostral part of the PPC. The cerebellar activation occurred in the right anterior parasagittal cortex, in a region associated with the production of arm movements. The frontal activation was located in the arm-related area of M1. The contribution of the PPC to movement guidance has recently been confirmed by several studies showing that on-line movement corrections are suppressed when this structure is lesionned or prevented from exerting its function through the application of a transcranial magnetic pulse at the onset of hand movement (Desmurget and Grafton, 2000).

Although the role of the PPC, the cerebellum, and the motor cortex in movement guidance has not been totally elucidated, a general model can be proposed. At a first level, one may suggest that the role of the PPC is to compute a motor error by comparing the target location and the estimated movement end point. This hypothesis is based on two main observations about the PPC, namely, (1) that the PPC has access to a representation of both the target and current hand location through afferent information coming from different sensory modalities and the main motor struc-

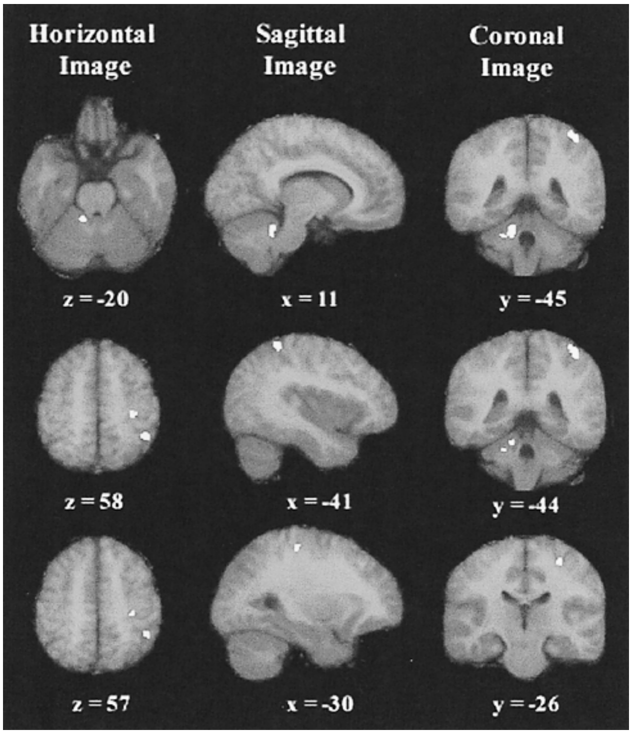

**Figure 2.** Areas of brain activation superimposed on a mean MRI in Talairach coordinates. On the sagittal images, positive values of $x$ designate the hemisphere ipsilateral to the reach arm (right one), and negative values of $x$ designate the contralateral hemisphere (left one). Top row is centered on the cerebellar activation site; middle row is centered on the PPC activation site; bottom row is centered on the precentral activation site. (From Desmurget, M., et al., 2001, Functional anatomy of nonvisual feedback loops during reaching: A position emission tomography study, *J. Neurosci.*, 21:2919–2928. © Elsevier Publishing Co.; reproduced with permission.)

tures, and (2) that the PPC is critical for merging the arm- and target-related signals into a common frame of reference (Andersen et al., 1997). Once computed, the motor error needs to be converted into an effective motor command (inverse computation). Converging evidence indicates that this function may be carried out by the cerebellum. In particular, it has been shown that patients with cerebellar lesions are impaired in defining the pattern of muscle activation required to direct the hand along a specific path, and that inverse models are represented within the cerebellum (Wolpert, Miall, and Kawato, 1998). At the extremity of the system, the cerebellar corrective signal might influence the ongoing motor command by modulating the neural signal issued by the primary motor cortex. In agreement with this view, it is known that the primary motor cortex receives substantial input from the cerebellum via the ventrolateral thalamus. Also, it is thought that the motor system is organized in a relative hierarchy such that the primary motor cortex is mainly involved in low-level aspects of motor control. Of course, the previous observations do not imply that other areas are not involved in movement guidance. A role for the basal ganglia, for instance, was proposed in a recent study on patients with Huntington's disease (Smith, Brandt, and Shadmehr, 2000). This role was not, however, confirmed by our group in subsequent work showing that Parkinson's disease patients were able to smoothly and quickly correct ongoing movement in an unconscious double-step study identical to the one used by Prablanc and Martin (1992).

## Conclusion

Our knowledge of the neural processes underlying eye-hand coordination has greatly improved over the past two decades. However, our understanding is still far from exhaustive, and many issues remain to be addressed. Current approaches will benefit from the development of independent motor theories within specific experimental and theoretical contexts. Our understanding of the processes whereby a visual input is transformed into a motor command would be greatly improved by comparative studies involving heterogeneous approaches as well as various areas of brain theory and neural networks. The complementary contributions gathered in the *Handbook* are a first step in this promising direction.

# Face Recognition: Neurophysiology and Neural Technology

*Rolf P. Würtz*

## Introduction

The ability to recognize other individuals is a major prerequisite for human social interaction and hence a rather important brain function. The most prominent cue for that recognition is the face. The ability to recognize persons from their faces is part of a spectrum of related skills that includes face segmentation (i.e., finding faces in a scene or image), estimation of the pose, estimating the direction of gaze, and evaluating the person's emotional state. This article focuses on recognition of identity. A more detailed treatment of the other aspects can be found in FACE RECOGNITION: PSYCHOLOGY AND CONNECTIONISM.

## Neurophysiology

From neuropsychological studies of patients with brain injuries, it is known that there are subsystems in the brain that are specialized for face processing. Brain injury can lead to loss of the ability to recognize faces, a deficit called *prosopagnosia*, while leaving recognition of general objects intact. The opposite dissociation is reported in Moscovitch, Winocur, and Behrmann (1997), in a patient with intact face recognition together with highly impaired general object recognition. Various stunning perceptual demonstrations show that faces are perceived differently when viewed upside down or as photographic negatives. Those image manipulations make little difference for the perception of general objects but can modify the perception of identity and expression considerably. These findings lead to the assumption that different brain circuits are used for processing general objects and for processing faces, but there is also considerable evidence that not only faces receive special treatment, but all object classes for which there is high expertise (Gauthier, Behrmann, and Tarr, 1999).

Other studies show that patients with prosopagnosia who exhibit no conscious recognition of facial identity still exhibit an unconscious reaction to familiar faces, which is revealed by changes in skin conductance. This mechanism seems to play a major role in the emotional reaction to facial stimuli.

Single-unit recordings of activity in the inferotemporal cortex of macaque monkeys have revealed neurons with a high responsiveness to the presence of a face, an individual, or the expression on a face (see Desimone, 1991, for a review). Although the notion of the optimal stimulus for a cell is very hard to probe experimentally, some of these cells are as close to grandmother cells (see Associative Networks) as the experimental evidence gets.

In humans, cells that become active when a familiar face is seen have been identified in the inferotemporal gyrus and the fusiform gyrus in both hemispheres. Their clusters do not form anatomically well-defined subregions but are neighbored by modules of different specificity, and their location and extent vary considerably among individuals.

A good account of the current knowledge about face recognition in the human brain is given by Haxby, Hoffman, and Gobbini (2000), whose model refines a cognitive model by Bruce and Young (see Young, 1998, chap. 3) and attaches anatomical locations to its modules. Haxby et al. propose a *core system* for face processing that consists of three interconnected modules. The first, located in the inferotemporal occipital gyrus, is responsible for the early extraction of features relevant for faces. The second, in the superior temporal sulcus, codes for the changeable properties of faces, such as the direction of gaze, lip movement, expression, and the like. Identity as an invariant face property is processed in the lateral fusiform gyrus. This core system communicates with other parts with a need for facial information, such as attention modules, auditory cortex, and emotional centers. The essence of face recognition—to link the visual information to a name and biographical knowledge about particular persons—is carried out in the anterior temporal lobe. These other parts make up the *extended system*.

## Computational Theory

As for all cases of object recognition, the main problem to be solved by a face recognition procedure is *invariance*. The same face can produce very different images with changes in position, pose, illumination, expression, partial occlusion, background, and so forth. The task of the recognition system is to generalize over all these variations and capture only the identity.

This sort of invariant recognition is a quotidian property of natural brains but does not come very naturally in current artificial neural network models. Even the simplest case, invariance under translations in the input plane, is difficult to obtain. One major approach starts with the observation that complex cells generalize about small translations of the signal. This can be iterated, and leads to hierarchical networks such as the Neocognitron: A Model for Visual Pattern Recognition (q.v.). A huge advantage of such purely feedforward networks is their speed of processing.

Very little is known about how invariant recognition can be learned from examples and generalized to other instances. In an abstract sense, the important long-term goal is to teach a network precisely the invariances required for a given problem domain. This is directly relevant for face recognition, because invariance under expression and slight deformations are very difficult to capture analytically.

If the only invariance required is translation, then template matching (see Object Recognition) can solve the problem rather efficiently. A stored pattern (which we will call "model") is compared to an image by shifting the model across the image and taking the scalar product with appropriate normalization at all possible image locations. The maximum of the resulting matrix can serve as as similarity measure between both images.

In order to extend this method to the more complicated invariances involved in face recognition, the notion of a *correspondence map* is helpful (Figure 1). Correspondence, central to many problems in computer vision, can be defined as follows: *Point pairs from two given images of the same face correspond if they originate from the same point on the physical face*.

Once these correspondences have been established for sufficiently many points, an invariant similarity measure between model and object can be defined as the sum or average over the similarities of local features of all corresponding point pairs. Because the points on the real face are not accessible to either the brain or a computer, these correspondences can only be estimated on the basis of image information. Strictly speaking, correspondences are defined only between images of the same person, but all faces are sufficiently similar in structure that the notion can be extended to correspondence maps between different faces. These maps have many applications beside recognition (see Face Recognition: Psychology and Connectionism).

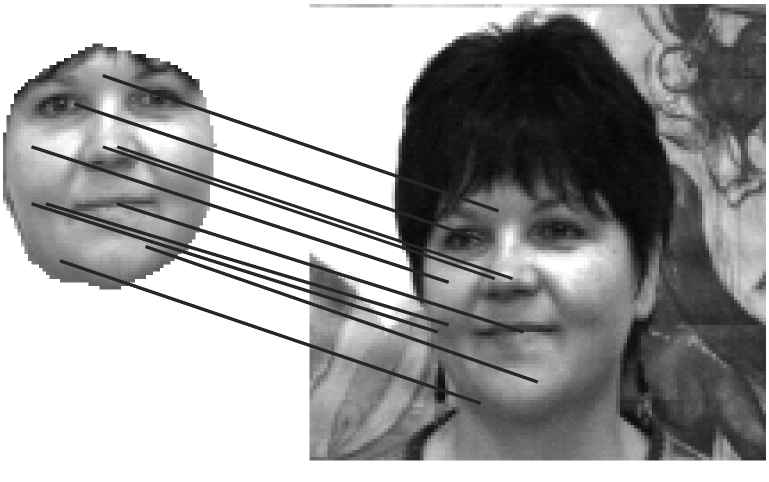

**Figure 1.** Correspondence maps provide a basis for ar similarity measure between two facial images, whic used for person identification. They also deliver in about pose, size, and expression, and are crucial for animation. Their computation is difficult and rarely perfect. The figure shows selected correspondences obtained with the algorithm from Würtz (1997).

A system to recognize a person out of a collection of known ones can proceed as follows. Correspondence maps are estimated between the given image and all stored models, similarities are calculated on the basis of the correspondence maps, and the model with the highest similarity is picked as the recognized person. A measure for the *reliability* of the recognition can be derived by a simple statistical analysis of the series of all similarity values.

Because correspondence finding is a slow process, the database of known individuals must be organized in such a way that the need for correspondence finding is minimized. Furthermore, it should not be applied to arbitrary images, but some filtering must select image portions that are likely to contain a face for processing and recognition.

Summarizing the computational theory reveals the following building blocks for a successful face recognition system:

1. A representation of the facial images
2. A method of solving the correspondence problem
3. A similarity measure derived from a pair of images and a correspondence map
4. Organization of the database of known individuals
5. Filtering of the visual data (face finding)

For general reviews of face recognition systems, see Grudin (2000) and Chellappa, Wilson, and Sirohey (1995).

## Image Representation

Many models for face recognition work directly on image gray values or retinal images. In this case, the correspondence problem becomes particularly difficult, as many points from very different locations share the same pixel value without actually corresponding to each other. A possible remedy consists in combining local patches of pixels. The larger the patch, the more this ambiguity is reduced. On the other hand, the features become more sensitive to distortions and changes in background and thus are of less value for the other required invariances. Patch building may also include linear combinations of pixel values. In this context, *Gabor functions* (see Gabor Wavelets and Statistical Pattern Recognition) as a model of simple and complex cells in V1 have turned out to be a good compromise between locality and robustness and are well-suited for correspondence finding.

The possibility of processing the amplitudes and phases of the Gabor wavelet responses separately is very useful for face processing. Amplitudes (which model the activity of complex cells) vary rather smoothly across the image, and so do the similarities of all image features to a single one. Consequently, they provide smooth similarity landscapes well-suited for matching templates or single feature vectors. The phases, on the other hand, vary as rapidly as dictated by their center frequency and proceed roughly linearly on image paths in the respective direction. Therefore, they can be used to estimate correspondences with subgrid accuracy (Wiskott et al., 1997; Würtz, 1997).

An important alternative for image representation is to use local features that are derived directly from the statistics of facial images. A prominent example is the neural network–based *local feature analysis* (Penev and Atick, 1996), which allows learning local descriptors by minimizing their correlation. This results in a sparse code adapted for the class represented by the training examples.

## Correspondence Finding

The representation of a face in terms of local features serves two purposes. First, correspondences must be estimated on the basis of feature similarity, and second, the feature similarities constitute the image similarity. In principle, different features can be used for both purposes.

Because of the ambiguities discussed above, simplifying assumptions must be made about the correspondence maps. A good candidate for such an assumption is *neighborhood preservation*. Consequently, algorithms for correspondence finding usually optimize a combined objective function that favors similarity between local features and smoothness of the correspondence map.

One implementation of this procedure is *elastic graph matching* (EGM) (Lades et al., 1993), in which stored models are represented as graphs vertex-labeled with vectors of local Gabor responses and edge-labeled with a distance constraint. The correspondence problem can be solved by optimizing the similarity between model graph and a (topologically identical) graph in the image in terms of similarity of both edge and vertex labels. This is a high-dimensional optimization problem that is usually simplified by applying a hierarchy of possible graph transformations. It starts with pure translation, later adds scale changes, and finally adds local displacements. In the first steps, Gabor amplitudes are used exclusively, which leads to smooth similarity landscapes and allows separating the different steps.

An alternative method, one that makes use of the pyramidal form of Gabor wavelet transform, is *Gabor pyramid matching* (Würtz, 1997). It starts with standard template matching of the Gabor amplitudes on a sparse grid and low spatial frequency and refines the results using higher spatial frequencies. Thus, neighborhood preservation is not explicitly coded into an objective function but is inherited from the undistorted matching on low frequencies. Very precise correspondences can be obtained by subsequent subgrid estimation using the Gabor phases. This method allows much better background suppression, because the need to know local features for each feature point on all scales is eliminated.

## Memory Organization

The importance of memory organization is due to the computational expense of the inevitable correspondence estimation, which should not be carried out separately on all stored models. Consequently, it is necessary to evaluate correspondences *between* the stored models. Adding this idea to EGM results in the so-called *bunch graph* (Wiskott et al., 1997). In that data structure, each vertex is labeled with one local feature vector from each person in the database, and care has to be taken during creation of the bunch graph that these feature vector are indeed taken from corresponding points. In addition to different matching schemes, bunch graphs can be used in two major modes. In one mode, it is assumed that the person to be recognized is indeed in the bunch graph, and is selected according to similarity. Alternatively, the feature most similar to the given image can be selected for each vertex separately, leading to a composition of the face image in terms of the local features of all persons in the bunch graph. Moreover, the vertices can carry additional information, such as sex, beardedness, or a genetic disease of the person they belong to. By majority voting, a decision about that feature for completely unknown persons can be made.

Eigenfaces (Turk and Pentland, 1991) are another technically successful approach to face recognition. Gray-value images of faces are prealigned by an optical flow method and then subjected to Principal Component Analysis (q.v.), which can be interpreted as a neuronal method. It turns out that a few components are sufficient to recognize identity. Recognition proceeds by projecting the image to be classified onto these components and applying a classifier to the resulting low-dimensional vector. Calculating the PC representation from a database of persons is rather time consuming, but projection and classification are very fast. This shows that the major strength of the eigenface method lies in very efficient memory organization.

## Neuronal Models

On the technical side, a large variety of neural network models have been applied to the problem of face recognition. They usually start from well-aligned faces with little variation. See Gong et al. (2000) for a good discussion of the application of neural classifiers and an excellent treatment of technical approaches to face recognition.

It is currently not known if there is neuronal machinery in the brain to explicitly estimate correspondences. However, DYNAMIC LINK ARCHITECTURE (q.v.) can be used to solve the correspondence problem, as follows (Lades et al., 1993). Two layers of neurons that represent the image space in model and image, respectively, are fully interconnected by dynamic links. They have an internal wiring that supports moving localized blobs of activity. The development of links is supported by feature similarity and synchronous activation of the connected neurons. The link dynamics then converge to a correspondence mapping. It has been extended by a competition between a multitude of model layers to a full-blown neural face recognition system. This system is sped up by a coarse-to-fine strategy working on the Gabor pyramid. The speedup is due to the possible parallelism between all refinement steps. That system also shows good background invariance, because model and image representation are the same as for pyramid matching.

## Face Finding

Having found a correct correspondence map from a stored model into an image in principle implies that segmentation has also been solved. However, applying correspondence-based techniques like bunch graph matching to arbitrary images yields plenty of misclassifications: depending on the parameters, either many faces go undetected or many nonfaces pass as faces.

It seems very difficult to encode the notion of a general face into a program or data structure. Therefore, for *finding* faces in images or video sequences, neural net classifiers are widely used. Typically, a whole set of segmented and roughly normalized face images is used to train a network. Then the network is applied to all points of an image to provide a face/nonface decision. A good review of the facefinding literature can be found in Hjelmås and Low (2000).

## Discussion

A correspondence map is a very general model of the variation of appearance of a face. Its estimation is computationally intensive, and the currently known neuronal models that can implement it cannot account for the rapidity of human recognition, even if run on highly parallel hardware like real neurons. The advantage of correspondence maps lies in the fact that much more information, such as the actual position, pose, and expression, can be determined from them.

The quality of technical face recognition systems is difficult to judge. On small data sets (less than 100 individuals), even naive template matching may yield respectable recognition rates. The use of standard databases, which is inevitable for achieving fair comparisons, raises the danger of overadapting the classifiers to the data. To prevent this, the Army Research Laboratory has set up a standard comparison procedure called the FERET test (Philips et al., 2000), in which where the major part of 14,126 images of 1,199 individuals is withheld for independent testing.

With this database, eight competitors underwent a test with the additional information about the (hand-labeled) eye position. Only two competitors, a bunch graph–based system and an eigenface-based system, took the realistic test on the images without any extra information. Both systems performed equally well on the data set with given eye coordinates, and the bunch graph–based system clearly won on the more difficult examples without additional information (Philips et al., 2000). These results underscore the need for very good correspondence estimation for successful face recognition.

# Face Recognition: Psychology and Connectionism

*Alice J. O'Toole*

## Introduction

Faces provide humans with rich information about their owners. From a brief glance across a dimly lit room, we can recognize the face of a friend. Faces also provide us with information important for social interaction, including the sex, race, approximate age, and current mood of a person. Humans can extract this information nearly instantaneously from the complex three-dimensional (3D) surface of the head. The skills humans have in perceiving and recognizing faces are even more impressive when we consider the number and diversity of people we must remember as individuals, and the fact that all faces share the same basic set of features (eyes, nose, and mouth), arranged in roughly the same configuration. Quantifying or even specifying the information that makes a face unique is a challenging problem.

Automatic or computer-based approaches to modeling face recognition have a long and relatively successful history among connectionist models of visual recognition. Commercial versions of facial recognition systems are now widely available and have already been employed in a variety of security applications. Although still not at the level of human performance on all tasks, with minimal viewpoint and illumination variation, the performance of these models compares favorably with the performance of humans (see FACE RECOGNITION: NEUROPHYSIOLOGY AND NEURAL TECHNOLOGY).

This article begins with a brief history of connectionist approaches to face recognition. Next, the broad range of tasks to which these models have been applied will be presented. Relating the models to psychological theories is accomplished by breaking the problem into the subtasks of representing faces and retrieving them from memory. Human and model performance can be compared along these dimensions. Finally, the article concludes with an overview of the challenges facing computational models of face processing at the beginning of the twenty-first century.

## History and Theoretical Background

Connectionist face recognition models are some of the first successful computational models of a visual recognition task. Perhaps because of the homogeneity of faces as a class of objects, and the utility of recognition within the class of faces, the problem of modeling face recognition has been more tractable than modeling object recognition (see OBJECT RECOGNITION). Early face recognition models date from the beginnings of associative models of memory. In the 1970s, Kohonen (1977) used faces to illustrate the potential of a linear autoassociative network to act as a parallel distributed memory for images. He used simple pixel-based encodings of faces and showed that the model could selectively retrieve memorized faces using partial or occluded memory keys. The work of Kohonen using autoassociative memories with faces provided the cornerstone for most current computational models of face recognition. The autoassociative memory brings together important aspects of the psychology of face recognition and the varied, yet related, computational approaches to the problem.

The key to this connection is that autoassociative memories can be shown to implement PRINCIPAL COMPONENT ANALYSIS (PCA; q.v.), the most common of current connectionist or statistical models of face recognition (cf. Phillips et al., 2000). PCA is a technique for representing a number of correlated variables using a lesser number of uncorrelated or orthogonal variables. Applied to a set of face representations (e.g., images, 3D surfaces), PCA produces a set of orthogonal "feature" axes, known variously as principal components (PCs), eigenvectors, eigenfeatures, or eigenfaces (Turk and Pentland, 1991). These axes are ordered according to the proportion of variance they explain in the set of faces analyzed. A critical property of PCA is that any face in the set of analyzed or "learned" faces can be represented or reconstructed as a weighted combination of PCs. This property is shared by more recent techniques, such as nonnegative matrix factorization, that produce a sparser representation of faces than PCA (Lee and Seung, 1999; see also SPARSE CODING IN THE PRIMATE CORTEX).

From a psychological point of view, it is reasonable to think of PCs as features, and of the weights required for reconstructing a face as its *feature values*. PCA and connectionist-style models have properties reminiscent of human memory for faces. First, the memory is distributed rather than localized. This means that individual face representations interfere with each other in a way that allows for natural confusions between similar faces. Second, at the level of groups of faces, the proportion of variance associated with individual PCs is indicative of the importance of individual features for describing the set of faces. This enables the statistical properties of a particular face-learning history to affect the performance of the model. For example, connectionist models that vary in the racial composition of the training set can simulate the "other-race effect" for human memory (O'Toole et al., 1994). This is the well-known finding that we recognize faces of our own race more accurately than faces of other races.

An important theoretical focus of the last decade has been the integration of connectionist models of face recognition into the *face space theory* of human face processing (Valentine, 1991). Valentine's face space theory posits that human memory for faces can be thought of metaphorically as a multidimensional face space. At the center of the space is the average or "prototype" face. Individual faces are represented as points in the space, with the axes of the space defining the features with which faces are encoded. The distance between any two faces is, therefore, a measure of their similarity.

The face space model accounts for some common psychological findings for face recognition. For example, it is well known that the faces rated by subjects as typical are recognized less accurately than faces rated as distinctive. The face space theory explains this difference based on the probable distribution of faces in the space. Typical faces are close to the average face, where the space is "crowded." Distinctive faces are located in the sparser parts of the space, away from the average. Typical faces, therefore, are more easily confused with other faces than are distinctive faces.

It has become increasingly clear that the majority of connectionist models of face recognition, including those based on PCA, implement a physical version of Valentine's (1991) face space. These physical face spaces provide powerful tools for testing psychological theories about the way humans represent and retrieve faces from memory.

## Face-Processing Tasks

Before proceeding, it is worth defining the range of face-processing tasks to which connectionist models have been applied. *Face recognition* involves a judgment about whether or not a face has been learned previously (i.e., is in the model's memory). This is distinct from *face identification*, which requires the retrieval of semantic information about a person whose face has been recognized (i.e., a name, or context or previous encounter). For *face verification*, a face is presented along with identifying information such as a name badge, and the model or machine must affirm or reject the face identification. This task has become increasingly important in recent years with the development of automatic security systems.

In addition to recognizing and identifying the faces of people we know, we must also be able to visually categorize faces along a number of general dimensions, including sex, race, age, and facial expression. Connectionist models have been applied to nearly all of these tasks, with varying levels of success (see O'Toole, Wenger, and Townsend, 2001, for a detailed review of face classification models). Of particular note, recent applications of connectionist models to the task of processing facial expression have become important in the context of human-computer interaction applications. They are also valuable tools for addressing the theoretical issues involved in human perception of emotion. Recent work by two groups have made inroads into the problem using PCA (Calder et al., 2001) and backpropagation models (Dailey, Cottrell, and Adolphs, 2001). Although there is still active debate on the psychological mechanisms involved in the processing of expressions, both models have achieved good performance and offer insight into the human solution to the problem.

## Representing Faces

Much of the scientific dialogue associated with connectionist models of face processing over the past 5 to 10 years has focused not on the algorithms, but on the representations to which they are applied. Although the basic models have remained relatively simple, the representations to which they have been applied have evolved quickly and have provided fascinating insights into the complexities of representing the information in faces. As noted, face space models are powerful tools for testing the validity of different underlying representations of faces. The general idea is that the models operate by deriving a face space that is sensitive to the statistical structure of the faces analyzed. However, the way in which these inputs are encoded (e.g., by images, 3D measures, geometrical measures) has a substantial impact on the layout of the face space, and thereby alters the distances between individual faces. This is easy to understand intuitively, as follows. Imagine two faces with highly similar shapes but very different coloring (pigmentation). Representing the faces using images will result in a rather different similarity estimate than representing the faces with 3D surface measures.

The face representations used most commonly in connectionist models of face processing can be divided into three types: (1) raw image codes, (2) partially aligned "pre-morph" codes, and (3) fully corresponded "pre-morph" codes (cf. O'Toole et al., 2001, for additional details).

The first connectionist models represented faces as raw images (Sirovich and Kirby, 1987). Although the faces were spatially scaled and aligned in the image so that the eyes or nose of all faces coincided, this code has the obvious disadvantage of being only minimally tolerant of changes in viewpoint and illumination. Notwithstanding, raw image codes, within these limits, have proved highly effective and accurate at the task of face recognition and have largely remained the standard in state-of-the-art computational models of face recognition (Phillips et al., 2000). Connectionist models based on these codes also provide a reasonable approximation to human judgments about the distinctiveness of a face and human accuracy in recognizing faces (see O'Toole et al., 1994).

More effective ways of aligning faces have been developed based on partially aligned "pre-morph" codes. These codes define a partial correspondence between the features of all faces and help bridge the gap between computational models of face recognition and computer graphics–based face synthesis. Pre-morph codes define a representation that can support a morphable transition between any two faces. Craw and Cameron (1991) first introduced the idea of a pre-morph code for face representation by dividing a face representation into *shape* and *shape-free* encoding. Though not yet exploited to its full potential, this method is valuable to psychologists because it allows independent manipulation of the shape and shape-free components of the face in psychological experiments. Face shape is defined by the spatial positions of a set of facial landmarks (corners of the eyes, mouth, etc.) in an image. Next, a complementary shape-free code of a face is created by morphing (or warping) the face into the average face shape, computed over a large number of faces. The encoding of an individual face, therefore, includes both its shape and shape-free parts. Hancock, Burton, and Bruce (1996) used this separated face code with PCA for modeling human face recognition and found a better fit to human performance than the purely image-based codes used previously.

Dividing the representation of faces in this way enables a separate analysis of the structure of a face and its image-based information, but is costly in terms of the preprocessing required. Successful use of these codes involves locating and marking (often by hand) a relatively large number of facial landmark points that match on all faces. A related representation, inspired by early visual processing, overcomes this problem in an interesting way. This approach characterizes the work of von der Malsburg and his colleagues over the years (see, e.g., Okada et al., 1998, and FACE RECOGNITION: NEUROPHYSIOLOGY AND NEURAL TECHNOLOGY). Okada et al. used banks of Gabor jets—filters with varying orientations and resolutions—to sample face images at multiple locations. The Gabor jets simulate the spatial frequency filtering that occurs in early visual processing in the cortex. Using a dynamic link architecture, face recognition occurs by allowing the relative locations of the Gabor jets to migrate to fit individual faces. In some ways, this implements the partial alignment discussed previously in a biologically plausible way. This model has been shown to support highly accurate face verification and is the basis of commercial identification security systems (see Phillips et al., 2000).

To simulate face synthesis and to implement a face space that is completely continuous (i.e., locations in the space are "possible" faces), however, true correspondences between meaningful facial landmarks are necessary. In recent work using elaborated optic flow algorithms, Blanz and Vetter (1999) have been able to completely automate the feature-matching process to produce "fully corresponded" face representations, using laser scans of human heads. *Fully corresponded* means that the matching process is carried out not only on the landmark points, but on *all* of the sample points. Specifically, Blanz and Vetter aligned the $x$, $y$, $z$ and $r$, $g$, $b$ sample points for a large number of individuals. From this corresponded representation of the laser scans, they defined a 3D morphable model of faces by analyzing the data with PCA. This model readily fits into the multidimensional face space theory outlined previously, but employs a sophisticated and nearly complete representation of the perceptual information in faces. Psychologists can use this model to precisely manipulate the information in faces. In particular, 3D shape versus 2D reflectance information in faces can be varied selectively. These manipulations have been used to test the contribution of 2D versus 3D information for human face recognition (see O'Toole et al., 2001, for a review of findings).

The morphable model was used to predict high-level face adaptation effects in human perception. Leopold et al. (2001) showed that trajectories can be defined through this space by connecting a face with the average face, and continuing the trajectory to the "other side of the mean" (Figure 1). This defines an "anti-face" or "opposite" to the original face, because it inverts all of the coordinates (feature values) on the PCs. For example, dark faces have light-colored anti-faces, and round, chubby faces have long, skinny anti-faces. Leopold et al. showed that the perception of a face can be facilitated by simply pre-viewing its anti-face for a few seconds.

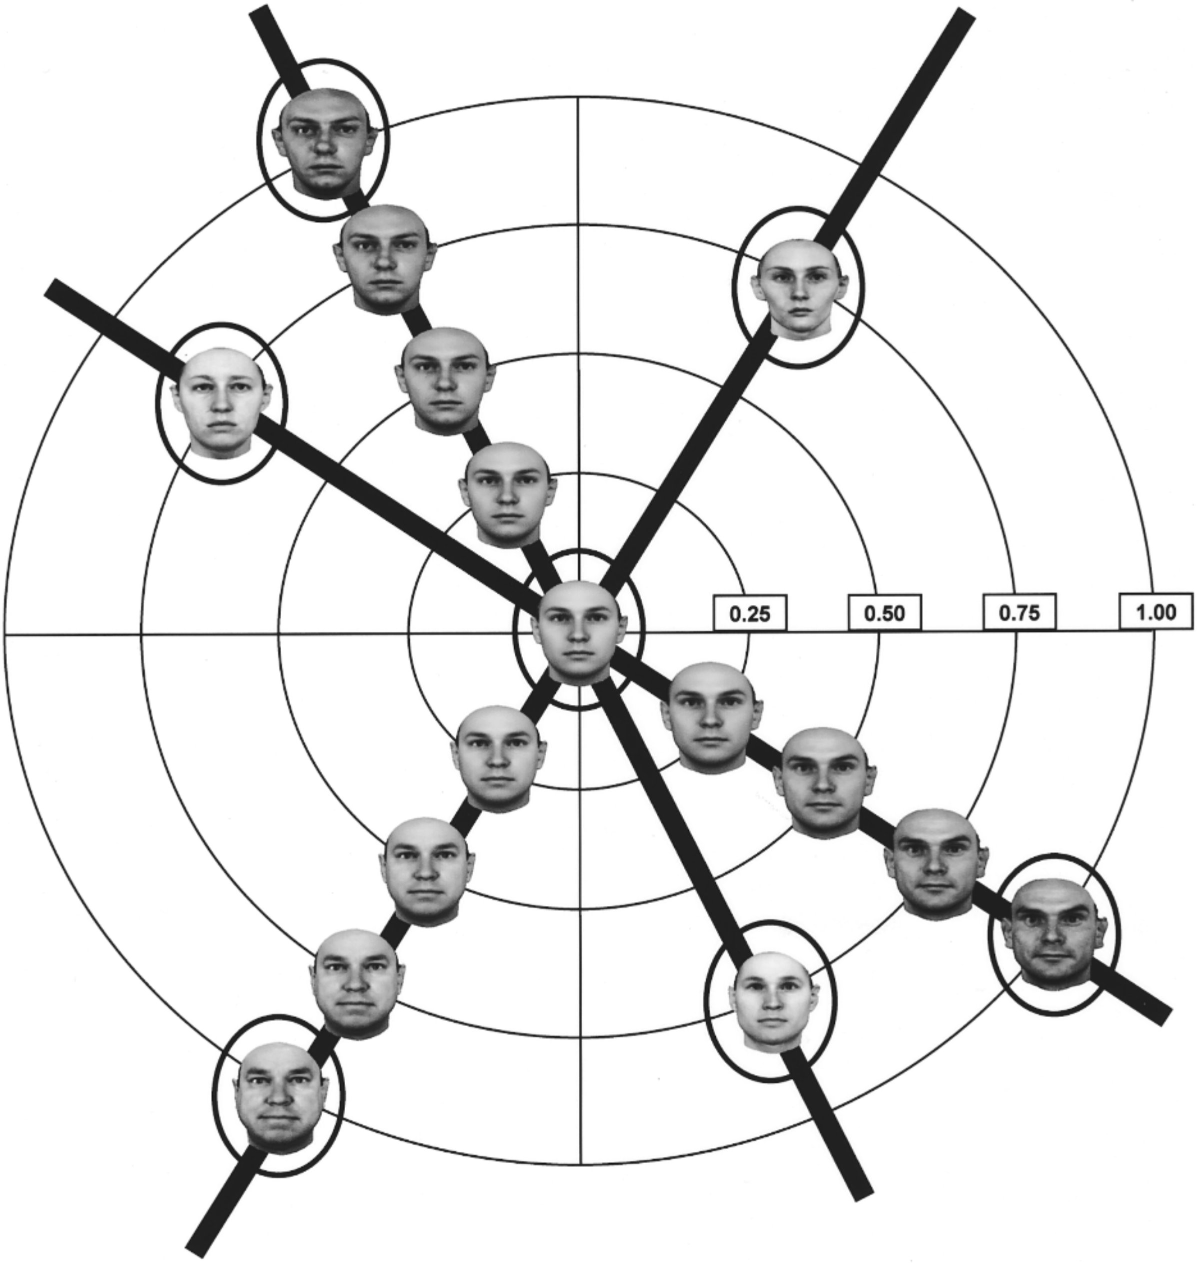

**Figure 1.** A face space created by the morphable model of Blanz and Vetter (1999) shows the continuous trajectory between a face and the mean or prototype of the face space. Anti-caricatures lie between the face and the prototype. On the other side of the mean is the anti-face, which is an opposite (i.e., all feature values are reversed) of the original face. (From Leopold, D. A., O'Toole, A. J., Vetter, T., and Blanz, V., 2001, Prototype-referenced shape encoding revealed by high-level aftereffects, *Nature Neurosci.*, 4:89–94. Reprinted with permission.)

This effect has been compared to simpler visual aftereffects, such as the perception of green after viewing red. Trajectories through this complicated face space, therefore, can be used to predict human performance in a rather precise way. Leopold et al. relate these findings to the activity of face-selective cells in inferotemporal cortex, which may encode high-level shape properties of objects.

In summary, face representations have evolved in sophistication and have provided connectionist and statistically based models with better and more precise information about faces. As these representations have improved, so too has the power of the models for simulating aspects of human performance with faces.

## Retrieving and Categorizing Faces

In the context of a computational model, face recognition involves a decision about whether or not a face has been learned previously. For the face space framework, this works as follows. The learned faces are points in a multidimensional space. Recognition is implemented by projecting a test face into this space to locate a match. Projection involves the representation of the test face using the features or eigenvectors derived from learned faces. If a good match is found—i.e., if the location of the test face in the space is close to a stored face—then the face should be "recognized." If there is no neighboring face sufficiently close to the test face, the face should be declared "novel." This way of testing face recognition algorithms produces "hit" and "false alarm" data very similar to those acquired in a standard human face recognition experiment.

It is clear that anything that alters the appearance of the face between learning and test time and that is included in the representation (e.g., illumination for a pixel-based code) will affect the accuracy of recognition. This interaction between the model representation and the retrieval process can be used to make predictions about the factors that will determine human accuracy for faces. These predictions can be used to test hypotheses about the kinds of representations employed in the visual system. At present, a variety of algorithms and representations are available. The work of assessing the accord between human and model performance in the context of psychological theories of these processes is under way.

## Discussion

Connectionist models of face recognition have a long and distinguished history. Their development has been spurred by the many and varied psychological issues inherent to the perception of human faces, and by a quickly emerging set of industrial applications. These include applications for security systems and biometric analysis of person identification. Connectionist algorithms are available for face recognition, verification, and classification. In the future, we can expect to see systems that track moving people and faces being merged into the better-developed face-processing algorithms discussed here.

# Fast Visual Processing

*Simon J. Thorpe and Michèle Fabre-Thorpe*

## Introduction

How long does the visual system take to process an image? Yarbus's pioneering studies of scanning eye movements in the 1960s showed that we typically make about three saccades a second. This finding implies that a few hundred milliseconds is enough for visual analysis and programming the next eye movement. By the 1970s, work by Irv Biederman and Molly Potter had shown that much information can be extracted from briefly glimpsed scenes, even at presentation rates of around 10 frames/s, a technique known as rapid sequential visual presentation (RSVP). In the early 1980s, one of the prime motivations for the development of connectionist and PDP models was Jerry Feldman's "100-step limit." Feldman argued that since many complex cognitive tasks can be performed in about half a second, and since interspike intervals for neurons are seldom shorter than 5 ms, the underlying algorithms should involve no more than about 100 sequential, though massively parallel, steps. These numbers were only ballpark figures and unrelated to any particular task, but Feldman's strategy has recently been taken a step further by measuring processing time on specific high-level visual tasks. In combination with knowledge about underlying anatomy and physiology, such information can provide insights into the processing strategies used by the brain.

There is an important distinction in neural computation between feedforward processing models and those with recurrent connections that allow feedback and iterative processing. Pure feedforward models (e.g., multilayer perceptrons, or MLPs) can operate very quickly in parallel hardware. But many authors, including, for example, Ullman (1996), Rao and Ballard (1999), and Grossberg (2001), have argued that sophisticated visual processing requires the interplay of bottom-up and top-down mechanisms. Such views are supported by the anatomy of the visual system, since neurons at virtually every level are influenced not only by feedforward projections but also by extensive feedback connections from later stages and horizontal connections within each layer. Should one conclude that, because the visual system has recurrent connections, pure feedforward mechanisms have no role to play? Perhaps not, because even in systems that use extensively recurrent connections, the very fastest behavioral responses might essentially depend on a single feedforward processing wave. This article considers how detailed measurements of processing speed can be combined with anatomical and physiological constraints to constrain models of how the brain performs particular computations.

## Measuring Processing Speed

The ultimate test for processing speed lies in behavior. If animals can make reliable behavioral responses to specific categories of stimuli with a particular reaction time, there can be no argument about whether the processing has been done. When a fly reacts to displacements of the visual world by changing wing torque 30 ms later, 30 ms is clearly enough for both visual processing and motor execution. Fast behavioral reactions are not limited to insects. For example, tracking eye movements are initiated within 70–80 ms in humans and within around 50 ms in monkeys (Kawano, 1999), and vergence eye movements, required to keep objects within the fixation plane, have latencies of around 85 ms in humans and less than 60 ms in monkeys (Miles, 1997). Such low values probably reflect the relatively simple visual processing needed to detect stimulus movement and the short path lengths in the oculomotor system. How fast could behavioral responses be on tasks that require more sophisticated visual processing?

In 1996, we reported fast behavioral responses on a challenging task for the visual system (Thorpe, Fize, and Marlot, 1996). Presented with color photographs flashed for only 20 ms, subjects had to release a button as quickly as possible if the image contained an animal, and not respond otherwise. Target and nontarget images were extremely varied, with targets including mammals, birds, fish, and insects in their natural environments. Furthermore, no image was shown more than once, which forced subjects to process each image from scratch with minimal contextual help. Despite all these constraints, accuracy was high (around 94%), with mean reaction times (RTs) typically around 400 ms.

While mean RT might be the obvious candidate for measuring processing speed, another useful value is the minimal time needed to complete the task. Using RT distributions, this value can be defined as the first time bin at which correct responses start to significantly outnumber erroneous responses to nontargets. Faster responses occurring with no bias toward targets are presumably anticipations triggered before stimulus categorization was completed. Remarkably, in the animal categorization task, these minimal response times can be less than 250 ms.

It might be thought that images associated with fast responses constitute a subpopulation particularly easy to analyze. However, we found no obvious features that characterize rapidly categorized images (Fabre-Thorpe et al., 2001), implying that, even with highly varied and unpredictable images, the entire processing sequence from photoreceptor to hand movement can be completed in under 250 ms. Remarkably, rhesus monkeys can also perform this task, but their minimal RTs are even faster, around 170–180 ms (Fabre-Thorpe, Richard, and Thorpe, 1998). As in the tracking and vergence eye movement studies mentioned earlier, humans take nearly 50% longer than their monkey cousins to perform a given task.

Such data clearly impose upper limits on the time needed for visual processing. However, they do not directly reveal how long visual processing takes because reaction times also include response execution. How much time should we allow for the motor part of the task? To get at this question, event-related potentials (ERPs) and magnetoencephalography (MEG) recordings can be used to track information processing between stimulus and response. For example, during performance of the animal categorization task, simultaneously recorded ERPs showed that the average response to correct target trials diverged sharply from the average response to correct nontarget trials at about 150 ms post stimulus. This remarkably robust differential ERP response appears specifically related to target detection and occurs well in advance of even the fastest behavioral responses. This value of 150 ms for visual categorization leaves no more than 100 ms for motor execution when behavioral responses occur at around 250 ms.

Processing speed can also be assessed at the level of single neurons by determining the point at which they start to show selectivity for particular visual inputs. By examining the information contained in neuronal responses at different times and in different visual structures, one can follow how processing develops over time. Surprisingly, using response latency to track the time course of visual processing is a relatively recent technique in experimental neuroscience. Nevertheless, by 1989 it was clear that the onset latencies of selective visual responses were a major constraint on models (Thorpe and Imbert, 1989). Face-selective neurons had been described in monkey inferotemporal cortex (IT) with typical onset latencies of around 100 ms. Beyond the visual system as such, neurons in the lateral hypothalamus were known to respond selectively to food after only 150 ms. Although these earlier studies suggested that visual processing could be very fast, they did not specifically determine at which point the neuronal response was fully selective. In 1992 it was demonstrated that even the first 5 ms of the responses in IT neurons could be highly selective to faces (Oram and Perrett, 1992). Since IT neurons can start responding before 100 ms, such data can be used to assign firm limits to the processing time required to reach a certain level of analysis.

## Implications for Computational Models

Determining the minimal time required to perform a particular task or computation is not enough to constrain models of the underlying mechanisms without taking into account underlying anatomy and physiology. Even if monkeys can perform an abstract categorization task in as little as 180 ms, this feat would tell us little about the underlying computations if the brain was an unstructured assembly of neurons. However, the underlying anatomical pathways involved are actually quite well known (see Visual Scene Perception; Object Recognition, Neurophysiology). Figure 1 illustrates a plausible route involving the various stages in the so-called ventral processing stream that leads to the inferotemporal cortex (V1-V2-V4-PIT-AIT), where neurons selective for complex visual forms are found. But since IT has no direct outputs to the motor system, information has to travel via such areas as prefrontal (PFC), premotor (PMC), and motor cortices (MC) before reaching the spinal cord.

On the basis of this diagram, we can start using neurophysiological data to estimate the processing time available at each step. For example, neurons in V1 can start firing 40 ms after stimulus onset, although 60 ms would be more typical. In IT, the earliest responses start at around 80 ms, with 100 ms being more typical. Given the number of processing steps involved, it would appear that the earliest responses in each area must be produced on the basis of only about 10 ms of activity in the previous stage.

How can such data be used to constrain models of processing? Bear in mind that this 10 ms value includes several components: synaptic transmission, integration of information by postsynaptic cells, spike initiation, and propagation to the next stage. Estimates of conduction velocity for intracortical axons suggest that conduction delays might be considerable. At 1–2 m/s, it would take 15–30 ms simply for information to propagate from V1 to IT (Nowak and Bullier, 1997), a substantial proportion of the 40 ms latency shift between the two areas. Moreover, few if any neurons that receive inputs from the preceding stage project directly to the next stage. In other words, processing in each cortical area almost certainly involves more than one layer of synapses, reducing further the amount of time available at each step. Together, such data imply

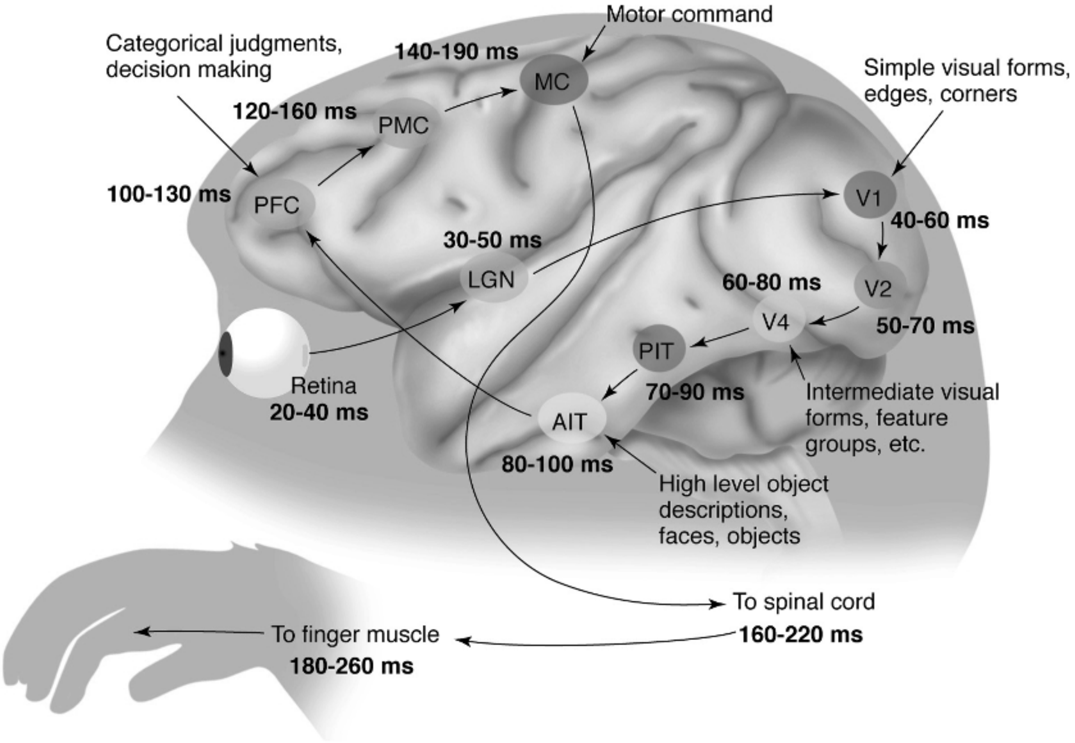

**Figure 1.** A possible input-output pathway for performing go/no-go visual categorization tasks in monkeys. Information passes from retina to lateral geniculate nucleus (LGN) before arriving in cortical area V1. Further processing occurs in areas V2, V4, and in the posterior and anterior inferotemporal cortex (PIT and AIT) before being relayed to the prefrontal (PFC), premotor (PMC), and motor cortices (MC). Finally, motor neuron activation in the spinal cord triggers hand movement. For each area, the two numbers provide approximate latency values for the earliest responses and for a typical average response. (From Thorpe and Fabre-Thorpe, *Science*, 2001. Reprinted with permission.)

that the earliest responses in any particular area are presumably based on just a few milliseconds of activity in neurons at earlier levels.

This conclusion has some profound implications for cortical computation. First, it implies that, at least in the case of the earliest responses in any particular structure, there will be little time for iterative processing involving recurrent loops at previous stages. Since neurons in areas such as IT have responses that can be selective from the very start, it must presumably be possible to generate such responses on the basis of a pure feedforward pass through the system. This view is also supported by a recent study that analyzed IT responses to sequences of images presented at high rates. As frame rate was progressively increased, response strength dropped, but some neurons were still able to respond selectively at a 72-Hz frame rate, i.e., with images lasting only 14 ms (Keysers et al., 2001). With an onset latency of around 100 ms, it would appear that as many as seven separate images were being processed at the same time in a sequential pipeline, each stage of the visual system effectively processing a different image.

A second major consequence of these temporal constraints concerns the nature of the neural code. It is generally assumed that neurons encode information in their firing rates. Indeed, in the vast majority of artificial neural networks, the spike trains of real neurons are replaced by a single continuous value, often fixed in the range 0 to 1, supposed to represent firing frequency. But how accurately can one determine a firing rate with only a few milliseconds to listen to the output of each neuron? Given that neurons only rarely fire above 100 Hz, very few will generate more than one spike in the time available. This rules out counting several spikes from the same neuron, or determining the interval between two spikes. Of course, one could measure firing rates across a population of neurons, but this would be an expensive strategy. Yet some alternative coding strategies can operate very efficiently, even with only one spike per neuron. For example, one could use the order in which neurons fire and the fact that the most strongly activated neurons tend to fire first (Thorpe, Delorme, and Van Rullen, 2001). Whatever the solution, it is clear that rapid processing poses a major challenge for computational neuroscience.

## Discussion

By combining the detailed time course of visual processing with information about anatomical organization and the characteristics of individual neurons, including their conduction velocities, we can go well beyond the global statements made by Feldman in the early 1980s. Specifically, we have seen that the earliest, highly selective responses of neurons in high-order areas appear to depend almost entirely on a feedforward wave of processing that is so fast that each neuron may well get to fire only one spike. Although this may seem far-fetched, there are simulations showing that simple feedforward networks of neurons that generate only one spike can perform sophisticated tasks that include detecting, localizing, and identifying faces in natural images (Thorpe et al., 2001).

On the other hand, vision cannot be reduced to a feedforward pass. Visual perception is much more complex than simply pressing a button when a particular category of object is present, and there is increasing evidence that this very rapid processing may well be largely unconscious. The formation of a fully segmented, conscious percept may well require far more complex processing than can be achieved in 100–150 ms, involving extensive use of feedback connections. Here again, temporal constraints can help determine the computations that can be performed with only feedforward processing and those that require recurrent mechanisms. For example, neuronal response properties that are not present at the onset of the response but take several tens of milliseconds to develop have recently been reported (Sugase et al., 1999; Lamme and Roelfsema, 2000). This progressive shaping of particular response properties is a hallmark of processing that requires recurrent mechanisms and feedback connections. In such cases, the initial very fast feedforward pass can act as a seeding process that allows subsequent processing to be performed in an intelligent top-down way.

This line of research, in which the details of the time course of visual processing are used to distinguish between different theoretical models of how the brain computes, constitutes a particularly clear example of the way in which experimental and theoretical work in brain theory can complement each other.

# Feature Analysis

*Michael J. Morgan*

## Introduction

A popular idea is that natural images can be decomposed into constituent objects, which are in turn composed of features. The space of all possible images is vast, but natural images occupy only a small corner of this space, and images of significant objects such as animals or plants occupy a still smaller region. The visual brain has evolved to analyze only the interesting regions of image space.

A feature description of an image reduces the number of dimensions required to describe the image. An image is a two-dimensional ($N$ by $N$) array of pointwise (or pixelwise) intensity values. If the number of possible pixel values is $p$, then the number of possible images is a set $\aleph$, of size $pN^2$. To distinguish all possible images having $N$ by $N$ pixels, we need a space of $N^2$ dimensions, which is too large in practice to search for a particular image.

The core idea behind feature analysis is that in real images, objects can be recognized in a space $\Re$ with a much smaller number of dimensions (a smaller dimensionality) than $\aleph$. The space $\Re$ is a *feature space*, and its dimensions are the features. A simple example of a feature space is color space, in which all possible colors can be specified in a three-dimensional space, with axes $L - M$, $L + M - S$ and $L + M + S$, and L, M, and S are the photon catches of the long-, medium-, and short-wavelength receptors, respectively. The reason why a three-dimensional space suffices to distinguish the very much higher-dimensional space of surface reflectance spectra is that there is huge redundancy in natural spectra. The reflectance at a given wavelength is highly correlated with reflectance at nearby wavelengths. We seek similar redundancies in space that will allow dimensional reduction of images.

## Features Are Not Necessarily Localized

Note that in this very general framework, there is no implication that features are spatially localized. Features could, for example, be Fourier components. The global Fourier transform has the same dimensionality as the original image and is thus not, according to the present definition, a feature space. But if we throw away Fourier components that are unimportant in distinguishing objects or if we quantize phase, dimensional reduction has been achieved, and we have a feature space. The familiar example of JPEG compression involves a feature space.

To distinguish between spatially localized and nonlocalized features, we shall follow physicists in calling the former *particles* and the latter *waves*. Wavelets (see Olshausen and Field, 1996) are hybrids that are waves within a region of the image but otherwise are particles. Another important distinction is between particles that have place tokens and those that do not. Although all particles have places in the image, it does not follow that these places will be represented by tokens in feature space. It is entirely feasible to describe some images as a set of particles of unknown position. Something like this happens in many descriptions of texture. A very active source of debate in visual psychophysics has been the extent to which the visual system uses place tokens (sometimes called local signs). For example, if the distance between two points *A* and *B* is seen as greater than the distance between two other points *C* and *D*, does this imply that there are place tokens for *A*, *B*, *C*, and *D*, or is some other mechanism involved (Morgan and Watt, 1997)?

The feature concept has proved useful in an impressive variety of different contexts.

### *Features in Ethology*

Lorenz and Tinbergen's concept of the innate releasing mechanism (IRM) with its releasing stimulus foreshadowed much later work in behavior and physiology. The red spot at the base of the herring gull beak, which the young attack to get food from the parent, and the silhouette of the hawk/goose, which elicits fear when moved only in the hawk direction, are classic features that have entered folk psychology.

### *Features in Physiology*

The classic paper "What the Frog's Eye Tells the Frog's Brain" (Lettvin et al., 1959) popularized the idea that special low-level sensory analyzers might exist for the purpose of responding to simple input features, the canonical example being the response of bug-detecting retinal ganglion cells to a small, moving spot. Hubel and Wiesel (1977) described bar and edge detectors in the visual cortex of cat and introduced an influential feature analysis scheme in which hierarchies of mechanisms would combine elementary features into ever increasingly complex objects. The hierarchical scheme, although not without its critics, was supported by the discovery of neurons in inferotemporal cortex (IT) responding selectively to images of complex objects such as a face or hand. Further studies of IT with simpler shapes found a columnar organization of IT with cells having similar response properties organized in repeating columns (Tanaka, 1996) (see Figure 1). The proposal that a ventral pathway leading to IT is responsible for object recognition gains support from lesioning and functional brain-imaging studies, although the idea of a single area for feature analysis is almost certainly too simple (Logothetis and Sheinberg, 1996).

### *Concept Learning*

Most dogs bark and have hair, tails, and ears. But not all dogs bark, and Wittgenstein famously pointed out that some concepts such as "a game" have no necessary features. Philosophers and animal psychologists met his challenge to the feature concept with the polymorphous concept (Watanabe, Lea, and Dittrich, 1993), an *n*-dimensional feature space in which instances of a concept occupy a subspace without sharp boundaries. Considerable research effort has been devoted to investigating the abilities of animals to learn both natural and artificially polymorphous concepts, a key issue being whether a linear model of feature combination will serve.

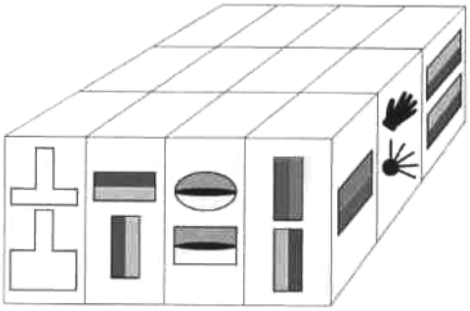

**Figure 1.** Columnar organization of inferotemporal cortex, based on work of Fujita et al. (see review by Tanaka, 1996). Columns of cells selective for similar complex shapes are interspersed with columns of cells unresponsive to these stimuli but selective to different complex shapes. (Source: Reproduced with permission from Stryker, M. P. (1992), *Nature (Lond.)*, 360:301. Note: In the original, different gray levels are in color, to show color preferences of the cells.)

### *Cognitive Psychology*

The idea that certain features can be analyzed at a preconscious level has proved fertile. Using the technique of visual search, Treisman (1988) suggested that only certain elementary features, and not their combinations, could serve as preconscious markers (Figure 2). This idea proved especially popular when linked, on rather slender evidence, with the discovery of specialized prestriate cortical areas in monkey devoted to the analysis of color and motion. However, the simple dichotomy between a fast, parallel search for features and a slow, serial search for combinations of features has come to be questioned (see the caption for Figure 2).

### *Image Compression*

The earliest pictures to be sent across the transatlantic telegraph took more than a week to transmit. Engineers soon reduced this time to three hours by encoding the image more economically. Image compression techniques are divided into those that preserve all the information in the original (error-free) and lossy techniques, which try to transmit only the important features (Gonzalez and Woods, 1993). An early pioneer of speeding up telegraph transmission by a lossy feature decomposition was Francis Galton, who proposed a set of features for transmitting face profiles over the telegraph using only four telegraphic "words." Appropriately for the man who invented the fingerprint, he saw this primarily as a forensic aid in sending profiles of wanted criminals around the world. Galton's feature space lays stress on five *cardinal points*. These are the notch between the brow and the nose, the tip of the nose, the notch between the nose and the upper lip, the parting of the lips and the tip of the chin (Figure 3).

The remainder of this review illustrates the concept of feature spaces and describes key issues, some resolved and others not.

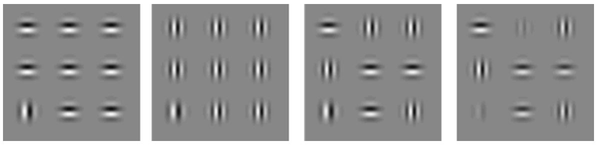

**Figure 2.** Searching for a single "odd man out" is easy (*A*) when the target has a very different orientation from the background elements or (*B*) when it has a different spatial frequency. Search times do not increase with the number of background elements (parallel search), provided that the orientation difference is sufficiently large. With smaller orientation differences (<10 degrees), search times do increase with the number of background elements, indicating a serial search. It might be thought that orientation and spatial frequency are easy search features because they are represented in primary visual cortex. However, (*C*) the conjunction of a particular spatial frequency and orientation is much harder to find, despite the fact that many V1 neurons are jointly tuned to orientation and frequency. If contrast is randomized (*D*), the search becomes harder still. The most powerful generalization about search is that it becomes harder when the number of different background elements increases. A standard ("back pocket") texture segmentation mechanism that responds to local contrasts in orientation, frequency, contrast, and color can explain most of these findings. (Source: Figures by J. A. Solomon.)

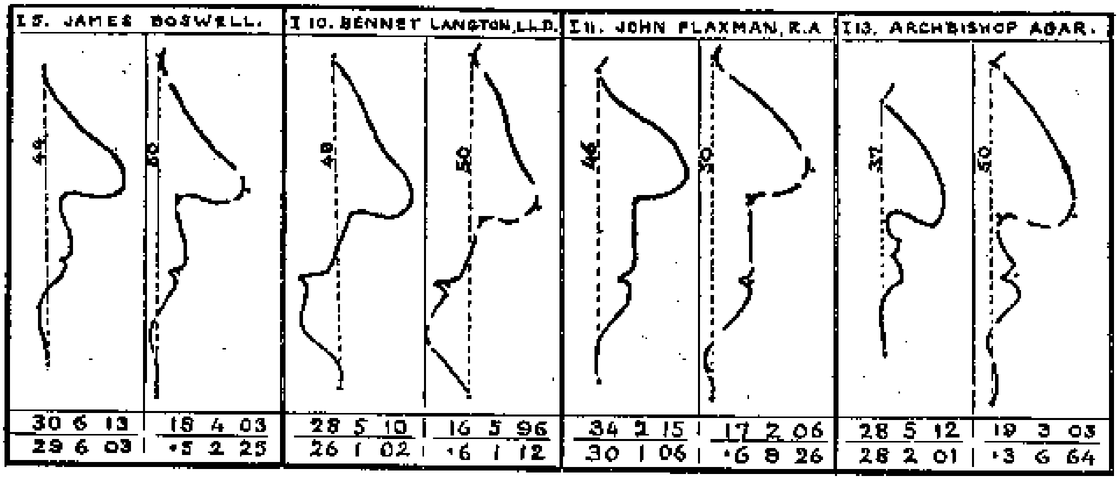

**Figure 3.** Face profiles described (left member of each pair) and reconstructed (right member of each pair) from 20 telegraphic numbers arranged in five groups of four (bottom). The code uses the relationships between five cardinal points on the profile. Galton was perhaps the first to use the term *cardinal points* to describe a multidimensional feature space for object recognition. (Source: From Galton, F., 1910, *Nature (Lond.)*, March 31, 127–130.)

## Principal Component Analysis of Faces

Galton was the first to treat faces as mathematical objects and to add them photographically. The *average face* was held to be especially beautiful, possibly because smallpox scars and other blemishes were removed. Galton also presented the average faces of groups such as rapists, clergymen, and athletes. Any particular face could then be correlated with each average in turn and described by a vector **V**. This vector will tell us the extent of resemblance of that face to the mean rapist, the mean clergyman, the mean athlete, and so on. The average images are a *basis set* for describing all faces. Dimensional reduction has been achieved, as long as the dimension of **V** is less than that of the original image space, $N^2$. Whether the clergyman-athlete-rapist space is a good one is another matter. It is probably not, because the dimensions are correlated. The aim of most feature analysis, including principal component analysis (PCA), is to ensure that the dimensions of the feature space are uncorrelated, or, in other words, that the axes in the space are *orthogonal*.

The idea behind PCA for faces (or Karhunen-Loeve expansion) is to find a set of features called *eigenvectors* that span the subspace of images in which faces lie (Turk and Pentland, 1991). Each eigenvector has dimensions $N^2$ and is a linear combination of a set of training faces, each of dimension $N$ by $N$ pixels. Equivalently, each face in the training set is a linear combination of the $N^2$ eigenvectors. To achieve dimensional reduction, only the most important eigenvectors are chosen as a basis set. These are the vectors that correlate most highly with the members of the training set. The most important, in this sense, is the average image, as defined by Galton.

Since the eigenvectors resemble faces when they are represented as 2D images, they can be called *eigenfaces*. Examples are shown in Figure 4. Once the eigenfaces have been created, each face in the training set can be described by a set of numbers representing its correlation to each of the eigenfaces in turn. If seven eigenfaces are chosen to span the face space, each face will be described by a vector of seven numbers instead of by its pixel values. A huge dimensional reduction has been achieved. The problem of recognizing a face is now a simple one of pattern recognition: finding the vector in memory that it most closely resembles.

PCA has been used for face detection, face recognition, and sex classification. Effective caricatures can be derived by exaggerating the differences of a face from the average. An intriguing experiment by Leopold, O'Toole, and Blanz (2001) suggests that the brain may use a feature space to identify faces. Observers were trained to discriminate "Adam," who was described by a vector in face space, from "Anti-Adam," who had the directly opposite vector. After adapting to Adam for some minutes, observers were more likely to classify the average face (midway between Adam and Anti-Adam) as Anti-Adam than as Adam. The inference is that there exist feature detectors that are tuned in face space and that identification depends on a population code comprising these detectors.

## Fourier Freaks and Feature Creatures

In broad terms, we now see that the code for early vision will be cracked when we find the basis set used by the brain for describing the image. One such basis set is the Fourier transform: sinusoids of differing frequency, orientation, and phase are the eigenfunctions of linear systems (Turk and Pentland, 1991). Following the application of certain key ideas in linear systems theory to vision (Robson, 1980), there was much debate about whether feature analysis or Fourier analysis was the preferred vehicle for understanding biological vision. This entertaining but ultimately fruitless debate is now essentially dead and buried. It made sense only when the "Fourier freaks" maintained that objects were recognized exclusively from their global amplitude spectrum. Since no one will now admit to having thought such a thing, it is pointless to provide historical detail.

Contrary to the view that the Fourier amplitude spectrum carries the important information in natural images, it is now recognized that the amplitude spectrum of most images is very similar (Field, 1987). The interesting features of images such as the boundaries of objects are represented in the relative *phases* of Fourier components. An edge or a bar in the image is a place where Fourier components undergo constructive interference. If the global amplitude spectra of two different images such as faces are interchanged, the hybrid images look like the images from which their phase spectra are derived (Figure 5). However, this is true only for the global Fourier transform. If the image is decomposed into a number of overlapping patches and each patch is transformed, it is the amplitude rather than the phase information in the patches that determines the appearance of the image if the patch size is sufficiently small (Figure 5). This is self-evidently true when the patch size is a single pixel, because the transform contains only the DC level and no phase information. But the limit is reached before a single pixel. Further work is needed to determine how the limiting patch size varies in different images and whether it is determined by cycles/image or cycles/degree of visual angle.

The consensus view now is that Fourier analysis in the visual system is limited to a local or *patchwise* Fourier analysis and that this is performed by neurons in V1 with localized, oriented, and spatial-frequency-tuned receptive fields (Robson, 1980). The idea of patchwise spatial frequency analysis fits in well with the architectural division of V1 into *hypercolumns*, each containing a full range of orientations and spatial frequencies, with a scatter of their receptive fields within a region of the image (Hubel and Wiesel, 1977). According to this model, the receptive fields of simple cells in V1 provide a *basis set* for describing local properties of the image, comparable to the wavelet transform in image processing (Olshausen and Field, 1996). Putting this simply, the idea is that an object can be recognized locally in an image by a series of numbers representing its effect on the activity of a population of detectors tuned individually in orientation and spatial frequency. Dimensional reduction is achieved because pointwise intensity values have been discarded and replaced by a more economical code. Just how many types of receptive field are needed to provide a satisfactory basis set for describing natural images is a question of equal interest to psychophysics and image processing.

PCA is far from being the only way to find a suitable basis set for natural images. Receptive fields like those in V1 emerge naturally as a basis set from a learning algorithm that seeks a sparse code for natural images (Olshausen and Field, 1996). The aim of sparse coding is to have each image activate the smallest possible number of members of the basis set. In physiological terms, the aim would be to have as many neurons as possible not activated at all by the image. Using this approach, Olshausen and Field derived a basis set having an impressive similarity to the receptive fields of V1 neurons (Figure 6).

## The Primal Sketch

The ability of line drawings to convey shape is very strong evidence that the feature space for object recognition may be of drastically reduced dimensionality, compared to the space of all possible images. Just a few lines drawn on a flat surface can suggest the face of a well-known person or the idea "no skateboarding allowed." Impressed by the effectiveness of cartoons, David Marr (1982) proposed that the earliest stages of vision transform the continuous gray-level image into a neural cartoon, which he called "the primal sketch." Since cartoons emphasize primarily the outlines of shapes, the main objective of the primal sketch is to find *edges* in the image, edges being the loci of points on the 3D object where an object

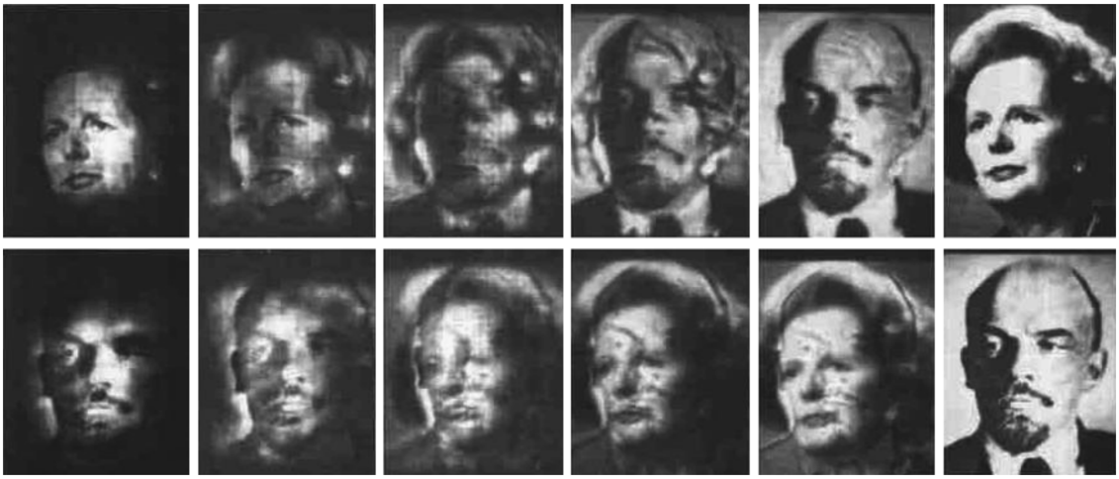

**Figure 5.** Images of two political theorists (rightmost panels), one of whose ideas have been recently discredited. Each thinker contributes his or her phase from the Fourier transform to each of the images on the left; the amplitude information comes from the other face. The Fourier transform is not global but is rather derived from overlapping patches, the size of which decreases (64, 32, 16, 8, and 4 pixels) from left to right. When the patch size is large, the appearance of the image is dominated by phase information; when it is small, the appearance is dominated by the amplitude of the Fourier components. At intermediate patch sizes, the appearance is composite. (Source: Reproduced with permission from Morgan et al., 1991.)

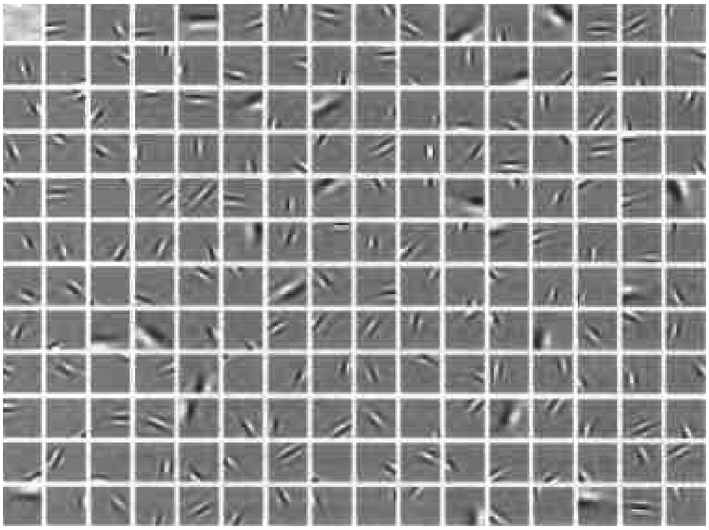

**Figure 6.** A basis set derived from ten 512 by 512 natural images of the American Northwest by a training algorithm aimed at maximizing the sparseness of the representation. The basis set bears a striking similarity to the receptive fields of V1 neurons, suggesting that they too form an efficient basis set for describing natural images. (Source: Reproduced with permission from Olshausen and Field, 1996.)

occludes itself or objects that are farther away (edge of a cube), or where there is a rapid change in the direction of the tangent plane to the object surface (outline of the nose on a face), or where there is some abrupt change in surface reflectance (boundary of the iris). It is a remarkable fact that much of the edge structure of an object in the image depends on its 3D structure—remarkable because we recognize objects from a variety of viewpoints or from sketches made from a variety of viewpoints.

If we consider an edge such as the outline of the nostril on a face, we shall find in its image a sudden change in luminance, which is not predictable from the gradual changes around it. A discontinuity is conveniently found by a local maximum or minimum in the first spatial derivative of the luminance profile or, equivalently, a *zero-crossing* in the second derivative. Ernst Mach (followed by William McDougall in his quaint "drainage" theory) was the first to conjecture that the visual system uses second derivatives to find features in the luminance profile, his evidence being the appearance of "Mach bands" on the inflection points in luminance ramps. Marr and Hildreth (see Marr, 1982) proposed that the receptive fields of retinal ganglion cells and simple cells in V1 make them nearly ideal second-derivative operators (Laplacians of Gaussians) and that their function is to produce the primal sketch. Different sizes of receptive field produce cartoons at different *spatial scales*, corresponding to the different frequencies in the Fourier transform but agreeing on the position of zero-crossings at the most significant points in the image. This recalls the fact that an edge or a bar in the image is a place where Fourier components undergo constructive interference. The primal sketch neatly uses wavelets to locate edges and turns them into particles.

A wide variety of phenomena have been used to investigate the nature of the "spatial primitives" or features in human vision. These include Mach bands, the Chevreul illusion, the apparent location of bars and edges in gratings and plaids with different spatial frequency components, and edge blur discrimination. Various primitives have been considered, such as zero-crossings, zero-bounded regions, and local energy maxima. Although it is now possible to predict the apparent location of edges and bars in images with a fair degree of accuracy, there is no consensus as yet about the nature or existence of primitives or about the way in which they are combined over spatial scale (Morgan and Watt, 1997).

## Summary

Features are useful for describing natural images because the latter have massive informational redundancy. Image space itself is too vast to search directly. Feature analysis depends on the proposition that the search for particular objects can be concentrated in a subspace of image space: *the feature space*. Biologists expect that there will be special sensory mechanisms for searching just the right subspace for a particular task. Ethologists and animal learning theorists concur. Useful hints about likely feature spaces may be obtained from engineers working on image compression. Although in the past feature analysis was contrasted with Fourier analysis, the modern synthesis is that a patchwise Fourier analysis by localized receptive fields in primary visual cortex (V1) provides the primitive basis set for the feature space of vision. These form the basis set for the elaboration of neurons responding selectively to geometrical features in area TE of the inferotemporal cortex, and these in turn from the basis for object recognition in different but overlapping areas of IT.

# Filtering, Adaptive

*John J. Shynk*

## Introduction

Adaptive filtering is an active area of research that has found widespread use in numerous signal processing and communications applications (Haykin, 2002). These applications include a wide range of important problems, such as noise canceling and noise reduction, channel equalization, co-channel signal separation, system identification, pattern recognition, fetal heart monitoring, and array processing (Ljung and Söderström, 1983; Qureshi, 1985; Giannakis, 1999). Adaptive filters are particularly useful for applications in which the underlying statistics are unknown or nonstationary, which is usually the case in practice (Widrow and Stearns, 1985). The parameters of an adaptive filter are adjusted to "learn" or track signal and system variations according to a performance criterion that is determined by the needs of the specific application.

The field of adaptive filtering was derived partly from work on neural networks and adaptive pattern recognition (Lippmann, 1987; Haykin, 1999). In pattern recognition applications, such as speech recognition and image classification, a neural network can be trained on a wide range of representative input patterns (called the training set). If the training set is sufficiently large, the neural net is capable of successfully classifying new patterns; for example, distorted patterns corrupted by noise will be mapped to the most similar pattern in the training set, as defined by some error criterion. Classification is performed by a threshold or decision device that quantizes the neural net output to one of many different levels representing the various classes.

An adaptive filter can be viewed as a signal combiner consisting of a set of adjustable weights (or coefficients represented by a polynomial) and an algorithm (learning rule) that updates these weights using the filter input and output, as well as other available signals. The filter may include internal signal feedback, whereby delayed versions of the output are used to generate the current output, and it may contain some nonlinear components. The single-layer perceptron is a well-known type of adaptive filter that has a binary output nonlinearity; it is also referred to as *adaline* (for *ada*ptive *li*near *ne*uron) (Widrow and Lehr, 1990) (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION). A multilayer perceptron contains many single-layer perceptrons interconnected to form a network that can implement a complex nonlinear system or represent a multidimensional signal pattern (Rumelhart and McClelland, 1986)

It is beyond the scope of this article to cover in depth the different types of adaptive filter configurations and the large number of adaptive algorithms. Instead, we will focus on the most widely used adaptive filter architecture and describe in some detail two representative adaptive algorithms. The least-mean-square (LMS) algorithm (Widrow and Stearns, 1985) computes the coefficients of a tapped delay line (TDL), which is basically a shift register with adjustable coefficients. The constant modulus algorithm (CMA) (Godard, 1980; Treichler and Agee, 1983) also computes the coefficients of a TDL, but, unlike the LMS algorithm, it does not require a training sequence. As we shall see, both algorithms are stochastic-gradient methods that iteratively search for the minimum of well-defined performance (cost) functions. Example CMA performance functions are plotted to reveal their nonquadratic shapes, and computer simulations of the CMA weight trajectories are shown to illustrate the algorithm's learning behavior for an equalization application.

## Adaptive Filter Components

An adaptive filter consists of two components: (1) an *adjustable set of weights* that filter or process the input signal and (2) an *adaptive algorithm* that modifies the weights to minimize a performance measure. To be more precise, define the weight vector

$$W(n) \triangleq [w_1(n), w_2(n), \ldots, w_N(n)]^T \tag{1}$$

and the input signal vector

$$X(n) \triangleq [x_1(n), x_2(n), \ldots, x_N(n)]^T \tag{2}$$

where the argument $n$ denotes discrete time and the superscript $T$ is matrix/vector transpose. This particular form of the signal vector contains $N$ distinct inputs and would be appropriate for multidimensional applications such as pattern recognition and array processing. However, there are many signal processing applications involving only one input signal, such as channel equalization, echo cancellation, and system identification. For these cases, the input signal vector would instead be

$$X(n) \triangleq [x(n), x(n-1), \ldots, x(n-N+1)]^T \tag{3}$$

where delayed versions of the input signal $x(n)$ are stored in a shift register or TDL.

The (scalar) filter output is given by the inner product

$$y(n) = W^T(n)X(n) = X^T(n)W(n) \tag{4}$$

It is typically used by the adaptive algorithm in a feedback mechanism that determines how $W(n)$ should be adjusted with each new input vector $X(n)$. In some applications, $y(n)$ is processed by a nonlinear device that yields a decision statistic for an underlying signal contained in the input $X(n)$. For example, in a digital communications application with binary ($\pm 1$) transmitted symbols in an additive white Gaussian noise channel (Proakis, 2001), the nonlinearity could be the signum function:

$$\operatorname{sgn}(y(n)) = \begin{cases} +1, & y(n) \geq 0 \\ -1, & y(n) < 0 \end{cases} \tag{5}$$

where we have arbitrarily assigned sgn(0) = +1. This detector uses the sign of the received signal $y(n)$ to determine the most likely transmitted symbol: +1 or −1. The signum function is also used for Rosenblatt's training algorithm (Lippmann, 1987), while a soft nonlinearity such as the hyperbolic tangent is used in the backpropagation algorithm for the multilayer perceptron (Widrow and Lehr, 1990).

The error signal in Figure 1 depends on the application and the performance function; we will provide details of the error in a subsequent section when the adaptive algorithms are discussed. However, at this point we should mention that the error can be generated in (at least) two basic ways. If a training signal $d(n)$ is available (such as in the previously mentioned digital communications application), then the error is a measure of how much $y(n)$ differs from $d(n)$; in this scenario, the training signal is sometimes called the *desired response* in the adaptive filtering literature. For some problems, however, a training signal is not available (also in the digital communications application); in this case, the error is computed in a *blind* manner, which means that it depends only on the adaptive filter input $X(n)$ and output $y(n)$, without any explicit desired-response information.

## Applications

Two representative applications of adaptive filtering are described in this section. Many signal processing applications fall into one of these general models. For example, adaptive channel equalization belongs to the field of deconvolution, and some co-channel signal separation techniques utilize an array processing formulation.

### Channel Equalization

The configuration for adaptive channel equalization is shown in Figure 2 (Qureshi, 1985). Observe that the adaptive filter is placed in *cascade* with the unknown channel. The goal of the adaptive filter is to mitigate the channel distortion (e.g., multipath propagation) and, in effect, estimate the channel *inverse*. The input of the adaptive filter is obtained from the channel output, which may be corrupted by an additive (Gaussian) noise process $v(n)$. The training signal (desired response) is the transmitted signal $x(n)$. However, since the channel and the adaptive filter each have a finite non-zero delay, it is necessary that the transmitted signal be delayed by an appropriate amount $\Delta > 0$ such that $d(n) = x(n - \Delta)$.

Clearly, since the purpose of any communication system is to transmit information (unknown to the receiver) across the channel, the configuration in Figure 2 for training the adaptive filter is not always feasible. Typically, there is a short training period at the beginning of transmission (start-up) whereby a signal known at the receive end is transmitted and used by the adaptive filter to adjust its weights. When the error rate is sufficiently reduced at the end of training, information can be successfully transmitted across the channel. During this time, the adaptive algorithm stops updating; or, alternatively, a decision-directed or blind adaptive algorithm can be employed that requires knowledge only of certain statistical properties of the transmitted signal (Haykin, 2002).

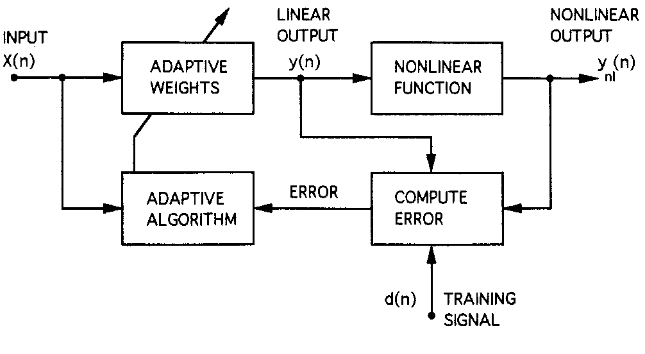

**Figure 1.** Adaptive filter components.

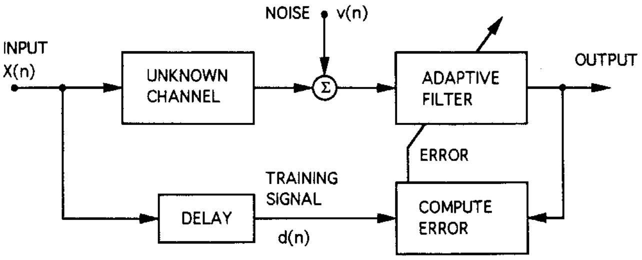

**Figure 2.** Adaptive channel equalization.

### Co-channel Signal Separation

In cellular communication systems, co-channel interference is becoming an increasingly important issue as the number of subscribers grows (Giannakis, 1999). Co-channel interference is due to frequency reuse, whereby multiple cells operate on the same carrier frequency. To mitigate co-channel interference, it would be desirable to incorporate adaptive antennas that have a directional (beamforming) capability to separate several co-channel signals, thus allowing for greater frequency reuse. In recent years there has been much interest in blind co-channel signal separation algorithms for antenna arrays that can adapt their parameters without using a training signal.

A block diagram of an adaptive array known as the constant modulus (CM) array (Gooch and Lundell, 1986) is shown in Figure 3, where the antenna elements are uniformly spaced and omnidirectional. It consists of two components: (1) a conventional adaptive antenna (beamformer) with weights updated by CMA, and (2) an adaptive signal canceler that removes from the input the co-channel signal captured by the CM array. The weights of the signal canceler are updated by the LMS algorithm using the received array signals as the desired response. A multistage implementation of this architecture, consisting of multiple beamformer/canceler systems in cascade, can be used to separate and recover several co-channel signals (one co-channel signal per stage).

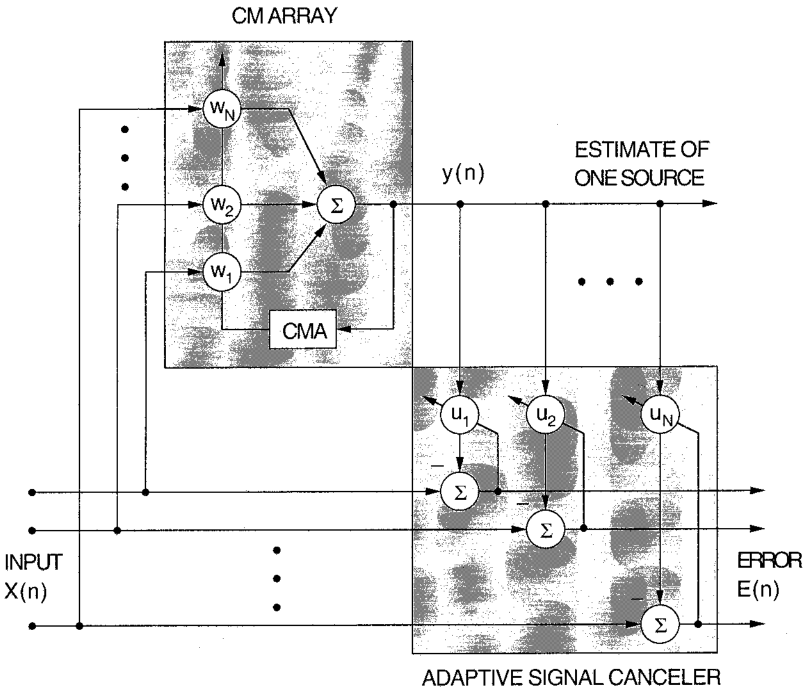
## Adaptive Algorithms

In this section, we consider two performance functions: the squared error, which employs a training sequence, and a constant modulus formulation, which yields a blind adaptive algorithm. Both algorithms have the following general form:

$$W(n+1) = W(n) + \mu[-\nabla(n)] \tag{6}$$

where $\nabla(n)$ is the *gradient* with respect to $W(n)$ of the corresponding performance function. The positive step size $\mu$ controls the transient and steady-state convergence properties of the adaptive weights. The goal of an adaptive algorithm is to adjust $W(n)$ such that it converges to a minimum (stationary point) of the performance function.

**Figure 3.** Co-channel signal separation.



### *Least-Mean-Square Algorithm*

Consider the following performance function:

$$C_{LMS}(n) = e^2(n) \tag{7}$$

where the error is

$$e(n) = d(n) - y(n) \tag{8}$$

and $d(n)$ is the training sequence. Note that $C_{LMS}(n)$ is a stochastic variable that fluctuates around the mean square error (MSE), given by

$$\xi_{LMS} = E[e^2(n)] \tag{9}$$

where $E[\cdot]$ denotes statistical expectation. For this reason, the weight update is referred to as a *stochastic-gradient* algorithm. $C_{LMS}(n)$ can be viewed as a very simple estimate of the ensemble average $\xi_{LMS}$. (In this article, we interchangeably refer to $\xi$ and its stochastic estimate $C(n)$ as performance functions.) Using Equations 4 and 8, and noting that $\partial(W^T(n)X(n))/\partial W(n) = X(n)$, the gradient of Equation 7 is

$$\nabla_{LMS}(n) = -2X(n)e(n) \tag{10}$$

resulting in the least-mean-square (LMS) algorithm (Widrow and Stearns, 1985):

$$W(n+1) = W(n) + 2\mu X(n)e(n) \tag{11}$$

Thus, with each new set of data $\{X(n), d(n)\}$, the error $e(n)$ is computed and the filter weights are updated in an attempt to learn the underlying signal statistics. The algorithm converges on average (i.e., in the mean) when $E[X(n)e(n)] = \underline{0}$ (the zero vector) which, after substituting $e(n)$, yields the following unique stationary point:

$$W_{LMS} = R^{-1}P \tag{12}$$

where $R \triangleq E[X(n)X^T(n)]$ and $P \triangleq E[X(n)d(n)]$ are signal correlations (an $N \times N$ matrix and an $N \times 1$ vector, respectively). Observe that the algorithm utilizes the output $y(n)$ before it is processed by any subsequent nonlinear device (as illustrated in Figure 1).

### *Constant Modulus Algorithm*

The constant modulus algorithm (CMA) is a blind equalization technique that attempts to restore the constant modulus property of certain communication signals (the binary digital communication signal with values ±1 is such an example). The performance function is a measure of the deviation of the modulus of the equalizer output $y(n)$ from a predetermined constant $r > 0$ according to Treichler and Agee (1983):

$$C_{CMA}(n) = \|y(n)|^p - r^p|^q \tag{13}$$

where $p$ and $q$ are positive integers, equal to 1 or 2, resulting in four versions of CMA. The scalar $r$ is usually chosen such that the gradient of $\xi_{CMA}$ (the expectation of Equation 13) with respect to the coefficients $W(n)$ is zero when the channel is perfectly equalized. (Note that although $C_{CMA}(n)$ depends on $p$ and $q$, in order to simplify the notation, we do not indicate this explicitly.)

The gradient of Equation 13 is

$$\begin{aligned}\nabla_{CMA}(n) = {} & pqX(n)y(n)|y(n)|^{p-2} \\ & \times (|y(n)|^p - r^p)^{q-1}\text{sgn}[|y(n)|^p - r^p]^q \end{aligned}\tag{14}$$

where sgn[·] is the signum function previously defined. For convenience, consider the case of $p = q = 2$. Substituting Equation 14 into Equation 6 yields the 2-2 version of CMA:

$$W(n+1) = W(n) - 4\mu X(n)y(n)(|y(n)|^2 - r^2) \tag{15}$$

This recursion does not depend on a training sequence; the update is a function only of $X(n)$ and $y(n) = W^T(n)X(n)$. Note that Equation 15 is similar to Equation 11, except that the scalar error $e(n)$ has been replaced by $-2y(n)(|y(n)|^2 - r^2)$.

Unfortunately, since $\xi_{CMA} = E[C_{CMA}(n)]$ is not a quadratic function of $W(n)$ (as is $\xi_{LMS}$), it is not possible to derive a simple general expression for the stationary point $W_{CMA}$. In fact, the stationary point is not necessarily unique, and there may be local as well as global minima (the gradient is zero at a local minimum, but a local minimum does not correspond to the overall minimum value of the performance function). However, for the sake of completeness, if we assume that the input $X(n)$ is a Gaussian random vector with zero mean, then it can be shown that the stationary points are given by the following implicit expression (Shynk and Chan, 1993):

$$W_{CMA}^T R W_{CMA} = r^2/3 \tag{16}$$

Thus, there is an infinity of solutions, all of which achieve the global minimum. Note, however, that this result does not apply in general, because $X(n)$ might be generated by an underlying constant modulus signal (which CMA is designed to handle), in which case $X(n)$ would not be exactly Gaussian.

## Convergence Results

In this section, we present some examples of the performance surfaces for CMA, as well as representative trajectories of the CMA weights during adaptation. A *performance surface* is a three-dimensional plot of the performance function versus two of the weight vector components.

### *CMA Performance Surfaces*

Suppose that CMA attempts to equalize a channel with the following transfer function (written using $z$-transform notation): $C(z) = 1 - 0.6z^{-1} + 0.36\,z^{-2}$. Assume that the transmitted signal is a sequence of binary symbols ±1 that are independent and equally likely (i.e., Bernoulli with $\Pr(+1) = \Pr(-1) = \frac{1}{2}$). The elements of the corresponding correlation matrix $R$ are $R(1, 1) = R(2, 2) = 1.4896$ and $R(1, 2) = R(2, 1) = -0.8160$. Figure 4*A* shows the performance surface of a two-weight ($N = 2$) equalizer for the CMA 2-2 performance function. Observe that there are two global minima and two local minima (there is also a local maximum at the origin $W = \underline{0}$). Thus, depending on how the algorithm is initialized, the adaptive weights may converge to any one of these four minima, two of which are not optimal. Similar results are shown in Figure 4*B* for the CMA 1-1 performance function. In contrast, the performance surface for the LMS algorithm (which uses training) is a paraboloid with a unique global minimum and no local minima (provided $R$ is positive definite) (Widrow and Stearns, 1985).

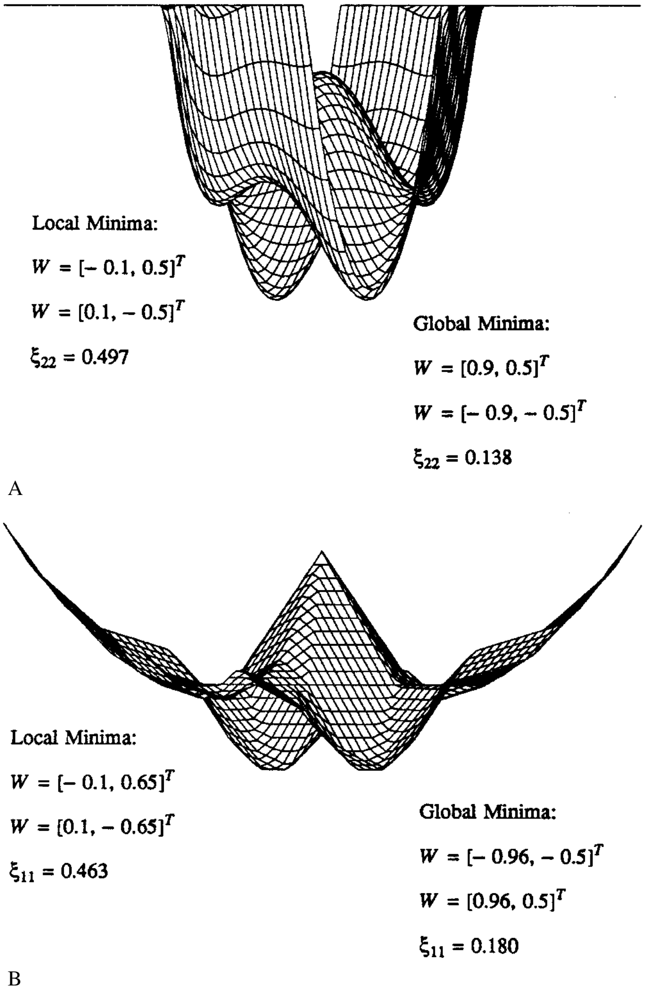


**Figure 4.** Performance surfaces $\xi_{CMA}$. *A*, CMA 2-2 ($p = q = 2$). *B*, CMA 1-1 ($p = q = 1$). (From Shynk, J. J., and Chan, C. K., 1993, Performance surfaces of the constant modulus algorithm based on a conditional Gaussian model, *IEEE Trans. Signal Proc.*, 41:1965–1969. © 1993, IEEE. Reprinted with permission.)

### *CMA Weight Trajectories*

In adaptive algorithms that employ a gradient update mechanism, such as LMS and CMA, a trade-off exists between the convergence rate and the steady-state value of the MSE (even though the MSE is not the performance function for CMA, it is typically used as a benchmark measure for the performance of a blind algorithm). Both of these properties are controlled by the step size $\mu$, as well as the statistics of the input $X(n)$. When $\mu$ is increased, the rate of convergence also increases, but so does the steady-state MSE. Thus, when comparing the convergence behavior of different stochastic-gradient algorithms, it is necessary that the steady-state and transient properties be considered together. For example, the convergence rates of two algorithms can be compared once the step sizes are chosen so that the algorithms achieve the same steady-state MSE.

Figure 5*A* shows this trade-off for CMA 2-2 for a channel equalization application. These "learning curves" were obtained by averaging the squared error between the equalizer output $y(n)$ and the desired (transmitted) signal $d(n)$ (with an appropriate delay) over ten independent computer runs; the resulting trajectories were then smoothed by a moving average filter. Observe that the steady-state MSE and the convergence rate increase with increasing $\mu$. In order to compare algorithms without having to explicitly consider the step size, several simulations can be performed for the algorithms, each simulation with a different value of $\mu$. From this series of simulations, the number of samples required to reach steady state can be determined, along with the steady-state value of the MSE. Using this information, the steady-state MSE can be plotted versus the convergence time for each algorithm. Examples of these "performance curves" for the four versions of CMA are shown in Figure 5*B* (Shynk et al., 1991). Notice that the performance curve for CMA 1-2 is generally higher than the other curves, indicating that it requires (for this example) more iterations to achieve the same steady-state MSE for a wide range of step size values.

## Discussion

Adaptive filters are widely used for a variety of signal processing applications. Although several configurations are possible, the linear combiner shown in Figure 1 is the most common, and the LMS algorithm, which is known to be robust (Haykin, 2002), is the most popular means of adjusting the adaptive weights. There are several

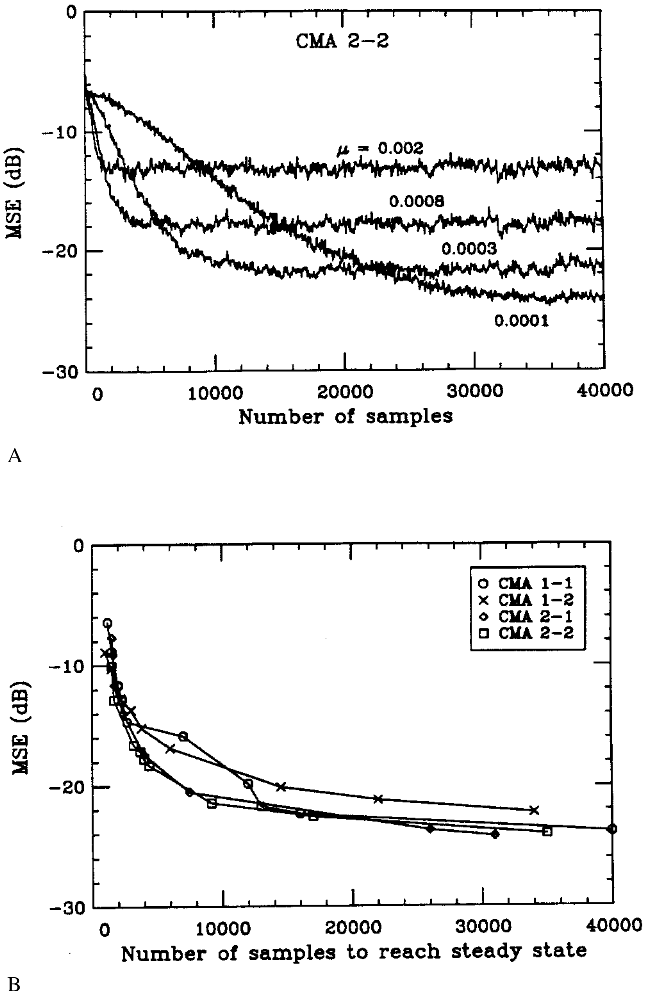

**Figure 5.** *A*, CMA learning curves. *B*, CMA performance curves. (From Shynk, J. J., Gooch, R. P., Giridhar, K., and Chan, C. K., 1991, A comparative performance study of several blind equalization algorithms, in *Proceedings of the SPIE Conference on Adaptive Signal Processing*. © 1991, SPIE. Reprinted with permission.)

variations of the LMS algorithm, including those that have less complexity or improved convergence properties. For example, CMA is a blind stochastic-gradient algorithm that can be used instead of the LMS algorithm when an explicit training sequence is not available. The recursive-least-squares (RLS) algorithm is an adaptive algorithm based on the method of least squares that offers faster convergence rates (compared with the LMS algorithm), but at the expense of an increased computational complexity (Haykin, 2002).

The adaptive filter configuration described in this article is the basic component of a multilayer perceptron. These additional layers provide greater nonlinear modeling capabilities, which is usually necessary for complex applications such as speech and image processing. Stochastic-gradient algorithms are typically used to adjust the weights of a multilayer perceptron. They are similar to the adaptive algorithms described in this article, but they have an additional degree of complexity owing to the cascade of layers. One such algorithm, known as the backpropagation algorithm (Rumelhart and McClelland, 1986), has been successfully applied to a number of signal processing problems (Widrow and Lehr, 1990).

# Forecasting

*Lyle H. Ungar*

## Introduction

Forecasting the future values of sequences of observations is, in many ways, ideally suited for neural networks. Large amounts of data may be available, and the underlying relationships are often nonlinear and unknown. Neural nets, mostly of the standard backpropagation type (see Backpropagation: General Principles), have been used with great success in many forecasting applications, including forecasting electricity load, freeway traffic volume, solar cycles, milk yields, tourism demand, grain drying times, ambient air quality, exchange rates, inflation, unemployment, disease epidemics, fish stock levels, sea surface temperatures, sales volumes, flood occurrence in Moravia, and rainfall in Bangladesh. However, in not all of such cases do neural networks outperform conventional ARMA models. This article looks at the use of neural nets for forecasting, with particular attention to understanding when they perform better or worse than other technologies.

The success of neural networks in forecasting depends significantly on the characteristics of the process being forecast. One may want to predict minute-by-minute progress of a chemical reaction, hour-by-hour power usage (load) for an electric power utility, daily weather, monthly prices of products and inventory levels, and quarterly or yearly sales and profits. These problems differ in the quantity and type of information available for forecasting, and hence call for different forecasting techniques. One also needs to choose an appropriate network architecture.

Forecasting problems can be characterized on a number of dimensions: (1) Is a single series of measurements used, as is often done in conventional forecasting, or are multiple related measurements available? (2) Are the data seasonal or not? Monthly or quarterly data such as sales volume or energy use often show strong seasonal variation, while annual data or data measured each second or minute do not. (3) The number of observations and (4) the degree of randomness (signal/noise ratio) of the process also strongly limit the complexity of the model that can be fit. If data are only available annually for the past 10 or 20 years, and if no measurement is available for most of the disturbances, one should not expect to be able to fit a complex model such as a neural network. This is unfortunately the case for many forecasting problems such as those represented in the Makerdakis collection (described below). (5) Finally, for some forecasting problems, one only requires prediction a single time step in the future, while for others, multiple time step forecasts are required. This has implications for the method used to train the neural network.

Before looking at neural networks, we will briefly review conventional forecasting methods. Forecasting has mostly been done using one of two different classes of methods, depending on whether the data are seasonal or not. For monthly data, such as sales or unemployment levels, the seasonal variation is often removed by dividing the series by an index representing the historical seasonal variation. For example, dividing the unemployment rate for each month (perhaps averaged over several years) by the average annual unemployment rate gives an index that indicates monthly variations. This index will have an average value of one. Dividing the actual unemployment rate in a given month by the index for that month gives the seasonally adjusted unemployment rate, which shows overall trends after typical monthly variations are accounted for. A linear or exponential regression (i.e., fitting the data as a linear or exponential function of time), or some form of smoothing such as a moving average, can then be used to make predictions of the deseasonalized unemployment. Actual levels are then forecast by multiplying these base predictions by the index for the month being forecast (Makridakis, Wheelwright, and McGee, 1983).

In contrast, for many complex processes such as chemical plant production, robots, or stock prices, the best prediction of the near future is obtained by using an appropriately weighted combination of recent measurements of the variable being predicted and other correlated variables. The most widely used approach is the Auto-Regressive Moving Average (ARMA) model. For example, to predict the value of a variable $y$ (such as a temperature or a pressure or a stock price) at time $t + 1$ using past values of $y$ and of a second variable $z$, one would use a linear regression to fit a model of the form

$$y_{t+1} = c_0 + c_1 y_t + c_2 y_{t-1} + c_3 y_{t-2} + \cdots + c_n z_t + c_{n+1} z_{t+1} + \cdots \quad (1)$$

Note that ARMA models differ from the linear regression models mentioned above in that they are functions of previous variables rather than of time.

Neural networks can be used to learn a nonlinear generalization of ARMA models of the form

$$y_{t+1} = f(y_t, y_{t-1}, y_{t-2}, \ldots, z_t, z_{t+1}, \ldots) \quad (2)$$

When the process is nonlinear and sufficient data are available, the neural networks will provide a more accurate model than the linear ARMA model. See Box and Jenkins (1970) for extensive descriptions of conventional ARMA models and the Box-Jenkins modeling approach, which involves picking a model of the form of Equation 1 with some subset of the coefficients set to zero. Later in this article we summarize the results of a number of studies that compare ARMA and neural network models.

Two other modeling methods are also often used by engineers, Kalman filtering and Wiener-Voltera series. Kalman filters (see KALMAN FILTERING: NEURAL IMPLICATIONS) assume a known model structure in which the parameters and their covariance, which is modeled explicitly, may be changing over time. Kalman filters are good for modeling relatively simple but noisy processes, but, unlike neural networks, they do not form nonparametric models that can accurately forecast the behavior of nonlinear systems. Wiener-Voltera series are polynomial expansions fitted to past data. As such, they, like neural nets, can approximate arbitrary functions. However, for models with multiple inputs they require more data than neural networks to obtain an equal level of accuracy.

## Using Neural Nets for Forecasting

Neural networks are most often used to fit ARMA-style models of raw time series data from one or more measurements, but they can also be used as a piece of larger forecasting systems, such as in combination with deseasonalizing (i.e., forecasting a time series from which the seasonal component has been removed, as described above). Even for the simpler ARMA-style models, attention to the method is required if one is making forecasts multiple time steps in the future rather than a single time step.

### *Direct Versus Recurrent Prediction*

A simple form of multistep forecasting is direct prediction (Figure 1*A*), in which a network takes past values as inputs and has separate outputs for predictions one, two, and more time steps in the future. Alternatively, one can train a network to predict one time step in the future and then use the network recursively to make multistep predictions (Figure 1*B*). Such networks are sometimes called *externally recurrent networks*, in contrast to networks that have internal memory. Direct forecasting networks are easier to build than externally recurrent nets because they do not require unfolding in time (described below), but the predictions are generally less accurate, since they have more parameters that must be fit from the same limited data.

The obvious way to train a network such as is used in Figure 1*B* is to minimize the error on the one-time-step predictions. Unfortunately, this does not give optimal networks for multistep predictions. To better understand this somewhat confusing point, consider the case of a simple linear ARMA model:

$$y_{t+1} = c_0 + c_1 y_t + c_2 y_{t-1} \quad (3)$$

A two-step-ahead prediction would then take the form

$$y_{t+2} = c_0 + c_1(c_0 + c_1 y_t + c_2 y_{t-1}) + c_2 y_t \quad (4)$$

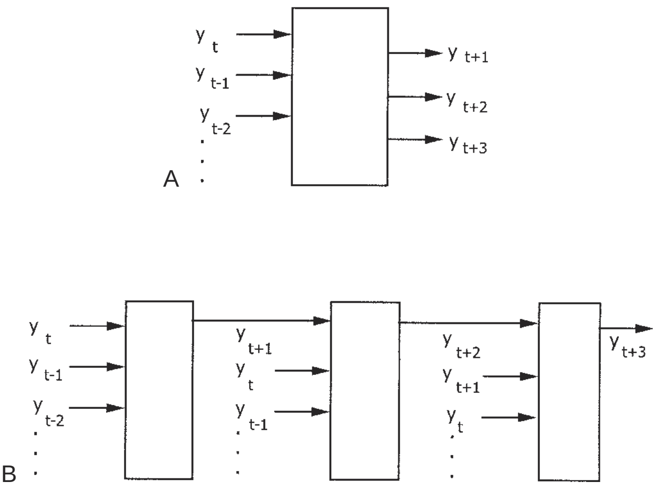

**Figure 1.** *A*, Direct prediction using a neural network. *B*, Recurrent one-step-ahead prediction using a neural network repeatedly.

Selecting coefficients $c_0$, $c_1$, and $c_2$ to minimize the prediction error for the one-step-ahead error yields a different equation than selecting the same coefficients to minimize the error in the two-step prediction. (Note that the former is a linear regression problem, whereas the latter requires nonlinear regression because the coefficients multiply each other.) More accurate long-range predictions are obtained by training to minimize the multistep prediction error. The solution using backpropagation uses the same unfolding in time or other solution methods as for internally recurrent networks (see Recurrent Networks: Learning Algorithms). This and related issues are covered in detail in books on conventional system identification methods (e.g., Ljung and Torsten, 1983). Much good work has been done using recurrent nets to model time series (e.g., Mozer, 1994).

### *Combining Neural Networks with Other Methods*

There are a number of ways in which neural networks can be combined with data preprocessing techniques, first principles (mechanistic) with partial models of the process being forecast, and with other forecasting techniques. Most commonly, if there is a strong seasonal component to the data, the data may be deseasonalized and the neural net used to forecast the basic trend. It may appear pointless to use a seasonal index when it is well known that neural networks can approximate arbitrary functions, which should include any seasonal variation. Experience indicates that if sufficient data are available, this is true, but that for shorter time series, deseasonalizing gives more accurate forecasts.

Similarly, when modeling complex physical systems, much better forecasts can be obtained with much less data when prior knowledge (e.g., in the form of mass, energy, or kinematic constraints on the variables, or in terms of monotonic relations between measured and forecast variables) is built into the network (Psichogios and Ungar, 1992). In a typical example, the equations governing a fermentation reactor are known except for the growth kinetics of the cells (e.g., yeast) in the reactor. If a neural network is used just to approximate the growth kinetics rather than to model the whole system, models are learned that are more accurate and that extrapolate better to operating regimens where no data are available. Such hybrid or "gray box" methods are popular in science and engineering.

Neural networks can also be used in conjunction with conventional forecasting methods. For example, one can often produce more accurate forecasts by providing several conventional forecasts as input to the neural network. In this case, the network serves partly as a combining method in which the network produces a weighted average of the different forecasts (Foster, Collopy, and Ungar, 1992). Such combining of forecasts is widely practiced in the forecasting community, mostly with relatively arbitrary combining weights.

## Assessing Neural Nets for Forecasting

There are several difficulties in assessing forecasting methods. The most serious is that the results of a single forecast tell little about whether the method will be superior for other forecasts. In testing any method, it is important to have a large set of representative time series on which the methods will be tested. An example of such a collection of time series that has been widely used to compare forecasting methods is the Makridakis competition, or M-competition, model (Makridakis et al., 1982). This competition included 1,001 series and evaluated 24 forecasting methods. The series were taken from a variety of organizations in a number of countries and included macroeconomic, microeconomic, industrial, and demographic data such as production levels, net sales, unemployment, spending, GNP, vital statistics, and infectious disease incidence. The series included yearly, quarterly, and monthly series, but no series arising from securities or commodities trading. These time series all involve only a single variable and do not provide correlated variables, which might enhance the predictions.

One must also decide which error criteria to use. The most obvious criterion, and the one that is optimized by standard neural networks, is minimization of the mean squared prediction error. This criterion has the property that a small number of unusual series may have a large effect on the error. In looking at combined errors for different time series, one must, of course, also normalize for the different magnitudes of the series. Thus, forecasters often measure performance by using measures that are more robust to outliers or atypical time series.

Three error measures that have proved particularly robust are the percentage of time a method had a lower absolute error than the "no-change" forecast (or "percent better"), the relative absolute error (or RAE), and the median absolute percent error (or mdAPE). The RAE is calculated as the geometric mean across all series $i$ of

$$\mathrm{RAE}_i = \frac{\sum_{t=1}^{T} |\tilde{x}(t) - x(t)|_i}{\sum_{t=1}^{T} |x(0) - (t)|_i} \tag{5}$$

where $\tilde{x}(t)$ is the forecast and $x(t)$ represents the true value of the series at time $t$. The RAE represents a comparison over the forecast horizon $T$ for series $i$ of the absolute error of the forecast method, compared to the no-change or random walk forecast. One then calculates a geometric mean over all the series:

$$\mathrm{RAE} = \left[\prod_{i=1}^{n} \mathrm{RAE}_i\right]^{1/n} \tag{6}$$

The median average percent error is defined as the median across all series $i$ of

$$\mathrm{APE}_i = \frac{1}{T}\sum_{t=1}^{T} 100\,\frac{|\tilde{x}(t) - x(t)|_i}{|x(t)|_i} \tag{7}$$

Good forecast performance is reflected in higher "percent betters" and lower RAEs and mdAPEs.

In assessing neural networks for forecasting, one must compare the accuracy of the neural networks with that of other statistical tools such as exponential smoothing (for a single time series) or linear ARMA models (for several correlated time series). Surprisingly, many studies fail to compare neural network forecasts with well-made conventional forecasts.

Table 1 lists some applications in which neural networks have been used for forecasting. Almost all of the studies used standard backpropagation networks with less than a dozen inputs and less than a dozen hidden nodes, with the exact architecture being selected by trial and error. Also, most of the studies used data from a single source, and most of the authors evaluated their results on the basis of the mean squared error on out-of-sample forecasts (i.e., error when forecasting data other than that used for building the model). Table 1 does not include any studies using chaotic time series such as from the Mackey-Glass equation, which give little insight into neural network forecasts of realistic data. See Vemuri and Rogers (1994) for a good collection of reprints of a wide variety for neural network forecasting studies, including all studies cited in Table 1 that are not listed in the references. There is also an extensive literature on neural network forecasting for process control (see Process Control in the First Edition). Process control and robotics applications have seen some of the most successful use of neural networks for forecasting, as the processes involved are often sufficiently multivariable and nonlinear to warrant the use of neural networks but sufficiently well characterized and free of noise to allow accurate models to be built.

## Dangers in Using Forecasts

Forecasts rely on a number of assumptions. They assume that the system that is modeled remains constant, i.e., that the model that held when the model was built still applies when the forecast is made. If the system structure is evolving over time, techniques from adaptive control may be more appropriate. It is also implicitly assumed when forecasting using neural networks with multiple inputs that the covariance structure of the inputs will remain constant. This presents a major difficulty when modeling systems that have feedback in them, if the feedback structure is variable. For example, consider a house controlled by a thermostat. One will typically find that the heater will be on more often when the house is cold (this is, after all, what the heating system is designed to do). Forecasts of future house temperature can be accurately made using historical temperature measurements. If, however, these forecasts are used as part of the control scheme (the thermostat), then instability often results, since the forecasts fail to account for the new thermostat behavior. Similar situations often occur in economics and marketing, where forecasts can result in new laws being passed or in new prices being charged (and resulting actions by competitors), thus invalidating the original forecast. Unfortunately, there is generally little that one can do other than monitoring forecasts and distrusting them or collecting more data, if the process being forecast changes. (This is true in linear regression as well, where it is impossible to tell which of two highly correlated inputs is responsible for changes in an output, but at least one can easily detect the problem in linear problems by examining the uncertainty on the regression coefficients, whereas it is usually concealed in neural nets.)

**Table 1.** Forecasting Using Neural Nets: Sample Results

| Application | Authors | Results | Compared with |
|---|---|---|---|
| Car sales, airline passengers | Tang et al. | NNet better for longer-term forecast; Box-Jenkins better for shorter | Box-Jenkins |
| Currency exchange rates | Weigend et al. | NNets better | Random guessing |
| Electric load forecasting | Park et al. | NNet better | Currently used technology (unclear what) |
| Electrochemical reaction | Hudson et al. | Prediction looks good | — |
| Flour prices | Chakraborty et al. | NNets better than ARMA | ARMA |
| Polypropylene sales | Chitra | NNets slightly better than ARMA | ARMA |
| Stock prices | White | NNets provide no benefit | Random walk |
| Widely varied (Makridakis collection) | Foster et al. | NNets better on quarterly data, worse on annual data | Many exponential smoothing and deseasonalizing methods |

## Discussion

Neural networks have many demonstrated successes as forecasting tools and a smaller number of documented failures. All the usual warnings about model building apply. In particular, to build a good model, one needs good data. When the data are noisy and occur in short series, neural networks often fail to do better than simple forecasting techniques. For example, the 181 yearly series of the M-competition, which have a mean length of 19 data points on which to base a prediction, do not provide a good basis for complex nonlinear models. Neural networks generally give significant improvements over conventional forecasting methods when applied to monthly data in the M-competition set but not when applied to yearly data (Hill, O'Connor, and Remus, 1996). This is probably due to the high ratio of noise to data in the yearly data.

It may also be the case that the data are truly random or that the key independent variables are not being measured. Research suggests that this is true of the stock market (White, 1988). If this is true, then neural networks will not produce useful market forecasts, although they may help sell forecasting products. Several fund managers claim that they are getting superior predictions using neural networks, but for obvious competitive reasons, they generally do not provide enough information to test the claims. Moody (1998) provides a good discussion of the issues in forecasting the economy.

Neural networks have proved successful in a number of applications such as forecasting prices (Chakraborty et al., 1992), product demand (Chitra, 1993), electric utility loads (Yu, Moghaddamjo, and Chen, 1992), and inventory levels (see Table 1). Such problems are characterized by ample measurements with a relatively high signal-to-noise ratio. In most cases, substantially better performance is obtained by using several related inputs to the network. For example, in forecasting wheat prices in three cities, superior performance was found by using recent wheat prices and measures of the local earning power. Similarly, in forecasting demand for polypropylene production, several macroeconomic variables were fed into the network. On longer, more deterministic time series, such as measuring the progress of a chemical reaction, neural networks have been shown to be a relatively accurate means of forecasting even chaotic series (Hudson et al., 1990; Lapedes and Farber in Vermuri and Rogers, 1994).

All of the applications cited above use standard backpropagation networks, occasionally with some degree of structure built into the network. For example, in the currency exchanges, excess weights were eliminated, while for forecasting wheat prices, past values of prices in three different cities were used to predict the logarithm of flour prices. All have demonstrated better performance than conventional forecasting methods, except when only short time series were available (10 to 30 data points) or when it was unclear if there was an underlying model other than a biased random walk (e.g., stock prices). However, the gains in accuracy over conventional forecasting methods are often relatively small, and overfitting is a common problem. Many companies are now using neural networks for problems such as demand forecasting. When sufficient data are available and care is taken to avoid overfitting, neural networks work well.

# Gabor Wavelets and Statistical Pattern Recognition

*John Daugman*

## Introduction

Starting around 1960, for about three decades investigation into the functioning of the mammalian primary visual cortex was dominated by recordings from single neurons. Using relatively simple stimuli such as oriented bars of light (e.g., Hubel and Wiesel, 1962, 1974), the apparent coding dimensions underlying spatial vision were mapped out by measuring tuning curves of individual neural responses as functions of stimulus parameters. Although methods later moved on, with innovations such as population recordings, noninvasive imaging with photovoltaic dyes, and novel anatomical techniques, the single-unit recording paradigm left a rich legacy of data that lent itself to modeling in engineering terms such as filtering, feature extraction, transform coding, and dimensionality reduction.

In this framework, the key functional concept is that of a neuron's *receptive field*, which specifies that region of two-dimensional (2D) visual space in which image events or structure can influence the neuron's activity. More exactly, the neuron's *receptive field profile* indicates the relative degree to which the cell is excited or inhibited by the distribution of light as a function of its spatial position within the receptive field. Through careful measurements with precisely defined stimuli, the receptive field profile of a *linear* neuron (one obeying proportionality and superposition in its responses to stimuli) reveals how it will respond to *any* pattern and allows the neuron to be analyzed in signal processing terms as a filter. The powerful mathematical tools of linear systems analysis (including Fourier analysis) are the basis of such extrapolations, subject always to the assumption of linearity. More recent findings of adaptive, nonlinear, remote interactions between visual neurons "beyond the classical receptive field" undermine the linear filter perspective and may even call into question the whole notion that a neuron has a stable receptive field profile. Nevertheless, impressive practical results have been achieved in engineering applications of one such model inspired by the classical receptive field data. This article reviews the model that has come to dominate the classical description of cortical simple cells and their inputs to complex cells, and it reviews some successful applications of that scheme within computer vision and statistical pattern recognition.

## Receptive Fields and 2D Gabor Wavelets

Typical two-dimensional receptive field profiles of simple cells in the feline visual cortex (Jones and Palmer, 1987) are shown in the top row of Figure 1. There are arguably five major degrees of freedom (i.e., independent forms of variation) spanned by the spatial receptive field structure of such neural populations. These can be regarded as defining the dimensions of the spatial visual code at this cortical level. The first two degrees of freedom are the *location* of a neuron's receptive field, defined by retinotopic coordinates ($x$, $y$). The third is the *size* of its receptive field (which can be described using a single scalar diameter, provided we view variation in the field width/length aspect ratio as a secondary population structure). The fourth is the *orientation* of the boundaries separating excitatory and inhibitory regions, as seen in Figures 1 and 3, normally also corresponding to the direction of receptive field elongation. The fifth is the *symmetry*, which may be even or odd, or some linear combination of these two canonical states. (Any function can be decomposed into the sum of an even function plus an odd function, and their relative amplitudes define a continuum that allows this fifth dimension to be regarded as *phase*.)

These degrees of freedom in the spatial visual code also correspond to certain dimensions of the "cortical architecture" (rules of topographic and modular organization), although such structure is

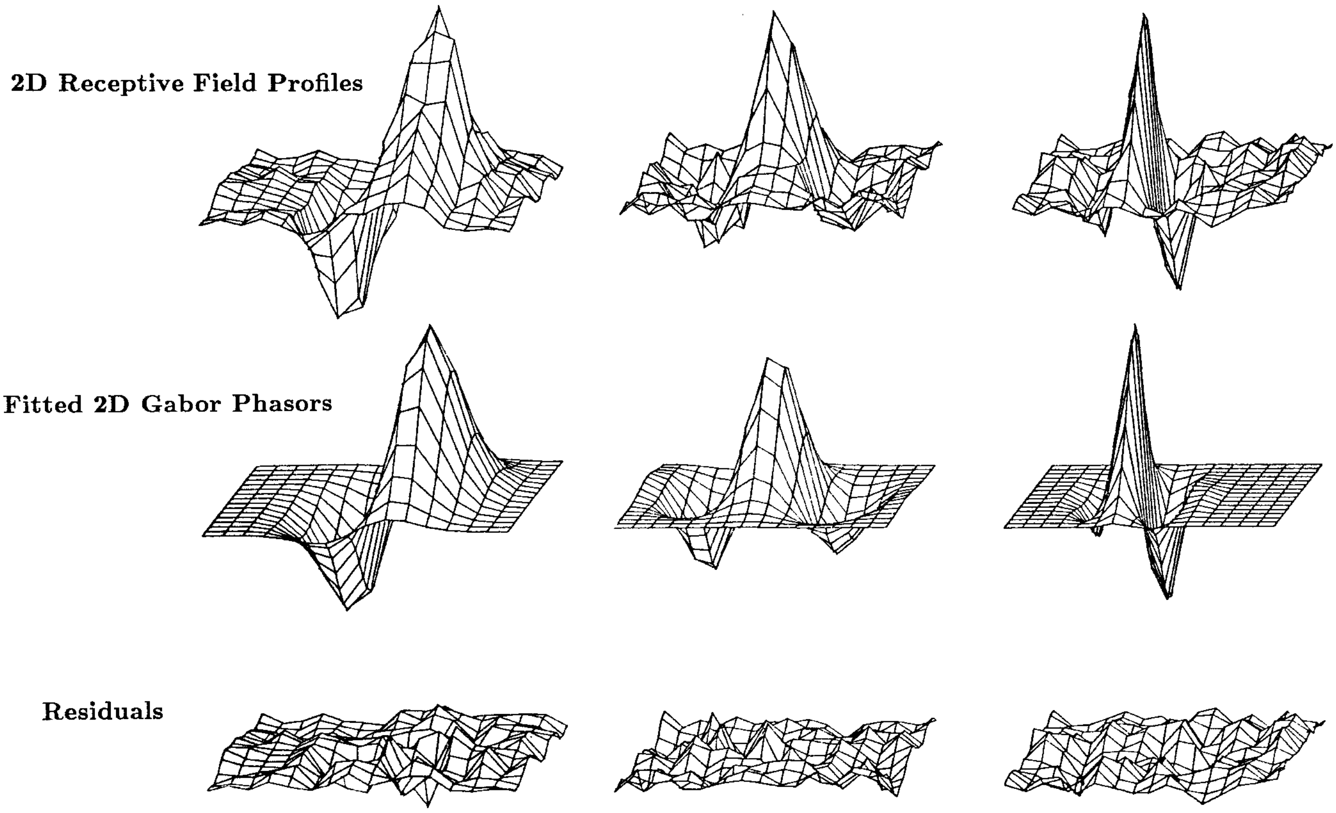

**Figure 1.** Typical 2D receptive field profiles of simple cells found in cat visual cortex, from measurements by Jones and Palmer (1987). The raw receptive field profiles (top row) are well-described by the 2D Gabor wavelet model (middle row) in 97% of the cells studied, yielding residuals (bottom row) that are indistinguishable from random error in chi-squared tests.

less pronounced for some variables than for others. The $(x, y)$ position coordinates of receptive fields in visual space form systematic (although nonconformal) topographic maps of these two dimensions across the cortical surface. Third, subpopulations of neurons that share the same orientation preference are grouped together into columns, and successive columns rotate systematically in preferred angle ("sequence regularity"). A similar structure exists for the grouping of cells by the dominant eye from which they receive input, the ocular dominance columns. These rather crystalline organizational principles were originally documented in seminal papers by Hubel and Wiesel (1962, 1974). Of the remaining two degrees of freedom, there is some evidence for pairwise grouping by quadrature (90°) phase relationship (Pollen and Ronner, 1981), and also some evidence for anatomical grouping by field size, either in different cortical layers or in adjacent columns analogous to those for orientation.

One benefit of identifying the primary degrees of freedom in a spatial image code is that it allows us to characterize the coding strategy in information-theoretic terms. The information-carrying capacity associated with each degree of freedom is a function of the number of individually resolvable states for that dimension. These define a kind of "information budget" that can be allocated in alternative ways among the different available degrees of freedom. Certain inescapable conflicts arise, however, that limit the extent to which some combinations of information can be simultaneously resolved. These conflicts take the form of an "uncertainty principle," whose mathematical form (Daugman, 1985) is just a 2D generalization of the one familiar from quantum physics in the famous work of Weyl and Heisenberg. One such conflict, or trade-off, will be intuitively clear from considering the oval receptive fields in Figure 3. Orientation resolution (the "sharpness" of orientation tuning) would be enhanced by making the ovals longer, but this would reduce their resolution for spatial location in that direction. Similarly, increasing the field width by adding more cycles of undulation would sharpen the tuning for spatial frequency, but at the cost of lost resolution for spatial location in this direction. The optimal solution for these trade-offs, achieving maximal *conjoint* resolution of image information in both 2D spatial and 2D spectral terms, is the family of complex-valued 2D Gabor wavelets. These were first introduced into vision modeling by Daugman (1980, 1985) as a generalization of the 1D elementary functions, "logons," originally proposed for signal expansions by Gabor (1946).

This family of complex-valued 2D wavelets defining filters with minimal conjoint uncertainty have the following parameterized form in the $(x, y)$ space domain:

$$G(x, y) = e^{-[(x-x_0)^2/\alpha^2 + (y-y_0)^2/\beta^2]} e^{-2\pi i[u_0(x-x_0) + v_0(y-y_0)]} \qquad (1)$$

where $(x_0, y_0)$ specify position in the image, $(\alpha, \beta)$ specify the filter's effective width and length, and $(u_0, v_0)$ specify the filter's modulation wave vector, which can be interpreted in polar coordinates as spatial frequency $\omega_0 = \sqrt{u_0^2 + v_0^2}$ and orientation (or direction) $\theta_0 = \arctan(v_0/u_0)$. The real and imaginary parts of this complex filter function describe associated pairs of simple cells in "quadrature phase" (90° phase relation), as were discovered by Pollen and Ronner (1981). The middle row of Figure 1 shows three examples of the real or imaginary parts of the complex filter of Equation 1, with parameters chosen to fit the experimentally measured receptive field profiles shown in the top row. Neural recordings by Jones and Palmer (1987) confirmed that this family of functions provided good fits to the receptive field profiles of about 97% of the simple cells whose 2D profiles they measured in cat visual cortex. (It should be noted, however, that other investigators have preferred other functions, such as differences of several offset Gaussians, which, having additional fitting parameters, offered better fits to their data.) The top row of Figure 1 illustrates three of the 131 simple-cell 2D receptive field profiles measured by Jones and Palmer. The bottom row shows the residuals obtained by subtracting the best-fitting 2D Gabor wavelet component (middle row) from each measured profile. For nearly all of the cells studied, these residuals were indistinguishable from random error in chi-squared tests. Although alternative analytic forms could be chosen to fit the available 2D receptive field data, there can be no doubt that the 2D Gabor wavelet model specifies an efficient set of coding primitives capturing 2D spatial location, orientation, size (or frequency), and phase (or symmetry) in a natural way.

The 2D Fourier transform $F(u, v)$ of a 2D Gabor wavelet, which reveals its spectral response selectivity in the Fourier plane, has exactly the same functional form as the space-domain function (i.e., it is "self-Fourier"), but with the parameters just interchanged or inverted:

$$F(u, v) = e^{-[(u-u_0)^2\alpha^2 + (v-v_0)^2\beta^2]}e^{2\pi i[x_0(u-u_0)+y_0(v-v_0)]} \tag{2}$$

Thus the 2D Fourier power spectrum $F(u, v)F^*(u, v)$ of a 2D Gabor wavelet is simply a bivariate Gaussian centered on $(u_0, v_0)$. Hence its peak response occurs for an orientation $\theta_0$ and spatial frequency $\omega_0$ as defined earlier, corresponding to the excitatory/inhibitory structure of the receptive field, as one would expect. Some authors have questioned the relevance of the Gabor wavelet property of optimal conjoint resolution in these two domains, or the specialness of the variance metric on which the measure of uncertainty is based. Perhaps the best reply is Aristotle's dictum that "vision is knowing what is where." The extraction of local image structure in terms of oriented undulatory primitives provides information in 2D spectral terms about "what," and the resolution of positional information indicates "where." If we wish to extract visual information simultaneously in terms of both what and where, as Aristotle said, then under the Heisenberg uncertainty principle we cannot do better than to construct our spatial visual code from 2D Gabor wavelets. It would appear that the evolution of the mammalian visual cortex may have been shaped by this criterion and thus converged on the coding primitives that optimize it.

## Compact Image Coding and 2D Gabor Transforms

Besides their optimality in terms of the uncertainty relation, 2D Gabor wavelets have many practical properties. They can be used to form a complete and compact image code, as a self-similar 2D wavelet expansion basis, despite their nonorthogonality (Daugman, 1988). Although Gabor wavelets do not technically satisfy the original admissibility conditions for wavelets such as orthogonality and strictly compact support, their practical advantages as coding primitives are not much diminished. For example, they can achieve significant image compression, with appropriate parameterization for wavelet dilations, rotations, and translations. If we take $\Psi(x, y)$ to be a chosen generic 2D Gabor wavelet as specified above in Equation 1, which may be called a "mother wavelet," then we can generate from this one function a complete self-similar family of "daughter wavelets" through the generating operation

$$\Psi_{mpq\theta}(x, y) = 2^{-2m}\Psi(x', y') \tag{3}$$

where the substituted variables $(x', y')$ incorporate dilations of the wavelet in size by octave factors $2^{-m}$, translations in position $(p, q)$, and rotations through angle $\theta$:

$$x' = 2^{-m}[x \cos(\theta) + y \sin(\theta)] - p \tag{4}$$

$$y' = 2^{-m}[-x \sin(\theta) + y \cos(\theta)] - q \tag{5}$$

It is noteworthy that as consequences of the similarity, shift, and modulation theorems of 2D Fourier analysis, together with the rotation isomorphism of the 2D Fourier transform, all of these effects of the generating function (Equation 3) applied to a 2D Gabor mother wavelet $\Psi(x, y) = G(x, y)$ in generating the 2D Gabor daughter wavelets $\Psi_{mpq\theta}(x, y)$ will have just corresponding or reciprocal effects on the wavelet's 2D Fourier transform $F(u, v)$ without any other change in functional form (Daugman, 1985). This family of 2D wavelets, and their 2D Fourier transforms, is each closed under the transformation groups of dilations, translations, rotations, and convolutions.

Any image can be represented completely in terms of such a basis of elementary expansion functions. An example of this in a progressive sequence is provided in Figure 2, showing the benchmark "Lena" image reconstructed from increasing numbers of 2D Gabor wavelets. It is interesting that even when only 100 or 500 wavelets are present and distributed across the entire image, already the primary facial features such as the eyes are discernible. Since facial features are essentially just localized undulations, parameterized for scale, position, orientation, and symmetry—that is, the same as the parameterizations of the Gabor wavelets themselves—it is perhaps not surprising that very efficient face codes can be constructed from such wavelets.

An error that occurs frequently in the literature is a confusion between Gabor *projection coefficients* (obtained merely by taking the convolution or inner product of each image region onto a local Gabor wavelet) and Gabor *expansion coefficients* (those needed to reconstruct the image as a linear combination of Gabor wavelets). Because these wavelets are not an orthogonal set (i.e., their mutual inner products are not zero), the expansion coefficients are not the same as the projection coefficients, nor can they easily be obtained from them. For this reason, it is incorrect to refer to the result of image convolutions with Gabor wavelets as a Gabor transform, since the resulting representation is not invertible. One approach for obtaining the Gabor expansion coefficients needed for an invertible image representation (thus defining a true *Gabor transform*) is a relaxation network method introduced in Daugman (1988). The progressive stages of image reconstruction shown in Figure 2 are based on expansion coefficients obtained by that relaxation network.

Interesting issues arise concerning how the "information budget" in a visual code should be allocated. For example, because all Gabor wavelets are indexed by their 2D location, the parameters that specify each wavelet's orientation and spatial frequency can be sequenced much more sparsely than Fourier components in a Fourier transform. Moreover, the necessary density of sampling in orientation and frequency is in a trade-off with the needed density of sampling in position (i.e., how much the wavelets overlap each other). The exact rules for the sampling densities necesssary in these various parameters in order to obtain a *complete* image code are dictated by *frame theory*. Whereas, for example, the 2D Fourier transform must sample the frequency plane along a uniform Cartesian grid, a 2D Gabor transform can sample the frequency plane on just a log-polar grid. This great reduction in sampling density for the higher frequencies is purchased by the wavelet position parameters. Illustrations of self-similar 2D Gabor representations of images, obtained with varying numbers of wavelet orientations (six, four, three, and two orientations in the sampling set), may be

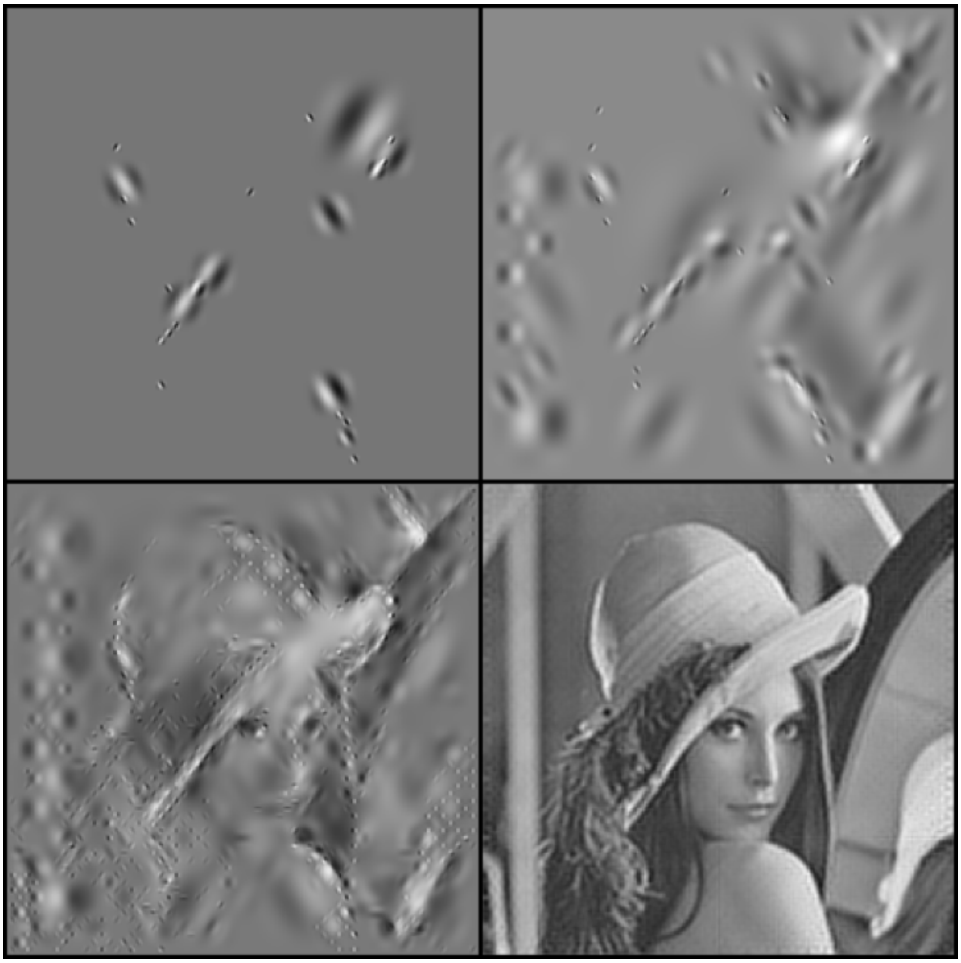

**Figure 2.** Illustration of the completeness of 2D Gabor wavelets as image coding primitives. The benchmark "Lena" picture is reconstructed by progressive numbers of wavelets in linear combination, of 25, 100, 500, and 10,000. The primary facial features are effectively represented by just a handful of such wavelets. However, because of their nonorthogonality, the wavelets require coefficients that differ from the simple inner product projection of the image onto them.

found in Daugman (1988). These sorts of considerations may be able to answer such longstanding neurobiological questions as "Why are there orientation columns in the cortex, and why is orientation sampled with those bandwidths and intervals? Why do receptive fields overlap this much?" Further neurobiological issues are raised by the fact that the Gabor wavelets are nonorthogonal. The consequences of this include paradoxes in the classical interpretation of what it is that a neuron's receptive field actually enables it to encode about an image. In particular, the classical view that a linear neuron's response (which is determined by the inner product of its receptive field profile with the local image) signifies the "relative presence" of its own structure in the local image region is paradoxical: it implies an incorrect image representation by the ensemble of neurons, given their mutual nonorthogonality.

## Facial Analysis and Recognition

Whereas simple cells are regarded as linear filters whose phase sensitivity is clearly determined by their alternating pattern of a few excitatory and inhibitory regions, the so-called "complex" cells that receive input from them have no such phase sensitivity, yet their orientation and spatial frequency tuning are similar to that of simple cells. A natural model therefore supposes that the inputs to complex cells come from quadrature pairs of simple cells, taking the sum of their squared responses, as shown at the top of Figure 3. This nonlinear combination not only achieves a weak kind of translation invariance (in that the complex cell responds to the stimulus but is indifferent to its phase, or position within the receptive field) but, more important, this arrangement can play a useful role in feature extraction for pattern recognition. This idea is illustrated for the case of a face image in Figure 4 (see the figure caption for a detailed explanation). Since major facial features are essentially localized undulations of a certain scale (frequency) and orientation, it is perhaps not surprising that facial features are easily represented and detected by operations using 2D Gabor wavelets.

This idea has been elaborated further in a number of full face recognition systems based on Gabor wavelets (e.g., Lades et al., 1993). Besides encoding a face by the coefficients of projection of particular regions of the face (centered on fiducial points) onto clusters of multiscale, oriented Gabor wavelets (renamed "jets"), the Lades scheme organizes the data into an elastic graph that can accommodate some distortion. A graph-matching technique searches for matches of the Gabor wavelet projection coefficients while allowing graph distortions corresponding to limited changes in facial expression, perspective angle, and pose. But the approach remains "appearance-based" (i.e., it is a 2D image representation for faces, not a 3D object representation), and as such it is susceptible to changes in perspective geometry and illumination geometry. Such variations in image capture conditions affect the wavelet projection coefficients in a manner for which the graph matching cannot compensate and is not invariant. For similar reasons, all current face recognition algorithms can work only under con-

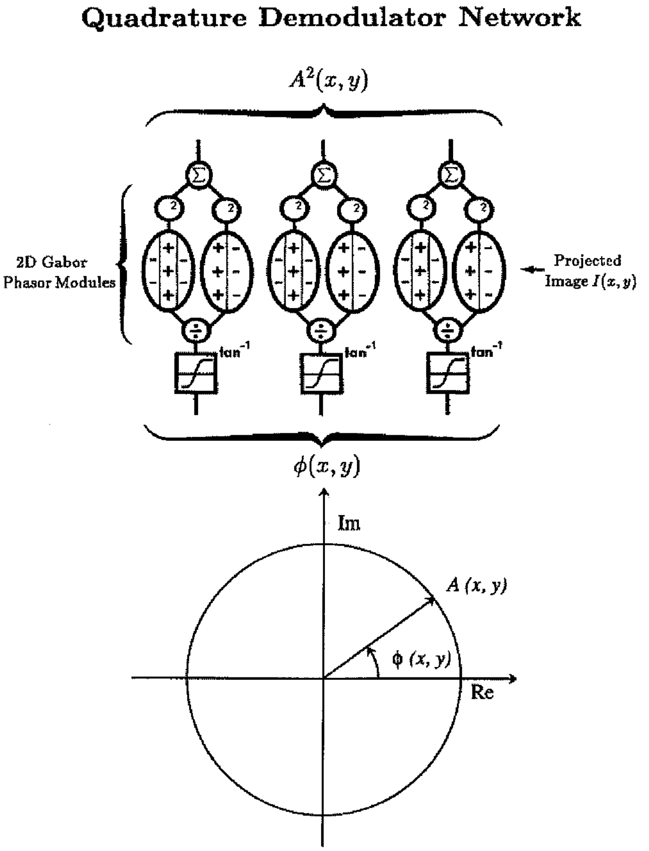

**Figure 3.** The 2D Gabor wavelet quadrature demodulation network. Even- and odd-symmetric receptive fields, of the kind associated with cortical simple cells, subserve a phasor resolution of information in the complex plane. The sum of the squares of quadrature simple-cell responses extracts an amplitude function $A(x, y)$ or modulus (top of network), while the ratio of their responses resolves the local phase function $\phi(x, y)$ (bottom of network). Such amplitude-and-phase descriptions of image structure can be very useful in computer vision.

strained imaging conditions, with fixed illumination and perspective geometry and relatively fixed expressions. Moreover, in realistic tests, the best systems have error rates approaching 50% when comparing images taken just 1 year apart.

## Phase and Amplitude Coding of Texture and Complex Patterns

An important goal of vision is *dimensionality reduction*: creating a succinct and useful representation of image structure having much lower dimension than the raw image itself. In a sense, standard edge detection strategies are examples of this idea, since edge maps can signify object structure, and they clearly have much lower dimension than the raw pixel count. However, many naturally occurring objects, such as faces and bodies, lack the planar or geometrical forms of manufactured objects that generate simple edge maps; instead, they are defined by continuous-tone structure, textures, and undulations, which are not well captured by detecting edges. We saw earlier that facial features are efficiently represented and detected by 2D Gabor wavelets; a similar subspace projection approach using these wavelets was successfully applied by Shustorovich (1994) to the problem of classifying and recognizing handwritten characters. A more general representation for image information (Daugman and Downing, 1995) reduces its dimensionality by *decorrelating* it not only in amplitude but also in phase, making use of the intriguing quadrature phase relationship found in the neurobiological recordings from cortical simple cells. As portrayed in Figure 3, the quadrature simple-cell structure not only supports an energy, or modulus, computation emerging from the top of the network as $A^2(x, y)$, but the same paired 2D Gabor receptive fields also support a computation of local phase $\phi(x, y)$, shown emerging from the bottom of the network. The arctangent-like "squashing function" that operates on the ratio of the simple-cell responses is a common feature of many neural network models, but here it serves trigonometrically to resolve a phase angle in the complex plane, as indicated in the phasor diagram at the bottom.

The representation of images in terms of local phase $\phi(x, y)$ and local amplitude $A(x, y)$ is a form of *predictive coding* that takes as its prediction the locally prevalent scale and orientation of image structure, and encodes the full detailed pattern as modulations of that prediction (Daugman and Downing, 1995). This lends itself not only to compact image coding but also to texture segmentation (i.e., the division of an image into regions defined by some local homogeneity of texture). The analysis of texture and its use for image segmentation are important topics in statistical pattern recognition. 2D Gabor wavelets have played dominant roles here, as reviewed in Bovic, Clark, and Geisler (1990) and Navarro, Tabernero, and Cristobal (1996). An alternative approach that explicitly computes Gabor phase rather than just energy for effective texture segmentation is given in du Buf (1990).

## Iris Recognition

In this section, we illustrate the principles discussed in this chapter with a practical application that is now coming into wide international use: the automatic visual recognition of persons by their iris patterns. Details about the algorithms that locate an iris and segment it from other tissues, mapping it into a doubly dimensionless coordinate system with invariance for size, translation, and pupil dilation, are given in Daugman (2001). The iris pattern is then demodulated by 2D Gabor wavelets (see Figure 3) in order to extract its *phase sequence* $\phi(x, y)$, with these phase values quantized very coarsely into only the nearest quadrant of the complex plane. This sets two bits of phase information for each wavelet applied in a particular location. An "IrisCode" comprising 2,048 such bits of pattern phase information is then compared against an enrolled database of other IrisCodes in search of a match. These comparisons are performed at the speed of 100,000 IrisCodes per second by the decision network shown in Figure 5. This network transforms the pattern recognition problem into a simple test of statistical independence on the 2D Gabor wavelet phase sequences derived from the patterns.

Results from 9.1 million comparisons between different iris patterns are given in Figure 6, based on images acquired at kiosks in Britain, the United States, Japan, and Korea in public trials of these algorithms over a 3-year period. In these trials, as well as in tests conducted by independent government laboratories (the largest involving 2.73 million iris comparisons), there has never been a single reported false match. The reason is because the 2D Gabor IrisCode extracts about 250 degrees of freedom, whose combinatorics generate binomial distributions with extremely rapidly attenuating tails. Since comparisons of phasor bits are Bernoulli trials whose values of $p$ and $q$ depend on whether a pair of IrisCodes comes from the same or from different eyes, the confidence levels associated with recognition decisions are determined by cumulatives of the binomial probability density of observing a fraction $x = m/N$ "true" exclusive-OR outcomes in $N$ comparisons:

$$f(x) = \frac{N!}{m!(N - m)!} p^m q^{(N-m)} \tag{6}$$

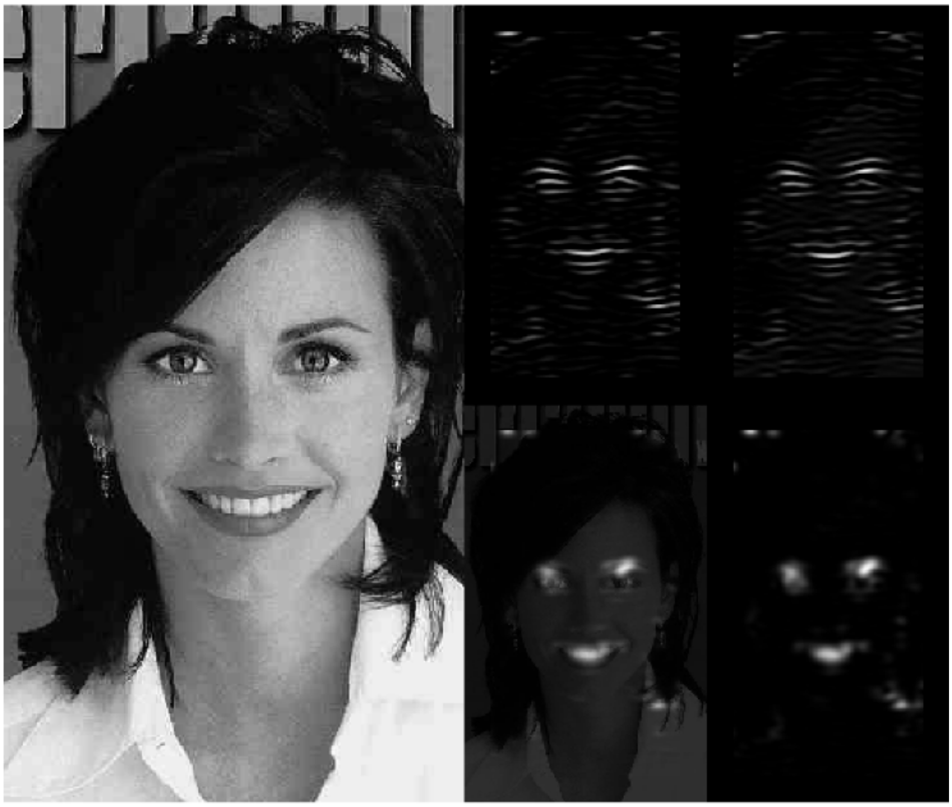

**Figure 4.** Illustration of facial feature detection by the quadrature demodulator network shown in Figure 3. *Left*, Input image. *Right* (clockwise from top left), the real part of the result of convolution with a 2D Gabor wavelet; the imaginary part from the same convolution (both of these representing the phase-sensitive simple-cell responses); the squared modulus $A^2(x, y)$, representing complex cell response; and this result superimposed on the original (faint) image, illustrating feature detection and localization.

The solid curve in Figure 6 superimposed on the raw data distribution is a plot of the Equation 6 binomial, and it provides a remarkably exact fit. It shows that there is vanishingly small probability that two different iris patterns could agree just by chance in more than about two-thirds of their bits, i.e., produce a fractional Hamming distance smaller than about 0.33. But images acquired

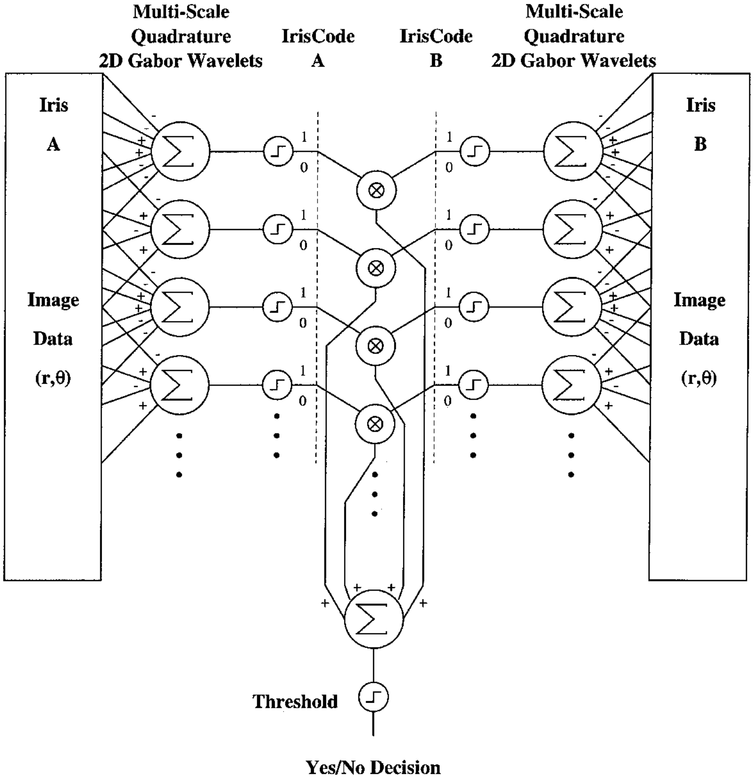

**Figure 5.** The comparison and recognition network used to make decisions about the identity of iris patterns. In effect, this network transforms the problem of pattern recognition into a test of statistical independence on the iris pattern phase sequences extracted by 2D Gabor wavelet demodulation (Figure 3).

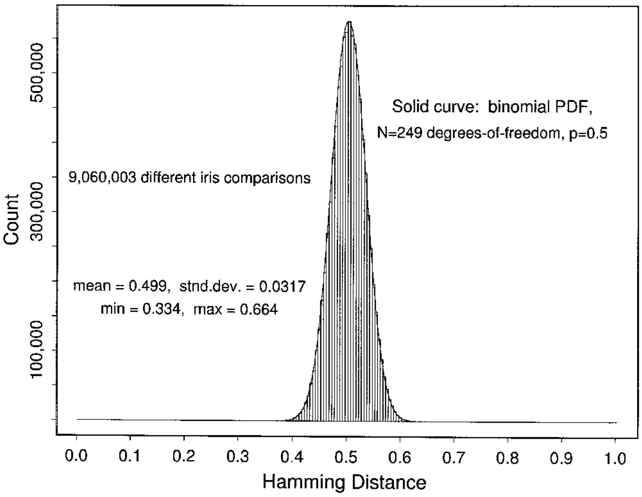

**Figure 6.** Results of 9.1 million comparisons between human iris patterns. Their Hamming distances are binomially distributed (solid curve, Equation 6). The rapidly decaying tails of such factorial distributions make it almost impossible for two different IrisCodes to disagree by chance in less than about a third of their bits (Hamming distance $< 0.33$). Thus, the failure of a simple test of statistical independence in this application of 2D Gabor wavelets allows reliable human identification with great tolerance for poor imaging.

from a given iris at different times and under different conditions score Hamming distances well below this, typically in the 0.10–0.15 range. Thus, this complex yet stable textural signature can provide a very accurate basis for automatically recognizing personal identity (in lieu of using PINs, cards, keys, passwords, or documents) for purposes such as border control, building entry, cash machines, computer login, authentication, and security measures in general. All current iris recognition systems installed worldwide use the 2D Gabor wavelet encoding, demodulation, and decision networks described here (Figures 3 and 5). Recent installations of this system include Heathrow Airport, Amsterdam-Schiphol, Washington-Dulles, and Charlotte Airports, for both passenger screening and control of access to restricted areas.

## Discussion

The role of 2D Gabor wavelets in the visual sciences began as a model proposed in 1980 for cortical simple-cell 2D receptive field profiles. Today these wavelets are used pervasively in computer vision, image processing, and pattern recognition (for an in-depth review, see Navarro et al., 1996), even though more recent investigations in neuroscience perhaps call into question the very idea that visual neurons even possess stable receptive field profiles. The benefits of performing image coding and analysis using these elementary detectors include the opportunity to describe image structure in terms of local phase and energy, allowing demodulation, which lends itself well to solving pattern recognition problems. Some practical applications now in widespread use include facial and texture analysis, and personal identification by automatic, real-time recognition of iris patterns. These examples illustrate the fruitful interaction that can occur between ideas originating in brain theory and ideas about artificial neural networks.

# Gait Transitions

*James J. Collins*

## Introduction

Legged animals typically employ multiple gaits for terrestrial locomotion. Bipeds, for example, walk, run, and hop, whereas quadrupeds commonly walk, trot, and bound. Animals make transitions between different gaits depending on their speed and the terrain. Experimental studies have demonstrated that animal locomotion is controlled, in part, by a central pattern generator (CPG), which is a network of neurons in the central nervous system (CNS) capable of producing rhythmic output (Shik and Orlovsky, 1976; Grillner, 1981; Pearson, 1993). (The control of locomotion, however, is not purely central; e.g., the output of a locomotor CPG is modulated by feedback from the periphery.) Shik and colleagues, for instance, showed that mesencephalic cats could exhibit a walking gait on a treadmill when the midbrain was electrically stimulated. Moreover, they found that such preparations could switch between different gaits if either the stimulation strength or the treadmill speed was varied.

Although the aforementioned studies established the existence of rhythm-generating networks in the CNS, a vertebrate CPG for legged locomotion remains to be identified or isolated. As a result, little is known about the specific characteristics of the neurons and interconnections making up such systems. Consequently, researchers have resorted to using modeling techniques to gain insight into the possible functional organization of these networks. The most popular approach has involved the analysis of systems of coupled oscillators. Coupled-oscillator models have been used to control the gaits of bipeds (Bay and Hemami, 1987; Taga, Yamaguchi, and Shimizu, 1991), quadrupeds (Stafford and Barnwell, 1985; Schöner, Jiang, and Kelso, 1990; Collins and Stewart, 1993a; Collins and Richmond, 1994), and hexapods (Beer, 1990; Collins and Stewart, 1993b).

The neural mechanisms underlying gait changes are not well understood. A key question in this regard is whether gait transitions involve (1) switching between different CPGs, or (2) bifurcations of activity in a single CPG. In this article, we discuss a number of modeling approaches that have been developed to explore the feasibility of using either one or the other of these mechanisms to generate gait transitions in coupled-oscillator networks.

## A Neuromodulatory Approach

As a model for legged-locomotion control, Grillner (1981) proposed that each limb of an animal is governed by a separate CPG, and that interlimb coordination is achieved through the actions of interneurons that couple together these CPGs. Within this scheme, gait transitions are produced by switching between different sets of coordinating interneurons; that is, a locomotor CPG is reconfigured to produce different gaits.

Grillner's proposed strategy has been adopted, in spirit, by several CPG modeling studies. Stafford and Barnwell (1985), for example, used a similar approach in a study of quadrupedal locomotion. They considered a CPG model that was composed of four coupled networks of oscillators. Each network controlled the muscle activities of a limb of a model quadruped. Stafford and Barnwell showed that this model could produce the walk, trot, and bound. In addition, they demonstrated that the walk-to-trot and walk-to-bound transitions could be generated by changing the relative strength of certain interoscillator connections or by eliminating others altogether. (Transitions in the reverse direction, e.g., bound-to-walk, were not reported.) Along similar lines, Bay and Hemami (1987) used a CPG network of four coupled van der Pol oscillators to control the movements of a segmented biped. Each limb of the biped was composed of two links, and each oscillator controlled the movement of a single link. Bipedal walking and hopping were simulated by using the oscillators' output to determine the angular positions of the respective links. Transitions between out-of-phase and in-phase gaits were generated by changing the nature of the interoscillator coupling; for example, the polarities of the network interconnections were reversed to produce the walk-to-hop transition.

This approach is, in principle, physiologically reasonable. For instance, the notion that supraspinal centers may call on functionally distinct sets of coordinating interneurons to generate different gaits is plausible but not yet experimentally established. In addition, from a different but relevant perspective, it has been shown that rhythm-generating neuronal networks can be modulated—reconfigured—through the actions of neuroamines and peptides, and that they are thereby enabled to produce several different motor patterns (see Pearson, 1993, and CRUSTACEAN STOMATOGASTRIC SYSTEM), at least in invertebrate preparations.

## A Synergetic Approach

Synergetics deals with COOPERATIVE PHENOMENA (q.v.) in nonequilibrium systems (Haken, Kelso, and Bunz, 1985). In synergetics, the macroscopic behavior of a complex system is characterized by a small number of collective variables, which in turn govern the qualitative behavior of the system's components.

Schöner et al. (1990) used a synergetic approach in a study of quadrupedal locomotion. They analyzed a network model that was made up of four coupled oscillators. Each oscillator represented a limb of a model quadruped. Three relative phases—the phase differences between the right-front and the left-front, left-hind, and right-hind oscillators, respectively—were used as collective variables to characterize the system's interlimb-coordination patterns. Gait transitions were modeled as nonequilibrium phase transitions, which, in this case, could also be interpreted as bifurcations in a dynamical system (see the next section). Schöner et al. demonstrated that various four-component networks could produce and switch (abruptly or gradually) between different gaits, such as the gallop, trot, and pace, if the coupling terms that operated on the relative phases were varied. Importantly, this work predicted that gait transitions should be accompanied by loss of stability; that is, signs of instability, such as spontaneous gait transitions, should arise near a switching point. Phenomena of this sort have been observed experimentally; the decerebrate cats in the Shik and Orlovsky study, for example, could, near the trot-gallop transition point, switch back and forth spontaneously between the trot and gallop.

This approach is significant in that it relates system parameter changes and stability issues to gait transitions. Its primary weakness, however, is that the physiological relevance of the aforementioned relative-phase coupling terms is unclear. This remains an open issue.

## A Group-Theoretic Approach

The traditional approach for modeling a locomotor CPG has been to set up and analyze, either analytically or numerically, the parameter-dependent dynamics of a hypothesized neural circuit. Collins and Stewart (1993a, 1993b), however, approached this problem from the perspective of group theory. Specifically, they considered various networks of symmetrically coupled nonlinear oscillators and examined how the symmetry of the respective systems leads to a general class of phase-locked oscillation patterns. Within this approach, the onset of a given pattern is modeled as a symmetric Hopf bifurcation, and transitions between different patterns are modeled as symmetry-breaking bifurcations of various kinds. In standard Hopf bifurcation, the dynamics of a nonlinear system change as some parameter is varied and a stable steady state becomes unstable, "throwing off" a limit cycle (or periodic solution). At a symmetric analog of a Hopf bifurcation, which is appropriate for symmetric dynamical systems, one or more periodic solutions, usually several, bifurcate. There may also be secondary branches of solutions and other more complicated bifurcations. Successive bifurcations tend to break more and more symmetry; i.e., they lead to states with less and less symmetry. Importantly, the pattern of bifurcations that can occur and the nature of the periodic states that arise through such bifurcations are controlled primarily by the symmetries of the system.

The theory of symmetric Hopf bifurcation thus predicts that symmetric oscillator networks with invariant structure can sustain multiple patterns of rhythmic activity. From the standpoint of CPGs, this prediction challenges the notion that a network's coupling architecture needs to be altered to produce different oscillation patterns. Importantly, the symmetry-breaking analysis is independent of the details of the oscillators' intrinsic dynamics and the interoscillator coupling. (The production of periodic states through symmetric Hopf bifurcation, however, does depend on the variation of some suitable system parameter.) This approach thus provides a framework for distinguishing model-independent features (attributable to symmetry alone) from model-dependent features.

Collins and Stewart used this approach to study the dynamics of symmetric networks of two, four, and six coupled oscillators. These networks were considered as models for bipedal, quadrupedal, and hexapodal locomotor CPGs, respectively. They demonstrated that many of the generic phase-locked oscillation patterns for these models correspond to animal gaits. They also showed that transitions between these gaits could be modeled as symmetry-breaking bifurcations occurring in such systems. These studies led to natural hierarchies of gaits, ordered by symmetry, and to natural sequences of gait bifurcations (Figure 1). This work thus related observed gaits and gait transitions to the organizational structures of the underlying CPGs.

This approach is significant in that it provides a novel mechanism for generating gait transitions in locomotor CPGs. Its primary disadvantage, however, is that its model-independent features cannot provide information about the internal dynamics of individual oscillators. In particular, the stability of the predicted gait patterns and the conditions under which one is selected over another depend on the specific parameters of the model under investigation.

## A Hardwired Network Approach

Motivated by the predictions of the above group-theoretic approach, Collins and Richmond (1994) conducted a series of computer experiments with a symmetric, hardwired locomotor CPG model that consisted of four coupled oscillators. They demonstrated that it was possible for such a network to produce multiple phase-locked oscillation patterns that correspond to three quadrupedal gaits: the walk, the trot, and the bound. Transitions between the different gaits were generated by varying the driving signal or by altering internal oscillator parameters. As observed in real animals (Alexander, 1989), transitions between the walk and trot, which were generated by varying the intrinsic frequency of the CPG oscillators and the amplitude of the driving signal, could be either gradual or abrupt, depending on the nature of the parameter variation. Similar parameter changes could also shift the CPG model from either the walk or the trot into the bound. However, once the CPG model was in bound, it maintained that gait even if the system parameters were returned to their original values for either walk or trot, i.e., there was "total" hysteresis in the network's dynamics. To produce transitions from bound, it was necessary to subject two of the CPG oscillators to an increased driving stimulus before the system parameters were changed to those of the desired gait. (Experimental data that indirectly support such a strategy for generating transitions from bound were provided by Afelt, Blaszczyk, and Dobrzecka, 1983. Specifically, they found that the initiation of the gallop-to-trot transition in dogs was characterized by kinematic changes in a *single pair* of diagonal limbs.) Importantly, the above *in numero* results were obtained without changing the relative strengths or polarities of the system's interconnections; i.e., the network maintained an invariant coupling architecture. Collins and Richmond (1994) also showed that the ability of the hardwired CPG network to produce and switch between multiple gaits was, in essence, a model-independent phenomenon: three different oscillator models—the Stein neuronal model, the van der Pol oscillator, and the FitzHugh-Nagumo model—and two different coupling schemes were incorporated into the network without impeding its ability to produce the three gaits and the aforementioned gait transitions. This general finding was likely attributable to the symmetry of the network, which was maintained in all the numerical experiments.

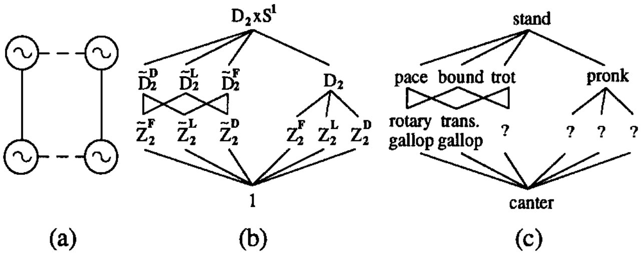

**Figure 1.** *A*, A rectangularly symmetric network of four coupled oscillators. The solid and dashed lines represent two forms of coupling. *B*, Patterns of symmetry breaking for the network in *A*. The respective group-theoretic symbols are described in Collins and Stewart (1993a). *C*, Quadrupedal gaits corresponding to the patterns in *B*.

Earlier, Beer (1990) had designed a hardwired CPG network for controlling hexapodal locomotion (see LOCOMOTION, INVERTEBRATE). In Beer's model, each leg of a model cockroach was controlled by a circuit made up of one pacemaker neuron, two sensory neurons, and three motor neurons. The pacemaker neurons of adjacent leg-controller circuits inhibited one another. If the pacemaker neurons of the network were identical, then the model could generate the tripod gait. To produce metachronal-wave gaits (in which waves of leg movements sweep from the back of the animal to the front), Beer varied the intrinsic frequencies of the pacemaker neurons such that the natural frequency of the back-leg pacemakers was lower than that of the middle-leg pacemakers, which was lower than that of the front-leg pacemakers. With this arrangement, the progression speed of the model cockroach could be changed, and transitions between different gaits could be produced by varying the tonic level of activity of a single command neuron, which was connected to every leg-controller circuit. This model's ability to generate and switch between different gaits was a direct consequence of the interactions between its coupled pacemaker neurons and their respective central and afferent inputs.

A similar model, made up of six coupled unit oscillators, was developed by Taga et al. (1991) to control bipedal locomotion. In this case, each unit oscillator controlled a single joint, i.e., an ankle, knee, or hip, of a multi-link biped. As with Beer's model, the CPG network was driven by a tonic activation signal, and each unit oscillator received feedback about the state of the system's limbs. With this arrangement, the biped's speed could be changed, and abrupt transitions between walking and running could be generated by varying the amplitude of the network's activation signal. Interestingly, these gait transitions exhibited hysteresis; i.e., the walk-to-run transition occurred at a faster progression speed than did the reverse transition. Similar hysteretic behavior has been observed in humans (Alexander, 1989). Taga et al., unfortunately, did not report on the model's ability to switch between out-of-phase gaits (i.e., walking and running) and in-phase gaits (i.e., hopping).

In these studies, gait transitions were produced by varying the CPG's driving signal. From a physiological standpoint, this pattern-switching mechanism is reasonable; e.g., experimental studies have shown that the output of a locomotor CPG can be modified by changes to its descending inputs. Nonetheless, it is important to note that the exact form of the driving signal or signals acting on a locomotor CPG is unknown. Similarly, it is unclear how externally applied stimulation signals are transmitted to locomotor CPGs. For instance, although the stimulation signal in the Shik and Orlovsky study was amplitude modulated (to produce gait transitions), this does not necessarily mean that the resulting descending signals were also amplitude modulated. In addition, although the results of the Shik study were largely independent of the stimulation frequency, there is evidence that frequency-modulated stimulation signals can affect the output of locomotor CPGs. Lennard and Stein (1977), for example, electrically stimulated the dorsolateral funiculus in spinal and intact turtles and found that an increase in the stimulus frequency resulted in an increased repetition rate of hindlimb swimming movements. Finally, it should be reiterated that it is most likely erroneous to assume (as it has been in several CPG modeling studies) that the net driving signal of a locomotor CPG consists only of descending influences from supraspinal centers. The results from several experimental studies indicate that a CPG "driving" signal may also consist of afferent inputs from peripheral sensory organs (Pearson, 1993).

## Discussion

The discussed modeling studies fall into two camps: (1) gait transitions are produced by changing the relative strength or polarity of the interoscillator coupling in a CPG; i.e., "different" CPGs are used to produce different gaits; or (2) gait transitions are generated by changing the CPG's driving signal; i.e., bifurcations in a single CPG are used to generate different gaits. Both of these pattern-switching mechanisms are physiologically plausible, and they each lead to realistic locomotor patterns; e.g., in most of these studies, the stepping frequency or progression speed of the model animal increased when the CPG network switched to "faster" gaits. However, for a consistent theory of gait transitions to emerge, additional experimental data about the functional organization and operation of locomotor CPGs will have to be obtained. In particular, work is needed: (1) to determine whether a locomotor CPG uses functionally distinct sets of coordinating interneurons to produce different motor patterns, (2) to establish the extent to which neuromodulatory mechanisms are employed in vertebrate motor systems, and (3) to clarify the nature of the peripheral and descending inputs that influence the output of a locomotor CPG. Further experimentation is also needed to examine the possible role of bifurcation in gait transitions. In this regard, future investigations should explore the extent of hysteresis in gait transitions and the occurrence of increased instabilities near switching points, as well as consider more extensively the effects of system-parameter variation on gait-transition dynamics.

# Gaussian Processes

*Chris K. I. Williams*

## Introduction

Much of the work in the field of artificial neural networks concerns the problem of supervised learning. Here we may be interested in regression problems (by which we mean the prediction of some real-valued variable(s)), or classification problems (predicting a class label) given the values of some input variables. Due to factors such as measurement noise, it is necessary to take a statistical view of the learning problem.

Given (possibly noisy) observations of a function at $n$ points, it is necessary to impose extra assumptions about the function if there is to be hope of predicting its value elsewhere. Here we take a Bayesian approach, placing a prior probability distribution over possible functions and then letting the observed data "sculpt" this prior into a posterior using the available data. The Bayesian approach can provide solutions to several problems, such as local optima in weight space, the setting of regularization parameters, overfitting, and model selection (see MacKay, 1992; Neal, 1996; and Bayesian Methods and Neural Networks).

One can place a prior distribution $P(\mathbf{w})$ on the weights $\mathbf{w}$ of a neural network to induce a prior over functions $P(y(\mathbf{x}; \mathbf{w}))$ but the computations required to make predictions are not easy, owing to the nonlinearities in the system, and one needs to resort to analytic approximations or Monte Carlo methods. Gaussian processes are a way of specifying a prior directly over function space; it is often simpler to do this than to work with priors over parameters. Gaussian processes (GPs) are probably the simplest kind of function space prior that one can consider, being a generalization of finite-dimensional Gaussian distributions over vectors.

A finite-dimensional Gaussian distribution is defined by a mean vector and a covariance matrix. A GP is defined by a *mean function* (which we shall usually take to be identically zero), and a *covariance function* $C(\mathbf{x}, \mathbf{x}')$, which indicates how correlated the value of the function $y$ is at $\mathbf{x}$ and $\mathbf{x}'$. This function encodes our assumptions about the problem (for example, that the function is smooth and continuous) and will influence the quality of the predictions.

Gaussian process prediction is illustrated in Figure 1. The upper panel shows a sample of five functions drawn from the prior. The lower panel shows five samples from the posterior after two observations have been made; notice that the posterior is tightly constrained near the observations, but varies more widely further away. Essentially, what has happened is that prior samples not consistent with the observations have been eliminated. The crucial computational point is that it is not necessary to draw samples to make predictions; for regression problems, only linear algebra is required. Below we give more detail on this computation, discuss how to use GPs for classification problems, and describe how data can be used to adapt the covariance function to the given prediction problem.

Further discussion of Gaussian processes is available in Schölkopf and Smola (2001), MacKay (1998), and Williams (1998).

## Gaussian Processes

### *Formal Definition*

A stochastic process is a collection of random variables $\{Y(\mathbf{x})|\mathbf{x} \in X\}$ indexed by a set $X$. In our case $X$ will often be $\mathbb{R}^d$, where $d$ is the number of inputs. The stochastic process is specified by giving the joint probability distribution for every finite subset of variables $Y(\mathbf{x}_1), \ldots, Y(\mathbf{x}_k)$ in a consistent manner. A Gaussian process (GP) is a stochastic process for which any finite set of $Y$-variables has a joint multivariate Gaussian distribution. A GP is fully specified by its mean function $\mu(\mathrm{x}) = E[Y(\mathbf{x})]$ and its covariance function $C(\mathbf{x}, \mathbf{x}') = E[(Y(\mathbf{x}) - \mu(\mathbf{x}))(Y(\mathbf{x}') - \mu(\mathbf{x}'))]$. For a multidimensional input space, a Gaussian process may also be called a Gaussian random field.

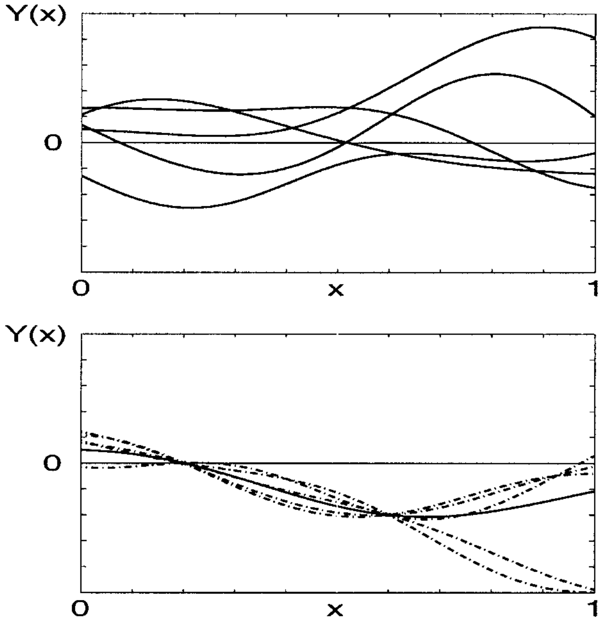

**Figure 1.** *Top*, Five samples from a Gaussian process prior. *Bottom*, Five samples from the Gaussian process posterior (shown as dot-dash lines) and the posterior mean (solid line), after observing the data points (0.2, 0) and (0.6, −1).

Below we consider Gaussian processes that have $\mu(\mathbf{x}) \equiv 0$. A non-zero $\mu(\mathbf{x})$ can be incorporated into the framework at the expense of a little extra complexity.

*Example: Bayesian linear regression.* Consider the model $y(x) = \sum_{i=1}^{m} w_i \phi_i(\mathbf{x}) = \mathbf{w}^T\boldsymbol{\phi}(\mathbf{x})$, where $\{\phi_i\}$ is a set of fixed basis functions and $\mathbf{w}$ is a vector of "weights." Let $\mathbf{w}$ have a Gaussian distribution with mean $\mathbf{0}$ and covariance $\Sigma$. Then $\mu(\mathbf{x}) = E[y(\mathbf{x})] = E[\mathbf{w}^T]\boldsymbol{\phi}(\mathbf{x}) = 0$ as $E[\mathbf{w}] = \mathbf{0}$. As the mean is zero we have that $C(\mathbf{x}, \mathbf{x}') = \boldsymbol{\phi}^T(\mathbf{x})E[\mathbf{w}\mathbf{w}^T]\boldsymbol{\phi}(\mathbf{x}') = \boldsymbol{\phi}^T(\mathbf{x})\Sigma\phi(\mathbf{x}')$. For example, using basis functions 1 and the components of $\mathbf{x}$ along with $\Sigma = I$ gives $C(\mathbf{x}, \mathbf{x}') = 1 + \mathbf{x}.\mathbf{x}'$.

In the case of a finite dimensional model we can make predictions using calculations in the parameter space (of dimension $m$), or a GP prediction (which is $n$-dimensional, where $n$ is the number of data points). For $m < n$ the parameter space method is preferable, but for many useful covariance functions (see, e.g., Equation 1) $m$ is infinite and the GP method is necessary.

### *Covariance Functions*

The only constraint on the covariance function is that it should generate a non-negative definite covariance matrix for any set of points in $X$. This gives wide scope, and different choices of $C(\mathbf{x}, \mathbf{x}')$ can give rise to such differing priors as straight lines of the form $y = w_0 + w_1x$ (as discussed above) to the very rough and jagged sample paths associated with a Wiener process (a model for Brownian motion) or an Ornstein-Uhlenbeck process.

One very common form of covariance function is the *stationary* covariance function, where $C(\mathbf{x}, \mathbf{x}')$ is a function of $\mathbf{x} - \mathbf{x}'$. The use of stationary covariance functions is appealing if one would like the predictions to be invariant under shifts of the origin in input space. For example, in one dimension letting $h = x - x'$, the covariance of the Ornstein-Uhlenbeck process is $C_{OU}(h) = v_0e^{-|h|/\lambda}$, where $v_0$ sets the overall variance of the process and $\lambda$ sets a length scale in the input space. Another example of a stationary covariance function is the "squared exponential" covariance function $C_{SE}(h) = v_0 \exp(-h^2/\lambda^2)$ (sometimes called the "Gaussian" covariance function).

One commonly-used covariance function for inputs in $\mathbb{R}^d$ is

$$C(\mathbf{x}, \mathbf{x}') = v_0 \exp\left\{-\sum_{l=1}^{d} \frac{(x_l - x_l')^2}{\lambda_l^2}\right\} \tag{1}$$

This is simply the product of $d$ squared-exponential covariance functions, but with different length scales on each dimension. The general form of the covariance function expresses the idea that cases with nearby inputs will have highly correlated outputs, and the $\lambda$ parameters allow a different distance measure for each input dimension. For irrelevant inputs, the corresponding $\lambda_l$ will become large, and the model will effectively ignore that input. This is closely related to the automatic relevance determination (ARD) idea of MacKay and Neal (Neal, 1996).

The term *kernel function* used in the support vector machines literature is broadly equivalent to the covariance function. Further information on kernel/covariance functions can be found in Schölkopf and Smola (2001, chaps. 4 and 13), MacKay (1998), Williams (1998), and references therein.

## Gaussian Processes for Regression Problems

In the previous section we discussed the properties of Gaussian processes. We now assume that we have input points $\mathbf{x}^n = \mathbf{x}_1, \ldots, \mathbf{x}_n$ and target values $\mathbf{t} = t_1, \ldots, t_n$ and wish to predict the function value $y_*$ corresponding to an input $\mathbf{x}_*$. We assume that the target values $t_i$ are obtained from the corresponding function value $y_i$ by means of additive Gaussian noise, i.e., $t_i = y_i + \varepsilon_i$ for $i = 1, \ldots, n$, where $\varepsilon_i$ is an independent zero-mean Gaussian random variable of variance $\sigma_v^2$. (The generalization to different variances at each location is straightforward, but notationally a bit more complex.) As the prior is a Gaussian process, the prior distribution over the $y_i$'s is given by $\mathbf{Y} \sim N(\mathbf{0}, K)$, where $K$ is the $n \times n$ covariance matrix with entries $K_{ij} = C(\mathbf{x}_i, \mathbf{x}_j)$. It is then easy to show that the prior distribution over the targets is $N(\mathbf{0}, K + \sigma_v^2 I_n)$ where $I_n$ is the $n \times n$ identity matrix.

To make a prediction for $y_*$ we now need to consider the $n + 1$-dimensional vector, which consists of the $n$ variables in $\mathbf{t}$ with the variable $y_*$ appended, and condition on $\mathbf{t}$ to obtain $P(y_*|\mathbf{t})$. As conditional distributions of jointly Gaussian variables are also Gaussian, it is clear that this distribution will be Gaussian, and our task is to compute the mean $\hat{y}(\mathbf{x}_*)$ and variance $\hat{\sigma}^2(\mathbf{x}_*)$. It turns out that

$$\hat{y}(\mathbf{x}_*) = \mathbf{k}^T(\mathbf{x}_*)(K + \sigma_v^2 I_n)^{-1}\mathbf{t} = \sum_{i=1}^{n} \alpha_i C(\mathbf{x}_i, \mathbf{x}_*) \tag{2}$$

$$\hat{\sigma}^2(\mathbf{x}_*) = C(\mathbf{x}_*, \mathbf{x}_*) - \mathbf{k}^T(\mathbf{x}_*)(K + \sigma_v^2 I_n)^{-1}\mathbf{k}(\mathbf{x}_*) \tag{3}$$

where $\mathbf{k}(\mathbf{x}_*)$ is the $n \times 1$ vector of covariances $(C(\mathbf{x}_1, \mathbf{x}_*), \ldots, C(\mathbf{x}_n, \mathbf{x}_*))^T$, and $\boldsymbol{\alpha} = (K + \sigma_v^2 I_n)^{-1}\mathbf{t}$. Unpacking Equation 2, we see that the prediction function $\hat{y}(\mathbf{x}_*)$ is a linear combination of the kernel functions $C(\mathbf{x}_i, \mathbf{x}_*)$, with coefficients given by the appropriate entries of the vector $\boldsymbol{\alpha}$.

Equations 2 and 3 require the inversion of an $n \times n$ matrix, which is in general an $O(n^3)$ operation. When $n$ is of the order of a few hundred, then this is quite feasible with modern computers. However, once $n \sim O(1000)$, these computations can be quite time-consuming, and much recent research effort has gone into developing approximation methods; see Tresp (2001) for a review. Note that in special cases (notably when the input space is $\mathbb{R}$ and for certain Markovian kernels), the necessary calculations can be carried out in linear time (see Wahba, 1990, for further details).

The use of Gaussian processes for regression problems has been studied extensively by Carl Rasmussen in (Rasmussen, 1996) and in his Ph.D. thesis (available at http://www.cs.utoronto.ca/~carl/). He carried out a careful comparison of the Bayesian treatment of Gaussian process regression with several other state-of-the-art methods on a number of problems and found that its performance is comparable to that of Bayesian neural networks as developed by Neal (1996), and consistently better than the other methods tested.

### *Adapting the Covariance Function*

Given a covariance function, it is straightforward to make predictions for new test points. However, in practical situations we are unlikely to know which covariance function to use. One option is to choose a parametric family of covariance functions (with a parameter vector $\boldsymbol{\theta}$) and then to search for parameters that give good predictions.

Adaptation of $\boldsymbol{\theta}$ is facilitated by the fact that the log likelihood $l = \log P(\mathbf{t}|\boldsymbol{\theta})$ can be calculated analytically as

$$l = -\tfrac{1}{2} \log \det(K + \sigma_v^2 I_n) - \tfrac{1}{2}\, \mathbf{t}^T(K + \sigma_v^2 I_n)^{-1}\mathbf{t} - \frac{n}{2} \log 2\pi \tag{4}$$

This is just the log likelihood of the vector $\mathbf{t}$ under a Gaussian with mean $\mathbf{0}$ and covariance $K + \sigma_v^2 I_n$. The evaluation of the likelihood and its partial derivatives with respect to the parameters takes time $O(n^3)$, unless special structure in the problem can be exploited. Given $l$ and its derivatives with respect to $\boldsymbol{\theta}$, it is straightforward to feed this information to an optimization package in order to obtain a local maximum of the likelihood.

One can also combine $P(\mathbf{t}|\boldsymbol{\theta})$ with a prior $P(\boldsymbol{\theta})$ to yield a Bayesian approach to the problem. Another approach to adapting $\boldsymbol{\theta}$ is to use the cross-validation (CV) or generalized cross-validation (GCV) methods, as discussed in Wahba (1990).

### *Relationship to Other Methods*

Prediction with Gaussian processes is certainly not a very recent topic; the basic theory goes back at least as far as the work of Wiener and Kolmogorov in the 1940s on time series. Gaussian process prediction is also well known in the geostatistics field (see Cressie, 1993), where it is known as "kriging," although this literature naturally has focused mostly on two- and three-dimensional input spaces.

As mentioned above, there is a close relationship between Bayesian approaches and regularization theory. This connection was described in Kimeldorf and Wahba (1970), and further details can be found in Wahba (1990), Poggio and Girosi (1990), and Generalization and Regularization in Nonlinear Learning Systems.

When the covariance function $C(\mathbf{x}, \mathbf{x}')$ depends only on $h = |\mathbf{x} - \mathbf{x}'|$, the predictor derived in Equation 2 has the form $\Sigma_i c_i C(|\mathbf{x} - \mathbf{x}_i|)$ and may be called a *radial basis function* (or RBF) network. This is one derivation of RBFs, which are described in more detail in Radial Basis Function Networks.

The Gaussian process approach adds a stochastic process view to the regularization viewpoint, giving us "error bars" on the prediction (Equation 3), an expression for $P(\mathbf{t}|\boldsymbol{\theta})$ and its derivatives, and allows us to use the Bayesian machinery for hierarchical models.

## Gaussian Processes for Classification Problems

Given training data and an input $\mathbf{x}$, the aim of a classifier is to predict the corresponding class label. This may be done by simply predicting a class label ("hard" classification), or by outputting an estimate of the posterior probabilities for each class $P(k|\mathbf{x})$ ("soft" classification), where $k = 1, \ldots C$ indexes the $C$ classes. Naturally, we require that $0 \le P(k|\mathbf{x}) \le 1$ for all $k$ and that $\Sigma_k P(k|\mathbf{x}) = 1$. A naive application of the regression method for Gaussian processes using, say, targets of 1 when an example of class $k$ is observed and 0 otherwise will not obey these constraints. Soft classification has the advantage that the posterior probability estimates can be used in a principled fashion with loss matrices, rejection thresholds, and so on.

For the two-class classification problem it is only necessary to represent $P(1|\mathbf{x})$, since $P(2|\mathbf{x}) = 1 - P(1|\mathbf{x})$. An easy way to ensure that the estimate $\pi(\mathbf{x})$ of $P(1|\mathbf{x})$ lies in [0, 1] is to obtain it by passing an unbounded value $y(\mathbf{x})$ through an appropriate function that has range [0, 1]. A common choice is the logistic function $\sigma(z) = 1/(1 + e^{-z})$ so that $\pi(\mathbf{x}) = \sigma(y(\mathbf{x}))$. The input $y(\mathbf{x})$ to the logistic function will be called the *activation*. In the simplest method of this kind, logistic regression, the activation is simply computed as a linear combination of the inputs, plus a bias, i.e., $y(\mathbf{x}) = \mathbf{w}^T\mathbf{x} + b$. Using a Gaussian process or other flexible methods allows $y(\mathbf{x})$ to be a nonlinear function of the inputs.

For the classification problem with more than two classes, a simple extension of this idea using the "softmax" function gives the predicted probability for class $k$ as

$$\pi(k|\mathbf{x}) = \frac{\exp\, y_k(\mathbf{x})}{\sum_m \exp\, y_m(\mathbf{x})} \qquad (5)$$

For the rest of this section we shall concentrate on the two-class problem; extension of the methods to the multiclass case is relatively straightforward.

Defining a Gaussian process prior over the activation $y(\mathbf{x})$ automatically induces a prior over $\pi(\mathbf{x})$. To make predictions for a test input $\mathbf{x}_*$ when using fixed parameters in the GP we would like to compute $\hat{\pi}_* = \int \pi_* P(\pi_*|\mathbf{t}, \boldsymbol{\theta}) d\pi_*$, which requires us to find $P(\pi_*|\mathbf{t}) = P(\pi(\mathbf{x}_*)|\mathbf{t})$ for a new input $\mathbf{x}_*$. This can be done by finding the distribution $P(y_*|\mathbf{t})$ ($y_*$ is the activation of $\pi_*$) as given by

$$P(y_*|\mathbf{t}) = \int P(y_*|\mathbf{y})P(\mathbf{y}|\mathbf{t})d\mathbf{y} = \frac{1}{P(t)}\int P(y_*|\mathbf{y})P(\mathbf{y})P(\mathbf{t}|\mathbf{y})d\mathbf{y} \qquad (6)$$

where $\mathbf{y} = (y_1, \ldots, y_n)$ denotes the activations corresponding to the data points. $P(\pi_*|\mathbf{t})$ can then be found from $P(y_*|\mathbf{t})$ using the appropriate Jacobian to transform the distribution. When $P(\mathbf{t}|\mathbf{y})$ is Gaussian, then the integral in Equation 6 can be computed exactly to yield Equations 2 and 3. However, the usual expression for $P(\mathbf{t}|\mathbf{y}) = \Pi_i P(t_i|y_i)$ and $P(t_i|y_i) = \pi_i$ if $t_i = 1$ and $P(t_i|y_i) = (1 - \pi_i)$ for $t_i = -1$ for classification data (where the $t$'s take on values of 1 or $-1$) means that the marginalization to obtain $P(y_*|\mathbf{t})$ is no longer analytically tractable. Faced with this problem, we can either use an analytic approximation to the integral in Equation 6 or use Monte Carlo methods to approximate it. These two approaches will be considered in turn.

First, we note that $P(y_*|\mathbf{t})$ is mediated through $P(\mathbf{y}|\mathbf{t})$ and that $P(y_*|\mathbf{y})$ is Gaussian, so that obtaining information about $P(\mathbf{y}|\mathbf{t})$ is the essential step. It is easy to find the maximum of this distribution by optimizing $\log P(\mathbf{y}) + \log P(\mathbf{t}|\mathbf{y})$ with respect to $\mathbf{y}$, e.g., with a Newton-Raphson iteration. It can be shown that the optimization problem is convex. This yields the *maximum a posteriori* estimator $\mathbf{y}^{MAP}$. We could build a classifier based on $\mathbf{y}^{MAP}$ by calculating $y^{MAP}(\mathbf{x}_*)$ as the mean of $P(y_*|\mathbf{y}^{MAP})$. This can then be fed through the logistic function to obtain an approximation to $\hat{\pi}_*$. This MAP solution is the one used in spline-smoothing approaches to classification (Wahba, 1990).

One can also make a Gaussian approximation to $P(\mathbf{y}|\mathbf{t})$ with mean $\mathbf{y}^{MAP}$ and inverse covariance matrix $-\nabla\nabla \log P(\mathbf{y}|\mathbf{t})$. This yields a Laplace approximation to the integral in Equation 6.

Neal (1998) has developed an MCMC method for the Gaussian process classification model. This works by generating samples from $P(\mathbf{y}|\mathbf{t})$ by updating each of the $n$ individual $y_i$'s sequentially using Gibbs sampling. This sampling process can be also be interleaved with sampling for the parameters $\boldsymbol{\theta}$. As with the regression problem, there has been much work on approximation schemes for large data sets; see Tresp (2001) for further details.

Classifiers using splines have been used extensively on a wide variety of problems, see Wahba (1990) and references in GENERALIZATION AND REGULARIZATION IN NONLINEAR LEARNING SYSTEMS. Gaussian process classifiers using MCMC sampling over $\boldsymbol{\theta}$ have been described in Williams and Barber (1998).

### *Relationship to Support Vector Machines*

We have seen that the *maximum a posteriori* solution $\mathbf{y}^{MAP}$ is obtained by minimizing $\Psi(\mathbf{y}) = -\log P(\mathbf{y}) - \log P(\mathbf{t}|\mathbf{y})$. This expression can be refined using $-\log P(\mathbf{t}|\mathbf{y}) = -\Sigma_i \log P(t_i|y_i)$ and $-\log P(t_i|y_i) = \log(1 + e^{-t_i y_i})$ to give

$$\Psi(\mathbf{y}) = \tfrac{1}{2}\, \mathbf{y}^T K^{-1}\mathbf{y} + \sum_i \log(1 + e^{-t_i y_i}) + c \qquad (7)$$

where $c$ is a constant independent of $\mathbf{y}$. The criterion optimized by the support vector machine (SVM) learning algorithm (Vapnik, 1995) is very similar, but with $g_{GP}(z) \overset{def}{=} \log(1 + e^{-z})$ replaced by $g_{SVM}(z) \overset{def}{=} [1 - z]_+$, where $[x]_+ = \max(x, 0)$. These are both monotonically decreasing functions of $z$, which are linear for $z \to -\infty$. They both decay to zero as $z \to \infty$, but the main difference is that the $g_{SVM}$ takes on the value 0 for $z > 1$, while $g_{GP}$ asymptotes to 0 as $z \to \infty$. The SVM optimization problem is convex, but inequality constraints mean that it is quadratic programming problem.

By replacing $g_{GP}$ with $g_{SVM}$ we obtain $y^{SVM}(\mathbf{x}_*)$ instead of $y^{MAP}(\mathbf{x}_*)$. To make a "hard" $(+1/-1)$ prediction, we simply take the predicted class label as $\mathrm{sgn}(y(\mathbf{x}_*))$. This is the SVM classifier. The effect of the flat region of $g_{SVM}$ is to introduce *sparsity* into the prediction of the corresponding $y^{SVM}(\mathbf{x}_*)$, where only those data points with $t_i y_i \leq 1$ contributing; these are known as the support patterns. Note that $g_{SVM}$ is not interpretable as a negative log likelihood as it does not normalize properly. For further discussion, see Wahba (1999) and SUPPORT VECTOR MACHINES.

## Discussion

In this article we have seen how Gaussian process priors over functions (which are in general infinite-dimensional objects) can be used in a computationally efficient manner to make predictions.

Methods such as Gaussian processes and support vector machines have come to be known by the umbrella term of *kernel machines* (see Schölkopf and Smola, 2001). The web site http://www.kernel-machines.org/ has extensive links to research publications and software in this area.

One key issue concerning obtaining good performance with kernel methods is the choice of kernel. The squared-exponential kernel is widely used in practice, but it encodes only a general notion of smoothness. For particular problems, incorporation of prior/domain knowledge requires "kernel engineering." A second key issue for kernel methods is developing good approximation algorithms for large data sets.

# Generalization and Regularization in Nonlinear Learning Systems

*Grace Wahba*

## Introduction

In this article we will describe generalization and regularization from the point of view of multivariate function estimation in a statistical context. Multivariate function estimation is not, in principle, distinguishable from supervised machine learning. However, until fairly recently, supervised machine learning and multivariate function estimation had fairly distinct groups of practitioners and little overlap in language, literature, and the kinds of practical problems under study.

In any case, we are given a *training set*, consisting of pairs of input (feature) vectors and associated outputs $\{\mathbf{t}(i), y_i\}$, for $n$ training or example subjects, $i = 1, \ldots, n$. From these data, it is desired to construct a map that *generalizes well*, that is, given a new value of $\mathbf{t}$, the map will provide a reasonable prediction for the unobserved output associated with this $\mathbf{t}$.

Most applications fall into one of two broad categories, which might be called nonparametric regression and classification. In *nonparametric regression, y* may be (any) real number or a vector of $r$ real numbers. The desired algorithm will produce an estimate $\hat{f}(\mathbf{t})$ of the expected value of a (new) $y$ to be associated with a (new) attribute vector $\mathbf{t}$. In the (two-class) *classification* problem, $y_i$ will be an indicator, whether or not the example (subject) came from class $\mathcal{A}$. In some classification applications, the desired algorithm will, given $\mathbf{t}$, return an indicator that predicts whether or not an example with attribute vector $\mathbf{t}$ comes from class $\mathcal{A}$ ("hard") classification. In other applications the desired algorithm will return $p(\mathbf{t})$, an estimate of the *probability* that the example with attribute vector $\mathbf{t}$ is in class $\mathcal{A}$ ("soft" classification). In some applications the feature vector $\mathbf{t}$ of dimension $d$ contains zeros and ones (for example, in a bitmap of handwriting); in others it may contain real numbers representing some physical quantities. Ordered or unordered category indicators are also possible, as in medical demographic studies. *Regularization*, loosely speaking, means that whereas the desired map is constructed to approximately send the observed feature vectors to the observed outputs, constraints are applied to the construction of the map, with the goal of reducing the generalization error (see also PROBABILISTIC REGULARIZATION METHODS FOR LOW-LEVEL VISION). In some applications, these constraints embody a priori information concerning the true relationship between input and output; alternatively, various ad hoc constraints have sometimes worked well in practice. Girosi, Jones, and Poggio (1995) give a wide-ranging review.

## Generalization and Regularization in Nonparametric Regression

### *Single-Input Spline Smoothing*

We will use Figure 1 to illustrate the ideas of generalization and regularization in the simplest possible nonparametric regression setup, that is, $d = 1$, $r = 1$, with $\mathbf{t} = t$ any real number in some interval of the real line. The circles (which are identical in each of the three panels of Figure 1) represent $n = 100$ (synthetically generated) input-output pairs $\{t(i), y_i\}$, generated according to the model

$$y_i = f_{TRUE}(t(i)) + \varepsilon_i, \quad i = 1, \ldots, n \tag{1}$$

where $f_{TRUE}(t) = 4.26(e^{-t} - 4e^{-2t} + 3e^{-3t})$, and the $\varepsilon_i$ came from a pseudo-random number generator for normally distributed random variables with mean 0 and standard deviation $\sigma = 0.2$. Given this training data $\{t(i), y_i, i = 1, \ldots, n\}$, the learning problem is to create a map that, if given a new value of $t$, will predict the response $y(t)$. In this case, the data are noisy, so that even if the new $t$ coincides with some predictor variable $t(i)$ in the training set, merely predicting $y$ as the response $y_i$ is not likely to be satisfactory. Also, this does not yet provide any ability to make predictions when $t$ does not exactly match any predictor values in the training set. It is desired to generate a curve that will allow a reasonable prediction of the response for any $t$ within a reasonable vicinity of the set of training predictors $\{t(i)\}$. The dashed line in each panel of Figure 1 is $f_{TRUE}(t)$; the three solid black lines in the three panels of Figure 1 are three solutions to the variational problem: find $f$ in the (Hilbert) space $W_2$ of functions with continuous first derivatives and square integrable second derivatives that minimizes

$$\frac{1}{n} \sum_{i=1}^{n} (y_i - f(t(i))^2 + \lambda \int (f^{(2)}(u))^2 du \tag{2}$$

for three different values of $\lambda$. The parameter $\lambda$ is known as the *regularization* or *smoothing parameter*. As $\lambda \to \infty$, $f_\lambda$ tends to the least squares straight line best fitting the data, and as $\lambda \to 0$ the solution tends to that curve in $W_2$ that minimizes the penalty functional $J(f) = \int (f^{(2)}(u))^2 du$ subject to interpolating the data (provided the $\{t(i)\}$ are distinct). This latter interpolating curve is known as a *cubic interpolating spline*, and minimizers of Equation 2 are known as *smoothing splines*. We remark that, here as well as in the sequel, although a variational problem is being solved in

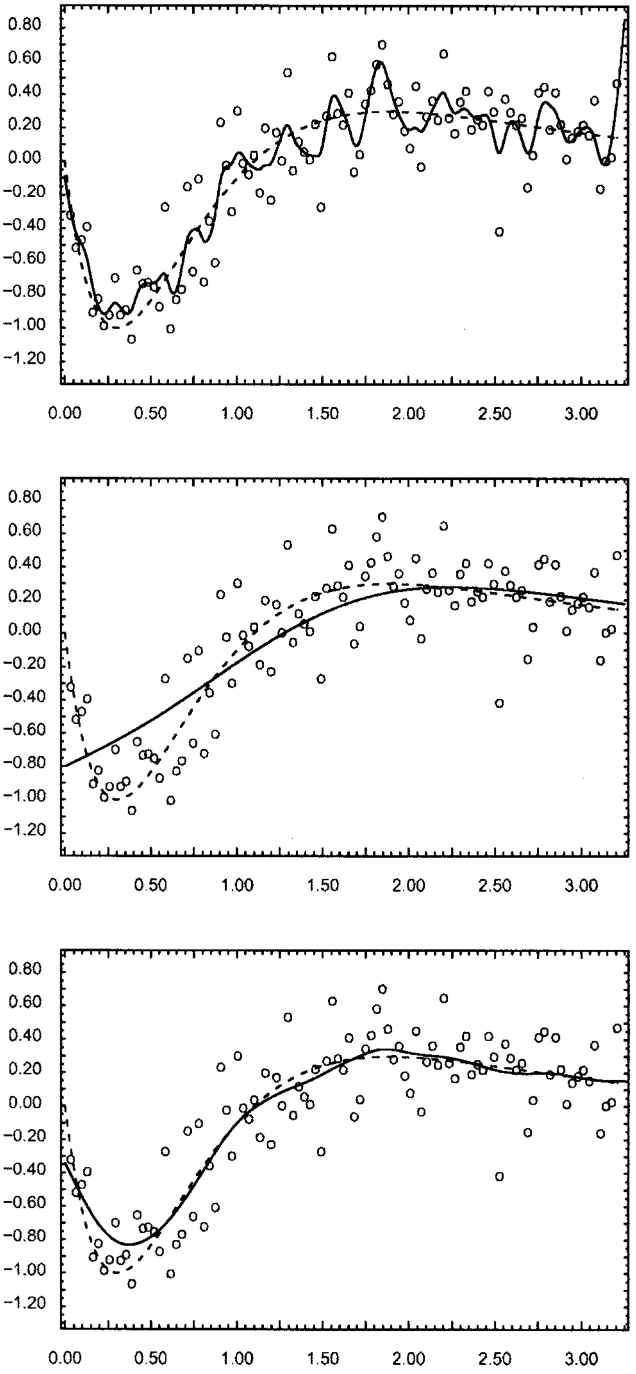

**Figure 1.** Training data (circles) have been generated by adding noise to $f_{TRUE}(t)$, shown by the dashed curve in each panel. All three panels have the same data. *Top*, Solid curve is fitted spline with $\lambda$ too small. *Middle*, Solid curve is fitted spline with $\lambda$ too large. *Bottom*, Solid curve is fitted spline with $\lambda$ obtained by generalized cross-validation.

an infinite dimensional Hilbert space, the solution is in an $n$-dimensional subspace with a known spanning set. (See Wahba, 1990, and references cited there for further information concerning these and other properties of splines, and further references.)

In the top panel of Figure 1 $\lambda$ has been chosen too small, and the wiggly solid line is attempting to fit the data too closely. It can be seen that using the wiggly curve in the top panel is not likely to give a good prediction of $y$, assuming that future predictor-response data are generated by the same mechanism as the training data. In the middle panel, $\lambda$ has been chosen too large; the curve has been forced to flatten out, and again it can be seen that the heavy line will not give a good prediction of $y$. In the bottom panel, $\lambda$ has been chosen by generalized cross-validation (GCV). This is a method that behaves similarly to leaving-out-one in many cases, but with computational and theoretical advantages (see Li, 1986; Wahba, 1990, chap. 4; Girard, 1998). It can be seen that the $\lambda$ obtained in this way does a good job of choosing the right amount of smoothing to best recover $f_{TRUE}$ of Equation 1. The $f_{TRUE}$ of Equation 1 would provide the best predictor of the response in an expected mean-square-error sense if future data were generated according to Equation 1. The curve in the bottom panel has a reasonable ability to *generalize*, that is, to predict the response given a new value $t$ of the predictor variable, at least if $t$ is not too far from the training predictor set $\{t(i)\}$.

For each positive $\lambda$, there exists a unique $\kappa = \kappa(\lambda)$ so that the minimizer $f_\lambda$ of Equation 2 is also the solution to the problem: Find $f$ in $W_2$ to minimize

$$L(y, f) = \frac{1}{n} \sum_{i=1}^{n} (y_i - f(t(i))^2 \tag{3}$$

subject to the condition

$$J(f) = \int (f^{(2)}(u))^2 du \leq \kappa \tag{4}$$

As $\lambda$ becomes large, the associated $\kappa(\lambda)$ becomes small, and conversely. In general, the term *regularization* refers to solving some problem involving best fitting, subject to some constraints on the solution. These constraints may be of various forms. When they involve a quadratic penalty involving derivatives, like $J(f)$, the method is commonly referred to as *Tikhonov regularization*. The "tighter" the constraints (i.e., the smaller $\kappa$, equivalently the larger $\lambda$), the further away the solution $f_\lambda$ will generally be from the training data; that is, $L$ will be larger. As the constraints get weaker and weaker, ultimately (if there are enough degrees of freedom in the method) the solution will interpolate the data. However, as is clear from Figure 1, a curve that runs through all the data points is *not* a good solution.

A fundamental problem in machine learning with noisy and/or incomplete data is to balance the "tightness" of the constraints with the "goodness of fit" to the data, in such a way as to minimize the generalization error, that is, the ability to predict the unobserved response for new values of $t$ (or $\mathbf{t}$). This trade-off is by now well known as the *bias-variance trade-off*, or, equivalently, the *goodness of fit–model complexity trade-off*. Methods abound in the statistical literature for univariate curve fitting, including Parzen kernel estimates, nearest neighbor estimates, orthogonal series estimates, least squares regression spline estimates, and, recently, wavelet estimates. Each method has one or more regularization parameters, whether they are kernel window widths, number of nearest neighbors included, number of terms in the orthogonal series expansion or regression basis, or factors or thresholds for shrinking or truncating wavelet coefficients, that control this trade-off. (See Ramsay and Silverman, 1997, and references therein.)

### *Multiple-Input, Single-Hidden-Layer Feedforward Neural Net*

A multiple-input, single-hidden-layer feedforward neural net (NN) predictor for the learning problem described in the Introduction is typically of the form

$$f_{NN}(\mathbf{t}) = \sigma_0\left(b_o + \sum_{j=1}^{N} w_j\sigma_h(\mathbf{a}_j'\mathbf{t}(i) + b_j)\right) \tag{5}$$

where the $\mathbf{a}_j$ and $\mathbf{t}$ are $d$-vectors. The function $\sigma_h$ is the so-called "activation function" of the hidden layer and $\sigma_0$ is the activation function for the output. $\sigma_h$ is generally a sigmoidal function, for example, $\sigma_h(\tau) = e^\tau/(1 + e^\tau)$, while $\sigma_0$ may be linear, sigmoidal or a threshold unit. Here $N$ is the number of hidden units, and the $w_j$, $\mathbf{a}_j$, and $b_j$ are "learned" from the training data by some appropriate iterative descent algorithm that tries to steer these values toward minimizing some distance measure, typically $L(y, f_{NN}) = (1/n)\Sigma_{i=1}^n(y_i - f_{NN}(\mathbf{t}(i)))^2$. It is clear that if $N$ is suffciently large and the descent algorithm is run long enough, it should be possible to drive the $L$ as close as one likes to zero. (In practice it is possible to get stuck in local minima.) However, it is also clear intuitively from Figure 1 that driving $L$ all the way to zero is not a desirable thing to do. Regularization in this problem may be done by controlling the size of $N$, by imposing penalties on the $w_j$, by stopping the descent algorithm early (that is, by not driving down $L$ as far as it can go), or by various combinations of these strategies. Each will influence how closely $f_{NN}$ will fit the data, how "wiggly" it will be, and how well it will be able to predict unobserved data that are generated by a similar mechanism as the observed data.

### *Multiple-Input Radial Basis Function and Related Estimates*

Radial basis functions are rapidly becoming a popular method for nonparametric regression (see RADIAL BASIS FUNCTION NETWORKS). We first describe a general form of nonparametric regression that will specialize to radial basis functions and other methods of interest. Let $R(\mathbf{s}, \mathbf{t})$ be *any* symmetric, strictly positive definite function on $E^d \times E^d$. Here, *strictly positive definite* means for any $K = 1, 2, \ldots,$ the $K \times K$ matrix with $j$, $k$th entry $R(\mathbf{s}(j), \mathbf{s}(k))$ is strictly positive definite whenever the $\mathbf{s}(1), \ldots, \mathbf{s}(K)$ are distinct. (A symmetric $K \times K$ matrix $M$ is said to be positive definite if for any $K$-dimensional column vector $x \neq 0$, $x'Mx$ is greater than or equal to 0, and is said to be strictly positive definite if $x'Mx$ is always strictly greater than 0.) Positive definiteness will play a key role in the discussion below because, among other reasons, any positive definite matrix can be the covariance matrix of a random vector and any positive definite function $R(\mathbf{s}, \mathbf{t})$ can be the covariance function of some stochastic process, $X(\mathbf{t})$. That is, there exists $X(\cdot)$ such that $Cov\, X(\mathbf{s})X(\mathbf{t}) = R(\mathbf{s}, \mathbf{t})$. Given training data $\{\mathbf{t}(i), y_i\}$, it is always possible in principle to obtain a (regularized) input-output map from this data by letting the model $f_{R,\lambda}$ be of the form

$$f_{R,\lambda}(\mathbf{t}) = \sum_{j=1}^{N} c_jR(\mathbf{t}, \mathbf{s}(j)) \tag{6}$$

where the $\mathbf{s}(j)$ are $N \leq n$ "centers" that are placed at distinct values of the $\{\mathbf{t}(i)\}$ and $c = (c_1, \ldots, c_N)'$ is chosen to minimize $L(y, f) + \lambda J(f)$. Here

$$L(y, f_{R,\lambda}) = \frac{1}{n}\sum_{i=1}^{n} (y_i - f_{R,\lambda}(\mathbf{t}(i))^2 \tag{7}$$

and the regularizing penalty $J(\cdot)$ is of the form

$$J(f_{R,\lambda}) = \sum_{j,k=1}^{N} c_jc_kJ_{jk} \tag{8}$$

where $J_{kj}$ are the entries of a non-negative definite quadratic form. The (strict) positive definiteness of $R$ guarantees that

$$L(y, f_{R,\lambda}) + \lambda J(f_{R,\lambda}) \tag{9}$$

always has a unique minimizer in $c$, for any non-negative $\lambda$. This follows by substituting Equation 6 into Equation 9, and using the fact that the columns of the $n \times N$ matrix with $i,j$ entry $R(\mathbf{t}(i), \mathbf{s}(j))$ are linearly independent since they are just $N$ columns of the $n \times n$ positive definite matrix with $i,j$ entry $R(\mathbf{t}(i), \mathbf{t}(j))$.

Radial basis function estimates are obtained for the special case where $R(\mathbf{s}, \mathbf{t})$ is of the special form

$$R(\mathbf{s}, \mathbf{t}) = r(\|W(\mathbf{s} - \mathbf{t})\|) \tag{10}$$

where $W$ is some linear transformation on $E^d$ and the norm is Euclidean distance. That is, $R(\mathbf{s}, \mathbf{t})$ depends only on some generalized distance in $E_d$ between $\mathbf{s}$ and $\mathbf{t}$. The regularization—that is, the effecting of the trade-off between goodness of fit to the data and "smoothness" of the solution—is performed by reducing $N$ and/or increasing $\lambda$. The choice of $W$ will also affect the "wiggliness" of $f_{R,\lambda}$ in the radial basis function case. Alternatively, a model can be obtained by choosing $N$ small and minimizing $L(y, f)$. In that case, $N$ and $W$ are the smoothing parameters.

In the special case $N = n$, $\mathbf{s}(i) = \mathbf{t}(i)$, the $f_{R,\lambda}$ can (for *any* positive definite $R$) be shown to be Bayes estimates (see Kimeldorf and Wahba, 1970; Wahba, 1990). Arguments can be given to show that if $n$ is large and $N < n$ is not too small, then they are good approximations to Bayes's estimates (see Wahba, 1990, chap. 7). In the special case $J_{i,j} = R(\mathbf{t}(i), \mathbf{t}(j))$, the Bayes model is easy to describe and we do it here; it is:

$$y_i = X(\mathbf{t}(i)) + \varepsilon_i \tag{11}$$

with $X(\mathbf{t})$ a zero-mean Gaussian process (see GAUSSIAN PROCESSES) with covariance $EX(\mathbf{s})X(\mathbf{t}) = bR(\mathbf{s}, \mathbf{t})$ and the $\varepsilon_i$ independent zero-mean Gaussian random variables with common variance $\sigma^2$, and independent of $X(\mathbf{t})$. In this case, the minimizer $f_{R,\lambda}$ of $L(y, f) + \lambda J(f)$, evaluated at $\mathbf{t}$, is the conditional expectation of $X(\mathbf{t})$, given $\mathrm{y}_1, \ldots, y_n$, provided that $\lambda$ is chosen as $\sigma^2/nb$. In general, pretending that one has a prior and computing the posterior mean or mode will have a regularizing effect. The preceding discussion extends to symmetric positive definite functions on *arbitrary* domains for $\mathbf{t}$, including those mentioned in the Introduction of this article.

Thin plate splines in $d$ variables (of order $m$) consist of radial basis functions plus polynomials of total degree less than $m$ in $d$ variables. ($2m - d > 0$ is required for technical reasons.) Letting $\mathbf{t} = (t_1, \ldots, t_d)$, the thin plate splines are minimizers (in an appropriate function space) of

$$\frac{1}{n}\sum_{i=1}^{n} (y_i - f(\mathbf{t}(i))^2 + \lambda \sum_{\alpha_1+\cdots+\alpha_d=m} \frac{m!}{\alpha_1! \cdots \alpha_d!}\int_{-\infty}^{\infty}\cdots\int_{-\infty}^{\infty} \times \left(\frac{\partial^m f}{\partial t_1^{\alpha_1}\cdots\partial t_d^{\alpha_d}}\right)^2 dt_1 \cdots dt_d \tag{12}$$

Setting $d = 1$, $m = 2$ gives the cubic spline case discussed earlier. Note that there is no penalty on polynomials of total degree less than $m$; the thin plate splines with a particular choice of $\lambda$ are Bayes estimates with an improper prior (that is, infinite variance) on the polynomials of total degree less than $m$ (see Wahba, 1990), and references cited therein).

Related variations on regularized estimates include additive smoothing splines, which are of the form

$$f(\mathbf{t}) = \mu + \sum_{\alpha=1}^{d} f_\alpha(t_\alpha) \tag{13}$$

where $\mu$ and the $f_\alpha$ are the solution to a variational problem of the form: Find $\mu$ and $f_1, \ldots, f_d$ in a certain function space to minimize

$$\frac{1}{n}\sum_{i=1}^{n} (y_i - f(\mathbf{t}(i))^2 + \sum_{\alpha=1}^{d} \lambda_\alpha J_\alpha(f_\alpha) \tag{14}$$

The $J_\alpha$ may be of the form of $J$ in Equation 4. Here, there is a *regularization parameter* for each component (see Hastie and Tibshirani, 1990; Wahba, 1990). These additive models generalize to smoothing spline analysis of variance (SS-ANOVA) models. In the SS-ANOVA models, interaction terms of the form $f_{\alpha\beta}(t_\alpha, t_\beta), f_{\alpha\beta\gamma}(t_\alpha, t_\beta, t_\gamma)$, etc., which satisfy side conditions making them uniquely determined, are added to the representation in Equation 13, and corresponding penalty terms with regularization parameters are added in Equation 14. The $f_\alpha$, etc., may be generalized to themselves, being radial basis functions. Behind these models are positive definite functions that are built up via tensor sums and products of positive definite functions (see Wahba, 1990; Wahba et al., 1995).

Regression spline ANOVA models may be obtained by setting the $f_\alpha, f_{\alpha\beta}$, etc. as linear combinations of a (relatively small) number of basis functions (usually splines). In this case the number of the basis functions is probably the most influential regularization parameter. These and similar methods again all have either explicit or implicit regularization parameters that govern the balance between the complexity of the model and the fit to the data—the bias-variance trade-off.

The usual criterion for the generalization error when the fit involves minimizing the observed residual sum of squares is the expected residual sum of squares for new data, $EL(y_{new}, f_\lambda) \equiv L(f_{TRUE}, f_\lambda) = (1/n)\Sigma_{i=1}^{n}(f_{TRUE}(\mathbf{t}(i)) - f_\lambda(\mathbf{t}(i)))^2$. Here the $y_{new}$ are new observations at the original $\mathbf{t}(i)$. Leaving out one, leaving out 10%, leaving out a one-third representative sample ("tuning set"), and GCV ("in-sample tuning") are popular methods for choosing the tuning parameters to minimize this criterion. Codes in Splus (smooth.spline()), SAS (tpspline), netlib (entire/gcv directory), Funfits (sreg, tps), R (smooth.Pspline, gss), and elsewhere are available for implementing the univariate spline, thin plate spline, and additive and interaction (ANOVA) splines with GCV to choose single or multiple smoothing parameters. Netlib (http://www.netlib.org/) and Funfits (http://www.cgd.ucar.edu/stats/software.shtml) are freeware. The smooth.Pspline code in R at http://www.r-project.org was used to generate Figure 1.

## Generalization and Regularization in Soft Classification

Soft classification is a natural goal in certain kinds of demographic medical studies. For example, suppose a large training set is available from a demographic study, consisting of observations $\{\mathbf{t}(i), y_i\}$, where $y_i$ is an indicator (1 or 0) of the presence or absence of some disease in subject $i$ at the end of the study and $\mathbf{t}(i)$ is a vector of values of risk factors for this subject at the beginning of the study. With this kind of data, it is frequently of interest to make a "soft" classification, that is, to estimate the *probability* $p(\mathbf{t})$ that a new subject with predictor vector $\mathbf{t}$ will contract the disease. A doctor, given this model, may advise new patients which risk factors are important for them to control to reduce the probability of their contracting the disease. A regularized (that is, "smooth") estimate for $p(\mathbf{t})$ is desirable. Regularized estimates can be obtained as follows. First, define

$$f(\mathbf{t}) = \log[p(\mathbf{t})/(1 - p(\mathbf{t}))] \qquad (15)$$

$f$ is known in the statistics literature as the log odds ratio, or logit. Then $p(\mathbf{t})$ is a sigmoidal function of $f(\mathbf{t})$; that is, $p(\mathbf{t}) = e^{f(\mathbf{t})}/(1 + e^{f(\mathbf{t})})$. We will get a regularized estimate for $f$. $L(y, f)$ of Equation 3 will be replaced by an expression more suitable for 0–1 data, by using the likelihood for these data. To describe the likelihood, note that if $y$ is a random variable with Prob$[y = 1] = p$ and Prob$[y = 0] = (1 - p)$, then the probability density (or likelihood) $P(y, p)$ for $y$, when $p$ is true, is just $P(y, p) = p^y (1 - p)^{(1-y)}$. This merely says $P(1, p) = p$ and $P(0, p) = (1 - p)$. Thus, the likelihood for $y_1, \ldots, y_n$ (assuming that the $y_i$ are independent) is

$$P(y_1, \ldots, y_n; p(\mathbf{t}(1), \ldots, p(\mathbf{t}(n)) = \prod_{i=1}^{n} p(\mathbf{t}(i))^{y_i}(1 - p(\mathbf{t}(i))^{(1-y_i)} \qquad (16)$$

Substituting $f$ for $p$ in Equation 16 and taking the negative logarithm gives the negative log likelihood $L(y, f)$ in terms of $f$:

$$-\log P(y_1, \ldots, y_n; f(\mathbf{t}(1), \ldots, f(\mathbf{t}(n)) \equiv nL(y, f) = \sum_{i=1}^{n} [\log(1 + e^{f(\mathbf{t}(i))}) - y_i f(\mathbf{t}(i))] \qquad (17)$$

It is natural for $L(y, f)$ to replace $L(y, f)$ in Equations 3, 7, and 14 when $y_i$ is restricted to 0 or 1, since $L(y, f_{TRUE})$ is (a multiple of) the negative log likelihood for $y$ generated by a model with Gaussian noise, as in Equation 1. A neural net implementation of soft classification would consist of finding $f_{NN}(\mathbf{t}) = \text{logit}p_{NN}(\mathbf{t})$ of the form of Equation 5 to minimize $L(y, f)$ of Equation 17. If $N$ is large enough, then, in principle, $f_{NN}$ may be driven so that $p_{NN}(\mathbf{t}(i))$ is close to 1 if $y_i$ is 1, and is close to 0 if $y_i$ is 0. Again, it is intuitively clear that this is not desirable. As before, a regularized or smooth $f_{NN}$ can be obtained by controlling $N$, penalizing the $w_i$, stopping the iterative fitting early, or some combination of these actions.

Penalized likelihood estimates of $f$ are obtained by minimizing $L(y, f) + J_\lambda(f)$, where $J_\lambda(f)$ is a penalty functional corresponding to those in Equations 2, 9, 12, or 14 and its generalizations. A popular definition for the generalization error is the (unobservable) comparative Kullback-Leibler distance of the estimate to the true probability distribution, which can be shown to be given by $EL(y_{new}, f_\lambda) = L(p_{TRUE}, f_\lambda)$. An estimate of $\lambda$ that minimizes this criterion can be obtained by withholding a representative subset $y_{[left-out]}$ of the training set and choosing $\lambda$ to minimize $L(y_{[left-out]}, f_\lambda)$. Leaving-out-one estimates are also possible but generally not feasible in this case. Generalized approximate cross-validation (GACV) is a feasible in-sample method of choosing $\lambda$; based on a leaving-out-one argument, it has been shown in simulation studies to provide a good estimate of the minimizer of $L(p_{TRUE}; f_\lambda)$ (see Wahba et al., 1999).

## Generalization and Regularization in Hard Classification

In the hard classification problem (here we will consider only two classes for simplicity), we are only interested in estimating whether an example with vector $\mathbf{t}$ is in class $\mathscr{A}$ or not. This is the typical situation in, for example, character recognition, voice recognition, and other situations where it is known that the $\mathbf{t}$'s from the two classes being examined are generally well separated. In that case (assuming, for simplicity, that the examples from the two classes are represented in the training set equally as is the future population of interest, and that costs of misclassification are the same for both classes), then the optimum classifier (to minimize the expected cost) would be $\mathscr{A}$ if $p(\mathbf{t})$ is greater than one-half, and not $\mathscr{A}$ otherwise. Equivalently, the same rule can be implemented by examining the sign of the logit $f(\mathbf{t})$. Here we are identifying $\mathscr{A}$ with the 1s, and optimum is with respect to minimizing the expected cost of future misclassification. Unfortunately, in general it is neither desirable nor feasible to estimate the logit $f$ directly by the methods described in the section on soft classification, because in the well-separated case, $f$ takes on values near ±∞, and solving the penalized likelihood problem of that section is likely to be unstable. Recently, Support Vector Machines (q.v.) have been shown to provide an excellent method for classification in this situation (see Burges, 1998).

The support vector machine (SVM) is implemented coding the $y_i$ as $\pm 1$ according as the $i$th example is in $\mathscr{A}$ or not. Given a positive definite function $R(\mathbf{s}, \mathbf{t})$, we find a function $f$ of the form $f(\mathbf{t}) = b + \Sigma_{i=1}^{n} c_i R(\mathbf{t}, \mathbf{t}(i))$ by finding $b$ and $c = (c_i, \ldots, c_n)$ to minimize

$$\frac{1}{n} \sum_{i=1}^{n} (1 - y_i f(\mathbf{t}(i)_+ + \lambda \sum_{i,j} c_i c_j R(\mathbf{t}(i), \mathbf{t}(j)) \qquad (18)$$

where $(\tau)_+ = \tau$ for $\tau > 0$ and 0 otherwise. Letting $f_\lambda$ be the minimizer of Equation 18, the classification algorithm is: for a new attribute vector $\mathbf{t}$, assign $\mathscr{A}$ if $f(\mathbf{t}) > 0$ and not $\mathscr{A}$ if $f(\mathbf{t}) < 0$. Lin (1999) has demonstrated the remarkable result that, under general circumstances with appropriately chosen $\lambda$, the SVM estimate $f_\lambda$ tends almost everywhere to either 1 or $-1$ and is an estimate of $\text{sign} f_{TRUE} \equiv \text{sign}(p_{TRUE} - 1/2)$, which is exactly what is needed to carry out the optimum classification algorithm. It is interesting to note that if the data $y_i$ in the penalized log likelihood estimate were recoded to $y_i = \pm 1$, then the $i$th term on the right of Equation 17 would become $\log(1 + e^{-y_i f(\mathbf{t}(i))})$, which is bounded below by $(\log 2)(1 - y_i f(\mathbf{t}(i)))_+$. A popular choice for $R(\mathbf{s}, \mathbf{t})$ is $R(\mathbf{s}, \mathbf{t}) = \exp -(1/\sigma^2)\|\mathbf{s} - \mathbf{t}\|^2$, where $\|\cdot\|$ is the Euclidean norm. In this choice of $R(\cdot, \cdot)$ the result may be sensitive to both $\sigma$ and $\lambda$. As before, the $\lambda$ and $\sigma$ may be chosen by leaving out a representative subset of the observations and choosing $\lambda$ and $\sigma$ to minimize some measure of the generalization error. Here the natural choice for generalization error would be the misclassification rate. A version of GACV for SVMs, again based on a leaving-out-one argument, may be used as an in-sample method for choosing $\lambda$ and $\sigma$ (see Wahba, Lin, and Zhang, 2000). The generalization error target for the GACV is $E(1/n)\Sigma_{i=1}^{n}(1 - y_{i\text{new}} f_\lambda(\mathbf{t}(i)))_+$. However, $(1/2)E(1/n)\Sigma_{i=1}^{n}(1 - y_{i\text{new}}\text{sign}[f_\lambda(\mathbf{t}(i))])_+$ is the expected misclassification rate, so that to the extent that $f_\lambda$ resembles sign $f_\lambda$, this criterion will be appropriate for the generalization error. There is a large literature on the multiclass case, generally involving repeated pairwise or one-versus-many comparisons. A multiclass SVM that deals with all classes simultaneously has recently been developed (Lee, Lin, and Wahba, 2001). This work also demonstrates how to modify the SVM to take into account nonrepresentative training sets and unequal misclassification costs.

## Choosing How Much to Regularize

At the time of this writing, it is a matter of lively debate and much research how to choose the various regularization parameters. Leaving out a large fraction of the training sample for this purpose and tuning the regularization parameter(s) to best predict the left-out data (according to whatever criterion of best prediction is adopted) is conceptually simple, defensible, and widely used (this is called out-of-sample tuning). Successively leaving-out-one, successively leaving-out-10%, and the in-sample methods GCV and GACV are all popular. (See also Ye, 1998, who discusses in-sample tuning methods related to GCV in the Gaussian case that allows comparisons across different regularized estimates.) In the normally distributed observational error case, if the standard deviation of the observational error ($\sigma$ in Equation 1) is known, then unbiased risk estimates become available (see Li, 1986; Wahba, 1990, and references therein). When there is a Bayesian model behind the regularization procedure, then maximum likelihood estimates may be derived (see Wahba, 1985), although in order for these and other Bayesian estimates to do a good job of minimizing the generalization error in practice, it is usually necessary that the priors on which they are based be realistic.

## Which Method Is Best?

Feedforward neural nets, radial basis functions, and various forms of splines all provide regularized or regularizable methods for estimating smooth functions of several variables, given a training set $\{\mathbf{t}(i), y_i\}$. Which approach is best? Unfortunately, there is no single answer to that question, nor is there likely to be one. The answer depends on the particular nature of the underlying but unknown "truth," the nature of any prior information that might be available about this truth, the nature of any noise in the data, the ability of the experimenter to choose the various smoothing or regularization parameters well, the size of the data set, the use to which the answer will be put, and the computational facilities available. From a mathematical point of view, the classes of functions well approximated by neural nets, radial basis functions, and additive and interaction splines (ANOVA splines) are not the same, although all of these methods have the capability of approximating large classes of functions. Of course, if a large enough data set is available, models utilizing all of these approaches can be built, tuned, and compared on data that have been set aside for this purpose. In-sample tuning methods for comparison across different regularized estimates in the hard and soft classification contexts are an area of active research.

# GENESIS Simulation System

*James M. Bower, David Beeman, and Michael Hucka*

## Introduction

GENESIS (the GEneral NEural SImulation System) was developed as a research tool to provide a standard and flexible means for constructing structurally realistic models of biological neural systems. "Structurally realistic" simulations are computer-based implementations of models whose primary objective is to capture what is known of the anatomical structure and physiological characteristics of the neural system of interest. The GENESIS project is based on the belief that progress in understanding structure-function relationships in the nervous system specifically, or in biology in general, will increasingly require the development and use of structurally realistic models (Bower, 1995). It is our view that only through this type of modeling will general principles of neural or biological function emerge.

There is considerable debate within the computational neuroscience community concerning the appropriate level of modeling. As illustrated in other articles in the *Handbook*, many modeling efforts are currently focused on abstract "general" representations of neural function rather than on detailed, realistic models. However, the history of science clearly indicates that realistic models play an essential role in the development of quantitative understanding of physical systems. For example, philosophers and priests for thousands of years invented "models" to account for the motion of the planets in the night sky. These models, the most famous of which is probably the Ptolemeic system, "replicated the data" and made quantitative predictions. The structure of these planetary models, however, already assumed the general principles on which the universe was organized. It was not until the sixteenth and seventeenth centuries, when Kepler and, later, Newton constructed realistic models of the solar system, that general principles such as universal gravitation emerged. The inverse square law for gravitational attraction fell out of a model that Newton constructed of the moon's movement around Earth; it was not an apple-induced inspiration.

It is our view that neuroscience is not yet ready for its Newton. Instead, we are still in need of Kepler. Viewed most generally, GENESIS is intended to provide a framework for quantifying the physical description of the nervous system in a way that promotes common understanding of its physical structure. At the same time, this physical description also provides the base for simulations intent on understanding fundamental relationships between the structure of the brain and its measurable behavior. Again, looking back at the evolution of planetary science, Kepler's realization that the motion of the planets was elliptical came about as a result of his careful analysis of the detailed positions of the planets obtained by Tycho Brahe. Kepler's development of a mathematical formalism to describe elliptical motion provided a seminal framework for the work of later physicists, including Newton. Similarly, it is our hope and expectation that the formalism being developed within the GENESIS project and other simulation systems such as NEURON (see NEURON SIMULATION ENVIRONMENT) will provide a means for neurobiologists to collaboratively construct a physical description of the nervous system. We believe strongly that general principles of organization, function, and computation will only emerge once this description has been constructed.

GENESIS was designed from the beginning to allow the development of simulations at any level of complexity, from subcellular components and biochemical reactions to whole cells, networks of cells and systems-level models. The earliest GENESIS simulations were biologically realistic large-scale simulations of cortical networks (Wilson and Bower, 1992). The De Schutter and Bower (1994a, 1994b) cerebellar Purkinje cell model is typical of a large, detailed single-cell model, with 4,550 compartments and 8,021 ionic conductances. GENESIS is now being used for large systems-level models of cerebellar pathways (Stricanne, Morissette, and Bower, 1998), and, at the other extreme, is increasingly being used to relate cellular and network properties to biochemical signaling pathways (Bhalla and Iyengar, 1999).

Although GENESIS continues to be widely used for single-cell modeling and for modeling small networks (see, e.g., HALF-CENTER OSCILLATORS UNDERLYING RHYTHMIC MOVEMENTS), we have seen a dramatic increase in the number of publications that report using GENESIS for large network models. We believe that this trend is largely due to the availability of our libraries of ion channels and complete cell models. A description of some notable large-scale network GENESIS simulations (many using parallel computers) that have been published recently can be found at http://www.genesis-sim.org/GENESIS/research/genres.html. This web page also contains links to a list of 170 papers based on research with GENESIS from groups outside of Caltech, and a summary of what various research groups are doing with GENESIS.

GENESIS is implemented in C, using the X Window System, and runs under most varieties of Unix, including Linux. There is also a parallel version of GENESIS (called PGENESIS) that runs on workstation networks, small-scale parallel computers, and large, massively parallel supercomputers. PGENESIS is being used for simulations that must be run many times independently (e.g., parameter searches), and for large-scale models (especially network models with thousands of neurons).

## The GENESIS Design Philosophy

The objectives of this project were to reduce redundant software design efforts, establish standards for simulation technology, and provide a common base for the exchange of models and scientific information. The object-oriented nature of the software allows different modelers to easily exchange and reuse whole models or model components. GENESIS also includes a customizable user interface for use by modelers and educators. From the beginning, GENESIS was also designed to serve as an instructional tool, because our involvement in several educational projects had demonstrated that simulations could provide flexible and dynamic learning tools for neuroscience education (Bower and Beeman, 1998).

The design of the GENESIS simulator and interface is based on a building-block approach. Simulations are constructed from modules that receive inputs, perform calculations on them, and then generate outputs. Model neurons are constructed from these basic components, such as compartments (short sections of cellular membrane) and variable conductance ion channels. Compartments are linked to their channels and are then linked together to form multi-compartmental neurons of any desired level of complexity. Neurons may be linked together to form neural circuits. This object-oriented approach is central to the generality and flexibility of the system, as it allows modelers to easily exchange and reuse models or model components. In addition, it makes it possible to extend the functionality of GENESIS by adding new commands or simulation components to the simulator, without having to modify the GENESIS base code.

Neural systems are particularly amenable to this object-oriented approach because they typically consist of discrete components interacting in quite stereotyped ways, and because the different simulations tend to use similar neural components, display routines, numerical integration routines, and the like. This modularity means that it is possible to quickly construct a new simulation or to modify an existing simulation by changing modules that are chosen from a library or database of standard simulation components. Individual modules or linked assemblies of modules (such as compartments with channels, entire cells, or networks of cells) can be easily replicated.

## Interacting with GENESIS

GENESIS uses a high-level simulation language to construct neurons and their networks. Commands may be issued either interactively to a command prompt, by use of simulation scripts, or through the graphical interface. A particular simulation is set up by writing a sequence of commands in the scripting language that creates the network itself and the graphical interface for a particular simulation. The scripting language and the modules are powerful enough that only a few lines of script are needed to specify a sophisticated simulation. The principal components of the simulation system and the various modes of interacting with GENESIS are shown in Figure 1.

The underlying level of the GENESIS user interface is the Script Language Interpreter (SLI). This is a command interpreter, similar to a Unix system shell, with an extensive set of commands related to building, monitoring, and controlling simulations. GENESIS simulation objects and graphical objects are linked together using the scripting language. The interpreter can read SLI commands either interactively from the keyboard (allowing interactive debugging, inspection, and control of the simulation) or from files containing simulation scripts.

The graphical user interface (GUI) is XODUS, the X-windows Output and Display Utility for Simulations. This provides a higher-level and user-friendly means for developing simulations and monitoring their execution. XODUS consists of a set of graphical objects that are the same as the computational modules from the user's point of view, except that they perform graphical functions. As with the computational modules, XODUS modules can be set up in any manner that the user chooses to display or enter data. Furthermore, the graphical modules can call functions from the script language, so that the full power of the SLI is available through the graphical interface. This makes it possible to interactively change simulation parameters in real time to directly observe the effects of parameter variations. For example, the mouse can be used to plant recording or injection electrodes into a graphical representation of the cell. In addition to provisions for plotting the usual quantities of interest (membrane potentials, channel conductances, and so forth), XODUS has visualization features that permit such choices as using color to display the propagation of action potentials or other variables throughout a multicompartmental model, or to display connections and cell activity in a network model.

The GENESIS simulation engine (see Figure 1) consists of the simulator base code that provides the common control and support routines for the system, including those for input/output and for the numerical solution of the differential equations obeyed by the various neural simulation objects. GENESIS provides a choice of numerical integration methods, including highly accurate and stable implicit methods such as the Crank-Nicholson method (De Schutter and Beeman, 1998).

In addition to receiving commands from the SLI and the GUI, the simulation engine can construct simulations using information from data files and from the precompiled GENESIS object libraries. For example, the GENESIS "cell reader" allows one to build complex model neurons by reading their specifications from a data file instead of from a lengthy series of GENESIS commands delivered to the SLI. Similarly, network connection specifications may be read from a data file with the "fileconnect" command.

The GENESIS object libraries contain the building blocks from which many different simulations can be constructed. These in-

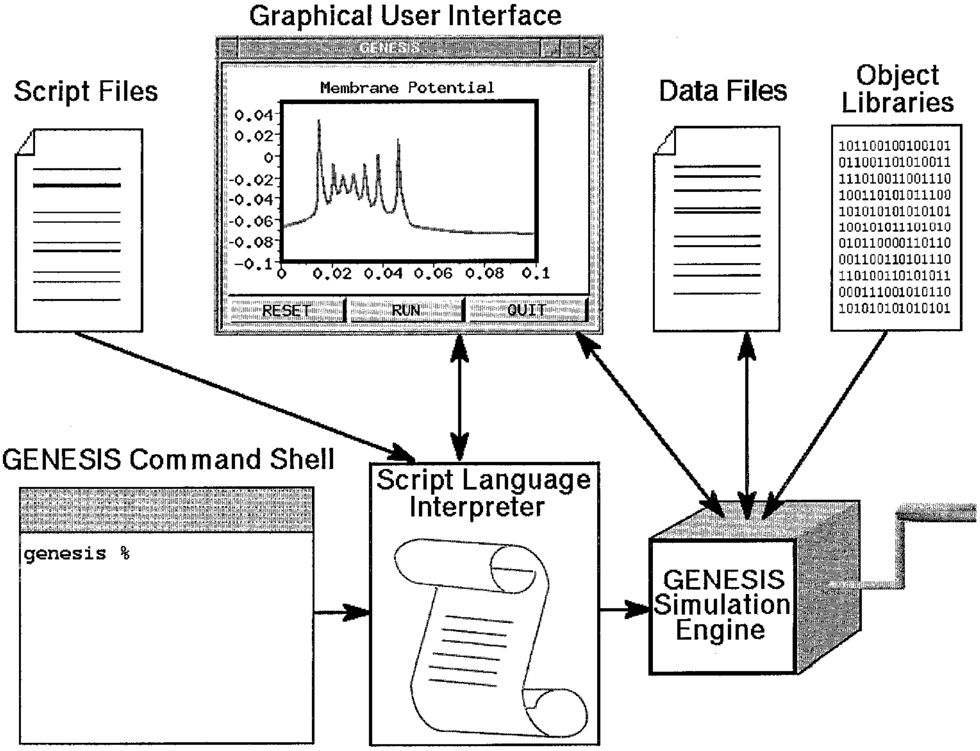

**Figure 1.** The components of GENESIS and modes of interaction. The Script Language Interpreter processes commands entered through the keyboard, script files, or the graphical user interface, and passes them to the GENESIS simulation engine. The simulation engine also loads compiled object libraries, reads and writes data files, and interacts with the GUI.

clude the spherical and cylindrical compartments from which the physical structure of neurons are constructed, voltage- and/or concentration-activated channels, dendrodendritic channels, and synaptically activated channels with synapses of several types, including Hebbian and facilitating synapses. In addition, there are objects for computing intracellular ionic concentrations from channel currents, for modeling the diffusion of ions within cells, and for allowing ligand gating of ion channels. There are also a number of "device objects" that may be interfaced to the simulation to provide various types of input to the simulation (e.g., pulse and spike generators, voltage clamp circuitry) or measurements (e.g., peristimulus and interspike interval histograms, spike frequency measurements, auto- and cross-correlation histograms).

The kinetics library supports kinetic-level modeling of biochemical pathways. This library currently includes objects for pools (molecular components), *n*-molecular reactions, enzymes, and channels to couple pools of different volume. The parameter search library provides a collection of objects and functions that automate the tedious process of adjusting model parameters to best reproduce experimental measurements carried out on the system being modeled.

## GENESIS Script Libraries and Tools

In addition to the object libraries that are compiled into GENESIS, there are a number of libraries that are implemented as simulation scripts. These are available within the GENESIS distribution and in the archives of the GENESIS users group.

The channel library currently contains models for 39 different types of potassium channels (including several types of calcium-dependent channels), 24 types of sodium channels, and 14 types of calcium channels. The available single-cell models include cerebral cortical pyramidal cells, hippocampal pyramidal cells, cerebellar Purkinje cells, mitral, granule, and tufted cells from the olfactory bulb, a hippocampal granule cell model, a thalamic relay cell, and an *Aplysia* R15 bursting pacemaker cell.

GENESIS makes use of the GUI to provide other features to make the simulator more easily usable by people with limited programming experience. A set of kits, implemented as simulation scripts, has been provided to ease the modeling process. Neurokit provides an environment for building, modifying, and testing single-cell models without any programming on the part of the user. Kinetikit is a user-friendly, click-and-drag interface for modeling models of chemical reactions such as occur in biochemical signaling pathways. In addition to defining and running kinetic models, it is intended to facilitate managing kinetic data in these complex models (Bhalla, 1998; Bhalla and Iyengar, 1999).

## GENESIS Documentation and Resources

GENESIS comes with extensive documentation. The GENESIS reference manual comes in three forms: a 566-page manual in Postscript format, and corresponding on-line help available either as plain text files viewable within the simulator or as hypertext help, which can be viewed with a web browser.

To complement the reference manual, we have published two editions of *The Book of GENESIS*. The most recent edition (Bower and Beeman, 1998) contains a CD-ROM with the GENESIS distribution, documentation, and files from the users group archives. It is widely used in both research and teaching, and consists of two parts serving complementary needs. Part I is designed to supplement instruction in neurobiology in upper division undergraduate and graduate neuroscience courses and includes chapters on various topics, each written by a known expert, to accompany a particular GENESIS tutorial. These interactive tutorial simulations are user-friendly, with on-line help, and may be used without any prior knowledge of the GENESIS simulator or computer programming. Part II serves as a user's guide to GENESIS, complementing the GENESIS reference manual, by introducing the basic features of GENESIS as well as the process of creating GENESIS simulations, providing a starting point for the development of new simulations. (For further details, please see http://www.genesis-sim.org/GENESIS/bog/bog.html.)

The tutorials mentioned above are included in the GENESIS distribution, along with other tutorials and demonstrations designed to aid new users in building GENESIS simulations. These illustrate the use of advanced GENESIS features, including objects for modeling calcium diffusion; objects for spike analysis, recording, and generation; the use of facilitating and Hebbian synapses; objects for modeling stochastic ion channels; and the parameter search library. Several of the tutorials are based on significant published research simulations, including the piriform cortex model (Wilson and Bower, 1992), the hippocampal pyramidal cell model (Traub et al., 1991), and the detailed cerebellar Purkinje cell model (De Schutter and Bower, 1994a, 1994b). In addition to their educational purpose, these tutorial simulations provide examples of well-constructed GENESIS simulations, and they have been used by others as the basis for the construction of new published research simulations.

Individuals or research groups who make serious use of GENESIS are encouraged to join the GENESIS users group, BABEL. There are currently 347 BABEL memberships, representing approximately 700 users. Members of BABEL are entitled to access the BABEL directories and participate in the e-mail newsgroup. The directories are used as a repository for the latest contributions by GENESIS users and developers. Such contributions include new simulations, libraries of cells and channels, additional simulator components, new documentation and tutorials, bug reports and fixes, and the posting of questions and hints for setting up GENESIS simulations. As the results of GENESIS research simulations are published, many of these simulations are being made available through BABEL.

## Use of GENESIS in Education

From its inception, GENESIS has had a strong educational component. We are currently aware of 49 institutions in 11 countries that have used GENESIS in teaching. Many of these institutions use GENESIS in association with *The Book of GENESIS* (Bower and Beeman, 1998).

GENESIS and the tutorials described in the previous sections are now being widely used in graduate and undergraduate instruction. Instructional options include full-semester courses in computational neuroscience or neural modeling, short intensive courses or workshops, course projects, and short units on computational neuroscience within courses on artificial neural nets. An example of the use of GENESIS tutorials as the basis for a short unit on neural modeling is available on the GENESIS web site as an HTML version of two lectures given at the University of Colorado.

GENESIS has also formed the basis for the laboratory section of the Methods in Computational Neuroscience course (1988–1996) at the Marine Biological Laboratory, a course in Mexico City in the summer of 1991, the Crete course in Computational Neuroscience (1996–1998), the EU Advanced Course in Computational Neuroscience (1999–2002), and the Computational Neuroscience course at the National Centre for Biological Sciences in Bangalore (1999–2000).

## Discussion

In the many years since the GENESIS project began at Caltech, its development has spread to many other institutions, including the

University of Texas at San Antonio, the University of Antwerp, the National Centre for Biological Studies in Bangalore, the University of Colorado, the Pittsburgh Supercomputer Center, the San Diego Supercomputer Center, and Emory University. In addition, the tools available for GUIs and the decentralization of computational resources as a result of widespread use of the World Wide Web have dramatically changed the environment for computer-based education and research. In a collaborative effort involving many institutions, we are currently redesigning and reimplementing GENESIS in order to modernize the user interface and link the process of modeling with on-line databases of models and model components. Our efforts are taking place in the context of a new software framework called the Modeler's Workspace (Forss et al., 1999; Hucka et al., 2002) and a simulator-independent representation of neural models called NeuroML (Goddard et al., 2001).

Further information about GENESIS and PGENESIS, as well as instructions for downloading and installation, may be obtained from the GENESIS web site, http://www.genesis-sim.org/GENESIS/. Inquiries concerning GENESIS should be addressed to genesis@genesis-sim.org.

# Geometrical Principles in Motor Control

*Ferdinando A. Mussa-Ivaldi*

## Introduction

The central role played by geometry in the control of motor behaviors was recognized in the early years of the last century by Nikolai Bernstein. Using only the tool of logical reasoning applied to common observations, Bernstein reached the conclusion that "there exist in the higher levels of the CNS projections of space, and not projections of joint and muscles" (Bernstein, 1967). This intuition led others to consider motor planning and execution as separate processes.

The transition from the spatial representation of a motor goal to a set of neuromuscular commands is in many respects similar to a *coordinate transformation*. This analogy is the perspective of this article. We will begin by describing three types of coordinate systems, each one representing a particular point of view on motor behavior. Then, we will examine the geometrical rules that govern the transformations between these classes of coordinates. Finally, we will see how a proper representation of dynamics may greatly simplify the transformation of motor plans into actions.

## Coordinate Systems for Motor Control

### Endpoint Coordinates

Consider a monkey in the act of reaching for an apple with a wooden stick. The free extremity of the stick is the site at which the monkey interacts with its environment. We call such a site an *endpoint*. The position of the stick is fully determined by six coordinates. This is the smallest set of numbers needed to specify unambiguously the location and orientation of a rigid object in 3D space. The coordinates of the stick can be measured with respect to three orthogonal axes originating, for example, from the monkey's shoulder.

In our example a position in endpoint coordinates is a point

$$r = (x, y, z, \theta_X, \theta_Y, \theta_Z)$$

The coordinates, $x$, $y$, and $z$ determine a translation with respect to the orthogonal axes. The angular coordinates, $\theta_X$, $\theta_Y$, and $\theta_Z$, determine an orientation with respect to the same axes. Consistent with this notation, a *force* in endpoint coordinates is a vector with three linear and three angular components:

$$F = (F_X, F_Y, F_Z, \tau_X, \tau_Y, \tau_Z)$$

### Generalized Coordinates

A different way of describing the position of the monkey's arm is to provide the set of joint angles that define the orientation of each skeletal segment either with respect to fixed axes in space or with respect to the neighboring segments. Joint angles are a particular instance of *generalized coordinates*. According to the standard definitions of analytical mechanics, generalized coordinates are independent variables that are suitable for describing the dynamics of a system (Goldstein, 1980).

Once a set of generalized coordinates has been defined, one may also define a *generalized force*. For example, if one uses joint angles as generalized coordinates, the corresponding generalized forces are the torques measured at each joint. The dynamics of a mechanical system are described by differential equations relating the generalized coordinates to their first and second time derivatives and to the generalized forces.

In vector notation, the dynamics equations for the skeletal system of the monkey's arm can be written as

$$I(q)\ddot{q} + G(q, \dot{q}) = C(q, \dot{q}, u(t)) \quad (1)$$

where $q = (q_1, q_2, \ldots, q_N)$ is the arm configuration in joint-angle coordinates, $\dot{q}$ and $\ddot{q}$ are, respectively, the first (velocity) and second (acceleration) time derivatives of $q$, $I$ is an $N \times N$ matrix of inertia (that is configuration dependent) and $G(q, \dot{q})$ is a vector of centripetal and Coriolis torques (Sciavicco and Siciliano, 2000). The whole left-hand side of Equation 1 represents the torque due to the inertial properties of the arm. The term $C(\cdot)$ stands for the net torque generated nonlinearly by the muscles, by the environment (e.g., the gravitational torque), and by other dissipative elements, such as friction. The time-function $u(t)$ is a control vector—for example, a set of neural signals directed to the motoneurons or a representation of a desired limb position at time $t$ (Equilibrium Point Hypothesis). Equation 1 may be regarded as a reformulation of Newtons's law: $Ma = F$. The left side represents the passive dynamics associated with limb inertia. The right side is the applied force, which, in this case, is the output of a control process.

### Actuator Coordinates

Actuator coordinates afford the most direct representation for the motor output of the central nervous system. A *position* in this coordinate system may be, for example, a collection of muscle lengths, $l = (l_1, l_2, \ldots, l_M)$. Accordingly, a force in the same coordinate system is a collection of muscle tensions, $f = (f_1, f_2, \ldots, f_M)$. The number of actuator coordinates depends on the level of detail of the model of control under consideration. *Unlike generalized coordinates, actuator coordinates do not constitute a system of mechanically independent variables*: one cannot set arbitrary values to $l_i$ without eventually violating some kinematic constraint.

## The Workspace and Its Transformations

Both the transformations from generalized coordinates to endpoint coordinates, and from generalized coordinates to actuator coordinates, are, in general, nonlinear mappings. In the case of the monkey's arm, the transformation from joint to hand coordinates is a nonlinear function

$$r = L(q) \quad (2)$$

where $r$ indicates the position of the hand in endpoint coordinates and $q$ is the joint configuration. The transformation from joint to muscle coordinates is another nonlinear mapping

$$l = M(q) \quad (3)$$

We deal briefly with transformations between the different representations of the workspace in the framework of differential geometry. A modern tutorial on this subject can be found in Jose and Saletan (1998).

### The Transformation of Vectors and Vector Fields

A function that associates a vector to each point of a multidimensional domain, $M$, is called a *vector field over M*. For example, one may rearrange the terms of the dynamics in Equation 1 so as to represent the arm's acceleration as a time-varying vector field over the state space described by $q$ and $\dot{q}$:

$$\ddot{q} = I^{-1}(q)[C(q, \dot{q}, u(t)) - G(q, \dot{q})] \quad (5)$$

Another vector field describes the viscoelastic behavior of the arm muscles. This behavior can be measured by stimulating each muscle and recording the resulting tension at different muscle length rates of shortening and times. Then, the collective mechanical output of the skeletomotor system is summarized by a force field in muscle coordinates

$$f = \alpha(l, \dot{l}, t) \quad (5)$$

Vector fields such as those expressed in Equations 4 and 5 determine the way in which a system reacts to its environment on one hand and to its control signals on the other. To investigate the transformation from planning to control of actions, we must understand how such mechanical fields are affected by a change of coordinates.

Let us begin by considering the laws that govern the transformation of a point from a set of coordinates, $x$, into a new set of coordinates, $\bar{x}$. The coordinate transformation is a nonlinear function

$$\bar{x} = T(x) \quad (6)$$

We assume this function to be continuous and sufficiently differentiable (the existence and continuity of second partial derivatives is enough for most practical purposes.) However, we do not require the existence of an inverse mapping, $x = T^{-1}(\bar{x})$. In many biologically relevant cases the two coordinate systems have different dimensions and the inverse mapping is not defined uniquely or does not exist at all.

Next, consider how a vector field is related to the corresponding vector field in the new coordinate system. Let us begin by considering a field of velocity vectors, $\dot{x} = v(x)$, and apply the chain rule:

$$\dot{\bar{x}} = \frac{d\bar{x}}{dt} = \frac{\partial \bar{x}}{\partial x} \cdot \dot{x}$$

As we are dealing with multivariate functions, the expression $\partial\bar{x}/\partial x$ represents the functional derivative, or *Jacobian* of the transformation $T$. The Jacobian is a position-dependent matrix, $J(x)$, whose elements are

$$[J(x)]_{i,j} = \frac{\partial \bar{x}_i}{\partial x_j}$$

and the transformation for the velocity vector can be rewritten as

$$\dot{\bar{x}} = J(x) \cdot \dot{x} \quad (7)$$

A vector that changes according to this law is said to be *contravariant*.

Does Equation 7 provide us with a rule for transforming the whole velocity field $v(x)$ into a new field $\bar{v}(\bar{x})$? The answer is generally negative. We may write $\dot{\bar{x}}$ as a function of $\bar{x}$:

$$\dot{\bar{x}} = J(T^{-1}(\bar{x}))v(T^{-1}(\bar{x})) = \bar{v}(\bar{x})$$

only if the mapping $T(x)$ can be inverted.

If a coordinate transformation cannot be inverted, we know how to transform a contravariant vector *at a given point* but we do not know how to transform a contravariant *field.*

The situation is quite different when dealing with vectors that in a change of coordinates transform like the gradient operator. Again, using the chain rule:

$$\frac{\partial}{\partial x} = \frac{\partial \bar{x}}{\partial x} \cdot \frac{\partial}{\partial \bar{x}}$$

that is,

$$\frac{\partial}{\partial x} = J^T(x) \cdot \frac{\partial}{\partial \bar{x}} \tag{8}$$

A vector following this type of transformation is said to be *covariant*. Note the dual or reciprocal nature of Equations 7 and 8. An infinitesimal displacement (or a velocity) is transformed by the Jacobian into the new coordinate system. The same Jacobian maps a covariant vector the other way around—from the new to the old coordinate system.

An example of a covariant vector is force, $F$. The covariance of force derives from the tensor invariance of work and power. *Work and power are indeed true scalar variables whose value is not modified by a change of coordinates.* In the original coordinate system, power is calculated as

$$F^T\dot{x}$$

and in the new coordinate system, as

$$\bar{F}^T\dot{\bar{x}}$$

By equating these two expressions and using Equation 7, we obtain

$$\bar{F}^T J(x)\dot{x} = F^T\dot{x}$$

Hence, the transformation of a force field, $\bar{F}(\bar{x})$, is

$$F(x) = J(x)^T\bar{F}(T(x)) \tag{9}$$

(compare with Equation 8).

Note that, here, the entire right side has been resolved in terms of $x$. We reach the important conclusion that unlike contravariant vectors, *covariant vectors transform globally, as fields*. No inverse transformation is required.

## Transforming Plans into Action

When we plan a movement such as "trace the shape of a circle with the left hand," we formulate the goal in terms of end point coordinates, without concern for the muscles that participate in the desired behavior. However, once we have decided to trace a circle, our brain must choose which muscles to activate and in which temporal sequence they should be activated. In carrying out this task, our brain must face the challenges associated with *kinematic redundancy*—the imbalance between the number of muscles, joints, and end point coordinates that is typical of any biological system. The issue of kinematic redundancy has attracted considerable attention both in robotics (Mussa-Ivaldi and Hogan, 1991) and in neural modeling (Hinton, 1984; Bullock, Grossberg, and Guenther, 1993).

The purpose of this section is to show how a proper representation of dynamics and of coordinate transformations leads to a simple solution for some problems associated with redundancy. The key for this solution lies in the representation of both the "high level" plans and the "low level" actuator actions as covariant fields of force.

## The Transformation of Dynamics

The dynamics of a limb (Equation 1) are expressed as an equilibrium condition between the field of generalized forces, $D(q, \dot{q}, \ddot{q})$, which represent passive elements such as limb inertia and the field of time-varying generalized forces, and $C(q, \dot{q}, t)$, which are generated by the neuromuscular controller:

$$D(q, \dot{q}, \ddot{q}) = C(q, \dot{q}, t) \tag{10}$$

We formulate the problem of executing a motor plan as the problem of deriving a control field, $C(q, \dot{q}, t)$, that generates a desired end point behavior. *This task is carried out as an approximation problem, after transforming the covariant fields corresponding to the planned behavior and to the neuromuscular mechanics into their corresponding images in generalized coordinates.*

The first step consists of expressing the motor plans as fields of force in endpoint coordinates:

$$F = \pi(r, \dot{r}, t) \tag{12}$$

For example, a reaching movement of the hand may be planned, as proposed by Flash and Hogan (1985), by specifying a time-varying field whose equilibrium point moves along a smooth trajectory (EQUILIBRIUM POINT HYPOTHESIS). Following a similar approach, the movements of a robotic arm in an obstacle-ridden environment can be efficiently planned by associating a field of repulsive forces to each obstacle and a field of attractive forces to the target location (POTENTIAL FIELDS AND NEURAL NETWORKS).

From our earlier consideration of vector fields, we may conclude that the planned field, $\pi(r, \dot{r}, t)$, has a unique image, $C_\pi(q, \dot{q}, t)$, in configuration space. *This is true regardless of kinematic redundancy.* The only condition for $C_\pi$ to be defined is that the kinematic transformation from generalized to endpoint coordinates be defined with its first partial derivatives. Operationally, we may construct $C_\pi$ as a combination of three mappings:

$$C_\pi = l_2 \circ \pi \circ l_1 : (q, \dot{q}, t) \overset{l_1}{\rightarrow} (r, \dot{r}, t) \overset{\pi}{\rightarrow} F \overset{l_2}{\rightarrow} Q$$

The first mapping, $l_1$, is the direct kinematics transformation ($q \rightarrow r$), its Jacobian ($q, \dot{q}, \dot{r}$), and the identity function ($t \rightarrow t$). The second mapping is the planned endpoint field, $\pi(r, \dot{r}, t)$. Finally, the third mapping, $l_2$, is the transformation from endpoint to generalized force, which, again, is provided by the Jacobian of the direct kinematics.

As an example, consider the planning of an endpoint behavior, corresponding to a moving equilibrium position, $r_E(t)$, with linear stiffness and viscosity (that is a linear PD controller in endpoint coordinates):

$$\pi(r, \dot{r}, t) = K(r - r_E(t)) + B\dot{r}$$

The image of this endpoint field in joint coordinates is

$$C_\pi(q, \dot{q}, t) = J^T(q)K(L(q) - r_E(t)) + J^T(q)BJ(q)\dot{q}$$

Note that $r_E(t)$ is a time-varying input function that does not require a measure of the actual hand position. This derivation applies to kinematically redundant limbs, as only the direct transformations, $L$ and $J$, are required.

On the other end of the planning/execution problem, one must deal with a number of actuators that, in any biological system exceeds the number of generalized coordinates. Microstimulation studies in frogs (Giszter, Mussa-Ivaldi, and Bizzi, 1993) and rats (Tresch and Bizzi, 1999) showed that the focal activation of interneuronal regions within the lumbar spinal cord impose a specific balance of muscle activations. This results in a force field

$$f = \alpha(l, \dot{l}, t) \sum_t \alpha_i \psi_i(l, \dot{l}, t) \tag{13}$$

This field has a well defined and measurable image in generalized coordinates, $\phi_\alpha(q, \dot{q}, t)$, which can be derived from the combination of three direct transformations:

$$\phi_\alpha = m_2 \circ \alpha \circ m_1 : (q, \dot{q}, t) \xrightarrow{m_1} (l, \dot{l}, t) \xrightarrow{\alpha} f \xrightarrow{m_2} Q$$

The first transformation, $m_1$, is the actuator kinematics ($M : q \to l$) together with its Jacobian ($q, \dot{q} \to \dot{l}$) and the identity mapping (t). The second transformation is the actuator force field, $\alpha(l, \dot{l}, t)$, and the third transformation, $m_2$, is again given by the Jacobian of $M$, $\mu(q) = \partial M(q)/\partial q$.

In generalized coordinates, the force field induced by a synergy of muscles is

$$\phi_\alpha(q, \dot{q}, t) = \sum_i \alpha_i \mu(q)^T \psi_i(M(q), \mu(q)\dot{q}, t)$$

Once again, this derivation of the synergy image in generalized coordinates remains valid for redundant limb because no inverse transformation is involved.

## Discussion

Microstimulation studies (Mussa-Ivaldi, Giszter, and Bizzi, 1994) as well as studies of reflex behaviors (Kargo and Giszter, 2000) have demonstrated that multiple muscle synergies can be combined by linear superposition to generate complex behaviors. In particular, Kargo and Giszter found that reflex responses to multiple cutaneous stimuli are accounted for by the linear superposition of the response fields triggered by each stimulus.

The finding of vector summation suggests that under descending supraspinal commands, the fields expressed by the spinal cord may form a broad repertoire:

$$\Gamma = \left\{ C_S(q, \dot{q}, t|c_\alpha) = \sum_\alpha c_\alpha \phi_\alpha(q, \dot{q}, t) \right\} \tag{14}$$

Each element of $\Gamma$ is generated by the descending commands selecting a group of synergies through the weighting coefficients, $c_\alpha$. Following this view, the neural control system may approximate a *target field* $C_\pi(q, \dot{q}, t)$ by finding the element of $\Gamma$ that is closest to the target field. The approximating field may be obtained by least squares methods, that is by determining a set of coefficients, $c_\alpha$, such that the norm

$$\|C_S(q, \dot{q}, t|c_\alpha) - C_\pi(q, \dot{q}, t)\|^2 \tag{15}$$

is at a minimum.

Field approximation has been directly applied to the generation of a desired trajectory, $q_D(t)$, in generalized coordinates (Mussa-Ivaldi and Bizzi, 2000). In this case, one may attempt to generate the appropriate controller by finding the parameters, $c_\alpha$, which minimize the difference between passive dynamics and control field in Equation 10 that is by minimizing

$$\|D(q, \dot{q}, \ddot{q}) - C_S(q, \dot{q}, t|c_\alpha)\|^2 \tag{16}$$

along the desired trajectory. Since the parameters, $c_\alpha$, appear linearly in $C_S$, this problem has a single global minimum at

$$c_\alpha = \sum_i [\Phi]^{-1}_{\alpha,i} \Lambda_i$$

with

$$\begin{cases} \Phi_{l,m} = \int \phi_l(q_D(t), \dot{q}_D(t), t) \cdot \phi_m(q_D(t), \dot{q}_D(t), t)dt \\ \Lambda_j = \int \phi_j(q_D(t), \dot{q}_D(t), t) \cdot D(q_D(t), \dot{q}_D(t), \ddot{q}(t))dt \end{cases} \tag{17}$$

The symbol · indicates the ordinary inner product.

The underlying idea of this method is that if the residual force error (16) could be reduced to zero, then the corresponding controller would produce exactly the desired trajectory. If, instead, there is a non-zero residual, then the problem of generating acceptable approximations becomes a problem of local stability: as residual forces may be regarded as a perturbation of the dynamics, one needs to insure that this perturbation does not lead to a motion that diverges from the desired trajectory. A study by Lohmiller and Slotine (1998) showed that the combination of control modules is stable if the modules are "contracting"—a condition germane to exponential stability.

If the modules corresponding to muscle synergies are stable, then the possibility of combining them provide the central nervous system with something equivalent to a movement's representation. The movements of a limb can be considered as "points" in an abstract geometrical space, where the force fields produced by a set of modules play a role equivalent to that of coordinate axes and the selection parameters that generate a particular movement may be regarded as generalized projections of this movement along these axes.

The theoretical view of motor control as a form of function approximation has found support in recent studies of adaptive learning. In a set of elegant experiments, Thoroughman and Shadmehr (2000) have asked subjects to execute movements of the hand against a field of perturbing forces. Subjects learned gradually to compensate these forces, thus recovering the normal kinematics of reaching movements. However, if the forces were suddenly suppressed during "catch trials," subjects showed a transient loss of learning that affected the following movements in variable amounts, depending on the angle between the movement in the catch trial and the following movement. Thorougman and Shadmehr were able to reproduce the process of adaptation as well as the subtle effects of catch trials by assuming that the motor control system composed a representation of the disturbing field as a linear superposition of Gaussian primitives. These primitives encode the force generated in response to a velocity, with a narrow variance parameter (approximately 10 cm/sec). The analysis of motor learning, together with the study of motor primitives in the spinal cord has provided us with a strong support for a theoretical view based on the idea that the central nervous system generate and update a broad spectrum of behaviors by combining elementary building blocks. The mathematical language of force fields and of their transformations is the proper framework for relating this computational mechanism to its observable mechanical effects.

# Global Visual Pattern Extraction

*Hugh R. Wilson and Frances Wilkinson*

## Introduction

Decades of research have established that visual pattern recognition begins with the extraction of local edge and contour information by orientation-selective simple cells in primary visual cortex (V1). At the highest levels of cortical form vision in inferior temporal cortex (IT), many neurons are sensitive to complex global patterns, including objects and faces (Desimone, 1991). This raises the key question "What processes occur at intervening stages of the form vision pathway to transform local V1 orientation information into global pattern representations?" It is known that the ventral form vision pathway includes at least areas V1, V2, V4, TEO, and TE (the highest level of IT), so there must be a sequence of transformations. Furthermore, mean receptive field size increases in diameter by roughly a factor of 2.5–2.7 from area to area in this processing hierarchy (Boussaoud, Desimone, and Ungerleider, 1991; Kobatake and Tanaka, 1994). Thus, a mean foveal receptive field diameter of about 0.4° in V1 is transformed into a mean of about 3.0° in V4 and about 15.0°–20.0° in TE. Clearly, such large receptive fields must be combining information from many V1 neurons, but what sorts of combinations actually occur?

Essentially the same question may be posed in cortical motion processing along the dorsal pathway comprising V1, V2, MT, MST, and higher parietal areas. V1 neurons extract only local motion vectors perpendicular to moving edge segments, while MST neurons are sensitive to complex optic flow patterns, including expansion and rotation (Tanaka and Saito, 1989). In the dorsal pathway, receptive field diameter also grows by a factor of 2.5–2.7 from area to area. Thus analogous questions are raised about transitions from local to global processing in both motion and form vision. This article suggests answers to these questions at intermediate levels of these two pathways, primarily V4 and MST.

## Global Processes in V4

Although primate V4 was originally believed to be a color vision area, more recent lesion studies have shown that it represents a major intermediate level of the cortical form vision system. Early physiological studies of V4 typically used the bar and grating stimuli that had proved so fruitful in elucidating orientation and spatial frequency selectivity in V1. Such stimuli, however, mainly revealed powerful end inhibition in V4. In a novel approach to V4, Gallant, Braun, and Van Essen (1993) used concentric, radial, and hyperbolic grating stimuli as well as conventional sinusoidal gratings. While many neurons responded well to all stimulus groups, two new groups were found: one responding optimally to concentric gratings and one responding optimally to radial or hyperbolic gratings. Very few neurons responded significantly better to conventional gratings than to the other classes. Using a very different approach, Kobatake and Tanaka (1994) also found that many V4 neurons were selective for concentric, radial, or cross-shaped stimuli.

In an attempt to relate these results to human form vision, it was natural to study Glass patterns, which can convey concentric (Figure 1), radial, and other structures. These patterns are normally generated by randomly placing dot pairs of fixed separation on the pattern such that the orientation defined by the pair is tangent to contours of the desired global pattern (e.g., concentric circles in Figure 1). By randomizing some percentage of the dots, the global structure conveyed by Glass patterns can be degraded. When psychophysical thresholds were measured in this manner, it was discovered that humans are most sensitive to concentric structure, somewhat less sensitive to radial or hyperbolic structure, and least

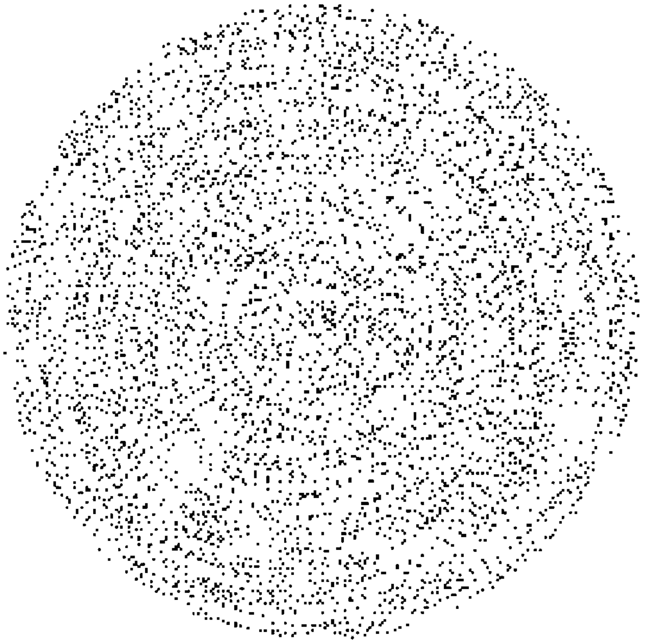

**Figure 1.** Concentric random dot Glass pattern. The global concentric structure in this pattern is produced by randomly positioning pairs of dots of fixed separation such that the orientation of the pair is locally tangent to a circle (not visible) concentric with the center of the pattern. Radial, hyperbolic, and parallel Glass patterns can be produced analogously.

sensitive to parallel or translational structure (Wilson, Wilkinson, and Asaad, 1997). Further experiments showed that the sensitivity to concentric structure resulted from linear pooling of concentric orientation information within an area estimated to be about 3.0°–4.0° in diameter. Similar results were obtained in experiments with radial Glass patterns (Wilson, 1999b).

The psychophysical data are contrary to what would be expected for V1 but consistent with primate V4 physiology (Gallant et al., 1993; Kobatake and Tanaka, 1994). Accordingly, we asked whether human V4 might also show similar stimulus selectivity. After localizing V1, V4, and the fusiform face area using standard techniques, fMRI responses were measured while viewing concentric, radial, and sinusoidal gratings (Wilkinson et al., 2000). As predicted, the data showed that V1 activation was the same for all three stimulus patterns, while the fMRI signals in V4 were significantly higher for concentric and radial gratings than for sinusoidal gratings (Wilkinson et al., 2000). Interestingly, only concentric gratings and faces produced significant activation of the fusiform face area, suggesting that analysis of concentric structure represents one component of face perception.

## Network Model

These data lead to the conclusion that human V4 is selectively sensitive to concentric and radial stimuli (and certainly other configural patterns), as is primate V4. The simple neural network diagrammed in Figure 2 describes a V4 concentric unit model consistent with these data (Wilson et al., 1997; Wilson, 1999b). Three stages make up the model, and these are hypothesized to represent V1, V2, and finally V4 processing. First, the stimulus is processed by oriented filters with properties of V1 simple cells (12 preferred orientations in 15° increments were used). Following this are contrast gain control and full-wave rectification operations for which there is experimental evidence. Next the responses are processed by larger second-stage filters oriented at right angles to their V1 inputs. This combination of filtering, rectification, and orthogonal filtering generates an end-stopped complex cell model that is sensitive to contour curvature (Wilson, 1999b). Finally, V2 responses that are concentric with the center of each V4 receptive field (gray circles) are summed linearly (Σ), and the result is passed through a threshold nonlinearity. An analogous model for V4 radial units has been constructed by simply changing the orientations of the V1 filters to be parallel to the V2 filters. These V4 models are configural in the sense that they pool all V1 orientations, but each from pattern-specific subregions of the V4 receptive field.

This model offers an explanation for the 2.5- to 2.7-fold increase in receptive field sizes from V1 to V2 and from V2 to V4. The V2 filters must be about this much larger than V1 filters to effectively process curvature, while the V4 receptive fields must sum V2 responses over a diameter around 3.0 times the V2 filter diameter to extract circular or radial structure. Smaller increases in receptive field size from V1 to V4 simply cannot extract the relevant configural information.

The fMRI discovery that concentric gratings activate the fusiform face area is consistent with the hypothesis that V4 concentric units constitute an intermediate stage in face perception. To test this idea, the model in Figure 2 was applied to a variety of faces. For example, model convolution with the transparent face-house image in Figure 3*A* produced a single peak of activation centered at the black dot (Wilson, Krupa, and Wilkinson, 2000a). Furthermore, the response of this unit was proportional to the mean radius of the head, as indicated by the vertical arrow. This ability of model V4 units to *measure* concentric image structure is produced by the contrast gain control following the V1 filters. This causes the final summation stage Σ to add the number of units active around the pattern circumference, thus producing a signal proportional to radius and independent of contrast over a considerable range (Figure 3*B*). The model is also capable of encoding aspects of head shape, including axis of elongation and bilateral symmetry, as a sparse population code (Wilson et al., 2000b).

## Global Unit Dynamics and Attention

There is considerable evidence that selective attention affects V4 neuron responses, and the evidence suggests that this results from biasing of competitive inhibitory networks (Reynolds, Chelazzi, and Desimone, 1999). Further evidence for such competitive inhibition among V4 concentric units has emerged from analysis of a visual illusion first introduced by Marroquin in 1978 (Wilson et al., 2000a). Marroquin patterns generate percepts of illusory circles appearing and vanishing at multiple locations within the pattern, much like the dynamic fluctuations in binocular rivalry. Psychophysical measurement of the visibility times of illusory circles in

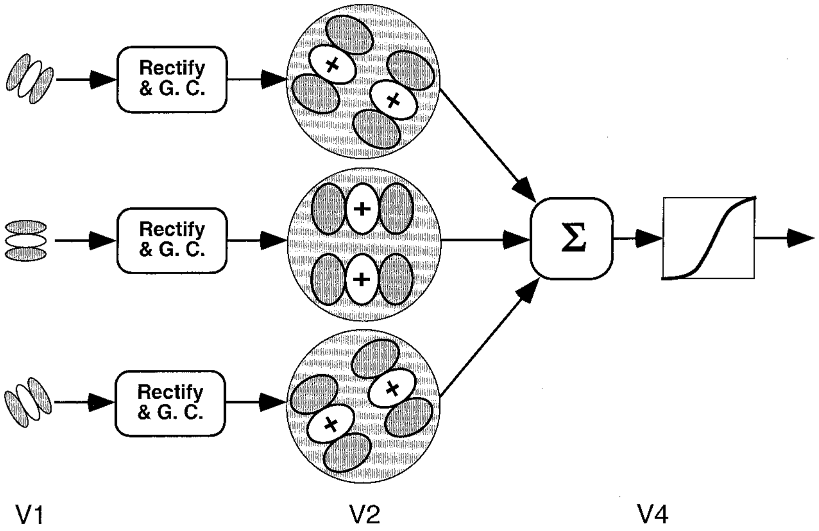

**Figure 2.** Global pooling model for a V4 concentric unit. Convolving the stimulus with 12 different oriented simple cell filters (only three shown for clarity) having elongated excitatory (white) and inhibitory (gray) zones makes up the V1 stage. This is followed by full-wave rectification and a contrast gain control. V2 processing incorporates filtering by oriented filters that are 2.5–2.7 times the diameter of V1 filters. Finally, responses of concentrically arranged V2 filters are summed (Σ) and passed through a threshold nonlinearity to produce the simulated V4 response. This produces a V4 receptive field size (large gray circles) about 3.0 times that of V2 units, in agreement with cortical physiology.

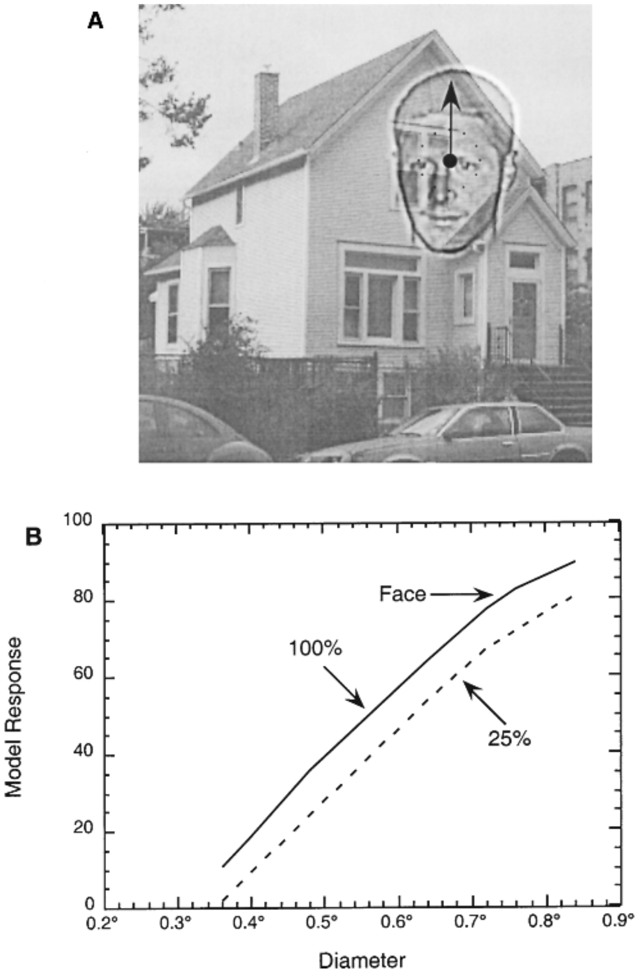

**Figure 3.** Image processing of a complex scene by the V4 model in Figure 2. *A*, Convolution of the model with a transparent face-house scene produces activation only at the center of the head (black dot), showing that the rectilinear house structure fails to affect model extraction of the ellipsoidal head shape. *B*, Response of maximally active V4 model unit in response to circles of different diameters. Owing to operation of the model contrast gain control, model responses are almost linear functions of diameter over more than a 2:1 size range despite contrast variations from 25% to 100%. The maximum model response to the head in *A* is indicated, and the radius estimated from the graph is plotted as an arrow in *A*.

the Marroquin pattern shows that they typically appear for a mean duration of 2.79 ± 2.75 s and are well described by a gamma distribution (Wilson et al., 2000a).

The V4 concentric unit model was extended to explain data on illusory circle visibility in Marroquin patterns by incorporating nonlinear dynamics and competitive inhibition. Individual neurons were simulated by using Wilson-Cowan-type spike rate equations in which a sigmoid function of postsynaptic potential $P$ is approached exponentially in time (Wilson, 1999a):

$$\tau \frac{dE}{dt} = -E + \frac{MP_+^2}{\sigma^2 + P_+^2} \tag{1}$$

where the nonlinearity is a Naka-Rushton function and $P_+ = \max\{P, 0\}$. The maximum spike rate is conventionally $M = 100$, and $\sigma$ is the semisaturation constant, that is, the value at which the Naka-Rushton function attains the value $M/2$.

Competitive inhibition was introduced by using the recurrent inhibitory spread function $\exp(-R^5/\sigma^5)$, where $R$ is radius between competitors. This network implements a *spatially regional* winner-take-all competition. This means that the most strongly stimulated unit within each mutually inhibitory region will switch on while all others in that region are suppressed by inhibition. As the region is spatially limited, however, there will be multiple regional winners in the network.

Such networks can produce oscillations (rather than approaching a stable equilibrium) only if the regional winners adapt slowly until other winners emerge (Wilson, 1999a). Excitatory neocortical neurons are known to possess ion currents (typically $Ca^{2+}$ mediated $K^+$ hyerpolarizations) that cause spike frequency adaptation. This reduces excitatory firing rates by a factor of about 3.0 within several hundred milliseconds following stimulus onset. The following equations describe activity in a network with such adaptation (Wilson, 1999a):

$$\tau_E \frac{dE_n}{dt} = -E_n + \frac{100P_+^2}{(10 + H_n)^2 + P_+^2}$$

where

$$\begin{aligned} P &= S_{\text{Marroquin}} - 0.6 \sum_{k \neq n} I_k \exp\left(-\frac{R_{nk}^5}{\sigma^5}\right) \\ \tau_I \frac{dI_n}{dt} &= -I_n + E_n \\ \tau_H \frac{dH_n}{dt} &= -H_n + gE_n \end{aligned} \tag{2}$$

$E_n$ is the response of an excitatory neuron with a postsynaptic potential $P$ that is the difference between stimulation $S$ derived from the Marroquin pattern minus the spatially weighted inputs from inhibitory neurons $I_k$, where $n \neq k$, so there is no inhibition of a neuron by the inhibitory neuron it drives. The hyperpolarizing variable $H_n$ produces spike frequency adaptation by increasing the semisaturation constant of the sigmoid nonlinearity in the first equation. Reasonable time constants are $\tau_E = 16$ ms, $\tau_I = 8$ ms, and $\tau_H = 400$ ms, the latter reflecting the much slower rate of spike frequency adaptation.

If Equation 1 is restricted to the case of two mutually inhibitory neurons, one can prove analytically that the system undergoes a Hopf bifurcation to a limit cycle oscillation at a critical value of the hyperpolarizing gain $g$ (Wilson, 1999a). To simulate the illusory oscillating circles of the Marroquin illusion, the equations were extended to a $64 \times 64$ neuron array, and input was generated by applying the V4 concentric unit model in Figure 2 to a Marroquin pattern. The resulting model dynamics produced a gamma distribution of visibility durations with mean 2.24 ± 1.93 s (Wilson et al., 2000a), which agrees well with the human data. As Equation 1 represents a totally deterministic network without noise, it might be conjectured that the gamma distribution generated by the network reflects chaotic dynamics. However, the largest Lyapunov exponent was negative, so the dynamics are not chaotic; they apparently represent a very complex, long-period limit cycle.

It is gratifying that model V4 concentric units plus the regional competitive inhibition engendered in Equation 2 can predict an illusion that had remained unexplained for over 20 years. However, the significance of this network probably lies in its relationship to selective attention, which is evident in V4 and is thought to involve biasing of neural competition (Reynolds et al., 1999). Spike frequency adaptation in cortical neurons is controlled by modulatory neurotransmitters (serotonin, dopamine, and histamine), which *reduce* adaptation magnitude. Thus, modulatory transmitters function to tune network parameters, here the hyperpolarizing gain $g$ in Equation 2. Reduction of $g$ for a few excitatory neurons in the network gives them an attentional advantage in subsequent competition. This suggests the hypothesis that biasing in V4 and other cortical areas may result from modulatory control of hyperpolarizing potentials in excitatory cells.

## Global Processing in Motion Networks

The V1-V2-MT-MST dorsal motion pathway also shows progressively increasing receptive field size from area to area, with MST receptive fields averaging 50° in diameter (Tanaka and Saito, 1989). As in the ventral form vision pathway, this is indicative of progressively more global processing as information progresses through the hierarchy. Indeed, direction selective neurons in V1 have relatively small receptive fields and respond only to the component of motion perpendicular to local contour orientation. MT neurons pool over a larger visual area, combining V1 and V2 motion vectors over a range of about ±90° to determine the direction of pattern or object motion (Wilson, 1999b). (The restriction of vector pooling to ±90° reflects the ecological constraint that motion vectors in opposite directions cannot result from motion of a single rigid object.) Finally, neurons in MST combine MT responses over broad areas to extract expansion and rotation components of optic flow (Tanaka and Saito, 1989).

Psychophysical evidence that similar motion expansion and rotation units exist in human vision was provided in experiments using a motion analog of Glass patterns (Morrone, Burr, and Vaina, 1995). To generate a percept of rotary motion, for example, a circular patch of random dots is flashed on the screen and followed by a second flashed patch in which each dot is moved a fixed distance around a circular contour from its previous position. If dots are moved outward in the second frame relative to the first, motion expansion is perceived, and so on. Using this approach, Morrone et al. (1995) demonstrated that humans were extremely good at detecting rotary, expanding, and translational motion. Further experiments showed that the visual system globally summed motion vectors directed radially outward in detecting motion expansion. Similarly, clockwise or counterclockwise motion vectors were summed to detect clockwise or counterclockwise rotation, respectively.

These experiments demonstrate global, configural motion summation and are a direct motion analogue of global, configural orientation summation in the detection of concentric and radial Glass patterns (Wilson, 1999b). In consequence, a configural model analogous to the V4 configural model in Figure 2 may be applied to motion. The first stage of a configural motion model would incorporate V1 direction selective Reichardt or motion energy units rather than oriented simple cells. Following rectification, there would be pooling over larger areas to extract local object motions in MT. Finally, there would be configural summation of appropriate MT responses throughout large regions to extract expanding, radial, or translational optic flow.

## Discussion

The evidence above indicates that similar global processes in higher cortical areas operate on local V1 orientation responses to extract shape information and on local V1 direction selective responses to detect optic flow patterns. Furthermore, the progressive enlargement of receptive field sizes in moving up either hierarchy is consistent with the requirements of global, configural processing. This leads to the natural question "Just how far do such global summation processes extend in cortical vision?" Certainly, receptive field size continues to increase from V4 to TEO and thence to TE (Boussaoud et al., 1991; Kobatake and Tanaka, 1994). Also, many TE receptive fields have been shown to respond to a complex object such as a face over a range of sizes and locations within visual space (Desimone, 1991). In principle, such size and position invariance can be generated by obvious extensions of the V4 configural model in Figure 2. Given the evidence for regional competitive inhibition in V4, a larger receptive field sensitive to concentric shape independent of position can be produced by summing V4 concentric unit responses over an area similar to that of the competitive inhibition in Equation 2. Similarly, size invariance can be produced by replicating the V4 model at several different spatial scales, each about an octave apart, allowing regional competition within each scale, and then summing responses across spatial scales in an area beyond V4. Thus, both size and position invariance can be explained by a further stage of global processing with inhibition.

Units that are responsive to global forms such as human and monkey faces have been hypothesized to emerge from configural pooling of appropriate V4 unit responses (Kobatake and Tanaka, 1994). Support for this is provided by the fMRI finding that concentric patterns, which are very effective in activating human V4, are also effective stimuli in the fusiform face area (Wilkinson et al., 2000). Combination of V4 concentric responses with responses of units encoding, for example, the configuration of eyes and nose, could produce face-selective neurons in TE.

Cortical feedback between areas (e.g., V2 to V1, V4 to V2) poses an unsolved problem for models of global pooling, as the models presented here contain no such feedback. Lamme (1995) has shown that V1 responses are enhanced after a 30- to 40-ms latency period if the stimulus is inside an object rather than part of the background, and he has conjectured that this reflects extrastriate feedback. As model V4 concentric units code the location and radius of ellipsoidal regions (see Figure 3), V4 feedback could enhance activity in bounded V1 regions. However, excitatory feedback of this sort, if unchecked, can result in self-organization of network activity into a steady state indicating a hallucination. As hallucinations of circles and faces are common in Charles Bonnet syndrome (Schultz and Melzack, 1993), one can speculate that they result from feedback between cortical areas, including V4. Charles Bonnet syndrome may thus provide a glimpse into the interplay between cortical feedback and global pattern extraction.

# Graphical Models: Parameter Learning

*Zoubin Ghahramani*

## Introduction

*Graphical models* combine graph theory and probability theory to provide a general framework for representing models in which a number of variables interact. Graphical models trace their origins to many different fields and have been applied in a wide variety of settings: for example, to develop probabilistic expert systems, to understand neural network models, to infer trait inheritance in genealogies, to model images, to correct errors in digital communication, and to solve complex decision problems. Remarkably, the same formalisms and algorithms can be applied to this wide range of problems.

Each node in the graph represents a random variable (or, more generally, a set of random variables). The pattern of edges in the graph represents the qualitative dependencies between the variables; the absence of an edge between two nodes means that any statistical dependency between these two variables is mediated via some other variable or set of variables. The quantitative dependencies between variables that are connected by edges are specified by means of parameterized conditional distributions, or, more generally, non-negative "potential functions." The pattern of edges and the potential functions together specify a joint probability distribution over all the variables in the graph. We refer to the pattern of edges as the *structure* of the graph, while the parameters of the potential functions are simply called the *parameters* of the graph. In this article, we assume that the structure of the graph is given, and that our goal is to learn the parameters of the graph from data. Solutions to the problem of learning the graph structure from data are given in GRAPHICAL MODELS: STRUCTURE LEARNING (q.v.).

We briefly review some of the notation from GRAPHICAL MODELS: PROBABILISTIC INFERENCE (q.v.). that we will need to cover parameter learning in graphical models. More in-depth treatments of graphical models can be found in Pearl (1988), Heckerman (1996), Jordan (1999), and Cowell et al. (1999).

There are two main varieties of graphical model. *Directed graphical models*, also known as BAYESIAN NETWORKS (q.v.), represent the joint distribution of $k$ random variables $\mathbf{X} = (X_1, \ldots, X_k)$ by a directed acyclic graph in which each node $i$, representing variable $X_i$, receives directed edges from its set of parent nodes $\pi_i$. The semantics of a directed graphical model are that the joint distribution of $\mathbf{X}$ can be factored into the product of conditional distributions of each variable given its parents. That is, for each setting $\mathbf{x}$ of the variable $\mathbf{X}$,

$$p(\mathbf{x}|\boldsymbol{\theta}) = \prod_{i=1}^{k} p(x_i|\mathbf{x}_{\pi_i}, \boldsymbol{\theta}_i) \tag{1}$$

This factorization formalizes the graphical intuition that $X_i$ depends on its parents $\mathbf{X}_{\pi_i}$. Given its parents, $X_i$ is statistically independent of all other variables that are not descendents of $X_i$. The set of parameters governing the conditional distribution that relates $\mathbf{X}_{\pi_i}$ to $X_i$ is denoted by $\boldsymbol{\theta}_i$, while the set of all parameters in the graphical model is denoted $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_k)$. Note that 1 is identical to Equation 1 in GRAPHICAL MODELS: PROBABILISTIC INFERENCE (q.v.), except that we have made explicit the dependence of the conditional distributions on the model parameters.

*Undirected graphical models* represent the joint distribution of a set of variables via a graph with undirected edges. Defining $\mathscr{C}$ to be the set of maximal cliques (i.e., fully connected subgraphs) of this graph, an undirected graphical model corresponds to the statement that the joint distribution of $\mathbf{X}$ can be factored into the product of functions over the variables in each clique:

$$p(\mathbf{x}|\boldsymbol{\theta}) = \frac{1}{Z(\boldsymbol{\theta})} \prod_{C \in C} \psi_C(\mathbf{x}_C|\boldsymbol{\theta}_{\mathscr{C}}) \tag{2}$$

where $\psi_C(\mathbf{x}_C|\boldsymbol{\theta}_C)$ is a potential function assigning a non-negative real number to each configuration $\mathbf{x}_C$ of $\mathbf{X}_C$, and is parameterized by $\boldsymbol{\theta}_C$. An undirected graphical model corresponds to the graphical intuition that dependencies are transmitted via the edges in the graph: each variable is statistically independent of all other variables, given the set of variables it is connected to (i.e., its neighbors). Note again that we have reproduced Equation 2 from GRAPHICAL MODELS: PROBABILISTIC INFERENCE (q.v.), while making explicit the parameters of the potential functions.

The article is organized as follows. We start by concentrating on directed graphical models. In the next section, we discuss the problem of learning maximum likelihood (ML) parameters when all the variables are observed. The following section generalizes this problem to the case in which some of the variables are hidden or missing, and introduces the Expectation-Maximization (EM) algorithm. We then turn to learning parameters of undirected graphical models using both EM and IPF. Finally, we discuss the Bayesian approach, in which a posterior distribution over parameters is inferred from data.

## Maximum Likelihood Learning from Complete Data

Assume we are given a data set $\mathbf{d}$ of $N$ independent and identically distributed observations of the settings of all the variables in our directed graphical model $\mathbf{d} = (\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(N)})$, where $\mathbf{x}^{(n)} = (x_1^{(n)}, \ldots, x_k^{(n)})$. The *likelihood* is a function of the parameters and is proportional to the probability of the observed data:

$$p(\mathbf{d}|\boldsymbol{\theta}) = \prod_{n=1}^{N} p(\mathbf{x}^{(n)}|\boldsymbol{\theta}) \tag{3}$$

We assume that the parameters are unknown and we wish to estimate them from data. We focus on the problem of estimating a single setting of the parameters that maximizes the likelihood formulated in Equation 3. (In contrast, the Bayesian approach to learning described in the last section starts with a prior distribution over the parameters $p(\boldsymbol{\theta})$ that is meant to capture background knowledge we may have about $\boldsymbol{\theta}$, and infers the posterior distribution over parameters given the data $p(\boldsymbol{\theta}|\mathbf{d})$, using Bayes's rule.) Equivalently, we can maximize the log likelihood:

$$\mathscr{L}(\boldsymbol{\theta}) = \log p(\mathbf{d}|\boldsymbol{\theta}) = \sum_{n=1}^{N} \log p(\mathbf{x}^{(n)}|\boldsymbol{\theta}) \tag{4}$$

$$= \sum_{n=1}^{N} \sum_{i=1}^{k} \log p(x_i^{(n)}|\mathbf{x}_{\pi_i}^{(n)}, \boldsymbol{\theta}_i) \tag{5}$$

where the last equality makes use of the factorization (Equation 1) of joint distribution in the directed graphical model. If we assume that the parameters $\boldsymbol{\theta}_i$ governing the conditional probability distribution of $X_i$ given its parents are distinct and functionally independent of the parameters governing the conditional probability distribution of other nodes in the graphical model, then the log likelihood decouples into a sum of local terms involving each node and its parents:

$$\mathscr{L}(\boldsymbol{\theta}) = \sum_{i=1}^{k} \mathscr{L}_i(\boldsymbol{\theta}_i) \tag{6}$$

where $\mathcal{L}_i(\boldsymbol{\theta}_i) = \Sigma_n \log p(x_i^{(n)}|\mathbf{x}_{\pi_i}^{(n)}, \boldsymbol{\theta}_i)$. Each $\mathcal{L}_i$ can be maximized independently as a function of $\boldsymbol{\theta}_i$. For example, if the **X** variables are discrete and $\boldsymbol{\theta}_i$ is the conditional probability table for $x_i$ given its parents, then the ML estimate of $\boldsymbol{\theta}_i$ is simply a normalized table containing counts of each setting of $X_i$ given each setting of its parents in the data set.

Maximum a posteriori (MAP) parameter estimation incorporates prior knowledge about the parameters in the form of a distribution $p(\boldsymbol{\theta})$. The goal of MAP estimation is to find the parameter setting that maximizes the posterior over parameters, $p(\boldsymbol{\theta}|\mathbf{d})$, which is proportional to the prior times the likelihood. If the prior factorizes over the parameters governing each conditional probability distribution, i.e., $p(\boldsymbol{\theta}) = \Pi_i p(\boldsymbol{\theta}_i)$, then MAP estimates can be found by maximizing

$$\mathcal{L}'(\boldsymbol{\theta}) = \sum_{i=1}^{k} \mathcal{L}_i(\boldsymbol{\theta}_i) + \log p(\boldsymbol{\theta}_i) \tag{7}$$

The log prior can be seen as a regularizer, which can help reduce overfitting in situations where there are insufficient data for the parameters to be well-determined (see Generalization and Regularization in Nonlinear Learning Systems). Although ML estimation is invariant to reparameterization, since the location of the maximum of the likelihood function does not change if you apply a one-to-one transformation $f : \boldsymbol{\theta} \to \phi$, MAP estimation is not. Indeed, for *any* $\tilde{\boldsymbol{\theta}}$ one can always find a one-to-one mapping such that the MAP estimate of $\phi$ is $f(\tilde{\boldsymbol{\theta}})$, as long as $p(\boldsymbol{\theta}|\mathbf{d}) > 0$ in a small neighborhood around $\tilde{\boldsymbol{\theta}}$. Thus, care should be taken in the choice of parameterization.

## Maximum Likelihood Learning with Hidden Variables

### *The Expectation-Maximization (EM) Algorithm*

Often, the observed data will not include the values of some of the variables in the graphical model. We refer to these variables as missing or hidden variables. With hidden variables, the log likelihood cannot be decomposed as in Equation 6. Rather, we find:

$$\mathcal{L}(\boldsymbol{\theta}) = \log p(\mathbf{x}|\boldsymbol{\theta}) = \log \sum_{\mathbf{y}} p(\mathbf{x}, \mathbf{y}|\boldsymbol{\theta}) \tag{8}$$

where **x** denotes the setting of the observed variables, **y** the setting of the hidden variables, and $\Sigma_{\mathbf{y}}$ is the sum (or integral) over **Y** required to obtain the marginal probability of the observed data. (For notational convenience, we have dropped the superscript ($n$) in Equation 8 by evaluating the log likelihood for a single observation.) Maximizing Equation 8 directly is often difficult because the log of the sum can potentially couple all of the parameters of the model. We can simplify the problem of maximizing $\mathcal{L}$ with respect to $\boldsymbol{\theta}$ by making use of the following insight. Any distribution $q(\mathbf{Y})$ over the hidden variables defines a *lower bound* on $\mathcal{L}$:

$$\mathcal{L}(\theta) = \log \sum_{\mathbf{y}} p(\mathbf{x}, \mathbf{y}|\boldsymbol{\theta}) = \log \sum_{\mathbf{y}} q(\mathbf{y}) \frac{p(\mathbf{x}, \mathbf{y}|\boldsymbol{\theta})}{q(\mathbf{y})} \tag{9}$$

$$\geq \sum_{\mathbf{y}} q(\mathbf{y}) \log \frac{p(\mathbf{x}, \mathbf{y}|\boldsymbol{\theta})}{q(\mathbf{y})} \tag{10}$$

$$= \sum_{\mathbf{y}} q(\mathbf{y}) \log p(\mathbf{x}, \mathbf{y}|\boldsymbol{\theta}) - \sum_{\mathbf{y}} q(\mathbf{y}) \log q(\mathbf{y}) \tag{11}$$

$$= \mathcal{F}(q, \boldsymbol{\theta}) \tag{12}$$

where the inequality is known as Jensen's inequality and follows from the fact that the log function is concave. If we define the *energy* of a global configuration $(\mathbf{x}, \mathbf{y})$ to be $-\log p(\mathbf{x}, \mathbf{y}|\boldsymbol{\theta})$, then some readers may notice that the lower bound $\mathcal{F}(q, \boldsymbol{\theta}) \leq \mathcal{L}(\boldsymbol{\theta})$ is the negative of a quantity known in statistical physics as the *free energy*: the expected energy under $q$ minus the entropy of $q$ (Neal and Hinton in Jordan, 1999). The EM algorithm (Dempster, Laird, and Rubin, 1977) alternates between maximizing $\mathcal{F}$ with respect to $q$ and $\boldsymbol{\theta}$, respectively, holding the other fixed. Starting from some initial parameters $\boldsymbol{\theta}_0$, the $\ell + 1$st iteration of the algorithm consists of the following two steps:

$$\textbf{E step:}\quad q_{[\ell+1]} \leftarrow \arg\max_{q} \mathcal{F}(q, \boldsymbol{\theta}_{[\ell]}) \tag{13}$$

$$\textbf{M step:}\quad \boldsymbol{\theta}_{[\ell+1]} \leftarrow \arg\max_{\theta} \mathcal{F}(q_{[\ell+1]}, \boldsymbol{\theta}) \tag{14}$$

It is easy to show that the maximum in the E step is obtained by setting $q_{[\ell+1]}(\mathbf{y}) = p(\mathbf{y}|\mathbf{x}, \boldsymbol{\theta}_{[\ell]})$, at which point the bound becomes an equality: $\mathcal{F}(q_{[\ell+1]}, \boldsymbol{\theta}_{[\ell]}) = \mathcal{L}(\boldsymbol{\theta}_{[\ell]})$. This involves inferring the distribution over the hidden variables given the observed variables and the current settings of the parameters, $p(\mathbf{y}|\mathbf{x}, \boldsymbol{\theta}_{[\ell]})$. Algorithms that solve this inference problem are presented in Graphical Models: Probabilistic Inference. These algorithms make use of the structure of the graphical model to compute the quantities of interest efficiently by passing local messages from each node to its neighbors. Exact inference results in the bound being satisfied, but is in general computationally intractable for multiply connected graphical structures. Even these "efficient" message-passing procedures can take exponential time to compute the exact solution in such cases. For such graphs, deterministic and Monte Carlo methods provide a tool for approximating the E step of EM. One deterministic approximation that can be used in intractable models is to increase but not fully maximize the functional with respect to $q$ in the E step. In particular, if $q$ is chosen to be in a tractable family of distributions $\mathcal{Q}$ (i.e., a family of distributions for which the required expectations can be computed in polynomial time), then maximizing $\mathcal{F}$ over this tractable family

$$\textbf{E step:}\quad q_{[\ell+1]} \leftarrow \arg\max_{q \in \mathcal{Q}} \mathcal{F}(q, \boldsymbol{\theta}_{[\ell]}) \tag{15}$$

is called a *variational approximation* to the EM algorithm (Jordan, Ghahramani, Jaakkola, and Saul in Jordan, 1999). This maximizes a lower bound to the likelihood rather than the likelihood itself.

The maximum in the M step is obtained by maximizing the first term in Equation 11, since the entropy of $q$ does not depend on $\boldsymbol{\theta}$:

$$\textbf{M step:}\quad \boldsymbol{\theta}_{[\ell+1]} \leftarrow \arg\max_{\theta} \sum_{\mathbf{y}} p(\mathbf{y}|\mathbf{x}, \boldsymbol{\theta}_{[\ell]}) \log p(\mathbf{y}, \mathbf{x}|\boldsymbol{\theta}) \tag{16}$$

This is the expression most often associated with the EM algorithm (Dempster et al., 1977), but it obscures the elegant interpretation of EM as coordinate ascent in $\mathcal{F}$. Since $\mathcal{F} = \mathcal{L}$ at the beginning of each M step (following an exact E step), and since the E step does not change $\boldsymbol{\theta}$, we are guaranteed not to decrease the likelihood after each combined EM step.

It is usually not necessary to explicitly evaluate the entire posterior distribution $p(\mathbf{y}|\mathbf{x}, \boldsymbol{\theta}_{[\ell]})$. Since $\log p(\mathbf{x}, \mathbf{y}|\boldsymbol{\theta})$ contains both hidden and observed variables in the network, it can be factored as before as the sum of log probabilities of each node given its parents (Equation 5). Consequently, the quantities required for the M step are the expected values, under the posterior distribution $p(\mathbf{y}|\mathbf{x}, \boldsymbol{\theta}_{[\ell]})$, of the same quantities (namely the *sufficient statistics*) required for ML estimation in the complete data case.

Consider a directed graphical with discrete variables, some hidden and some observed. Each node is parameterized by a conditional probability table that relates its values to the values of its parents. For example, if node $i$ has two parents, $j$ and $k$, and each variable can take on $L$ values, then $\boldsymbol{\theta}_i$ is an $L \times L \times L$ table, with entries $\boldsymbol{\theta}_{i,rst} = P(X_i = r|X_j = s, X_k = t)$. In the complete data setting where $X_i$, $X_j$, $X_k$ are observed, the ML estimate is:

$$\hat{\theta}_{i,rst} = \frac{\#(X_i = r, X_j = s, X_k = t)}{\#(X_j = s, X_k = t)} \tag{17}$$

where #(·) denotes the count (frequency) with which the bracketed expression occurs in the data. However, if all three variables were hidden, then one could use the EM algorithm for learning the directed graphical model (Lauritzen, 1995; Russell et al., 1995). The analogous M step for $\theta_{i,rst}$ would be:

$$\hat{\theta}_{i,rst} = \frac{\sum_{n} P(Y_i = r, Y_j = s, Y_k = t|\mathbf{X} = \mathbf{x}^{(n)})}{\sum_{n} P(Y_j = s, Y_k = t|\mathbf{X} = \mathbf{x}^{(n)})} \tag{18}$$

The sufficient statistics of the data required to estimate the parameters are the counts of the setting of each node and its parents; no other information in the data is relevant for ML parameter estimation. The *expectation* step of EM computes the expected value of these sufficient statistics.

The EM algorithm provides an intuitive way of dealing with hidden or missing data. The E step "fills in" the hidden variables with the distribution given by the current model. The M step then treats these filled-in values as if they had been observed, and reestimates the model parameters. It is pleasantly surprising that these steps result in a convergent procedure for finding the most likely parameters. Although EM is intuitive and often easy to implement, it is sometimes not the most efficient algorithm for finding ML parameters.

The EM procedure for learning directed graphical models with hidden variables can be applied to a wide variety of well-known models. Of particular note is the special case known as the Baum-Welch algorithm for training hidden markov models (Rabiner 1989; see Hidden Markov Models). In the E step it uses a local message-passing algorithm called the forward-backward algorithm to compute the required expected sufficient statistics. In the M step it uses a parameter reestimation equation based on expected counts, analogous to Equation 18. The EM algorithm can also be used to fit a variety of other models that have been studied in the machine learning, neural networks, statistics, and engineering literatures. These include linear dynamical systems, factor analysis, mixtures of Gaussians, and mixtures of experts (see Roweis and Ghahramani, 1999, for a review). It is straightforward to modify EM so that it maximizes the parameter posterior probability rather than the likelihood.

## Parameter Learning in Undirected Graphical Models

When compared to learning the parameters of directed graphical models, undirected graphical models present an additional challenge: the partition function. Even if each clique has distinct and functionally independent parameters, the partition function from Equation 2,

$$Z(\boldsymbol{\theta}) = \sum_{\mathbf{x}} \prod_{C \in \mathscr{C}} \psi_C(\mathbf{x}_C|\boldsymbol{\theta}_C) \tag{19}$$

couples all the parameters together. We examine the effect this coupling has in the context of an undirected graphical model that has had a great deal of impact in the neural networks field: the Boltzmann machine (Ackley, Hinton, and Sejnowski, 1985).

Boltzmann machines are undirected graphical models over a set of $k$ binary variables $S_i \in \{0, 1\}$ (see also Simulated Annealing and Boltzmann Machines). The probability distribution over the variables in a Boltzmann machine is given by

$$\begin{aligned} P(\mathrm{s}|W) &= \frac{1}{Z(W)} \exp\left\{\tfrac{1}{2} \sum_{i=1}^{k} \sum_{j \in \mathrm{ne}(i)} W_{ij} s_i s_j\right\} \\ &= \frac{1}{Z(W)} \prod_{(ij)} \exp\{W_{ij} s_i s_j\} \end{aligned} \tag{20}$$

The first equation uses standard notation for Boltzmann machines, where $W$ is the symmetric matrix of weights (i.e., model parameters) and ne($i$) is the set of neighbors of node $i$ in the Boltzmann machine. The second equation writes it as a product of clique potentials, where ($ij$) denotes the clique consisting of the pair of connected nodes $i$ and $j$. (Actually, in Boltzmann machines, the maximal cliques in the graph may be very large, although the interactions are all pairwise; because of this pairwise constraint on interactions, we abuse terminology and consider the "cliques" to be the pairs, no matter what the graph connectivity is.)

Assuming that $S_i$ and $S_j$ are observed, taking derivatives of the log probability of the $n$th data point with respect to $W_{ij}$,

$$\begin{aligned} \frac{\partial \log P(\mathbf{s}^{(n)}|W)}{\partial W_{ij}} &= s_i^{(n)} s_j^{(n)} - \sum_{s} s_i s_j P(\mathbf{s}|W) \\ &= \langle s_i s_j \rangle_n^+ - \langle s_i s_j \rangle^- \end{aligned} \tag{21}$$

we find that it is the difference between the correlation of $S_i$ and $S_j$ in the data and the correlation of $S_i$ and $S_j$ in the model (the $\langle \cdot \rangle$ notation means expectation). The standard ML gradient descent learning rule for Boltzmann machines therefore tries to make the model match the correlations in the data. The same learning rule applies if there are hidden variables.

The second term arises from the partition function. Note that even for fully observed data, although the first term can be computed directly from the observed data, the second term depends potentially on all the parameters, underlining the fact that the partition function couples the parameters in undirected models. Even for fully observed data, computing the second term is nontrivial; for fully connected Boltzmann machines it is intractable and needs to be approximated.

### *The IPF Algorithm*

Consider the following problem: Given an undirected graphical model, and an initial set of clique potentials, we wish to find the clique potentials closest to the initial potentials that satisfy a certain set of consistent marginals. Closeness of probability distributions in this context is measured using the Kullback-Leibler divergence. The simplest example is a clique of two discrete variables, $X_i$ and $X_j$, where the clique potential is proportional to the contingency table for the joint probability of these variables $P(X_i, X_j)$, and the marginal constraints are $P(x_i) = \hat{P}(x_i)$ and $P(x_j) = \hat{P}(x_j)$. These constraints could, for example, have come from observing data with these marginals. A very simple and intuitive iterative algorithm for trying to satisfy these constraints is to start from the initial table and satisfy each constraint in turn. For example, if we want to satisfy the marginal on $X_i$:

$$P_l(x_i, x_j) = P_{l-1}(x_i, x_j) \frac{\hat{P}(x_i)}{P_{l-1}(x_i)} \tag{22}$$

This has to be iterated over $X_i$ and $X_j$, since satisfying one marginal can change the other marginal. The simple algorithm is known as Iterative Proportional Fitting (IPF), and it can be generalized in several ways (Darroch and Ratcliff, 1972).

More generally, we wish to find a distribution in the form

$$p(\mathbf{x}) = \frac{1}{Z} \prod_{c} \psi_c(\mathbf{x}_c) \tag{23}$$

that minimizes the Kullback-Leibler divergence to some prior $p_0(\mathbf{x})$ and satisfies a set of constraints (the data) of the form:

$$\sum_{\mathbf{x}} a_r(\mathbf{x}) p(\mathbf{x}) = h_r \tag{24}$$

where $r$ indexes the constraint. If the prior is set to the uniform distribution and the constraints are measured marginal distributions over all the variables in each of the cliques of the graph, then the problem solved by IPF is equivalent to finding the maximum likelihood clique potentials given a complete data set of observations.

IPF can be used to train an ML Boltzmann machine if $\hat{P}(S_i, S_j)$ is given by the data set for all pairs of variables connected in the Boltzmann machine. The procedure is to start from the uniform distribution (i.e., all weights set to 0), then apply IPF steps to each clique potential until all marginals match those in the data. One can generalize this by starting from a nonuniform distribution, which would give a Boltzmann machine with minimum divergence from the starting distribution.

But what if some of the variables in the Boltzmann machine are hidden? Byrne (1992) presents an elegant solution to this problem using ideas from alternating minimization (AM) and information geometry (Csizár and Tusnády, 1984). One step of the alternating minimization computes the distribution over the hidden variables of the Boltzmann machine, given the observed variables. This is the E step of EM, and can also be interpreted within information geometry as finding the probability distribution that satisfies the marginal constraints and is closest to the space of probability distributions defined by the Boltzmann machines. The other step of the minimization starts from $W = 0$ (the maximum entropy distribution for a Boltzmann machine) and uses IPF to find the Boltzmann machine weights that satisfy all the marginals found in the E step, $\hat{P}_{ij} = \langle s_i s_j \rangle^+$. This is the M step of the algorithm; a single M step thus involves an entire IPF optimization. The update rule for each step of the IPF optimization for a particular weight is:

$$W_{ij} \leftarrow W_{ij} + \log\left[\frac{\hat{P}_{ij}}{\langle s_i s_j\rangle^-}\,\frac{(1 - \langle s_i s_j\rangle^-)}{(1 - \hat{P}_{ij})}\right] \qquad (25)$$

This algorithm is conceptually interesting, as it presents an alternative method for fitting Boltzmann machines with ties to IPF and alternating minimization procedures. However, it is impractical for large, multiply connected Boltzmann machines, since computing the exact unclamped correlations $\langle s_i s_j \rangle^-$ can take exponential time.

Although we have presented this EM-IPF algorithm for the case of Boltzmann machines, it is widely applicable to learning many undirected graphical models. In particular, in the E step, marginal distributions over the set of variables in each clique in the graph are computed conditioned on the settings of the observed variables. A propagation algorithm such as the Junction Tree algorithm can be used for this step (see GRAPHICAL MODELS: PROBABILISTIC INFERENCE). In the M step the IPF procedure is run so as to satisfy all the marginals computed in the E step. There also exist Junction-Tree-style propagation algorithms that exploit the structure of the graphical model to solve the IPF problem efficiently (Jirouŝek and P̂reuĉil, 1995; Teh and Welling, 2002).

## Bayesian Learning of Parameters

A Bayesian approach to learning starts with some a priori knowledge about the model structure—the set of arcs in the Bayesian network—and model parameters. This initial knowledge is represented in the form of a prior probability distribution over model structures and parameters, and is updated using the data to obtain a posterior probability distribution over models and parameters. In this article we will assume that the model structure is given, and we focus on computing the posterior probability distribution over parameters (see GRAPHICAL MODELS: STRUCTURE LEARNING for solutions to the problem of inferring model structure; see also BAYESIAN METHODS AND NEURAL NETWORKS).

For a given model structure **m**, we can compute the posterior distribution over the parameters:

$$p(\boldsymbol{\theta}|\mathbf{m}, \mathbf{d}) = \frac{p(\mathbf{d}|\boldsymbol{\theta}, \mathbf{m})p(\boldsymbol{\theta}|\mathbf{m})}{p(\mathbf{d}|\mathbf{m})} \qquad (26)$$

If the data set is $\mathbf{d} = (\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(N)})$ and we wish to predict the next observation, $\mathbf{x}^{(N+1)}$, based on our data and model, then the Bayesian prediction

$$p(\mathbf{x}^{(N+1)}|\mathbf{d}, \mathbf{m}) = \int p(\mathbf{x}^{(N+1)}|\boldsymbol{\theta}, \mathbf{m}, \mathbf{d})p(\boldsymbol{\theta}|\mathbf{m}, \mathbf{d})d\boldsymbol{\theta} \qquad (27)$$

averages over the uncertainty in the model parameters. This is known as the *predictive distribution* for the model.

In the limit of a large data set, and as long as the prior over the parameters assigns non-zero probability in the region around the ML parameter values, the posterior $p(\boldsymbol{\theta}|\mathbf{m}, \mathbf{d})$ will be sharply peaked around the maxima of the likelihood, and therefore the predictions of a single ML model will be similar to those obtained by Bayesian integration over the parameters.

Often, models are fit with relatively small amounts of data, so asymptotic results are not applicable and the predictions of the ML estimate will differ significantly from those of Bayesian averaging. In such situations it is important to compute or approximate the averaging over parameters in Equation 27. For certain discrete models with Dirichlet distributed priors over the parameters, and for certain linear-Gaussian models, it is possible to compute these integrals exactly. Otherwise, approximations can be used. There are a large number of approximations to the integral over the parameter distribution that have been used in graphical models, including Laplace's approximation, variational approximations, and a variety of MCMC methods (see Neal, 1993, for a review).

## Discussion

There are several key insights regarding parameter learning in graphical models. When there are no hidden variables in a directed graphical model, the graph structure determines the statistics of the data needed to learn the parameters: the joint distribution of each variable and its parents in the graph. Parameter estimation can then often occur independently for each node. The presence of hidden variables introduces dependencies between the parameters. However, the EM algorithm transforms the problem so that in each M step the parameters of the graphical model are again uncoupled. The E step of EM "fills in" the hidden variables with the distribution predicted by the model, thereby turning the hidden-data problem into a complete-data problem.

The intuitive appeal of EM has led to its widespread use in models of unsupervised learning where the goal is to learn a generative model of sensory data. The E step corresponds to perception or recognition: inferring the (hidden) state of the world from the sensory data; while the M step corresponds to learning: modifying the model that relates the actual world to the sensory data. It has been suggested that top-down and bottom-up connections in cortex play the roles of generative and recognition models (see HELMHOLTZ MACHINES AND SLEEP-WAKE LEARNING). From a graphical model perspective, the bottom-up recognition model in Helmholtz machines can be thought of as a graph that approximates the distribution of the hidden variables given the observed variables, in much the same way as the variational approximation approximates that same distribution.

Undirected graphical models pose additional challenges. The partition function is usually a function of the parameters, and can introduce dependencies between the parameters even in the case of complete data. The IPF algorithm can be used to fit undirected graphical models from complete data, and an IPF-EM algorithm can be used when there are hidden data as well.

Although ML learning is adequate when there are enough data, in general it is necessary to approximate the average over the parameters. Averaging avoids overfitting; it is hard to see how overfitting can occur when nothing is "fit" to the data. Non-Bayesian methods for avoiding overfitting often also involve averaging, for example, via bootstrap resampling of the data. Even with parameter averaging, predictions can suffer in quality if the assumed structure of the model—the conditional independence relationships—is incorrect. To overcome this, it is necessary to generalize the approach presented in this article to learn the structure of the model as well as the parameters from data. This topic is covered in Graphical Models: Structure Learning (q.v.).

# Graphical Models: Probabilistic Inference

*Michael I. Jordan and Yair Weiss*

## Introduction

A *graphical model* is a type of probabilistic network that has roots in several different research communities, including artificial intelligence (Pearl, 1988), statistics (Lauritzen and Spiegelhalter, 1988), error-control coding (Gallager, 1963), and neural networks. The graphical models framework provides a clean mathematical formalism that has made it possible to understand the relationships among a wide variety of network-based approaches to computation, and in particular to understand many neural network algorithms and architectures as instances of a broader probabilistic methodology.

Graphical models use graphs to represent and manipulate joint probability distributions. The graph underlying a graphical model may be directed, in which case the model is often referred to as a *belief network* or a *Bayesian network* (see Bayesian Networks), or the graph may be undirected, in which case the model is generally referred to as a *Markov random field.* A graphical model has both a structural component—encoded by the pattern of edges in the graph—and a parametric component—encoded by numerical "potentials" associated with sets of edges in the graph. The relationship between these components underlies the computational machinery associated with graphical models. In particular, general *inference algorithms* allow statistical quantities (such as likelihoods and conditional probabilities) and information-theoretic quantities (such as mutual information and conditional entropies) to be computed efficiently. These algorithms are the subject of the current article. *Learning algorithms* build on these inference algorithms and allow parameters and structures to be estimated from data (see Graphical Models: Parameter Learning and Graphical Models: Structure Learning).

## Background

Directed and undirected graphical models differ in terms of their Markov properties (the relationship between graph separation and conditional independence) and their parameterization (the relationship between local numerical specifications and global joint probabilities). These differences are important in discussions of the family of joint probability distribution that a particular graph can represent. In the inference problem, however, we generally have a specific fixed joint probability distribution at hand, in which case the differences between directed and undirected graphical models are less important. Indeed, in the current article, we treat these classes of model together and emphasize their commonalities.

Let $U$ denote a set of nodes of a graph (directed or undirected), and let $X_i$ denote the random variable associated with node $i$, for $i \in U$. Let $X_C$ denote the subset of random variables associated with a subset of nodes $C$, for any $C \subseteq U$, and let $X = X_U$ denote the collection of random variables associated with the graph.

The family of joint probability distributions associated with a given graph can be parameterized in terms of a product over *potential functions* associated with subsets of nodes in the graph. For directed graphs, the basic subset on which a potential is defined consists of a single node and its parents, and a potential turns out to be (necessarily) the conditional probability of the node given its parents. Thus, for a directed graph, we have the following representation for the joint probability:

$$p(x) = \prod_i p(x_i|x_{\pi_i}) \tag{1}$$

where $p(x_i|x_{\pi_i})$ is the *local conditional probability* associated with node $i$, and $\pi_i$ is the set of indices labeling the parents of node $i$. For undirected graphs, the basic subsets are *cliques* of the graph—

subsets of nodes that are completely connected. For a given clique $C$, let $\psi_C(x_C)$ denote a general potential function—a function that assigns a positive real number to each configuration $x_C$. We have

$$p(x) = \frac{1}{Z} \prod_{C \in \mathscr{C}} \psi_C(x_C) \tag{2}$$

where $\mathscr{C}$ is the set of cliques associated with the graph and $Z$ is an explicit normalizing factor, ensuring that $\Sigma_x p(x) = 1$. (We work with discrete random variables throughout for simplicity.)

Equation 1 can be viewed as a special case of Equation 2. Note in particular that we could have included a normalizing factor $Z$ in Equation 1, but, as is easily verified, it is necessarily equal to 1. Second, note that $p(x_i|x_{\pi_i})$ is a perfectly good example of a potential function, except that the set of nodes that it is defined on—the collection $\{i \cup \pi_i\}$—is not in general a clique (because the parents of a given node are not in general interconnected). Thus, to treat Equation 1 and Equation 2 on an equal footing, we find it convenient to define the so-called *moral graph* $\mathscr{G}^m$ associated with a directed graph $\mathscr{G}$. The moral graph is an undirected graph obtained by connecting all of the parents of each node in $\mathscr{G}$, and removing the arrowheads. On the moral graph, a conditional probability $p(x_i|x_{\pi_i})$ is a potential function, and Equation 1 reduces to a special case of Equation 2.

## Probabilistic Inference

Let $(E, F)$ be a partitioning of the indices of the nodes in a graphical model into disjoint subsets such that $(X_E, X_F)$ is a partitioning of the random variables. There are two basic kinds of inference problem that we wish to solve

- *Marginal probabilities*:

$$p(x_E) = \sum_{x_F} p(x_E, x_F)$$

- *Maximum a posteriori (MAP) probabilities*:

$$p^*(x_E) = \max_{x_F} p(x_E, x_F)$$

From these basic computations we can obtain other quantities of interest. In particular, the *conditional probability* $p(x_F|x_E)$ is equal to

$$p(x_F|x_E) = \frac{p(x_E, x_F)}{\sum_{x_F} p(x_E, x_F)}$$

and this is readily computed for any $x_F$ once the denominator is computed—a marginalization computation. Moreover, we often wish to combine conditioning and marginalization, or conditioning, marginalization, and MAP computations. For example, letting $(E, F, H)$ be a partitioning of the node indices, we may wish to compute

$$p(x_F|x_E) = \frac{p(x_E, x_F)}{\sum_{x_F} p(x_E, x_F)} = \frac{\sum_{x_H} p(x_E, x_F, x_H)}{\sum_{x_F} \sum_{x_H} p(x_E, x_F, x_H)}$$

We first perform the marginalization operation in the numerator and then perform a subsequent marginalization to obtain the denominator.

### *Elimination*

In this section we introduce a basic algorithm for inference known as *elimination*. Although elimination applies to arbitrary graphs (as we will see), our focus in this section is on trees.

We proceed via an example. Referring to the tree in Figure 1*A*, let us calculate the marginal probability $p(x_5)$. We compute this probability by summing the joint probability with respect to $\{x_1, x_2, x_3, x_4\}$. We must pick an order over which to sum, and with some malice aforethought, let us choose the order (1, 2, 4, 3). We have

$$\begin{aligned} p(x_5) &= \sum_{x_3} \sum_{x_4} \sum_{x_2} \sum_{x_1} p(x_1, x_2, x_3, x_4, x_5) \\ &= \sum_{x_3} \sum_{x_4} \sum_{x_2} \sum_{x_1} p(x_1)p(x_2|x_1)p(x_3|x_2)p(x_4|x_3)p(x_5|x_3) \\ &= \sum_{x_3} p(x_5|x_3) \sum_{x_4} p(x_4|x_3) \sum_{x_2} p(x_3|x_2) \sum_{x_1} p(x_1)p(x_2|x_1) \\ &= \sum_{x_3} p(x_5|x_3) \sum_{x_4} p(x_4|x_3) \sum_{x_2} p(x_3|x_2) m_{12}(x_2) \end{aligned}$$

where we introduce the notation $m_{ij}(x_j)$ to refer to the intermediate terms that arise in performing the sum. The index $i$ refers to the variable being summed over, and the index $j$ refers to the other variable appearing in the summand (for trees, there will never be more than two variables appearing in any summand). The resulting term is a function of $x_j$. We continue the derivation:

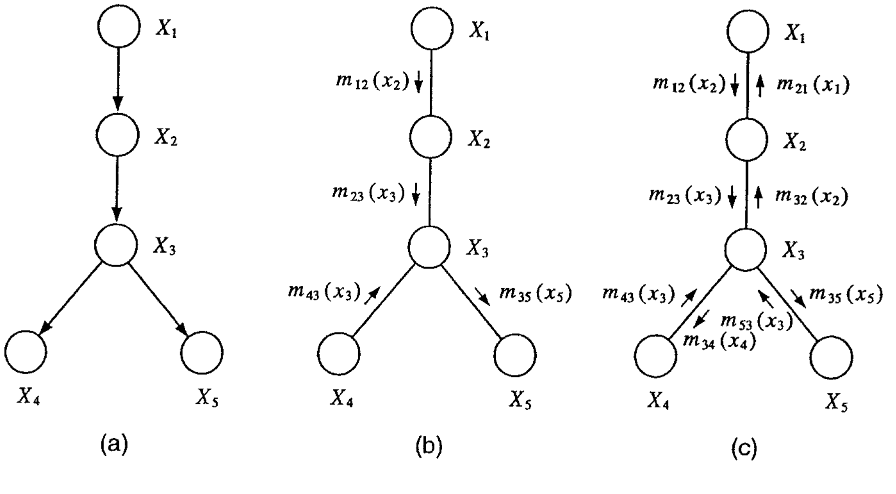

**Figure 1.** *A*, A directed graphical model. *B*, The intermediate terms that arise during a run of ELIMINATE can be viewed as messages attached to the edges of the moral graph. Here the elimination order was (1, 2, 4, 3). *C*, The set of all messages computed by the sum-product algorithm.

$$
\begin{aligned}
p(x_5) &= \sum_{x_3} p(x_5|x_3) \sum_{x_4} p(x_4|x_3) \sum_{x_2} p(x_3|x_2) m_{12}(x_2) \\
&= \sum_{x_3} p(x_5|x_3) \sum_{x_4} p(x_4|x_3) m_{23}(x_3) \\
&= \sum_{x_3} p(x_5|x_3) m_{23}(x_3) \sum_{x_4} p(x_4|x_3) \\
&= \sum_{x_3} p(x_5|x_3) m_{23}(x_3) m_{43}(x_3) \\
&= m_{35}(x_5)
\end{aligned}
$$

The final expression is a function of $x_5$ only and is the desired marginal probability.

This computation is formally identically in the case of an undirected graph. In particular, an undirected version of the tree in Figure 1*A* has the parameterization

$$p(x) = \frac{1}{Z} \psi_{12}(x_1, x_2) \psi_{23}(x_2, x_3) \psi_{34}(x_3, x_4) \psi_{35}(x_3, x_5)$$

The first few steps of the computation of $p(x_5)$ are then as follows:

$$
\begin{aligned}
p(x_5) &= \frac{1}{Z} \sum_{x_3} \psi_{35}(x_3, x_5) \sum_{x_4} \psi_{34}(x_3, x_4) \sum_{x_2} \psi_{23}(x_2, x_3) \\
&\quad \times \sum_{x_1} \psi_{12}(x_1, x_2) \\
&= \frac{1}{Z} \sum_{x_3} \psi_{35}(x_3, x_5) \sum_{x_4} \psi_{34}(x_3, x_4) \sum_{x_2} \psi_{23}(x_2, x_3) m_{12}(x_2)
\end{aligned}
$$

and the remainder of the computation proceeds as before.

These algebraic manipulations can be summarized succinctly in terms of a general algorithm that we refer to here as ELIMINATE (Figure 2). The algorithm maintains an "active list" of potentials that, at the outset, represent the joint probability, and at the end represent the desired marginal probability. Nodes are removed from the graph according to an elimination ordering that must be specified. The algorithm applies to both directed and undirected graphs. Also, as we will see shortly, it is in fact a general algorithm, applying not only to trees but to general graphs.

## *Message-Passing Algorithms*

In many problems we wish to obtain more than a single marginal probability. Thus, for example, we may wish to obtain both $p(x_4)$ and $p(x_5)$ in Figure 1*A*. Although we could compute each marginal with a separate run of ELIMINATE, this fails to exploit the fact that common intermediate terms appear in the different runs. We would like to develop an algebra of intermediate terms that allows them to be reused efficiently.

Suppose in particular that we wish to compute $p(x_4)$ in the example in Figure 1*A*. Using the elimination order (1, 2, 5, 3), it is easily verified that we generate the terms $m_{12}(x_2)$ and $m_{23}(x_3)$ as before, and also generate new terms $m_{53}(x_3)$ and $m_{34}(x_4)$.

```
ELIMINATE($G$)
  place all potentials $\psi_c(x_C)$ on the active list
  choose an ordering $I$ of the indices $F$
  for each $X_i$ in $I$
    find all potentials on the active list that reference $X_i$
      and remove them from the active list
    define a new potential as the sum (with respect to $x_i$) of the
      product of these potentials
    place the new potential on the active list
  end
  return the product of the remaining potentials
```

**Figure 2.** A simple elimination algorithm for marginalization in graphical models.

As suggested by Figure 1*B*, the intermediate terms that arise during elimination can be viewed as "messages" attached to edges in the moral graph. Rather than viewing inference as an elimination process, based on a global ordering, we instead view inference in terms of local computation and routing of messages. The key operation of summing a product can be written as follows:

$$m_{ij}(x_j) = \sum_{x_i} \psi_{ij}(x_i, x_j) \prod_{k \in N(i) \setminus j} m_{ki}(x_i) \tag{3}$$

where $N(i)$ is the set of neighbors of node $i$. Thus, summing over $x_i$ creates a message $m_{ij}(x_j)$ that is sent to the node $j$. The reader can verify that each step in our earlier computation of $p(x_5)$ has this form.

A node can send a message to a neighboring node once it has received messages from all of its other neighbors. As in our example, a message arriving at a leaf node is necessarily a marginal probability. In general, the marginal probability at a node is given by the product of all incoming messages:

$$p(x_i) \propto \prod_{k \in N(i)} m_{ki}(x_i) \tag{4}$$

The pair of equations given by Equations 3 and 4 defines an algorithm known as *sum-product algorithm* or the *belief propagation algorithm*. It is not difficult to prove that this algorithm is correct for trees.

The set of messages needed to compute all of the individual marginal probabilities for the graph in Figure 1*A* is shown in Figure 1*C*. Note that a pair of messages is sent along each edge, one message in each direction.

Neural networks also involve message-passing algorithms and local numerical operations. An important difference, however, is that in the neural network setting, each node generally has a single "activation" value that it passes to all of its neighbors. In the sum-product algorithm, on the other hand, individual messages are prepared for each neighbor. Moreover, the message $m_{ij}(x_j)$ from $i$ to $j$ is not included in the product that node $j$ forms in computing a message to send back to node $i$. The sum-product algorithm avoids double-counting.

## *Maximum a posteriori (MAP) Probabilities*

Referring again to Figure 1*A*, let us suppose that we wish to compute $p^*(x_5)$, the maximum probability configuration of the variables $(X_1, X_2, X_3, X_4)$, for a given value of $X_5$. Again choosing a particular ordering of the variables, we compute

$$
\begin{aligned}
p^*(x_5) &= \max_{x_3} \max_{x_4} \max_{x_2} \max_{x_1} p(x_1) p(x_2|x_1) p(x_3|x_2) p(x_4|x_3) p(x_5|x_3) \\
&= \max_{x_3} p(x_5|x_3) \max_{x_4} p(x_4|x_3) \max_{x_2} p(x_3|x_2) \\
&\qquad \times \max_{x_1} p(x_1) p(x_2|x_1)
\end{aligned}
$$

and the remaining computation proceeds as before. We see that the algebraic operations involved in performing the MAP computation are isomorphic to those in the earlier marginalization computation. Indeed, both the elimination algorithm and the sum-product algorithm extend immediately to MAP computation; we simply replace "sum" with "max" throughout in both cases. The underlying justification is that "max" commutes with products just as "sum" does.

## *General Graphs*

Our goal in this section is to describe the *junction tree algorithm*, a generalization of the sum-product algorithm that is correct for arbitrary graphs. We derive the junction tree algorithm by returning to the elimination algorithm.

The first point to note is that ELIMINATE is correct for arbitrary graphs—the algorithm simply describes the creation of intermediate terms in a chain of summations that compute a marginal probability. Thus the algorithm is correct, but it is limited to the computation of a single marginal probability.

To show how to generalize the elimination algorithm to allow all individual marginals to be computed, we again proceed by example. Referring to the graph in Figure 3*A*, suppose that we wish to calculate the conditional probability $p(x_1)$. Let us use the elimination ordering (5, 4, 3, 2). At the first step, in which we sum over $x_5$, we remove the potentials $\psi_{35}(x_3, x_5)$ and $\psi_{45}(x_4, x_5)$ from the active list and form the sum

$$m_{32}(x_3, x_4) = \sum_{x_5} \psi_{35}(x_3, x_5)\psi_{45}(x_4, x_5)$$

where the intermediate term, which is clearly a function of $x_3$ and $x_4$, is denoted $m_{32}(x_3, x_4)$. (We explain the subscripts below.) The elimination of $X_5$ has created an intermediate term that effectively links $X_3$ and $X_4$, variables that were not linked in the original graph. Similarly, at the following step, we eliminate $X_4$:

$$m_{21}(x_2, x_3) = \sum_{x_4} \psi_{24}(x_2, x_4)m_{32}(x_3, x_4)$$

and obtain a term that links $X_2$ and $X_3$, variables that were not linked in the original graph.

A graphical record of the dependencies induced during the run of ELIMINATE is shown in Figure 3*B*. We could also have created this graph according to a simple graph-theoretic algorithm in which nodes are removed in order from a graph where, when a node is removed, its remaining neighbors are linked. Thus, for example, when node 5 is removed, nodes 3 and 4 are linked. When node 4 is removed, nodes 2 and 3 are linked. Let us refer to this algorithm as GRAPH ELIMINATE.

We can also obtain the desired marginal $p(x_1)$ by working with the "filled-in" graph in Figure 3*B* from the outset. Noting that the cliques in this graph are $C_1 = \{x_1, x_2, x_3\}$, $C_2 = \{x_2, x_3, x_4\}$, and $C_3 = \{x_3, x_4, x_5\}$, and defining the potentials:

$$\begin{aligned}
\psi_{C_1}(x_1, x_2, x_3) &= \psi_{12}(x_1, x_2)\psi_{13}(x_1, x_3)\\
\psi_{C_2}(x_2, x_3, x_4) &= \psi_{24}(x_2, x_4)\\
\psi_{C_3}(x_3, x_4, x_5) &= \psi_{35}(x_3, x_5)\psi_{45}(x_4, x_5)
\end{aligned}$$

we obtain exactly the same product of potentials as before. Thus we have

$$\begin{aligned}
p(x) &= \frac{1}{Z}\psi_{12}(x_1, x_2)\psi_{13}(x_1, x_3)\psi_{24}(x_2, x_4)\psi_{35}(x_3, x_5)\psi_{45}(x_4, x_5)\\
&= \frac{1}{Z}\psi_{C_1}(x_1, x_2, x_3)\psi_{C_2}(x_2, x_3, x_4)\psi_{C_3}(x_3, x_4, x_5)
\end{aligned}$$

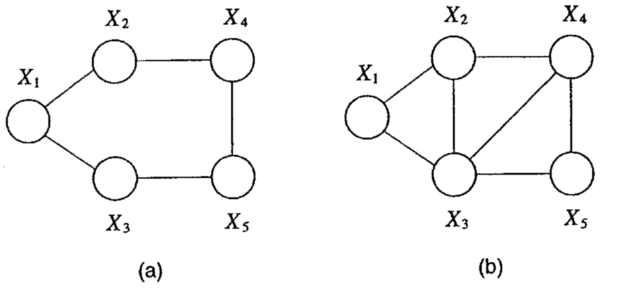

**Figure 3.** *A*, An undirected graphical model. *B*, The same model, with additional edges that reflect the dependencies created by the elimination algorithm.

We have essentially transferred the joint probability distribution from Figure 3*A* to Figure 3*B*. Moreover, the steps of the elimination algorithm applied to Figure 3*B* are exactly the same as before, and we obtain the same marginal. An important difference, however, is that in the case of Figure 3*B* all of the intermediate potentials created during the run of the algorithm are also supported by cliques in the graph.

Graphs created by GRAPH ELIMINATE are known as *triangulated graphs*, and they have a number of special properties. In particular, they allow the creation of a data structure known as a *junction tree* on which a generalized message-passing algorithm can be defined. A junction tree is a tree in which each node is a clique from the original graph. Messages, which correspond to intermediate terms in ELIMINATE, pass between these cliques.

Although a full discussion of the construction of junction trees is beyond the scope of the article, it is worth noting that a junction tree is not just any tree of cliques from a triangulated graph. Rather, it is a maximal spanning tree (of cliques), with weights given by the cardinalities of the intersections between cliques.

Given a triangulated graph, with cliques $C_i \in \mathcal{C}$ and potentials $\psi_{C_i}(x_{C_i})$, and given a corresponding junction tree (which defines links between the cliques), we send the following "message" from clique $C_i$ to clique $C_j$:

$$m_{ij}(x_{S_{ij}}) = \sum_{C_i\setminus S_{ij}} \psi_{C_i}(x_{C_i}) \prod_{k\in\mathcal{N}(i)\setminus j} m_{ki}(x_{S_{ki}}) \qquad (5)$$

where $S_{ij} = C_i \cap C_j$, and where $\mathcal{N}(i)$ are the neighbors of clique $C_i$ in the junction tree. Moreover, it is possible to prove that we obtain marginal probabilities as products of messages. Thus

$$p(x_{C_i}) \propto \prod_{k\in\mathcal{N}(i)} m_{ki}(x_{S_{ki}}) \qquad (6)$$

is the marginal probability for clique $C_i$. (Marginals for single nodes can be obtained via further marginalization: i.e., $p(x_i) = \Sigma_{C\setminus i}p(x_C)$, for $i \in C$.)

The junction tree corresponding to the triangulated graph in Figure 3*B* is shown in Figure 4, where the corresponding messages are also shown. The reader can verify that the leftward-going messages are identical to the intermediate terms created during the run of ELIMINATE. The junction tree algorithm differs from ELIMINATE, however, in that messages pass in all directions, and the algorithm yields all clique marginals, not merely those corresponding to a single clique.

The sum-product algorithm described earlier in Equations 3 and 4 is a special case of Equations 5 and 6, obtained by noting that the original tree in Figure 1*A* is already triangulated and has pairs of nodes as cliques. In this case, the "separator sets" $S_{ij}$ are singleton nodes.

Once again, the problem of computing MAP probabilities can be solved with a minor change to the basic algorithm. In particular, the "sum" in Equation 5 is changed to a "max."

There are many variations on exact inference algorithms, but all of them are either special cases of the junction tree algorithm or are close cousins. The basic message from the research literature on exact inference is that the operations of triangulating a graph

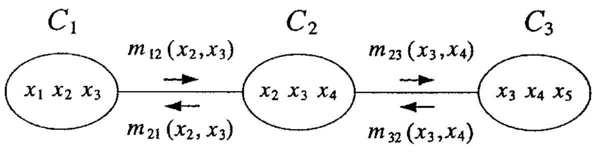

**Figure 4.** The junction tree corresponding to the triangulated graph in Figure 3*B*.

and passing messages on the resulting junction tree capture in a succinct way the basic algebraic structure of probabilistic inference.

### Cutset Conditioning

In the method of *cutset conditioning*, we identify a "cutset"—defined (in the graphical model literature) as a set of nodes whose removal from the graph yields a tree. For example, in Figure 3*A*, any single node is a cutset. Denoting the indices of the cutset by $Q$, we loop over all instantiations $x_Q$, computing the conditional marginals $p(x_i|x_Q)$. The unconditional marginals are then given by $p(x_i) = \Sigma_{x_Q} p(x_i|x_Q)p(x_Q)$.

By considering an augmented graph in which edges are drawn from the nodes in the cutset to all other nodes in the graph, we can view cutset conditioning as a special case of the junction tree algorithm (Shachter, Andersen, and Szolovits, 1994). Note, however, that an implementation of cutset conditioning method involves operating on a single tree at a time, with cliques that are never larger than two nodes. Essentially, cutset conditioning involves implementing the junction tree algorithm in a way that trades time for space.

### Computational Complexity

The computational complexity of the junction tree algorithm is a function of the size of the cliques upon which message-passing operations are performed. In particular, summing a clique potential is exponential in the number of nodes in the clique.

The problem of finding the optimal triangulation—the triangulation yielding the smallest maximal clique—turns out to be NP-hard. Clearly, if we had to search over all possible elimination orderings, the search would take exponential time. Triangulation can also be defined in other ways, however, and practical triangulation algorithms need not search over orderings. But the problem is still intractable, and can be a practical computational bottleneck.

An even more serious problem is that in practical graphical models, the original graph may have large cliques, or long loops, and even the optimal triangulation would yield unacceptable complexity. This problem is particularly serious because it arises not during the "compile time" operation of triangulation, but during the "run time" operation of message-passing. Problems in error-control coding and image processing are particularly noteworthy for yielding such graphs, as are discretizations of continuous-time problems and layered graphs of the kinds studied in the neural network field. To address these problems, we turn to the topic of approximate probabilistic inference.

## Approximate Inference

The junction tree algorithm focuses on the algebraic structure of probabilistic inference, exploiting the conditional independencies present in a joint probability distribution, as encoded in the pattern of (missing) edges in the graph. There is another form of structure in probability theory, however, that is not exploited in the junction tree framework, and which leads us to hope that successful approximate inference algorithms can be developed. In particular, laws of large numbers and other concentration theorems in probability theory show that sums and products of large numbers of terms can behave in simple, predictable ways, despite the apparent combinatorial complexity of these operations. Approximate algorithms attempt to exploit these numerical aspects of probability theory.

We discuss two large classes of approximate inference algorithms in this section—Monte Carlo algorithms and variational algorithms. Although these classes do not exhaust all of the approximation techniques that have been studied, they capture the most widely used examples.

### Monte Carlo Algorithms

Monte Carlo algorithms are based on the fact that while it may not be feasible to compute expectations under $p(x)$, it may be possible to obtain samples from $p(x)$, or from a closely related distribution, such that marginals and other expectations can be approximated using sample-based averages. We discuss three examples of Monte Carlo algorithms that are commonly used in the graphical model setting—Gibbs sampling, the Metropolis-Hastings algorithm, and importance sampling (for a comprehensive presentation of these methods and others, see Andrieu et al., 2003).

*Gibbs sampling* is an example of a Markov chain Monte Carlo (MCMC) algorithm. In an MCMC algorithm, samples are obtained via a Markov chain whose stationary distribution is the desired $p(x)$. The state of the Markov chain is a set of assignments of values to each of the variables, and, after a suitable "burn-in" period so that the chain approaches its stationary distribution, these states are used as samples.

The Markov chain for the Gibbs sampler is constructed in a straightforward way: (1) at each step one of the variables $X_i$ is selected (at random or according to some fixed sequence), (2) the conditional distribution $p(x_i|x_{U\setminus i})$ is computed, (3) a value $x_i$ is sampled from this distribution, and (4) the sample $x_i$ replaces the previous value of the $i$th variable.

The implementation of Gibbs sampling thus reduces to the computation of the conditional distributions of individual variables given all of the other variables. For graphical models, these conditionals take the following form:

$$p(x_i|x_{U\setminus i}) = \frac{\prod_{C\in\mathscr{C}} \psi_C(x_C)}{\sum_{x_i} \prod_{C\in\mathscr{C}} \psi_C(x_C)} = \frac{\prod_{C\in\mathscr{C}_i} \psi_C(x_C)}{\sum_{x_i} \prod_{C\in\mathscr{C}_i} \psi_C(x_C)} \tag{7}$$

where $\mathscr{C}_i$ denotes the set of cliques that contain index $i$. This set is often much smaller than the set $\mathscr{C}$ of all cliques, and in such cases each step of the Gibbs sampler can be implemented efficiently. Indeed, the conditional of node $i$ depends only on the neighbors of node $i$ in the graph, and thus the computation of the conditionals often takes the form of a simple message-passing algorithm that is reminiscent of the sum-product algorithm.

A simple example of a Gibbs sampler is provided by the *Boltzmann machine*, an undirected graphical model in which the potentials are defined on pairwise cliques. Gibbs sampling is often used for inference in the Boltzmann machine, and the algorithm in Equation 7 takes the form of the classical computation of the logistic function of a weighted sum of the values of neighboring nodes.

When the computation in Equation 7 is overly complex, the *Metropolis-Hastings algorithm* can provide an effective alternative. The Metropolis-Hastings algorithm is an MCMC algorithm that is not based on conditional probabilities and thus does not require normalization. Given the current state $x$ of the algorithm, Metropolis-Hastings chooses a new state $\tilde{x}$ from a "proposal distribution" $q(\tilde{x}|x)$, which often simply involves picking a variable $X_i$ at random and choosing a new value for that variable, again at random. The algorithm then computes the "acceptance probability":

$$\alpha = \min\left(1, \frac{q(x|\tilde{x})}{q(\tilde{x}|x)} \frac{\prod_{C\in\mathscr{C}_i} \psi_C(\tilde{x}_C)}{\prod_{C\in\mathscr{C}_i} \psi_C(x_C)}\right)$$

With probability $\alpha$ the algorithm accepts the proposal and moves to $\tilde{x}$, and with probability $1 - \alpha$ the algorithm remains in state $x$. For graphical models, this computation also turns out to often take the form of a simple message-passing algorithm.

While Gibbs sampling and Metropolis-Hastings aim at sampling from $p(x)$, *importance sampling* is a Monte Carlo technique for computing expectations in which samples are chosen from a simpler distribution $q(x)$, and these samples are reweighted appropriately. In particular, we approximate the expectation of a function $f(x)$ as follows:

$$\begin{aligned} E[f(x)] &= \sum_x p(x)f(x) \\ &= \sum_x q(x)\left(\frac{p(x)}{q(x)}f(x)\right) \\ &\approx \frac{1}{N}\sum_{i=1}^{N}\frac{p(x^{(t)})}{q(x^{(t)})}f(x^{(t)}) \end{aligned}$$

where the values $x^{(t)}$ are samples from $q(x)$. The choice of $q(x)$ is in the hands of the designer, and the idea is that $q(x)$ should be chosen to be relatively simple to sample from, while reasonably close to $p(x)$ so that the weight $p(x^{(t)})/q(x^{(t)})$ is reasonably large. In the graphical model setting, natural choices of $q(x)$ are often provided by simplifying the graph underlying $p(x)$ in some way, in particular by deleting edges.

The principal advantages of Monte Carlo algorithms are their simplicity of implementation and their generality. Under weak conditions, the algorithms are guaranteed to converge. A problem with the Monte Carlo approach, however, is that convergence times can be long, and it can be difficult to diagnose convergence.

We might hope to be able to improve on Monte Carlo methods in situations in which laws of large numbers are operative. Consider, for example, the case in which a node $i$ has many neighbors, such that the conditional $p(x_i|x_{U\backslash i})$ has a single, sharply determined maximum for most configurations of the neighbors. In this case, it would seem wasteful to continue to sample from this distribution; rather, we would like to be able to compute the maximizing value directly in some way. This way of thinking leads to the variational approach to approximate inference.

### *Variational Methods*

The key to the variational approach lies in converting the probabilistic inference problem into an optimization problem, such that the standard tools of constrained optimization can be exploited. The basic approach has a similar flavor to importance sampling, but instead of choosing a single $q(x)$ a priori, a family of approximating distributions $\{q(x)\}$ is used, and the optimization machinery chooses a particular member from this family.

We begin by showing that the joint probability $p(x)$ can be viewed as the solution to an optimization problem. In particular, define the *energy* of a configuration $x$ by $E(x) = -\log p(x) - \log Z$, and define the *variational free energy* as follows:

$$\begin{aligned} F(q) &= \sum_x q(x)E(x) + \sum_x q(x) \log q(x) \\ &= -\sum_x q(x) \log p(x) + \sum_x q(x) \log q(x) - \log Z \end{aligned}$$

The variational free energy is equal (up to an additive constant) to the Kullback-Leibler divergence between $q(x)$ and $p(x)$. It is therefore minimized when $q(x) = p(x)$ and attains the value of $-\log Z$ at the minimum. We have thus characterized $p(x)$ variationally.

Minimizing $F$ is as difficult as doing exact inference, and much effort has been invested in finding approximate forms of $F$ that are easier to minimize. Each approximate version of $F$ gives an approximate variational inference algorithm.

For example, the simplest variational algorithm is the *mean field* approximation, in which $\{q(x)\}$ is restricted to the family of factorized distributions: $q(x) = \Pi_i q_i(x_i)$. In this case $F$ simplifies to

$$\begin{aligned} F_{MF}(q) &= -\sum_C \sum_{x_C} \log \psi_C(x_C) \prod_{i\in C} q_i(x_i) \\ &\quad + \sum_i \sum_{x_i} q_i(x_i) \log q_i(x_i) \end{aligned}$$

subject to the constraint $\Sigma_{x_i} q_i(x_i) = 1$.

Setting the derivative with respect to $q_i(x_i)$ equal to zero gives

$$q_i(x_i) = \alpha \exp\left(\sum_{C\in\mathscr{C}_i}\sum_{x_{C\backslash i}} \log \psi_C(x_C) \prod_{j\in C, j\neq i} q_j(x_j)\right) \quad (8)$$

where $\alpha$ is a normalization constant chosen so that $\Sigma_{x_i} q_i(x_i) = 1$. The sum over cliques $C_i$ is a sum over all cliques that node $i$ belongs to.

Equation 8 defines an approximate inference algorithm. We initialize approximate marginals $q(x_i)$ for all nodes in the graph and then update the approximate marginal at one node based on those at neighboring nodes (note that the right-hand side of Equation 8 depends only on cliques that node $i$ belongs to). This yields a message-passing algorithm that is similar to neural network algorithms; in particular, the value $q(x_i)$ can be viewed as the "activation" of node $i$.

More elaborate approximations to the free energy give better approximate marginal probabilities. While the mean field free energy depends only on approximate marginals at single nodes, the *Bethe free energy* depends on approximate marginals at single nodes $q_i(x_i)$ as well as on approximate marginals on cliques $q_C(x_C)$:

$$\begin{aligned} F_\beta(q) &= \sum_C \sum_{x_C} q_C(x_C) \log \frac{q_C(x_C)}{\psi_c(x_C)} \\ &\quad - \sum_i (d_i - 1) \sum_{x_i} q_i(x_i) \log q_i(x_i) \end{aligned}$$

where $d_i - 1$ denotes the number of cliques that node $i$ belongs to.

The approximate clique marginals and the approximate singleton marginals must satisfy a simple marginalization constraint: $\Sigma_{x_{C\backslash i}} q_C(x_C) = q_i(x_i)$. When we add Lagrange multipliers and differentiate the Lagrangian, we obtain a set of fixed point equations. Surprisingly, these equations end up being equivalent to the "sum-product" algorithm for trees in Equation 3. The messages $m_{ij}(x_j)$ are simply exponentiated Lagrange multipliers. Thus the Bethe approximation is equivalent to applying the local message-passing scheme developed for trees to graphs that have loops (see Yedidia, Freeman, and Weiss, 2001). This approach to approximate inference has been very successful in the domain of error-control coding, allowing practical codes based on graphical models to nearly reach the Shannon limit.

## Discussion

The unified perspective on inference algorithms that we have presented in this article has arisen through several different historical strands. We briefly summarize these strands here and note some of the linkages with developments in the neural network field.

The elimination algorithm has had a long history. The "peeling" algorithm developed by geneticists is an early example (Cannings, Thompson, and Skolnick, 1978), as are the "decimation" and "transfer matrix" procedures in statistical physics (Itzykson and Drouffe, 1991). For a recent discussion of elimination algorithms, including more efficient algorithms than the simple ELIMINATE algorithm presented here, see Dechter (1999).

Belief propagation has also had a long history. An early version of the sum-product algorithm was studied by Gallager (1963) in the context of error-control codes (see Kschischang, Frey, and Loeliger (2001) for a recent perspective). Well-known special cases of sum-product include the forward-backward algorithm for hidden Markov models (see HIDDEN MARKOV MODELS), and the Kalman filtering/smoothing algorithms for state-space models. A seminal presentation of the sum-product algorithm was provided by Pearl (1988).

The variant of the junction tree algorithm that we have defined is due to Shafer and Shenoy (1990), and has also been called the *generalized distributive law* by Aji and McEliece (2000). A closely related variant known as the *Hugin algorithm* arose from the work of Lauritzen and Spiegelhalter (1988); it is described by Jensen (2001).

Many neural network architectures are special cases of general graphical model formalism, both representationally and algorithmically. Special cases of graphical models include essentially all of the models developed under the rubric of unsupervised learning (see UNSUPERVISED LEARNING WITH GLOBAL OBJECTIVE FUNCTIONS, INDEPENDENT COMPONENT ANALYSIS, and HELMHOLTZ MACHINES AND SLEEP-WAKE LEARNING), as well as Boltzmann machines (see SIMULATED ANNEALING AND BOLTZMANN MACHINES), mixtures of experts (see MODULAR AND HIERARCHICAL LEARNING SYSTEMS), and radial basis function networks (see RADIAL BASIS FUNCTION NETWORKS). Many other neural networks, including the classical multilayer perceptron (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION) can be profitably analyzed from the point of view of graphical models. For more discussion of these links, see the articles in Jordan (1999).

# Graphical Models: Structure Learning

*David Heckerman*

## Introduction

The article GRAPHICAL MODELS: PARAMETER LEARNING (q.v.) discussed the learning of parameters for a fixed graphical model. In this article, we discuss the simultaneous learning of parameters and structure. Real-world applications of such learning abound and can be found in, for example, *Proceedings of the Conference on Uncertainty in Artificial Intelligence* (1991 and after). An index to software for parameter and structure learning can be found at http://www.cs.berkeley.edu/murphyk/Bayes/bnsoft.html.

For simplicity, we concentrate on directed-acyclic graphical models (DAG models), but the basic principles described here can be applied more generally. We describe the Bayesian approach in detail and mention several common non-Bayesian approaches.

We use notation that is slightly different from that used in the article on parameter learning. In particular, we use $\mathbf{X} = (X_1, \ldots, X_n)$ to denote the $n$ variables that we are modeling, $\mathbf{x}$ to denote a configuration or observation of $\mathbf{X}$, and $\mathbf{d} = (\mathbf{x}^1, \ldots, \mathbf{x}^N)$ to denote a random sample of $N$ observations of $\mathbf{X}$. In addition, we use $\mathbf{Pa}_i$ to denote the variables corresponding to the parents of $X_i$ in a DAG model and $\mathbf{pa}_i$ to denote a configuration of those variables. Finally, we shall use the terms *model* and *structure* interchangeably. In particular, a DAG model (and hence its structure) is described by (1) its nodes and arcs, and (2) the distribution class of each of its local distributions $p(x_i|\mathbf{pa}_i)$.

## The Bayesian Approach

When we learn a model and its parameters, we presumably are uncertain about their identity. When following the Bayesian approach—in which all uncertainty is encoded as (subjective) probability—we encode this uncertainty as prior distributions over random variables corresponding to structure and parameters. In particular, let $\mathbf{m}$ be a random variable having states $\mathbf{m}^1, \ldots, \mathbf{m}^M$ corresponding to the possible models. (Note that we are assuming the models are mutually exclusive.) In addition, let $\boldsymbol{\theta}^1, \ldots, \boldsymbol{\theta}^M$ be random variables corresponding to the unknown parameters of each of the $M$ possible models. Then we express our uncertainty prior to learning as the prior distributions $p(\mathbf{m})$, and $p(\boldsymbol{\theta}^1), \ldots, p(\boldsymbol{\theta}^M)$.

Given data $\mathbf{d}$, a random sample from the true but unknown joint distribution for $\mathbf{X}$, we compute the posterior distributions for each $\mathbf{m}$ and $\boldsymbol{\theta}^m$ using Bayes's rule:

$$p(\mathbf{m}|\mathbf{d}) = \frac{p(\mathbf{m})p(\mathbf{d}|\mathbf{m})}{\sum_{m'} p(\mathbf{m}')p(\mathbf{d}|\mathbf{m}')} \tag{1}$$

$$p(\boldsymbol{\theta}^m|\mathbf{d}, \mathbf{m}) = \frac{p(\boldsymbol{\theta}^m|\mathbf{m})p(\mathbf{d}|\boldsymbol{\theta}^m, \mathbf{m})}{p(\mathbf{d}|\mathbf{m})} \tag{2}$$

where

$$p(\mathbf{d}|\mathbf{m}) = \int p(\mathbf{d}|\boldsymbol{\theta}^m, \mathbf{m})p(\boldsymbol{\theta}^m|\mathbf{m})d\boldsymbol{\theta}^m \tag{3}$$

is called the *marginal likelihood.* Given some hypothesis of interest, $h$, we determine the probability that $h$ is true given data $\mathbf{d}$ by averaging over all possible models and their parameters:

$$p(h|\mathbf{d}) = \sum_m p(\mathbf{m}|\mathbf{d})p(h|\mathbf{d}, \mathbf{m}) \tag{4}$$

$$p(h|\mathbf{d}, \mathbf{m}) = \int p(h|\boldsymbol{\theta}^m, \mathbf{m})p(\boldsymbol{\theta}^m|\mathbf{d}, \mathbf{m})d\boldsymbol{\theta}^m \tag{5}$$

For example, $h$ may be the event that the next case $\mathbf{X}^{N+1}$ is observed in configuration $\mathbf{x}^{N+1}$. In this situation, we obtain

$$p(\mathbf{x}^{N+1}|\mathbf{d}) = \sum_m p(\mathbf{m}|\mathbf{d}) \int p(\mathbf{x}^{N+1}|\boldsymbol{\theta}^m, \mathbf{m})p(\boldsymbol{\theta}^m|\mathbf{d}, \mathbf{m})d\boldsymbol{\theta}^m \tag{6}$$

where $p(\mathbf{x}^{N+1}|\boldsymbol{\theta}^m, \mathbf{m})$ is the likelihood for the model. It is important to note that, in the Bayesian approach, no single model is learned. Instead, data is used to update the probability that each possible model is the correct one.

Unfortunately, this approach, sometimes called *Bayesian model averaging* or the *full Bayesian approach,* is often impractical. For example, the number of different DAG models for a domain containing $n$ variables grows superexponentially with $n$. Thus, the approach can only be applied in those few settings where one has strong prior knowledge that can eliminate almost all possible models.

Statisticians, who have been confronted by this problem for decades in the context of other types of models, use two approximations to address this problem: *Bayesian model selection* and *selective Bayesian model averaging.* The former approach is to select a likely model from among all possible models and use it as if it were the correct model. For example, to predict the next case, we use

$$\begin{aligned} p(\mathbf{x}^{N+1}|\mathbf{d}) &\cong p(\mathbf{x}^{N+1}|\mathbf{m}, \mathbf{d}) \\ &= \int p(\mathbf{x}^{N+1}|\boldsymbol{\theta}^m, \mathbf{m})p(\boldsymbol{\theta}^m|\mathbf{d}, \mathbf{m})d\boldsymbol{\theta}^m \end{aligned} \tag{7}$$

where $\mathbf{m}$ is the selected model. The latter approach is to select a manageable number of good models from among all possible models and pretend that these models are exhaustive. In either approach, we need only the *relative* model posterior—$p(\mathbf{m})p(\mathbf{d}|\mathbf{m})$—to select likely models.

Both approaches can be characterized as *search-and-score* techniques. That is, in these approaches, we search among a large set of models looking for those with good scores. The use of these approximate methods raise several important questions. Do they yield accurate results when applied to graphical model learning? If so, can we compute the model posteriors and perform a search efficiently?

The question of accuracy is difficult to answer in theory. Nonetheless, several researchers have shown experimentally that the selection of a single good hypothesis often yields accurate predictions (e.g., Cooper and Herskovits, 1992; Heckerman, Geiger, and Chickering, 1995) and that selective model averaging using Monte Carlo methods can sometimes be efficient and yield even better predictions (Madigan et al., 1996). These results, which are somewhat surprising, are largely responsible for the considerable interest in learning graphical models.

In the remainder of this section, we address computational efficiency. In particular, we consider situations in which (relative) model posteriors can be computed efficiently as well as efficient search procedures.

We note that model averaging, model selection, and selective model averaging all help avoid overfitting—situations where models perform well on training data and poorly on new data. In particular, the marginal likelihood balances the fit of the model structure to data with the complexity of the model. One way to understand this fact is to note that, when the number of cases $N$ is large and other conditions hold, the marginal likelihood can be approximated as follows:

$$p(\mathbf{d}|\mathbf{m}) \cong p(\mathbf{d}|\hat{\boldsymbol{\theta}}, \mathbf{m}) - \frac{|\boldsymbol{\theta}|}{2} \log N$$

where $\hat{\boldsymbol{\theta}}$ is the maximum-likelihood estimator of the data (e.g., Kass and Raftery, 1995). The first quantity in this expression represents the degree to which the model fits the data, which increases as the model complexity increases. The second quantity, in contrast, penalizes model complexity.

### *Computation of the Marginal Likelihood*

Under certain conditions, the marginal likelihood of a graphical model—and hence its relative posterior—can be computed efficiently. In this section, we examine a particular set of these conditions for structure learning of DAG models. We note that a similar set of conditions holds for the learning of decomposable UG models. For details, see Lauritzen (1996).

Given any DAG model $\mathbf{m}$, we can factor the likelihood of a single sample as follows:

$$p(\mathbf{x}|\boldsymbol{\theta}_m, \mathbf{m}) = \prod_{i=1}^{n} p(x_i|\mathbf{pa}_i, \boldsymbol{\theta}_i, \mathbf{m}) \tag{8}$$

We shall refer to each term $p(x_i|\mathbf{pa}_i, \boldsymbol{\theta}_i, \mathbf{m})$ in this equation as the *local likelihood for* $X_i$. Also, in this equation, $\boldsymbol{\theta}_i$ denotes the set of parameters associated with the local likelihood for variable $X_i$.

The first condition in our set of sufficient conditions yielding efficient computation is that each local likelihood is in the exponential family. One example of such a factorization occurs when each variable $X_i \in \mathbf{X}$ is finite, having $r_i$ possible values $x_i^1, \ldots, x_i^{r_i}$, and each local likelihood is a collection of multinomial distributions, one distribution for each configuration of $\mathbf{Pa}_i$—that is,

$$p(x_i^k|\mathbf{pa}_i^j, \boldsymbol{\theta}_i, \mathbf{m}) = \theta_{ijk} > 0 \tag{9}$$

where $\mathbf{pa}_i^1, \ldots, \mathbf{pa}_i^{q_i}$ ($q_i = \Pi_{X_i \in \mathbf{Pa}_i} r_i$) denotes the configurations of $\mathbf{Pa}_i$, and $\boldsymbol{\theta}_{ij} = ((\theta_{ijk})_{k=2}^{r_i})_{j=1}^{q_i}$ denotes the parameters. The parameter $\theta_{ij1}$ is given by $1 - \Sigma_{k=2}^{r_i}\theta_{ijk}$. We shall use this example to illustrate many of the concepts in this article. For convenience, we define the vector of parameters

$$\boldsymbol{\theta}_{ij} = (\theta_{ij1}, \ldots, \theta_{ijr_i})$$

for all $i$ and $j$. Examples of other exponential families can be found in Bernardo and Smith (1994).

The second assumption for efficient computation is one of parameter independence. In our multinomial example, we assume that the parameter vectors $\boldsymbol{\theta}_{ij}$ are mutually independent. Note that, when this independence holds and we are given a random sample $\mathbf{d}$ that contains no missing observations, the parameters remain independent:

$$p(\boldsymbol{\theta}_m|\mathbf{d}, \mathbf{m}) = \prod_{i=1}^{n} \prod_{j=1}^{q_i} p(\boldsymbol{\theta}_{ij}|\mathbf{d}, \mathbf{m}) \tag{10}$$

Thus, we can update each vector of parameters $\boldsymbol{\theta}_{ij}$ independently.

The third assumption is that each independent parameter set has a conjugate prior (e.g., Bernardo and Smith, 1994). In our multinomial example, we assume that each $\boldsymbol{\theta}_{ij}$ has a Dirichlet prior $\text{Dir}(\boldsymbol{\theta}_{ij}|\alpha_{ij1}, \ldots, \alpha_{ijr_i})$. In this case, we obtain

$$p(\boldsymbol{\theta}_{ij}|\mathbf{d}, \mathbf{m}) = \mathrm{Dir}(\boldsymbol{\theta}_{ij}|\alpha_{ij1} + N_{ij1}, \ldots, \alpha_{ijr_i} + N_{ijr_i}) \quad (11)$$

where $N_{ijk}$ is the number of cases in $\mathbf{d}$ in which $X_i = x_i^k$ and $\mathbf{Pa}_i = \mathbf{pa}_i^j$. Note that the collection of counts $N_{ijk}$ are sufficient statistics of the data for the model $\mathbf{m}$.

Under these conditions, we can compute the marginal likelihood efficiently and in closed form. For our multinomial example (as first derived in Cooper and Herskovits, 1992), we obtain

$$p(\mathbf{d}|\mathbf{m}) = \prod_{i=1}^{n} \prod_{j=1}^{q_i} \frac{\Gamma(\alpha_{ij})}{\Gamma(\alpha_{ij} + N_{ij})} \cdot \prod_{k=1}^{r_i} \frac{\Gamma(\alpha_{ijk} + N_{ijk})}{\Gamma(\alpha_{ijk})} \quad (12)$$

where $\alpha_{ij} = \sum_{k=1}^{r_i} \alpha_{ijk}$ and $N_{ij} = \sum_{k=1}^{r_i} N_{ijk}$.

Under these same conditions, the integral in Equation 7 also can be computed efficiently. In our example, suppose that, for a given outcome $\mathbf{x}_{N+1}$ of $\mathbf{X}_{N+1}$, the value of $X_i$ is $x_i^k$ and the configuration of $\mathbf{Pa}_i$ is $\mathbf{pa}_i^j$, where $k$ and $j$ depend on $i$. Using Equations 4, 8, and 9, we obtain

$$p(\mathbf{x}_{N+1}|\mathbf{d}, \mathbf{m}) = \int \left( \prod_{i=1}^{n} \theta_{ijk} \right) p(\boldsymbol{\theta}_m|\mathbf{d}, \mathbf{m}) d\boldsymbol{\theta}_m$$

Because parameters remain independent given $\mathbf{d}$, we get

$$p(\mathbf{x}_{N+1}|\mathbf{d}, \mathbf{m}) = \prod_{i=1}^{n} \int \theta_{ijk}\, p(\boldsymbol{\theta}_{ij}|\mathbf{d}, \mathbf{m}) d\boldsymbol{\theta}_{ij}$$

Finally, because each integral in this product is the expectation of a Dirichlet distribution, we have

$$p(\mathbf{x}_{N+1}|\mathbf{d}, \mathbf{m}) = \prod_{i=1}^{n} \frac{\alpha_{ijk} + N_{ijk}}{\alpha_{ij} + N_{ij}} \quad (13)$$

To compute the relative posterior probability of a model, we must assess the structure prior $p(\mathbf{m})$ and the parameter priors $p(\boldsymbol{\theta}^m|\mathbf{m})$. Unfortunately, when many models are possible, the assessment process will be intractable. Nonetheless, under certain assumptions, we can derive the structure and parameter priors for many models from a manageable number of direct assessments. Several authors have discussed such assumptions and corresponding methods for deriving priors (e.g., Buntine, 1991; Cooper and Herskovits, 1992; Heckerman et al., 1995; Cowell et al., 1999). In the following two sections, we examine some of these approaches.

## *Priors for Model Parameters*

First, let us consider the assessment of priors for the parameters of DAG models. We consider the approach of Heckerman, Geiger, and Chickering (1995)—herein, HGC—who address the case for $\mathbf{X}$ where the local likelihoods are multinomial distributions. A similar approach exists for situations where the local likelihoods are linear regressions (Heckerman and Geiger, 1995).

Their approach is based on two key concepts: Markov equivalence and distribution equivalence. We say that two models for $\mathbf{X}$ are *Markov equivalent* if they represent the same set of conditional-independence assertions for $\mathbf{X}$. For example, given $\mathbf{X} = \{X, Y, Z\}$, the models $X \to Y \to Z$, $X \leftarrow Y \to Z$, and $X \leftarrow Y \leftarrow Z$ represent only the independence assertion that $X$ and $Z$ are conditionally independent given $Y$. Consequently, these models are equivalent. Another example of Markov equivalence is the set of *complete models* on $\mathbf{X}$. A complete model is one that has no missing edge and that encodes no assertion of conditional independence. When $\mathbf{d}$ contains $n$ variables, there are $n!$ possible complete models, one model structure for every possible ordering of the variables. All complete models for $\mathbf{X}$ are Markov equivalent. In general, two models are Markov equivalent if and only if they have the same structure, ignoring arc directions, and the same v-structures. A *v-structure* is an ordered tuple $(X, Y, Z)$ such that there is an arc from $X$ to $Y$ and from $Z$ to $Y$, but no arc between $X$ and $Z$.

The concept of distribution equivalence is closely related to that of Markov equivalence. Suppose that all models for $\mathbf{X}$ under consideration have local likelihoods in the family $\mathcal{F}$. This is not a restriction per se, because $\mathcal{F}$ can be a large family. We say that two model structures $\mathbf{m}_1$ and $\mathbf{m}_2$ for $\mathbf{X}$ are *distribution equivalent with respect to* $\mathcal{F}$ if they can represent the same joint probability distributions for $\mathbf{X}$, that is, if, for every $\boldsymbol{\theta}_{m1}$, there exists a $\boldsymbol{\theta}_{m2}$ such that $p(\mathbf{x}|\boldsymbol{\theta}_{m1}, \mathbf{m}_1) = p(\mathbf{x}|\boldsymbol{\theta}_{m2}, \mathbf{m}_2)$, and vice versa.

Distribution equivalence with respect to some $\mathcal{F}$ implies Markov equivalence, but the converse does not hold. For example, when $\mathcal{F}$ is the family of generalized linear regression models, the complete model structures for $n \geq 3$ variables do not represent the same sets of distributions. Nonetheless, there are families $\mathcal{F}$—for example, multinomial distributions and linear regression models with Gaussian noise—where Markov equivalence implies distribution equivalence with respect to $\mathcal{F}$ (see HGC). The notion of distribution equivalence is important, because if two model structures $\mathbf{m}_1$ and $\mathbf{m}_2$ are distribution equivalent with respect to a given $\mathcal{F}$, then it is often reasonable to expect that data cannot help to discriminate them. That is, we expect $p(\mathbf{d}|\mathbf{m}_1) = p(\mathbf{d}|\mathbf{m}_2)$ for any data set $\mathbf{d}$. HGC call this property *likelihood equivalence.*

Now let us return to the main issue of this section: the derivation of parameter priors from a manageable number of assessments. HGC show that the assumption of likelihood equivalence combined with the assumption that the $\boldsymbol{\theta}_{ij}$ are mutually independent imply that the parameters for any *complete* model $\mathbf{m}_c$ must have a Dirichlet distribution with constraints on the hyperparameters given by

$$\alpha_{ijk} = \alpha p(x_i^k, \mathbf{pa}_i^j|\mathbf{m}_c) \quad (14)$$

where $\alpha$ is the user's equivalent sample size and $p(x_i^k, \mathbf{pa}_i^j|\mathbf{m}_c)$ is computed from the user's joint probability distribution $p(\mathbf{d}|\mathbf{m}_c)$ (discussions of equivalent sample size can be found in, e.g., Heckerman et al., 1995). Note that this result is rather surprising, as the two assumptions leading to the constrained Dirichlet solution are qualitative.

To determine the priors for parameters of *incomplete* models, HGC use the assumption of *parameter modularity,* which says that if $X_i$ has the same parents in models $\mathbf{m}_1$ and $\mathbf{m}_2$, then

$$p(\boldsymbol{\theta}_{ij}|\mathbf{m}_1) = p(\boldsymbol{\theta}_{ij}|\mathbf{m}_2)$$

for $j = 1, \ldots, q_i$. They call this property parameter modularity, because it says that the distributions for parameters $\boldsymbol{\theta}_{ij}$ depend only on a portion of the graph structure, namely, $X_i$ and its parents.

Given the assumptions of parameter modularity and parameter independence, it is a simple matter to construct priors for the parameters of an arbitrary model given the priors on complete models. In particular, given parameter independence, we construct the priors for the parameters of each node separately. Furthermore, if node $X_i$ has parents $\mathbf{Pa}_i$ in the given model, then we identify a complete model structure where $X_i$ has these parents, and use Equation 14 and parameter modularity to determine the priors for this node. The result is that all terms $\alpha_{ijk}$ for all model structures are determined by Equation 14. Thus, from the assessments $\alpha$ and $p(\mathbf{d}|\mathbf{m}_c)$, we can derive the parameter priors for all possible model structures. We can assess $p(\mathbf{d}|\mathbf{m}_c)$ by constructing a parameterized model, called a *prior network,* that encodes this joint distribution.

## *Priors for Model Structures*

Now let us consider the assessment of priors on structure. The simplest approach for assigning priors to models is to assume that every model is equally likely. Of course, this assumption is typically inaccurate and is used only for the sake of convenience. A simple refinement of this approach is to ask the user to exclude various structures (perhaps based on judgments of cause and effect), and then impose a uniform prior on the remaining structures. We use this approach in an example described later.

Buntine (1991) describes a set of assumptions that leads to a richer yet efficient approach for assigning priors. The first assumption is that the variables can be ordered (e.g., through a knowledge of time precedence). The second assumption is that the presence or absence of possible arcs are mutually independent. Given these assumptions, $n(n - 1)/2$ probability assessments (one for each possible arc in an ordering) determines the prior probability of every possible model. One extension to this approach is to allow for multiple possible orderings. One simplification is to assume that the probability that an arc is absent or present is independent of the specific arc in question. In this case, only one probability assessment is required.

An alternative approach, described by Heckerman et al. (1995), uses the prior network described in the previous section. The basic idea is to penalize the prior probability of any structure according to some measure of deviation between that structure and the prior network. Heckerman et al. (1995) suggest one reasonable measure of deviation.

### *Search Methods*

In this section, we examine search methods for identifying DAG models with high scores. Consider the problem of finding the best DAG model from the set of all DAG models in which each node has no more than $k$ parents. Unfortunately, the problem for $k > 1$ is NP-hard even when we use the restrictive prior given by Equation 14 (Chickering, 1996). Thus, researchers have used heuristic search algorithms, including greedy search, greedy search with restarts, best-first search, and Monte Carlo methods.

One consolation is that these search methods can be made more computationally efficient when the model score is factorable. Given a DAG model for domain $\mathbf{X}$, we say that a score for that model $\mathrm{S}(\mathbf{m}, \mathbf{d})$ is *factorable* if it can be written as a product of variable-specific scores:

$$\mathrm{S}(\mathbf{m}, \mathbf{d}) = \prod_{i=1}^{n} s(X_i, \mathbf{Pa}_i, \mathbf{d}_i) \tag{15}$$

where $\mathbf{d}_i$ is the data restricted to the variables $X_i$ and $\mathbf{Pa}_i$. An example of a factorable score is Equation 12 used in conjunction with any of the structure priors described previously.

Most of the commonly used search methods for DAG models also make successive arc changes to the graph structure, and employ the property of factorability to evaluate the merit of each change. One commonly used set of arc changes is as follows. For any pair of variables, if there is an arc connecting them, then this arc can either be reversed or removed. If there is no arc connecting them, then an arc can be added in either direction. All changes are subject to the constraint that the resulting DAG contains no directed cycles. We use $E$ to denote the set of eligible changes to a graph, and $\Delta(e)$ to denote the change in log $p(\mathbf{d}|\mathbf{m})p(\mathbf{m})$ resulting from the modification $e \in E$. Given a factorable score, if an arc to $X_i$ is added or deleted, only $c(X_i, \mathbf{Pa}_i, \mathbf{d}_i)$ need be evaluated to determine $\Delta(e)$. If an arc between $X_i$ and $X_j$ is reversed, then only $c(X_i, \mathbf{Pa}_i, \mathbf{d}_i)$ and $c(X_j, \Pi_j, \mathbf{d}_j)$ need be evaluated.

One simple heuristic search algorithm is greedy hill climbing. We begin with some DAG model. Then, we evaluate $\Delta(e)$ for all $e \in E$, and make the change $e$ for which $\Delta(e)$ is a maximum, provided it is positive. We terminatae search when there is no $e$ with a positive value for $\Delta(e)$. Candidates for the initial model include the empty graph, a random graph, and the prior network used for the assessment of parameter and structure priors.

A potential problem with any local-search method is getting stuck at a local maximum. One method for escaping local maxima is greedy search with random restarts. In this approach, we apply greedy search until we hit a local maximum. Then we randomly perturb the structure, and repeat the process for some manageable number of iterations. Another method for escaping local maxima is simulated annealing. In this approach, we initialize the system at some temperature $T_0$. Then we pick some eligible change $e$ at random, and evaluate the expression $p = \exp(\Delta(e)/T_0)$. If $p > 1$, then we make the change $e$; otherwise, we make the change with probability $p$. We repeat this selection and evaluation process $\alpha$ times or until we make $\beta$ changes. If we make no changes in $\alpha$ repetitions, then we stop searching. Otherwise, we lower the temperature by multiplying the current temperature $T_0$ by a decay factor $0 < \gamma < 1$, and continue the search process. We stop searching if we have lowered the temperature more than $\delta$ times. Thus, this algorithm is controlled by five parameters: $T_0$, $\alpha$, $\beta$, $\gamma$, and $\delta$. To initialize this algorithm, we can start with the empty graph, and make $T_0$ large enough so that almost every eligible change is made, thus creating a random graph. Alternatively, we may start with a lower temperature, and use one of the initialization methods described for local search.

Another method for escaping local maxima is best-first search. In this approach, the space of all models is searched systematically using a heuristic measure that determines the next best structure to examine. Experiments (e.g., Heckerman et al., 1995) have shown that, for a fixed amount of computation time, greedy search with random restarts produces better models than does best-first search.

One important consideration for any search algorithm is the search space. The methods that we have described search through the space of DAG models. Nonetheless, when likelihood equivalence is assumed, one can search through the space of model equivalence classes. One benefit of the latter approach is that the search space is smaller. One drawback of the latter approach is that it takes longer to move from one element in the search space to another. Experiments have shown that the two effects roughly cancel.

### *Example: College Plans*

In this section, we consider an analysis of data, obtained by Sewell and Shah (1968), regarding factors that influence the intention of high school students to attend college. This analysis was given previously by Heckerman in Jordan (1999).

Sewell and Shah (1968) measured the following variables for 10,318 Wisconsin high school seniors: *sex* (SEX): male, female; *socioeconomic status* (SES): low, lower middle, upper middle, high; *intelligence quotient* (IQ): low, lower middle, upper middle, high; *parental encouragement* (PE): low, high; and *college plans* (CP): yes, no. Our goal in this analysis is to understand the relationships among these variables.

The data are (completely) described by the counts in Table 1. Each entry denotes the number of cases in which the five variables take on some particular configuration. The first entry corresponds to the configuration SEX = male, SES = low, IQ = low, PE =

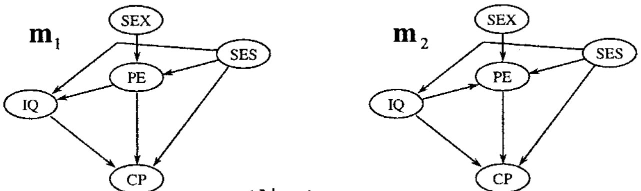
low, and CP = yes. The remaining entries correspond to configurations obtained by cycling through the states of each variable such that the last variable (CP) varies most quickly. Thus, for example, the upper (lower) half of the table corresponds to male (female) students.

To generate priors for model parameters, we used the method described earlier in this section with an equivalent sample size of five and a prior network describing a uniform distribution over **X**. (The results we report remain qualitatively the same for equivalent sample sizes ranging from 3 to 40.) For structure priors, we assumed that all models were equally likely, except that we excluded structures (based on causal considerations) where SEX and/or SES had parents, and/or CP had children. We used Equation 12 to compute the marginal likelihoods of the models. The two most likely models that we found after an exhaustive search over all structures are shown in Figure 1. Note that the most likely model has a posterior probability that is extremely close to 1. Both models show a reasonable result: that CP and SEX are independent, given the remaining variables.

### *Methods for Incomplete Data*

Among the assumptions that yield an efficient method for computing the marginal likelihood, the one that is most often violated is the assumption that all variables are observed in every case. In many situations, some variables will be hidden (i.e., never observed) or will be observed for only a subset of the data samples. There are a variety of methods for handling such situations—at greater computational cost—including Monte Carlo (MC) approaches (e.g., DiCiccio et al., 1995), large-sample approximations (e.g., Kass and Raftery, 1995), and variational approximations (e.g., Jordan et al. in Jordan, 1999).

In this section, we examine a simple MC approach called *Gibbs sampling* (e.g., MacKay in Jordan, 1999). In general, given variables $\mathbf{X} = \{X_1, \ldots, X_n\}$ with some joint distribution $p(x)$, we can use a Gibbs sampler to approximate the expectation of a function $f(x)$ with respect to $p(x)$. This approximation is made as follows. First, we choose an initial state for each of the variables in **X** somehow (e.g., at random). Next, we pick some variable $\mathbf{X}_i$, unassign its current state, and compute its probability distribution given the states of the other $n - 1$ variables. Then, we sample a state for $\mathbf{X}_i$ based on this probability distribution, and compute $f(x)$. Finally, we iterate the previous two steps, keeping track of the average value of $f(x)$. In the limit, as the number of cases approach infinity, this average is equal to $\mathrm{E}_{p(x)}(f(x))$ provided two conditions are met. First, the Gibbs sampler must be *irreducible.* That is, the probability distribution $p(x)$ must be such that we can eventually sample any possible configuration of **X** given any possible initial configuration of **X**. For example, if $p(x)$ contains no zero probabilities, then the Gibbs sampler will be irreducible. Second, each $X_i$ must be chosen infinitely often. In practice, an algorithm for deterministically rotating through the variables is typically used. An introduction to Gibbs sampling and other Monte Carlo methods, including methods for initialization and a discussion of convergence, is given by Neal (1993).



$$\frac{p(\mathbf{d}\,|\,\mathbf{m}_1)}{p(\mathbf{d}\,|\,\mathbf{m}_2)} \cong 8.3 \times 10^9$$

**Figure 1.** The a posteriori most likely models.

To illustrate Gibbs sampling, consider again the case where every variable in **X** is finite, the parameters $\boldsymbol{\theta}_{ij}$ for a given DAG model **m** are mutually independent, and each $\boldsymbol{\theta}_{ij}$ has a Dirichlet prior. In this situation, let us approximate the probability density $p(\boldsymbol{\theta}_m|\mathbf{d}, \mathbf{m})$ for some particular configuration of $\boldsymbol{\theta}_m$, given an incomplete data set **d**. First, we initialize the states of the unobserved variables in each case somehow. As a result, we have a complete random sample $\mathbf{d}_c$. Second, we choose some variable $X_{il}$ (variable $X_i$ in case $l$) that is not observed in the original random sample $D$, and reassign its state according to the probability distribution

$$p(x'_{il}|\mathbf{d}_c\backslash x_{il}, \mathbf{m}) = \frac{p(x'_{il}, \mathbf{d}_c\backslash x_{il}|\mathbf{m})}{\sum_{x''_{il}} p(x''_{il}, \mathbf{d}_c\backslash x_{il}|\mathbf{m})}$$

where $\mathbf{d}_c\backslash x_{il}$ denotes the data set $\mathbf{d}_c$ with observation $x_{il}$ removed, and the sum in the denominator runs over all states of variable $X_{il}$. As we have seen, the terms in the numerator and denominator can be computed efficiently (see Equation 12). Third, we repeat this reassignment for all unobserved variables in **d**, producing a new complete random sample $\mathbf{d}'_c$. Fourth, we compute the posterior density $p(\boldsymbol{\theta}_m|\mathbf{d}'_c, \mathbf{m})$ as described in Equations 10 and 11. Finally, we iterate the previous three steps, and use the average of $p(\boldsymbol{\theta}_m|\mathbf{d}'_c, \mathbf{m})$ as our approximation.

Monte Carlo approximations are also useful for computing the marginal likelihood given incomplete data. One Monte Carlo approach uses Bayes's theorem:

$$p(\mathbf{d}|\mathbf{m}) = \frac{p(\boldsymbol{\theta}_m|\mathbf{m})p(\mathbf{d}|\boldsymbol{\theta}_m, \mathbf{m})}{p(\boldsymbol{\theta}_m|\mathbf{d}, \mathbf{m})} \qquad (16)$$

For any configuration of $\boldsymbol{\theta}_m$, the prior term in the numerator can be evaluated directly. In addition, the likelihood term in the numerator can be computed using DAG-model inference (e.g., Kjaerulff in Jordan, 1999). Finally, the posterior term in the denominator can be computed using Gibbs sampling, as we have just described.

## Non-Bayesian Approaches

In this section, we consider several commonly used alternatives to the Bayesian approach for structure learning.

One such class of algorithms mimic the search-and-score approach of Bayesian model selection but incorporate a non-Bayesian score. Alternative scores include (1) prediction accuracy on new data, (2) prediction accuracy over cross-validated data sets, and (3) non-Bayesian information criteria such as AIC.

Another class of algorithms for structure learning is the *constraint-based* approach, described by Pearl (2000) and Spirtes, Glymour, and Scheines (2001). In this set of algorithms, statistical tests are performed on the data to determine independence and dependence relationships among the variables. Then, search methods are used to identify one or more models that are consistent with those relationships.

To illustrate this approach, suppose we seek to learn one or more DAG models given data for three finite variables ($X_1$, $X_2$, $X_3$). Assuming each local likelihood is a collection of multinomial distributions, there are 11 possible DAG models that are distinct: (1) a complete model, (2) $X_1 \rightarrow X_2 \rightarrow X_3$, (3) $X_1 \rightarrow X_3 \rightarrow X_2$, (4) $X_2 \rightarrow X_1 \rightarrow X_3$, (5) $X_1 \rightarrow X_2 \leftarrow X_3$, (6) $X_1 \rightarrow X_3 \leftarrow X_2$, (7) $X_2 \rightarrow X_1 \leftarrow X_3$, (8) $X_1 \rightarrow X_2X_3$, (9) $X_1 \rightarrow X_3X_2$, (10) $X_2 \rightarrow X_3X_1$, and (11) $X_1X_2X_3$, where $X_iX_j$ means there is no arc between $X_i$ and $X_j$. There are other possible models that are not listed, but each such model represents a set of distributions that is equivalent to one of the other models above. For example, $X_3 \rightarrow X_2 \rightarrow X_1$ and model 2 are distribution equivalent.

Now, suppose that statistical tests applied to the data reveal that the *only* independence relationship is that $X_1$ and $X_3$ are independent. Only models 1 and 5 can exhibit only this independence. Furthermore, if we use parameter prior assignments of the form described earlier in this section, then model 1 will exhibit this independence with probability zero. Consequently, we conclude that model 5 is correct (with probability one).

One drawback of the constraint-based approach is that any statistical test will be an approximation for finite data, and errors in the tests may lead the search mechanism to (1) conclude that the found relationships are inconsistent or (2) return erroneous models. One advantage of the approach over most search-and-score methods is that more structures can be considered for a fixed amount of computation, because the results of some statistical tests can greatly constrain model search.

# Grasping Movements: Visuomotor Transformations

*Giuseppe Rizzolatti and Giacomo Luppino*

## Introduction

When one attempts to pick up an object, one executes two distinct motor operations. One—reaching—consists of bringing the hand toward an object's location in space, the other—grasping—consists of shaping the hand and fingers in anticipation of the object's size, shape, and orientation (Arbib, 1981; Jeannerod, 1988). This article focuses on grasping. Its aim is to examine where in the cerebral cortex visual information on intrinsic properties of objects is transformed into hand movements and how this transformation occurs.

## Motor Areas for Grasping

The agranular frontal cortex of primates consists of several distinct motor areas (Rizzolatti and Luppino, 2001; Picard and Strick, 2001). Their location in the monkey cerebral cortex is shown in Figure 1. Recent data showed that many of them contain distal movement representations (Rizzolatti and Luppino, 2001).

Since the early electrical cortical stimulation experiments, it has been known that the largest and most detailed representation of distal movements is that of the primary motor cortex (F1 or area 4; see Porter and Lemon, 1993). Following lesion of this area, grasping movements, especially those demanding a subtle control of fingers, are lost. The deficit is characterized by a dramatic decrease in force and a loss of the capacity to control individual fingers, but does not affect the mechanisms underlying visuomotor transformation for grasping movements. This view is confirmed by neurophysiological findings showing that the visual properties (brisk responses to abrupt stimulus presentation) of the few neurons that respond to visual stimuli, do not match those necessary for grip formation.

This last finding raises the problem of which of the areas that have access to the F1 neural machinery also have the visual properties required for organizing grasping movements. Anatomical data and recording studies have shown that this area is F5. This area is richly connected with F1 and many of its neurons respond to the presentation specific visual stimuli (Rizzolatti and Luppino, 2001).

## Area F5

Area F5 forms the rostral part of inferior area 6. A fundamental property of F5 is that the discharge of most of its neurons correlates with specific actions (or fragments of a specific action) much better than with elementary movements. A clear instance of this behavior is represented by F5 neurons that discharge when the monkey grasps an object with its right hand, with its left hand, or with its mouth. It is obvious that in this case a description of neuron behavior in terms of elementary movements makes little sense (Rizzolatti et al., 1988).

Using the effective action as classification criterion, F5 neurons were subdivided into various classes. Among them the most represented are "grasping" neurons, "holding" neurons, "tearing" neurons, and "manipulating" neurons. The largest F5 class is related to grasping.

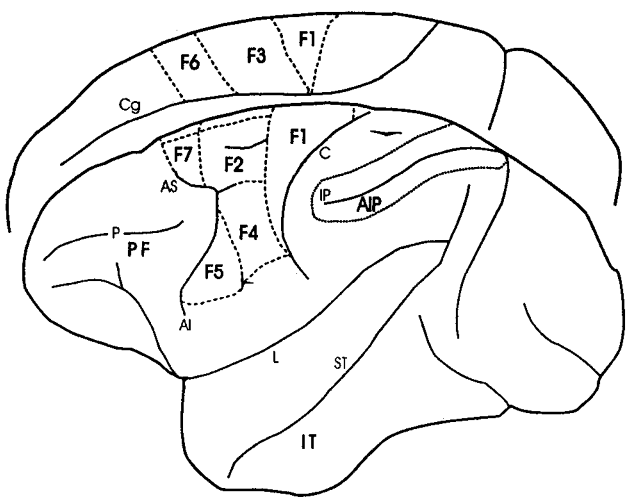

**Figure 1.** Lateral and mesial views of the monkey cerebral cortex showing the location of the agranular frontal areas and of other cortical areas or sectors referred to in the text. Motor areas in which distal movements are represented are F1, F3, F2, and F5. The intraparietal sulcus (IP) is opened. AI, inferior arcuate sulcus; AS, superior arcuate sulcus; C, central sulcus; Cg, cingulate sulcus; IT, inferotemporal cortex; L, lateral fissure; P, principal sulcus; PF, prefrontal cortex; ST, superior temporal sulcus.

Typically, grasping neurons discharge for actions made with the contralateral as well as the ipsilateral hand. Many of them code specific hand grips. Three basic grip types are extensively represented: precision grip, finger prehension, and whole-hand prehension. Most neurons are selective for one of these types of grasping, the precision grip being the most represented. The temporal relations between neuron discharge and grasping movements vary among neurons. Some of them fire only during the last part of grasping, i.e., during finger flexion. Others start to fire with finger extension and continue to fire during finger flexion. Finally, others are activated in advance of the movement initiation and often cease to discharge only when the object is grasped.

Rizzolatti and co-workers proposed that F5 contains a "vocabulary" of motor acts related to prehension. The "words" of the vocabulary are comprised of populations of neurons related to different motor actions. There are various categories of "words." Some indicate very general commands, e.g., "grasp," "hold," and "tear." Others indicate how the objects have to be grasped, held, or torn (e.g., by precision grip, finger prehension, whole-hand prehension, or their subtypes). Finally, a third group of "words" is concerned with the temporal segments of the actions (e.g., hand aperture, hand closure).

The presence in F5 of a store of "words" or motor schemas (Arbib, 1981) has two important consequences. First, since information is concentrated in relatively few abstract elements, the number of variables to be controlled is much less than it would be if the movements were described in terms of motor neurons or muscles. This solution to the problem of controlling the large number of hand degrees of freedom is remarkably similar to that proposed theoretically (Arbib, Iberall, and Lyons, 1985). Second, the retrieval of the appropriate movement is simplified. Both for internally generated actions and for those emitted in response to an external stimulus, a schema, or a small ensemble of schemas, must be selected. In particular, the retrieval of a movement in response to a visual object is reduced to the task of matching its size and orientation with the appropriate schema.

How can the motor vocabulary of F5 be addressed? The simplest way to examine this issue is to present different types of stimuli—for example, different objects—and to establish whether the recorded neuron respond to them. Using this approach, "visual" responses are observed in about 20%–30% of F5 neurons. According to the type of stimuli that is effective, two separate classes of neurons have been distinguished. Neurons of the first class (*canonical* neurons) respond to the presentation of graspable objects (Rizzolatti et al., 1988). Neurons of the second class (*mirror* neurons) respond when the monkey sees object-directed actions (Rizzolatti and Luppino, 2001).

The functional properties of canonical neurons and inactivation experiments showed that this class of F5 visuomotor neurons is crucially involved in visuomotor transformations for grasping objects.

The properties of canonical neurons were recently studied in a task in which monkeys were trained to fixate objects of different size and shape and, after a go signal, to grasp them (Murata et al., 1997). The timing of the different phases of the task was such as to allow one to identify the neuron's activity related to object presentation, the preparatory phase preceding the movement, and movement execution. Most neurons were further tested in a task in which monkeys had to fixate an object, but not to grasp it. At the go signal they had only to release a switch. The main result of the experiment was that canonical neurons discharge in response to object presentation even in the absence of any subsequent movement directed toward it. In the majority of neurons the visual discharge was evoked either exclusively by one object or by a small set of objects. Furthermore, the visual responses were evoked only by objects whose size and shape were congruent with the grip coded by the neurons (i.e., neurons visually activated by small objects discharged also selectively during precision grip, while neurons visually activated by large objects, discharged during whole hand prehension).

Recently, a paradigm similar to that described previously was employed to study the effects of inactivation of F5 with muscimol, a GABAergic agonist (Gallese et al., 1997). Small and large inactivations were performed. As a control, in separate sessions, the hand field of F1 was inactivated. The most interesting result was that following F5 inactivations (bank sector of F5) the monkeys were unable to shape the hand according to the intrinsic visual properties of the object. The deficit was particularly evident for small objects, where it was also present following limited inactivations. After large inactivations, however, the prehension of large objects was also affected. An important observation was that the monkeys, in spite of their visuomotor deficit, were still able to grasp and manipulate objects after touching them without any apparent skill impairment. Thus, the execution of individual finger movements was preserved. In contrast, after inactivation of F1 hand field, the monkeys showed a hypotonic paralysis and lack of individual finger movements (Schieber and Poliakov, 1998). Another important difference between F1 and F5 inactivations was that, following F5 inactivation, both hands were affected, not just the hand contralateral to the lesion.

## Anterior Intraparietal Area

What is the origin of F5 visual information? Injection of neural tracers in F5 showed that this area receives a strong input from the inferior parietal lobule and, in particular, from an area located in the rostral part of the lateral bank of the intraparietal sulcus—area AIP (Rizzolatti and Luppino, 2001). The functional properties of area AIP have been extensively studied by Sakata and his co-workers (Murata et al., 2000).

The paradigms used by Sakata and colleagues were basically similar to those described for F5. In their initial experiments, monkeys were trained to manipulate four different types of switches, each of which required a peculiar type of grasping. The movements were performed under visual guidance and in the dark. According to each neuron's behavior in the task, neurons were subdivided into three main classes. Neurons of the first class, "motor dominant" neurons, discharged equally well during movements performed in light and in dark. These neurons represented about one-third of the task-related neurons. Neurons of the second class, "visual dominant" neurons, were activated only when the task was performed in the light. They represented about 25% of the studied neurons. Neurons of the third class, "visual and motor" neurons, were less active during movement performed in the dark than in the light. They represented about 40% of the studied neurons.

Neurons belonging to "visual dominant" and "visual and motor" classes typically responded as soon as the object to be grasped was presented. To better study the visual properties of AIP neurons, another series of experiments was carried out by the same authors using a variety of 3D objects. They included spheres, cubes, cones, cylinders, rings, and plates of different sizes and orientations. Furthermore, the neurons were also tested in a condition in which there was no request to act on the presented objects. The results showed that most of the recorded neurons were selective for object shape. Of these, one-third were highly selective, being activated only by one of the six shapes used in the experiment, while half were moderately selective, being activated by two or three different shapes. Many shape-selective neurons were also selective for object size. Finally, in "visual and motor" neurons, a clear congruence was observed between object and motor selectivity.

It is clear from this overview of the functional properties of AIP that the neurons of this area share many common features with F5 neurons. There are also, however, some important differences. First, there are no "visual dominant" neurons in F5. Second, purely motor neurons are much more frequent in F5 than in AIP. Third, most AIP neurons discharge during the whole action leading to the grasping of the objects, often remaining active during the object holding period. In contrast, F5 grasping neurons are typically active only during some of the phases of the grasping/holding action.

Taken together, these data strongly suggest that AIP and F5 form a parieto-frontal circuit devoted to the visuomotor transformation for hand-object interactions (Jeannerod et al., 1995). They predict also that an inactivation of AIP should disrupt the monkey's capacity to preshape the hand and fingers in anticipation of object grasping. This prediction was fully confirmed by experiments in which different sectors of AIP were reversibly inactivated using muscimol microinjections. After inactivation, monkeys showed marked deficits of contralateral hand preshaping without any deficit in arm reaching (Gallese et al., 1997).

## Circuit for Grasping in Humans

Earlier brain imaging experiments failed to convincingly demonstrate the existence of a cortical circuit for grasping movements in humans. Recent data by Binkofski et al. (1999) clearly demonstrated that a circuit specifically involved in object manipulation exists also in humans. By using fMRI, they showed that the manipulation of complex objects results in an activation of ventral premotor cortex (BA 44) and of a region in the intraparietal sulcus. If one considers the anatomical location of these areas, and, for area 44, the cytoarchitectonics similarities with F5, it is very likely that this circuit is the human homologue of the monkey circuit formed by F5-AIP.

## Discussion

The data described previously indicate that areas AIP and F5 form the key elements in a circuit that transforms visual information on intrinsic properties of objects into grasping movements. Various attempts have been made to explain how AIP and F5 neurons perform this transformation (Sakata et al., 1992; Gallese et al., 1997; Fagg and Arbib, 1998).

Common to all these proposals is the idea that "visual dominant" neurons of AIP code the object's intrinsic properties and, then, either directly or via other AIP elements, send this information to specific sets of F5 neurons. F5 neurons transform the received information into patterns of hand movements that are appropriate to the size and shape of the objects to be grasped. Finally, the F5 grasping pattern recruits specific F1 neurons that command grasping execution.

According to Sakata and co-workers, the AIP discharge associated with movements represents a corollary discharge originating in the premotor cortex. Its function is that of creating a reverberatory activity that keeps active AIP neurons. AIP "visual-and-motor" neurons are, therefore, a kind of "memory" that keeps the representation of the object active during the entire movement execution. In this way the representation of the object remains present even when vision of the object is obstructed by the hand movements. Finally, the "motor dominant" neurons would represent an intermediate stage in the transmission of F5 corollary discharge to the AIP "visual-and-motor" neurons.

Sakata's model did not take into consideration the fact that an object may be grasped in several ways and that the chosen grip depends, in addition to the object visual properties, on object semantics and on what the individual who grasps the object wants to do with it. Let us imagine a mug. Once the mug is recognized as a mug, it is grasped by the handle, if one wants to drink from it. However, if one wants to throw the mug at somebody or simply to move it, one will take it by its body or by its upper edge. These possible ways of grasping depend on (1) a preliminary object recognition, and (2) on motor decisions, and obviously not on the visual intrinsic properties of the object. Thus, a more complete model of how F5-AIP circuit works, also requires information (1) from circuits that code object semantics (inferotemporal lobe, IT) and (2) from circuits where decision are taken on what to do. To solve these problems, Fagg and Arbib (1998) proposed that AIP provides F5 not with a single visual description of the object, but with multiple descriptions of the possible way in which a given object may be grasped (affordances). This multitude of possibilities is sent to F5, where the selection of the desired grip is made on the basis of prefrontal inputs that signal the nature of the object as well as the current goals of the organism. Finally, the control exerted by F6 (pre-SMA) on F5 will determine whether the external contingencies allow the action execution.

Fagg and Arbib's model (1998, FARS) is not only physiologically plausible, but has also been computationally implemented. Anatomically, FARS relies heavily on connections between prefrontal cortex and F5. There is evidence, however, that although these connections are very modest, rich connections exist between prefrontal cortex and AIP. Furthermore, AIP, unlike F5, receives a direct input from IT. These findings suggest an alternative possibility, namely that information on object semantics and the goals of the individuals influence AIP rather than F5 neurons. Thus, the fundamental process for selecting an appropriate grip occurs in AIP by biasing those affordances that will lead to the grip appropriate to the individual intention. According to this view, AIP describes several affordances, but information on that bias is able to influence F5. This affordance then activates the F5 neurons for the appropriate grip. The selected action remains a potential action until an appropriate signal comes from F6. A version of the FARS model, modified according to these considerations, is shown in Figure 2.

# Habituation

*Adam S. Bristol, Angela L. Purcell, and Thomas J. Carew*

## Introduction

Habituation, one of the simplest and most common forms of learning, is typically defined as the progressive decrement in a behavioral response with repeated presentations of the eliciting stimulus. Despite its apparent simplicity, a complete understanding of the underlying neural mechanisms of habituation has not been achieved in any preparation. In this article, we briefly review the fundamental characteristics of habituation and describe several experimental preparations in which the neural basis of habituation has been examined. We conclude by describing attempts to model the habituation process in computational terms, the success and shortcomings of these attempts, and directions for future research.

## Characteristics of Habituation

Historically, the unambiguous identification of habituation as a form of learning has been complicated by the necessity of distinguishing it from other causes of response decrement, such as sensory adaptation and motor fatigue. A landmark publication by Thompson and Spencer (1966) presented nine behavioral criteria for identifying habituation. These criteria have been successfully applied to a wide variety of systems and continue to be used today. They are:

1. Repeated stimuli result in diminishing response (within-session, short-term habituation).
2. After a series of stimuli and a period of rest, the response recovers spontaneously.
3. During repeated series of stimuli separated by spontaneous recovery, habituation occurs more rapidly within each series (savings).
4. The rate and/or magnitude of habituation increases with increases in stimulation frequency.
5. The rate and/or magnitude of habituation decreases with increases in stimulus intensity.
6. When a steady level of habituation has been reached during a series, additional stimuli prolong the time until spontaneous recovery (“subzero” habituation).

7. Habituation to one type of stimulus may result in habituation to other similar stimuli (generalization).
8. The presentation of a strong stimulus different from the habituating stimulus leads to a recovery of the habituated response (dishabituation).
9. Repetition of the dishabituating stimulus leads to successively less dishabituation (habituation of dishabituation).

Two important features of habituation, stimulus generalization and dishabituation (Criteria 7 and 8), are important indicators that the decrease in responding is not due to sensory or effector fatigue. Additionally, the finding that spontaneous recovery occurs more quickly with shorter interstimulus interval (ISI) training (Groves and Thompson, 1970) would not be predicted if sensory adaptation or muscle fatigue were the cause of the response decrement.

Thompson and Spencer's (1966) criteria have been highly influential in the study of habituation, but they have not gone without criticism (for a thorough evaluation, see Hinde, 1970). Moreover, subsequent studies have warranted amendments to these guidelines. First, Davis (1970) questioned the notion that habituation increases with shorter ISIs (Criterion 4) because, within a single training session, training and testing intervals are confounded. That is, when comparing different ISIs (e.g., 2 s and 10 s), both the training and testing intervals for each ISI are different because the response to each stimulus serves as both a training trial and a measure of behavioral habituation. When he controlled for differences in testing conditions, Davis (1970) found that *longer* ISIs resulted in greater and longer-lasting retention, although the rate of habituation was faster with short ISI. This is consistent with the finding that spontaneous recovery occurs more rapidly after short ISIs than long ISIs (Groves and Thompson, 1970) and with the general notion that massed training produces inferior learning relative to spaced training.

Second, the Thompson and Spencer criteria did not distinguish between short-term and long-term forms of habituation. Criterion 3 states that the rate of habituation increases across repeated training sessions, a form of "savings." However, the criteria do not reflect another common feature of multiple habituation trials, namely, that the first response of each repeated session is often progressively diminished, indicating a longer-lasting retention of habituation across sessions. Importantly, short- and long-term forms of habituation have been experimentally dissociated in a number of preparations, including *Aplysia, C. elegans*, crab, and rat.

The third amendment to the Thompson and Spencer criteria comes from work by Christoffersen (1997), who recently conducted a comparative analysis of the kinetics of short-term habituation across a wide variety of species and behaviors. He noted that, despite variability in response types, there is a characteristic learning curve for within-session habituation consisting of a rapid and pronounced early phase of habituation resulting from only a few response activations (from 5 to 15) and a second, slowly declining phase. However, he found that some behaviors do not seem to have a rapid, early phase and that many more stimuli (from 50 to several hundreds) are required to achieve the same absolute level of response decrement. The kinetics of the learning curves could be fitted by the equation:

$$H_{n+1} = H_n(1 + P_n) \tag{1}$$

in which $H_n$ is the degree of habituation of a normalized reflex before the $n$th stimulus and $P_n$ is a factor that determines the change in $H$ from stimulus $n$ to $n + 1$. The factor $P_n$ decreases as habituation increases, such that

$$P_n = P_1(H_{\max} - H_n) \tag{2}$$

where $H_{\max}$ is the maximum amount of habituation. Interestingly, when Christoffersen (1997) solved for the plasticity parameter, $P_1$, for numerous cases of habituation, he found that it was many times smaller for slowly habituating reflexes than for rapidly habituating reflexes, suggesting two distinct types of habituation. Thus, this computational approach to examining habituation extends Thompson and Spencer's criteria by indicating that not all reflexes habituate with the same rapidity.

## Experimental Preparations and Neural Mechanisms Underlying Habituation

Habituation has been extensively studied in invertebrate preparations, in particular the defensive reflexes of the mollusk *Aplysia* and crayfish, as their relatively simple and accessible nervous systems provide the opportunity to study the neural basis of behavior in considerable detail (see Invertebrate Models of Learning: *Aplysia* and *Hermissenda*). Importantly, these preparations meet many of the criteria put forth by Thompson and Spencer and show short- and long-term forms of habituation. Reflex habituation has also been studied in vertebrate preparations, first in the scratch reflex of the dog and later in the vestibulo-ocular reflex (VOR) in goldfish, and the prey-catching orienting response in frog. (See Scratch Reflex, Vestibulo-Ocular Reflex, and Visuomotor Coordination in Frog and Toad for more discussion.)

Neurophysiological studies in invertebrates examining the mechanisms underlying behavioral habituation have led to the widespread notion that habituation results from homosynaptic depression (the activity-dependent decrement in synaptic efficacy) of one or more synapses in a reflex circuit (i.e., an intrinsic mechanism). There are numerous examples showing that synaptic depression occurs during or as a result of a habituation process and that the kinetics of synaptic depression are similar to those of behavioral habituation (for a review, see Christoffersen, 1997). However, even in *Aplysia*, where synaptic depression has been firmly linked to habituation, there is evidence suggesting that other mechanisms may contribute. For example, Stopfer and Carew (1996) found that *facilitation* of the tail sensorimotor synapses accompanied habituation of the tail-elicited siphon withdrawal reflex, suggesting that plasticity at interneuronal sites underlies habituation of this reflex.

Such an "intrinsic" mechanism, where plasticity occurs within the circuit mediating the behavior, is the most popular model, but cases in which habituation also involves modulation from cells extrinsic to the circuit (e.g., heterosynaptic depression) have also been reported. For example, whereas homosynaptic depression of presynaptic sensory cells has been found to contribute to habituation of the crayfish tail-flip reflex, more recent investigations have implicated an increase in tonic descending inhibition as an additional mechanism of habituation in this system (Krasne and Teshiba, 1995). Thus, even within the same animal, homosynaptic and heterosynaptic mechanisms may contribute to habituation in different response systems.

Additional evidence of "top-down" processing in habituation has come from studies of higher vertebrate systems. Frogs with lesions of the medial pallium, a homolog of the mammalian hippocampus, show no habituation of the orienting response to repeated visual stimuli (Finkenstadt, 1989). In a different behavioral paradigm, decerebrate rats failed to show long-term habituation of acoustic startle despite exhibiting short-term habituation (Leaton, Casella, and Borszcz, 1985). These data suggest that short-term and long-term forms of habituation may develop by separate mechanisms, with short-term habituation occurring within the circuit mediating the reflex (perhaps by homosynaptic depression) and long-term habituation occurring via descending modulatory input (perhaps by heterosynaptic depression or tonic synaptic inhibition). Experiments in *Aplysia* have indicated a morphological correlate of long-term habituation: a decreased number of synaptic endings (Bailey and Chen, 1983).

The experiments of Sokolov (1960) on the orienting reflex in humans demonstrate the complex "top-down" control of habituation. For instance, he showed that habituation of the orienting response did not generalize to other stimuli but was stimulus specific, such that any change in the stimulus parameters (e.g., intensity, duration) resulted in a reinstatement of the response (dishabituation). His observation that even *decreases* in stimulus intensities resulted in dishabituation argued against homosynaptic depression of sensory processing. In an incredible demonstration of top-down processing, he showed that habituated responses spontaneously recovered during sleep, became resistant to rehabituation during sleep, and returned to the habituated state when the subject reawakened. These data led him to propose a "comparator theory" of habituation, in which an internal representation, or "template," is created in the brain, to which subsequent external stimuli are compared. Stimuli that "match" the internal representation are habituated, whereas stimuli that are "mismatches" evoke a response (i.e., dishabituation). Sokolov (1960) proposed a neural model of habituation based on his theory in which the cortex, the site of the comparator mechanism, inhibits the reticular formation and, hence, the physiological correlates of the orienting response.

In summary, habituation has been linked to homosynaptic depression within the reflex circuit in a variety of systems. Accordingly, homosynaptic depression continues to be widely regarded as the cellular mechanism underlying habituation, especially short-term forms. However, considerable evidence demonstrating the importance of extrinsic modulatory processes, such as descending cortical input in mammals and tonic inhibition in crayfish, suggests that some forms of habituation may be due to mechanisms both intrinsic and extrinsic to the reflex circuit.

## Computational Models of Habituation

Habituation is particularly well-suited for a computational analysis. First, the habituated response is a repeatable behavior, thus allowing for a detailed analysis of the kinetics of learning (i.e., ISI function, trials to criterion, etc.). Second, the habituated behavior is, in many cases, an evoked reflex that relies on a relatively simple neural circuit; for example, in invertebrate preparations such as *Aplysia* and crayfish, many of the individual neural elements in the reflex circuit have been identified. Third, the general underlying assumption guiding computational modeling—namely, that network output is linked to circuit architecture, cellular properties, and synaptic plasticity—also guides physiological studies of behavior, thus allowing the results of computational and biological analyses of habituation to inform each other.

Most attempts at modeling habituation have been top-down and have focused either implicitly or explicitly on short-term, within-session habituation typically involving synaptic plasticity-like learning mechanisms. For example, Horn (1967) put forth a remarkably modern theoretical network model based on synaptic mechanisms very similar to homosynaptic depression and heterosynaptic facilitation. In his model, various features of habituation and dishabituation are accounted for by independent decrementing and facilitating processes, foreshadowing the dual process theory of Groves and Thompson (1970). Stanley (1976) took a similar approach, but added mathematical complexity to his modeling of habituation of the hindlimb flexion reflex in spinal cats. He posited a circuit architecture consisting of two independent pathways, (1) a direct pathway between input and output capable of use-dependent decrement and (2) an indirect pathway with an additional intercalated element between input and output capable of use-dependent enhancement. This simple organization captured the essence of the dual process theory: repetitive low-intensity stimulation of the direct pathway resulted in synaptic decrement, whereas moderate- and high-intensity stimulation increasingly recruited the indirect, facilitatory pathway, leading to dishabituation (and sensitization). Synaptic change was simulated using a first-order differential equation:

$$\tau \frac{dy(t)}{dt} = \alpha(y0 - y(t)) - \mathrm{S}(t) \tag{3}$$

where $y0$ is the initial synaptic strength, $\mathrm{S}(t)$ is the effect of external stimulation (which could be habituating or sensitizing), $\tau$ is a time constant governing the rate of habituation, and $\alpha$ determines the rate of recovery. This model yielded exponential learning curves typical of the short-term habituation data with varying intensity stimulation but could not account for long-term habituation.

Wang and Arbib (1992) modified the traditional first-order differential equation to include an activity-gated input and included a second equation that, by regulating the rate of recovery, captured the transition from short-term to long-term habituation in their model of habituation of prey-catching behavior in frogs. These two equations took the form:

$$\tau \frac{dy(t)}{\mathrm{d}t} = \alpha z(y0 - y(t)) - \beta y(t)\mathrm{S}(t) \tag{4}$$

$$\frac{dz(t)}{dt} = \gamma z(t)(z(t) - 1)\mathrm{S}(t) \tag{5}$$

where the second term in Equation 4 constitutes activity-gated input with $\beta$ as a rate parameter. In Equation 5, which regulates recovery, variable $z(t)$ generates an inverse S-shaped curve under constant stimulation $\mathrm{S}(t)$. When $z(t)$ is large after few trials, recovery is rapid. In contrast, when $z(t)$ is small, as it is after many trials, recovery is slow. Thus, as habituation progresses, recovery becomes more prolonged, producing longer-lasting habituation. This approach yielded simulated results that resembled experimental data for short recovery times (minutes) but underestimated forgetting for longer recovery times (hours).

Recently, Anastasio (2001) presented a computational model of habituation of the goldfish VOR to sinusoidal stimulation that is conceptually similar to the comparator theory of Sokolov (1960). Structurally, the model is based on a simplified view of vestibular neuroanatomy: a direct excitatory path through the brainstem (BS) to the output of the circuit, the vestibular nucleus (VN), and an inhibitory and plastic indirect path through the vestibulocerebellum (VC) (Figure 1). Behavioral VOR habituation shows frequency-specificity and nonlinearity; the most pronounced habituation occurs at the peak stimulus amplitude and does not occur at the same rate for the two directions of sinusoidal head rotations. These features suggested that the habituation mechanism does not treat the stimulus as a continuous function but as discrete units that habituate independently. Thus, a primary component of the model is that the sinusoidal stimulus is partitioned into segments or patterns. In the model, habituation occurs because of a pattern correlation mechanism in which the VC compares the similarity (the correlation) of the current stimulus (the pattern) with the representation of previous stimuli (a history vector stored in the VC) and weights the inhibition of the VN according to the maximum correlation using the equation:

$$y(t) = x(t) - w_k r_k(t) \tag{6}$$

where $y(t)$ is the output of the VC at time step $t$, $x\ (t)$ is the value of the input pattern, and $w_\mathrm{k}$ is the weight value corresponding to the pattern having the maximum correlation, $r_\mathrm{k}$, with the history vector. After filtering and dithering the simulation output to mimic neuromuscular dynamics, Anastasio (2001) showed that the model can accurately account for the features of behavioral VOR habituation, thus providing a computational mechanism for producing

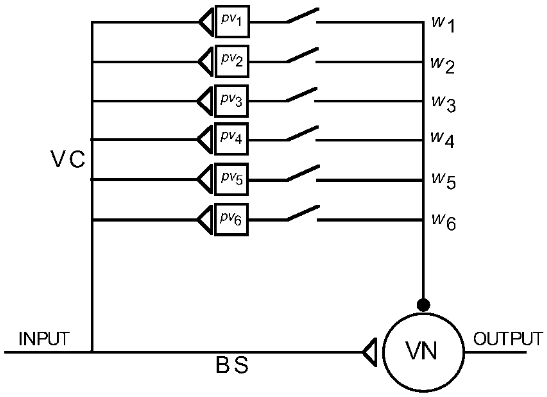

**Figure 1.** Anastasio's (2001) pattern correlation model of VOR habituation. Open triangles represent excitatory connections. Solid circles represent inhibitory connections. BS, brainstem; VC, vestibulocerebellar nucleus; VN, vestibular nucleus. Pattern vectors and their respective weights are represented by $pv_i$ and $w_i$ ($i = 1, 2, \ldots, 6$). discontinuous, nonlinear output plasticity from a continuous, elementary function input. Moreover, the pattern correlation model achieves computational instantiations of a Sokolov-like comparator mechanism by storing and matching a history vector to subsequently present stimuli.

## Discussion

Habituation continues to be an attractive paradigm in the study of the neural basis of learning and memory. Experimental studies have identified at least two important neural mechanisms of habituation, homosynaptic depression within the reflex circuit and extrinsic descending modulatory input. Although the computational models of habituation described above have achieved success in accounting for important aspects of behavioral habituation in some systems, much work remains to be done in simulating processing in known biological circuitry. There are several well-studied model systems conducive to a biologically realistic computational analysis, such as the tail-flip escape reflex in crayfish and the tap-elicited withdrawal reflex in the nematode. In each of these cases, much of the underlying neural circuitry is known. Habituation in the crayfish tail-flip reflex, due to both afferent depression as well as descending inhibition, is attractive because it offers the opportunity to analyze the interaction and cooperativity of mechanisms intrinsic and extrinsic to the reflex circuit. The nematode *C. elegans* is attractive because of the possibility of a genetic analysis of habituation (see Rose and Rankin, 2001). Progress in understanding the computational processes of habituation in complex vertebrates and mammals will require greater knowledge of underlying circuitry and neurophysiology. The goal of future work, both experimental and computational, will be to account for the intriguing complexity of this not-so-simple form of learning.

# Half-Center Oscillators Underlying Rhythmic Movements

*Andrew A. V. Hill, Stephen D. Van Hooser, and Ronald L. Calabrese*

## Introduction

The half-center oscillator model was first proposed by T. Grahm Brown (1914) to account for the observation that spinal cats could produce stepping movements even when all dorsal roots were severed, thereby eliminating sensory feedback from the animals' motion. He envisioned pools of interneurons controlling flexor and extensor motor neurons (the half-centers) that had reciprocal inhibitory connections, and that were capable of sustaining alternating oscillatory activity if properly activated. In the model, he assumed that the duration of reciprocal inhibition was limited by some intrinsic factor, e.g., synaptic fatigue, and that the neuron pools (half-centers) showed rebound excitation. In the intervening years we have learned that almost all rhythmic movements of animals are programmed in part by central pattern-generating networks that comprise neural oscillators (MOTOR PATTERN GENERATION; SPINAL CORD OF LAMPREY: GENERATION OF LOCOMOTOR PATTERNS; CRUSTACEAN STOMATOGASTRIC SYSTEM; and LOCOMOTION, VERTEBRATE). In many of these motor pattern-generating networks, in both vertebrates and invertebrates, reciprocal inhibitory synaptic interactions between neurons or groups of neurons are found (Calabrese, 1995). We are beginning to understand how the intrinsic membrane properties of the component neurons interact with reciprocal inhibition to initiate and sustain oscillation in these networks.

## Theoretical Framework

A theoretical framework for understanding how reciprocally inhibitory neurons oscillate (i.e. how half-center oscillators work) was developed by Wang and Rinzel (1992) (OSCILLATORY AND BURSTING PROPERTIES OF NEURONS). Their model neurons are minimal. Each contains a synaptic conductance that is a sigmoidal function of presynaptic membrane potential with a set threshold and instantaneous kinetics, a constant leak conductance, and a voltage-gated postinhibitory rebound current, $I_{pir}$. $I_{pir}$ was originally envisioned to be a T-like $Ca^{2+}$ current (low-threshold, inactivating), but its expression in the model can also accommodate an h current (hyperpolarization activated inward current) (Wang and Rinzel, 1992) or a $Ca^{2+}$ dependent $K^+$ current (Grillner et al., 2000). Two different modes of oscillation appear in the model, "release" and "escape" (Wang and Rinzel, 1992). For the release mode to occur, the synaptic threshold must be above the steady state membrane potential of the uninhibited neurons. In the release mode, the inactivation of $I_{pir}$ erodes the depolarized or active phase of a neuron so that it falls below threshold for synaptic transmission. Consequently, its partner is released from inhibition and rebounds into the active depolarized state. For the escape mode to occur the synaptic threshold must be below the steady-state voltage of the neurons when uninhibited. This condition can be accomplished simply by increasing $g_{pir}$. In the escape mode, once inactivation of $I_{pir}$ is removed by the hyperpolarization associated with inhibition, it activates and overcomes the maintained synaptic current so that the neuron escapes into the active phase and thus inhibits its partner.

Skinner, Kopell, and Marder (1994) have extended this analysis using similar model neurons based on the Morris-Lecar equations (low-threshold noninactivating inward current and delayed rectifier current) with a synaptic conductance, which is a steep sigmoidal function of presynaptic membrane potential with a set threshold and instantaneous kinetics. Such model neurons, like the Wang and Rinzel neurons, oscillate between a depolarized plateau and a sustained inhibitory trough. Each of the two modes of oscillation can be further differentiated depending on whether the escape or release is intrinsic or synaptic. If the release is due to a cessation of synaptic transmission (crossing synaptic threshold), it is synaptic release, but if it is due to termination (deactivation of the inward current, activation of the delayed rectifier, or both) of the depolarized plateau, it is intrinsic release. If the escape is due to the commencement of synaptic transmission (crossing synaptic threshold), it is synaptic escape, but if it is due to expression of the depolarized phase (crossing plateau threshold), it is intrinsic escape. Varying the synaptic threshold causes transitions between the modes.

These theoretical studies have been corroborated by hybrid systems studies in which artificial reciprocal inhibitory synapses were introduced between crustacean stomatogastric neurons that are normally unconnected by using dynamic clamp (Sharp, Skinner, and Marder, 1996). To obtain robust oscillations an artificial h current was also added. By adjusting the synaptic threshold of the artificial synapses it was possible to capture all of the richness of the dynamic systems analysis. More recently, a theoretical analysis, based on work in crustacean stomatogastric networks, has shown that even passive neurons employing graded synapses can generate oscillation in the half-center configuration (Manor et al., 1999). Although the models used in the theoretical analyses are simplistic, the major insights that they impart can be transferred to biological neurons, which are connected by simplistic artificial synapses. Real neurons display more complicated intrinsic membrane properties and plastic synaptic interactions that may blur the conclusions of these analyses, but nevertheless they serve as a useful organizing point for the exploration of richer biological systems.

## Leech Heartbeat

This review will now focus on the motor pattern generating network that controls heartbeat in the leech. Progress has been made in understanding the role reciprocal inhibitory synaptic interactions and membrane properties play in generating oscillations by combining experimental analyses with realistic modeling.

A network of seven bilateral pairs of segmental heart (HN) interneurons produces rhythmic activity (at about 0.1 Hz) that paces segmental heart motor neurons, which in turn drive the two hearts. The synaptic connections among the interneurons and from the interneurons to the motor neurons are inhibitory. The first four pairs of heart interneurons control the timing of the network. The timing oscillation is dominated by the activity of the third and fourth pairs of heart interneurons. Reciprocally inhibitory synapses between these bilateral pairs of oscillator interneurons, combined with their ability to escape from inhibition and begin firing, pace the oscillation (Figure 1*A*). Thus, each of these two reciprocally inhibitory heart interneuron pairs can each be considered an elemental half-center oscillator. The first two pairs of heart interneurons act as coordinating fibers, serving to link these two elemental oscillators (Figure 1*B*).

Several ionic currents have been identified in single electrode voltage-clamp studies that contribute to the activity of oscillator heart interneurons (Calabrese, Nadim, and Olsen, 1995). These include, in addition to the fast $Na^+$ current that mediates spikes, two low-threshold $Ca^{2+}$ currents [one rapidly inactivating ($I_{CaF}$) and one slowly inactivating ($I_{CaS}$)], three outward currents [a fast transient $K^+$ current ($I_A$) and two delayed rectifier-like $K^+$ currents, one inactivating ($I_{K1}$), and one persistent ($I_{K2}$)], a hyperpolarization-activated inward current ($I_h$) (mixed $Na^+/K^+$, $E_{rev} = -20$ mV), a low-threshold persistent $Na^+$ current ($I_P$) and a leakage current ($I_L$). The inhibition between oscillator interneurons consists of a graded component that is associated with the low-threshold $Ca^{2+}$ currents and a spike-mediated component that appears to be mediated by a high-threshold $Ca^{2+}$ current. Spike-mediated transmission varies in amplitude throughout a burst according to the baseline level of depolarization (Olsen and Calabrese, 1996). Graded transmission wanes during a burst owing to the inactivation of low-threshold $Ca^{2+}$ currents.

Much of this biophysical data has been incorporated into a detailed conductance-based model of an elemental (two-cell) oscillator (Nadim et al., 1995, Hill et al., 2001). This model uses standard Hodgkin-Huxley representations of each voltage-gated current. Synaptic transmission in the model is complex. A spike-triggered alpha-function is used describe the postsynaptic conductance associated each action potential and the maximal conductance reached is a function of the past membrane potential to reflect the fact that spike-mediated transmission varies in amplitude throughout a burst according to the baseline level of depolarization. Graded

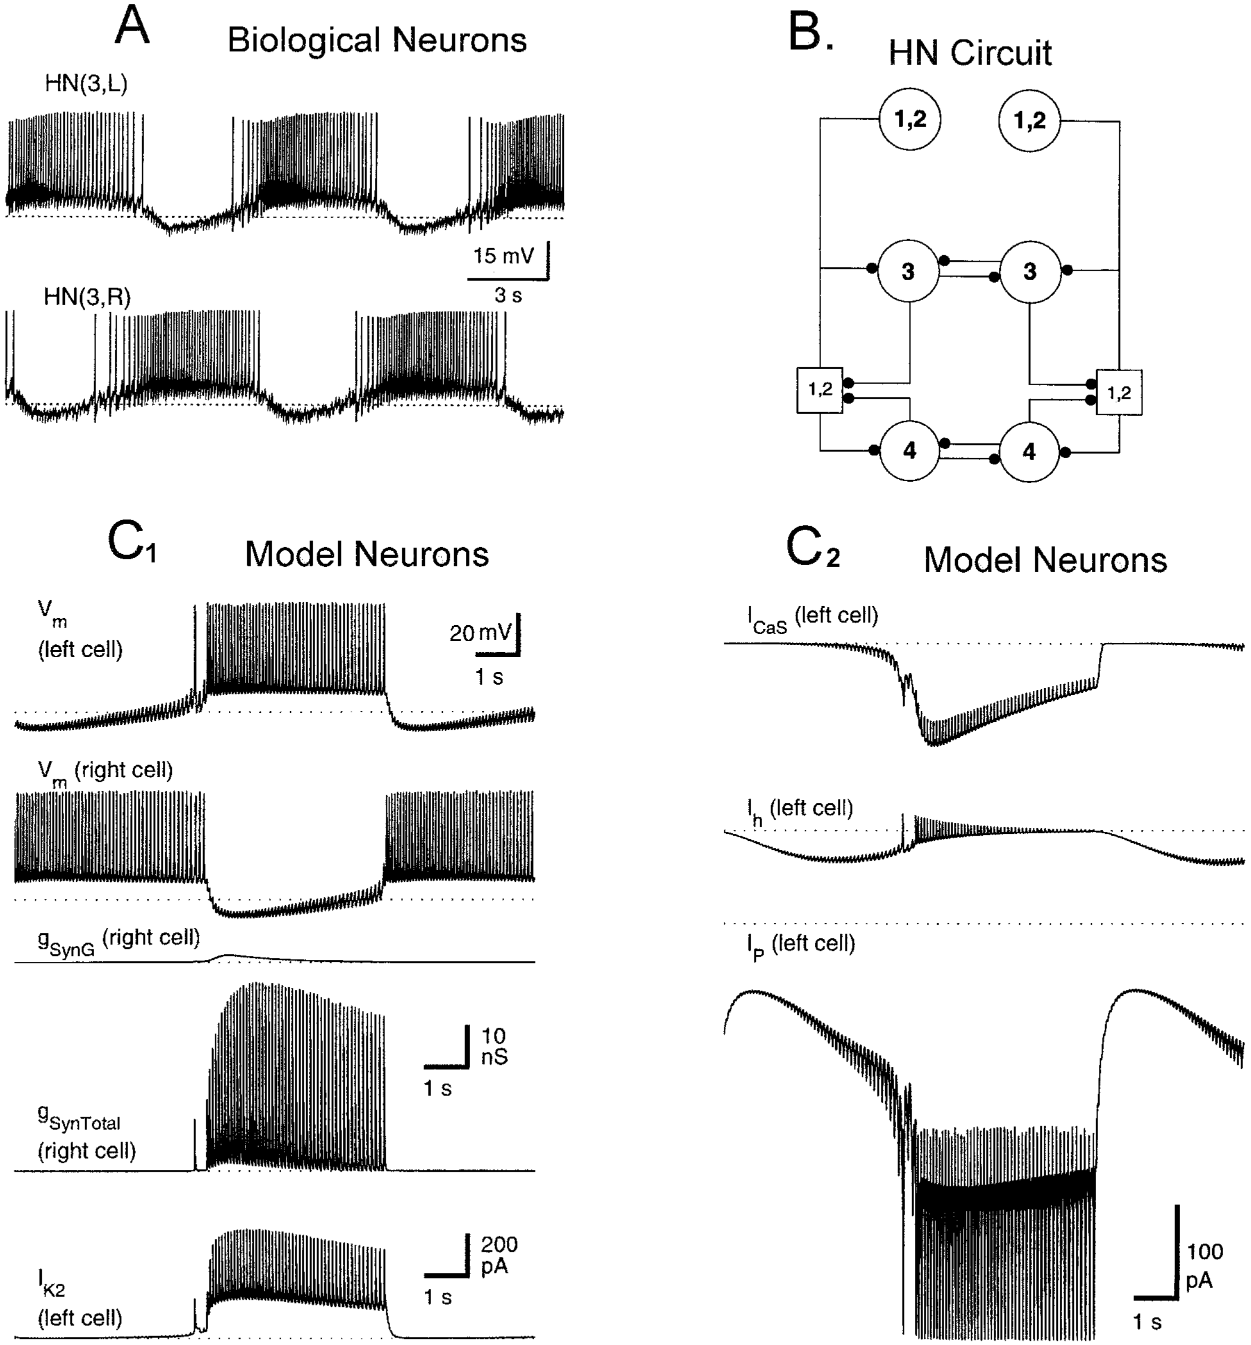

**Figure 1.** *A*, Simultaneous intracellular recordings showing the normal rhythmic activity of two reciprocally inhibitory heart (HN) interneurons that compose a half-center oscillator in an isolated ganglion preparation. Heart interneurons are indexed by body side (R, L) and ganglion number. *B*, Circuit diagram showing inhibitory synaptic connections among the HN interneurons of the timing network. Coordinating neurons HN(1) and HN(2) are functionally equivalent and are lumped together in the diagram. The HN(1) and HN(2) neurons receive synaptic inputs, initiate action potentials, and make synaptic outputs at sites located in the third and fourth ganglia (open squares). *C1–C2*, Synaptic conductances and some major intrinsic currents that are active during a single cycle of the third-generation model of a two-cell HN interneuron oscillator (half-center). The graded synaptic conductance ($g_{SynG}$) is shown at the same scale as the total synaptic conductance ($g_{SynTotal}$), which is the sum of the graded and spike-mediated conductances. The slow calcium current ($I_{CaS}$), the hyperpolarization-activated current ($I_h$), and the persistent sodium current ($I_P$) are shown to the same scale. Note that $I_P$ is active throughout the entire cycle period (Hill and Calabrese, unpublished). In *A* and *C* dashed lines indicate −50 mV in voltage traces, 0 nA in current traces, and 0 nS in conductance traces.

synaptic transmission is represented by a synaptic transfer function, which relates postsynaptic conductance (the result of transmitter release) to presynaptic $Ca^{2+}$ build-up and decline, via low-threshold $Ca^{2+}$ currents and a $Ca^{2+}$ removal mechanism, respectively. The model is now in it fouth generation (Hill et al., 2001), having been upgraded each time by the incorporation of new data from experiments suggested by the previous generation of the model (Olsen and Calabrese, 1996). Free parameters in the model are the maximal conductance ($gmax_{ion}$) for each current (voltage-gated or synaptic). The $gmax_{ion}$s were adjusted to be close to the average observed experimentally. The reversal potential, $E_{ion}$, for each current was determined experimentally and they were considered fixed. Final selection of parameters to form a canonical model was dictated by model behavior under control conditions, passive response of the model to hyperpolarizing current pulses, and reaction of the model to current perturbations. The model cells were tuned by adjusting leak parameters ($E_{leak}$ and $gmax_{leak}$) so that they fire tonically when all inhibition between them was blocked. This tuning was chosen because under conditions of our experiments, which use sharp microelectrodes for recordings, the neurons fire tonically when synaptically isolated with bicuculline (Schmidt and Calabrese, 1992). Recent unpublished work (Gaudry, Cymbalyuk, and Calabrese, Department of Biology, Emory University) suggest that oscillator heart interneurons burst endogenously when isolated with bicuculline. Because the cells must be recorded extracellularly to reveal this bursting, we hypothesize that their bursting behavior is very sensitive to leak parameters that are altered with intracellular recording methods.

The canonical model generates activity, which closely approximates that observed for an elemental half-center oscillator (Figure 1*C*). Analysis of current flows during this activity (Figure 1*C*) indicates that graded transmission occurs only at the beginning of the inhibitory period due to inactivation of the low-threshold $Ca^{2+}$ currents that mediate this inhibition. Thus, graded inhibition helps turn off the antagonist neuron, but sustained inhibition of the antagonist neuron is all spike-mediated. The inward currents in the model neurons act to overcome this inhibition and force a transition to burst phase of oscillation. $I_P$ is active throughout the activity cycle, providing a persistent excitatory drive to the system. $I_h$ is slowly activated by the hyperpolarization-associated inhibition, adding a delayed inward current that drives further activation of $I_P$ and eventually the low-threshold $Ca^{2+}$ currents ($I_{CaS}$ and $I_{CaF}$). These regenerative currents support burst formation. $I_P$, because it does not inactivate, provides steady depolarization to sustain spiking, while the low-threshold $Ca^{2+}$ currents help force the transition to the burst phase but inactivate as the burst proceeds, thus spike frequency slowly wanes during the burst. Outward currents also play important roles, especially the $I_K$s. $I_{K2}$, which activates and deactivates relatively slowly and does not inactivate, regulates the amplitude of the depolarization that underlies the burst, while $I_{K1}$, which activates and deactivates relatively quickly and inactivates, controls spike frequency.

Increasing $gmax_{SynS}$ (the maximal spike-mediated synaptic conductance) in the model slows the oscillation while reducing $gmax_{SynS}$ speeds the oscillation. Under canonical conditions graded transmission is suppressed (Nadim et al., 1995). Analysis of state variables (m and h) for low-threshold $Ca^{2+}$ currents indicates that deinactivation of these currents is not effective during the inhibitory period. In the canonical model cells, as in the real cells, the potential for prolonged and intense graded transmission is revealed on rebound from a hyperpolarizing pulse.

The period of the oscillation is sensitive to the level of $gmax_h$, as would be predicted from its key role in forcing the transition from the inhibitory phase to the burst phase. Decreasing $gmax_h$ from canonical levels slows the oscillation proportionately, while increasing it speeds the oscillations. In contrast, increasing g*max* of $I_P$, the other inward current active during the inhibited phase, slows the oscillation and decreasing g*max*$_P$ speeds the oscillation. These observations indicate that the predominate effect of Ip is to prolong the burst phase and concomitant inhibition of the antagonist heart interneuron, rather than to promote escape during the inhibited phase. Addition of a slowly activating and deactivating outward current ($I_{KF}$), which is induced by the endogenous neuropeptide FMRFamide, speeds the cycling of the elemental oscillator model as it does in the biological oscillator interneurons (Nadim and Calabrese, 1997).

It appears that in the heart interneuron half-center oscillators forces that promote both escape and release are at work. Spike-mediated transmission gradually wanes during a burst because of the slowly declining envelope of depolarization during the burst phase, which slows spike frequency and down modulates IPSP amplitude (Figure 1*C*). This decline in the inhibition of the inhibited cell represents a release. Indeed, if this decline is eliminated in the model by eliminating inactivation from $I_{CaS}$, then oscillations cease (Hill et al., 2001). Nevertheless, whenever $I_h$ is sufficiently activated to overcome the waning synaptic current, a transition from the inactive state to the active state occurs, and the “trigger point” for this release is determined by $gmax_h$, which is consistent with an escape mechanism (Hill et al., 2001). Thus this half-center oscillator is not easily categorized, but the theoretical comparisons have been illuminating.

To fully explore the leech heart interneurons half-center model and a model of the entire heartbeat timing network, they can be downloaded from http://calabreselx.biology.emory.edu by anonymous ftp. Various UNIX-based operating systems, including LINUX, are supported.

## Conclusions

The half-center-based pattern generators controlling swimming in the pelagic mollusk *Clione* (Arshavsky et al., 1993), in tadpoles (Xenopus) (Roberts et al., 1998), and in lampreys (Grillner et al., 2000), which have also been extensively analyzed and modeled, employ neurons that have pacemaking or bursting properties. Both the *Clione* and the *Xenopus* tadpole swim oscillators appears to operate in the intrinsic release mode (Arshavsky et al., 1993). “Spike” (active state) termination terminates inhibition and allows the antagonist cell to rebound into the active state. Perhaps this mode is more suited to the operational frequency range of these oscillators, which are some ten times faster (about 1 Hz) than the leech heartbeat oscillator.

# Hebbian Learning and Neuronal Regulation

*Gal Chechik, David Horn, and Eytan Ruppin*

## Introduction

Since its conception half a century ago, Hebbian learning has become a fundamental paradigm in the neurosciences. The idea that neurons that fire together wire together has become fairly well understood, as in the case of NMDA-dependent long-term potentiation in the hippocampus (Bliss and Collingridge, 1993). However, for both computational and biological reasons, this type of plasticity has to be accompanied by synaptic changes that are not synapse specific but neuron specific; i.e., they involve many synapses of the same neuron. Biologically, such interactions are inevitable as synapses compete for finite resources and are subject to common processes of the same neuron to which they all belong. Computationally, neuron-specific modifications of synaptic efficacies are required in order to obtain efficient learning, or to faithfully model biological systems. Hence, *neuronal regulation*, defined here as a process modulating all synapses of a postsynaptic neuron, is a general phenomenon that complements Hebbian learning.

There exists evidence for cellular mechanisms resulting in normalization of synaptic efficacies, some of which operate to maintain total synaptic strength and others to regulate mean postsynaptic activity (Miller, 1996). Among these mechanisms are cellular regulation of the number of synapses or of trophic factors, competition between synapses for some finite resources, changes in presynaptic and postsynaptic learning thresholds, or activity-dependent regulation of conductances. Normalization of synaptic efficacies is also induced by certain types of plasticity as an emergent phenomenon, for example in the case of spike-time-dependent plasticity (Song, Miller, and Abbott, 2000). Of particular interest are the findings by Turrigiano et al. (1998), who studied cultures of pyramidal neurons of postnatal rats. They observed slow postsynaptic up- or down-regulation of adenosine monophosphate (AMPA)-mediated synaptic currents in a way that maintained the mean firing activity of the neuron. This scaling resulted in overall synaptic normalization through a multiplicative factor that is inversely related to the neuron's activity.

What are the computational consequences of such neuronal-level processes? It turns out that learning through Hebbian learning alone raises many theoretical difficulties and questions, such as: What stops the positive feedback loop of Hebbian learning and guarantees some normalization of the synaptic efficacies of a neuron? How can a neuron acquire specificity to particular inputs without being prewired? How can memories be maintained throughout life, while synapses suffer degradation due to metabolic turnover? As we will see, neuronal regulation provides a possible answer to all of the above.

We can divide the computational problems to be looked at according to the traditional dichotomy of supervised and unsupervised learning. In unsupervised learning, the important role of neuronal regulation is to allow for *competition* between the various synapses, leading to *normalization* of the synaptic efficacies. This role will be further explained in the next section, where we review some basic learning paradigms, discuss the difference between multiplicative ($\Delta\mathbf{w} \propto \mathbf{w}$) and additive ($\Delta\mathbf{w} = const$) scaling, and identify some applications to biological systems. We will then turn to supervised learning paradigms, and show that neuronal regulation improves the *capacity* of associative memory models and can be used to guarantee the *maintenance* of biological memory systems.

## Unsupervised Learning

When Hebbian plasticity operates in a network in an unsupervised manner, a positive feedback loop is created. To illustrate the problem, think of a presynaptic cell *A* that causes the firing of a postsynaptic cell *B*. Because of Hebbian plasticity, the efficacy of the synapse $w_{BA}$ from *A* to *B* is strengthened. This leads to an increase in the ability of cell *A* to activate cell *B*, which in turn leads to strengthening of the same synapse again. When this positive feedback is unconstrained, it leads to synaptic runaway, i.e., the divergence of synaptic efficacies. It seems reasonable to assume that synaptic values are limited by some upper bound that stops this process. Even then a problem emerges: different afferents will activate different synapses of the target neuron *B*. When all of them get saturated at their upper bounds, the neuron will not have any discrimination ability. This problem may be solved by introducing constraints, such as limiting the total synaptic strength of a neuron, $\Sigma_i w_i^2 = const$. This results in competition between synapses: the increased strength of one synapse causes a decrease in the strength of another, preventing saturation of all synapses.

## *Multiplicative Versus Additive Constraints*

Normalization prevents synaptic divergence; thus, the combined operation of Hebbian learning and normalization induces new dynamics of synaptic efficacies. This combined dynamics was described by Oja (1982), showing that multiplicative weight normalization of a neuron with real-valued stochastic input extracts the first principal component of the input distribution (also known as PRINCIPAL COMPONENT ANALYSIS [q.v.] or Karunen Leove feature extraction).

Whereas PCA extraction follows for multiplicative normalization, the results change if other types of constraints, such as additive normalization, are imposed (Miller and MacKay, 1994). Although multiplicative normalization leads to a graded weight vector that represents even weak correlations in the input (upper plot of Figure 1*B*), additive normalization yields a sharpened receptive field where weights saturate at their lower and upper bounds in a way that reflects only the maximally correlated inputs (Figure 1*B*, bottom). Similar results were obtained for competitive learning, where only the weights of the winning unit are changed (Goodhill and Barrow, 1994).

## *Neuronal Regulation and Synaptic Normalization*

What is the relation between synaptic normalization and neuronal regulation? Normalization of synaptic efficacies involves all synapses of a postsynaptic neuron, and thus requires neuronal-level computation. Moreover, in some cases synaptic normalization is an emergent result of synaptic changes that depend on neuronal activity. We approach this idea by discussing two learning models: the Oja learning rule mentioned earlier and the Bienenstock, Cooper, and Munro (BCM) model.

Using the linear perceptron $V = \Sigma_i w_i x_i$, Oja's learning rule can be implemented by $\Delta w_i = \eta V(x_i - V w_i)$. Here, neuronal regulation is explicitly manifested by the second term, which provides a multiplicative correction that is independent of the specific input $x_i$ but is determined by the neuronal output $V$. Interestingly, this neuronal regulation term guarantees $\Sigma_i w_i^2 = 1$.

The BCM model (Bienenstock, Cooper, and Munro, 1982) is another example of complex interplay of neuronal regulation and synaptic competition. In the BCM approach, both Hebbian potentiation and depression are used in defining the synaptic learning rule: synapses are potentiated when the presynaptic neuron fires frequently, and depressed otherwise. The boundary between potentiation and depression is determined by the activity of the postsynaptic neuron, which is where neuronal regulation comes in. This component of neuronal regulation leads to competition between synapses and introduces statistical correlations (Intrator and Cooper, 1992) that are higher than the second order used in PCA. Thus, the BCM model captures high-order statistical structures in the input and tunes the efficacies of incoming synapses accordingly.

## *Biological Models*

The BCM model was developed to describe the emergence of orientation-selective cells and ocular dominance in the visual cortex and their dependence on the stimuli that the visual system receives during its critical developmental stages. A study that discusses the same issues with particular emphasis on the dynamics of synaptic efficacies under additive and multiplicative normalization schemes is that of Miller and MacKay (1994). They show that when the inputs to a neuron have positive correlations only, additive normalization leads to the convergence of weights to an on-center-off-surround receptive field, or to a bilobed receptive field, depending on the parameter regime. When the cell receives inputs from both eyes, additive normalization leads to ocular dominance through the sharpening of receptive fields. Multiplicative normalization can lead in this case to ocular dominance only if the inputs from both eyes are negatively correlated.

A convenient system for the study of neuronal regulation is the vertebrate neuromuscular junction (NMJ). Its development is characterized by an initial stage of superinnervation (each muscle fiber is innervated by several motor neurons) followed by withdrawal of axon terminals until a state of single innervation is reached. Modeling the NMJ, Willshaw (1993) has shown that competition for postsynaptic resources explains the decrease in innervation, yet fails to account for other experimental findings such as incomplete innervation after artificial partial denervation during development.

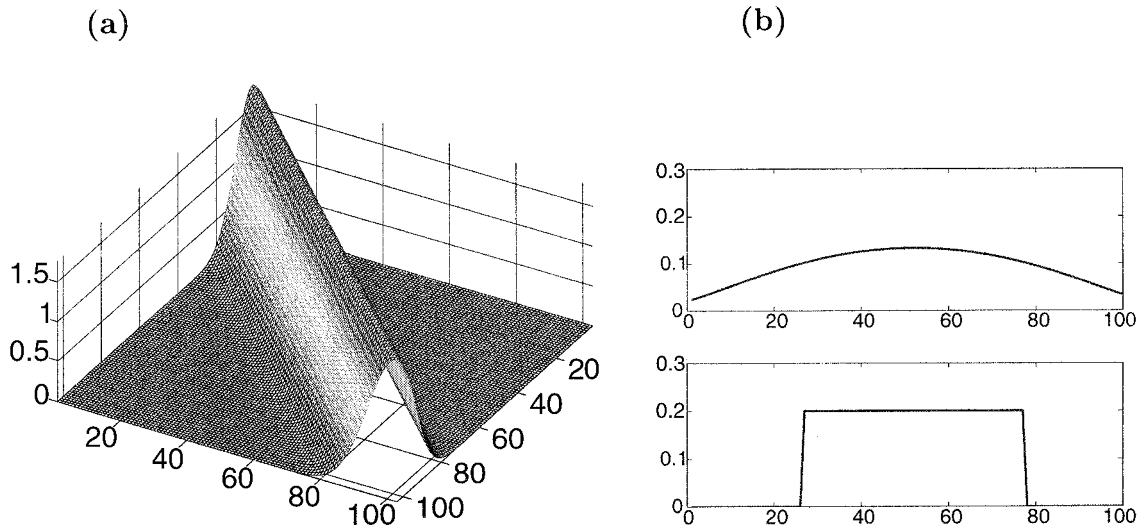

**Figure 1.** Steady states of synaptic weights under multiplicative and additive normalization in a toy example of a neuron with 100 inputs. *A*, The correlation matrix of all inputs. *B*, Under multiplicative constraints, the weights converge onto the first principal component (upper plot), while an additive rule leads to a binary separation of weights that reach their extremal values (bottom plot).

However, a combination of post- and presynaptic competition provides a good account of the data. Indeed, the efficacy of the neuromuscular synapse during the period preceding axonal withdrawal was traced by Colman, Nabekura, and Lichtman (1997), who found changes in quantal content and efficacy. These changes led to continuous strengthening of some synapses with a parallel weakening of the rest, suggesting the operation of a cascade of pre- and postsynaptic processes regulating synaptic efficacies. This is therefore an interesting example in which both pre- and postsynaptic normalization cooperate during early development.

Finally, we wish to point out that competition may arise also through effects other than neuronal regulation. An example is the case of spike-time-dependent synaptic plasticity, in which potentiation of excitatory synapses occurs when the presynaptic spike shortly precedes the postsynaptic spike, and depression occurs when the opposite temporal order holds. Song et al. (2000) assumed that spike-dependent synaptic potentiation is weaker than depression and showed that in a neuron that is driven by net positive input, the excitatory synapses will be weakened. This eventually leads to a balanced input in which the more relevant excitatory synapses are strengthened. Thus, effective competition between synapses may occur even in the absence of an explicit neuronal regulatory term, one that depends on the postsynaptic neuron only.

## Supervised Learning

We saw that in unsupervised learning, neuronal regulation solves the problem of synaptic runaway and guarantees specificity of neuronal response through synaptic competition. In supervised learning, normalization constraints introduced by neuronal regulation provide both maintenance of memory systems and high memory capacity.

### *Memory Maintenance*

The concept of neuronal regulation was introduced by Horn, Levy, and Ruppin (1998) in the context of associative memory networks, while these authors were developing a model that could account for the stability of memory systems in the face of continuous metabolic turnover of synapses. This repetitive process of synaptic degeneration and buildup occurs on a time scale of few days. Under these conditions, one wonders how memories can be stored in synaptic connections for prolonged periods. It turns out that neuronal regulation may play an important role in bringing about the necessary homeostasis of this system, i.e., account for its ability to continue to both learn and retrieve memories (Horn et al., 1998).

To understand this issue, let us consider an associative memory system that is tested through activation by random inputs. Neurons that belong to memories with large basins of attraction will be much more active than those that participate only in memories with small basins of attraction. At this point, we introduce neuronal regulation through multiplicative synaptic corrections that are inversely proportional to the activity of the postsynaptic neuron. This will upregulate weak memories and downregulate strong ones. The multiplicative nature of the correction guarantees that the relative weights of different memories on the same neuron are maintained. The result of this procedure is depicted in Figure 2. As can be seen, repeated synaptic degradation and neuronal regulation leads to normalization of the basins of attraction.

The homeostasis strategy suggested by Horn et al. (1998) involves repeated sessions of random activation, synaptic degradation, and neuronal regulation that provide the required maintenance of the network after it goes through some period of Hebbian learning. It can be shown that the combined effect of synaptic degradation and neuronal regulation also results in the removal of weak synapses, owing to emerging synaptic competition (Chechik, Meilijson, and Ruppin, 1999). This can provide insight into the phenomenon of synaptic pruning that is believed to occur during early development in mammals (see Quartz and Sejnowski, 1997, for a review of the constructive versus selectionist approaches to brain development).

### *Learning Capacity*

Normalization of synaptic efficacies plays a crucial role in producing effective Hebbian learning: Without normalization, Hebbian

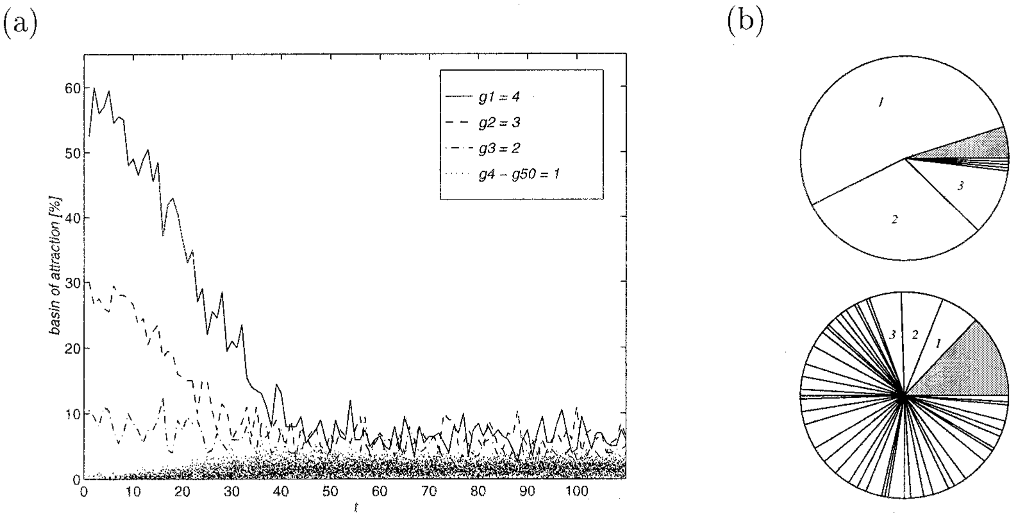

**Figure 2.** *A*, Size of basins of attraction as measured by the percentage of retrievals of specific memories. Fifty memories are stored in a system of a thousand neurons. Three of the memories are stronger (parametrized by *g*) than the rest, overshadowing all others before the corrective dynamic action of NR is introduced. *B*, Shares of memory space (relative sizes of basins of attraction) at the beginning (upper figure) and the end (lower figure) of the simulation that consists of repeated cycles of synaptic degradation and neuronal regulation. Random inputs lead either to encoded memories or to the null attractor (gray shading) in which all activity stops. (From Horn, D., Levy, N., and Ruppin, E., 1998, Synaptic maintenance via neuronal regulation, *Neural Computat.*, 10:1–18. Reprinted with permission.)

learning leads to poor associative memory capacity that does not grow with the size of the network.

Several authors (e.g., Dayan and Willshaw, 1991; Chechik, Meilijson, and Ruppin, 2001) have studied the space of additive Hebbian learning rules for associative memory networks with low-activity patterns (i.e., patterns where only a low fraction of the neurons fire). Such learning rules determine the changes in synaptic efficacy when a memory pattern is stored, and may be formally written as $\Delta w_{ij} = aS_iS_j + bS_i + cS_j + d$, where $S_i \in \{0, 1\}$ is the activity of the $i$th neuron of the stored pattern. Analyzing the associative memory capacity of such learning rules shows that only a constrained subspace of learning rules leads to effective memory storage. Figure 3 illustrates this phenomenon, showing the capacity resulting from such rules within a subspace of two parameters. Most learning rules are ineffective and lead to low memory capacity because they create correlations between synaptic weights even when the stored memory patterns are uncorrelated. Moreover, all effective learning rules fulfill a constraint that depends on the fraction of firing neurons within the stored memory patterns (a global network parameter). Unfortunately, small perturbations in the learning rule parameters lead to violation of this constraint, and consequently to memory capacity collapse.

Interestingly, learning with effective learning rules lead to a vanishing sum of synaptic efficacies for each neuron. This is true, for example, for the learning rules on the ridge in Figure 3. More important, the converse also holds: a vanishing synaptic sum guarantees effective learning. Thus, enforcing through neuronal regulation the condition that the sum of synaptic efficacies vanishes yields high memory capacity, irrespective of the generalized Hebbian rule one starts with (Chechik et al., 2001).

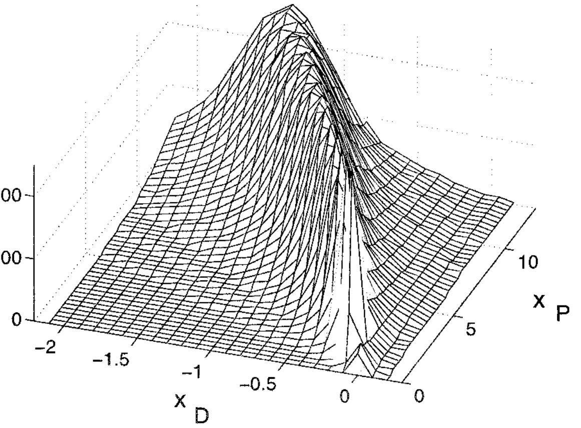

**Figure 3.** The memory capacity of an associative memory network for various learning rules. The number of memories that can be stored in a 1,000-neurons network and later retrieved from distorted cue is plotted as a function of two parameters: the strength of synaptic potentiation ($x_P$) and heterosynaptic depression ($x_D$). These two parameters span the two-dimensional subspace of learning rules $\Delta w_{ij} = x_P S_i S_j + x_D S_i (1 - S_j)$, where $S_i \in \{0, 1\}$ is the activity of the $i$th neuron. Apparently, only a one-dimensional set of learning rules provides effective learning. (From Chechik, G., Meilijson, I., and Ruppin, E., 2001, Effective learning with ineffective Hebbian learning rules, *Neural Computat.*, 13:817–840. Reprinted with permission.)

## Discussion

Hebbian mechanisms per se fail to provide robust and effective learning, both in supervised and in unsupervised scenarios. Although some synapse-specific mechanisms may provide partial remedies for these problems, the current article focused on neuronal regulation of synaptic efficacies and its role in complementing Hebbian learning. Experimental evidence exists for cellular mechanisms that regulate synapses to maintain global constraints on activity or total synaptic strengths (Turrigiano et al., 1998). This evidence suggests that neuronal regulation and Hebbian learning are distinct mechanisms: they are mediated through different receptors (NMDA versus AMPA) and operate on different time scales. From a computational standpoint, the combined operation of Hebbian learning and neuronal regulation provides powerful learning capabilities, ranging from PCA and ICA extraction to robust associative memory learning. We conclude that the functional interplay between synaptic and neuronal mechanisms plays a fundamental role in biological neural networks.

# Hebbian Synaptic Plasticity

*Yves Frégnac*

## Introduction

Appropriate levels of description must be chosen in order to analyze dynamic changes in brain function during development, learning, and perception. One approach is to go from simple phenomenological rules to complex mechanistic scenarios of synaptic plasticity and to evaluate progressively how each level of complexity affects the processing and adaptive capacities of the overall network. This article briefly summarizes the historical foundations and subsequent elaboration by theoreticians and experimenters of a simple activity-dependent algorithm of synaptic plasticity proposed by Donald Hebb in 1949. The predictions derived from Hebb's postulate can be generalized for different levels of integration (i.e., synaptic efficacy, functional coupling, adaptive change in behavior) simply by adjusting the variables derived from various measures of neural activity and the time scale over which each operates. It is thus interesting to consider to what degree this association law may be independent of the biological substrate that is considered and should be viewed as one of the most general computational principles in brain dynamics.

Five major questions will be addressed:

1. Should the definition of Hebbian plasticity refer to a simple positive correlational rule of learning, or are there biological justifications for including additional pseudo-Hebbian terms (such as synaptic depression due to disuse or competition) in a generalized phenomenological algorithm?
2. What are the spatiotemporal constraints (e.g., input specificity, temporal associativity) that characterize the induction process? In particular, should the Hebbian postulate be interpreted as a co-activity rule, or should it incorporate a causal temporal asymmetry, where presynaptic activity precedes postsynaptic activity by a few milliseconds in order to induce synaptic potentiation?
3. Do the predictions of Hebbian-based algorithms account for most forms of activity-dependent dynamics in synaptic transmission throughout phylogenesis? How do the predictions depend on the complexity of the considered neural network (e.g., direct sensory motor connections in *Aplysia* versus associative networks in neocortex)?
4. On which time scales (perception, learning, epigenesis) and at which stage of development of the organism (embryonic life, critical postnatal developmental periods, adult age) are activity-dependent changes in functional links predicted by Hebb's rule?
5. Are there examples of correlation-based plasticity that contradict the predictions of Hebb's postulate (i.e., those termed anti-Hebbian modifications)?

## The Conceptual Framework of Cell Assemblies

### *Pre-Hebbian Theories*

Long before our current knowledge of the synapse-neuron-based structure of the brain, philosophers of antiquity had already theorized how causal relations between external events could be established by the human mind and had pointed out the necessity of repeating sequences of activation in order to link mental representations (Aristotle, ca. 350 B.C.). The application of association theories to the brain can be traced back to as early as 1890: according to William James, the adaptive capacities of our brain depend on mechanistic laws of association that operate under the guidance of central neural structures such as cerebral cortex in higher vertebrates: "When two elementary brain processes have been active together or in immediate succession, one of them, on re-occurring tends to propagate its excitement into the other" (James, 1890). These concepts of association are immediately applicable to the understanding of behavioral learning, and the first extension of classical conditioning in cellular terms was proposed by Jerzy Konorski, a contemporary of Donald Hebb, who assumed that "when the excitation of a given center is synchronous with the rise of excitation in another center, conditioned excitatory connexions are formed from the first of these centers to the latter" (Konorski, 1948).

A second field of application of association theories is the transient formation of mental representations during perception or dreams. In contrast to the previous proposals, the effect produced by repeated associations is no longer restricted to sequences of external events but extends to autonomous activity of the brain. Rather than being transformed under a long-lasting "mnesic" form, the trace of the association is seen here as a reversible facilitation, promoting neural links over the time required for the establishment of the percept (a few hundred milliseconds). In his seminal essay *Le rêve*, Yves Delage hypothesized that each cortical neuron exhibits an intrinsic characteristic periodicity in its activity (Delage, 1919). The relative diversity of the intrinsic frequencies adopted by possible future functional partners (heterochrony) would be dynamically restructured during perception and give place to transient and highly synchronized states (parachrony) among the activated members of the functional assembly.

### *A Neurophysiological Postulate to Build Assemblies*

The physiological association principle proposed by Hebb was in fact just one of several keystones incorporated in a multilevel model of cerebral functioning during perceptual and learning processes. The main concept of a *cellular assembly*, pivotal to his theory, designated an activity process that reverberates in *a set of closed pathways*. The neurophysiological postulate of Hebbian synapses was introduced as one possible way to reinforce functional coupling between co-active cells and thus of growing assemblies. Similar hypotheses were developed at a higher hierarchical level of organization that allowed the linkage between cognitive events and their recall in the form of a temporally organized series of activations of assemblies. Donald Hebb referred to this final binding process as a *phase sequence*. Thus, Hebb's postulate appears simply as a putative low-level biophysical mechanism for establishing the perseverance of activity among assemblies: "When an axon of cell A is near enough to excite cell B, and repeatedly or consistently takes part in firing it, some growth process or metabolic change takes part in one or both cells such that A's efficiency, as one of the cells firing B, is increased" (Hebb, 1949).

The formulation of Hebb's postulate requires not only close temporal coincidence but also the spatial convergence of one neuron onto another, supporting a causal relationship between the afferent activity and the postsynaptic spike. It provides a specific prediction: a period of maintained positive temporal correlation between pre- and postsynaptic activity will lead to an increase in the efficacy of synaptic transmission. Hebb did not elaborate on whether the modifications responsible for this decrease in *synaptic resistance* were presynaptic, postsynaptic, or both. Neither did he describe the biophysical substrate responsible for the modification, leaving the choice open between "metabolic change" and "oriented growth." Both of these options turned out to be true. Historically, Hebb's postulate referred exclusively to excitatory synapses. A symmetric, if not synergetic, version of Hebb's postulate was proposed much later for the case of inhibitory synapses (Stent, 1973), in which functional coupling can be increased by reducing the strength of inhibitory synapses activated at the same time that action potentials are fired in the postsynaptic cell. Some models introduced inhibitory plasticity well before it was proved analytically that the use of negative weights is required for endowing associative memories with an optimal mapping and memory capacity. Thus, the effective gain between input and output, defined at an ideal Hebbian synapse, should be envisioned as a dynamic variable between positive and negative boundaries, depending on whether the net effect induced by the input is excitatory or inhibitory (Figures 1*A* and 1*B*). Some theoretical studies also proposed that synaptic gain could change sign during development (Bienenstock, Cooper, and Munro, 1982), a suggestion later found to apply to inhibitory neocortical or hippocampal circuits.

### *Post-Hebbian Theories: Dynamic Binding of Assemblies*

Peter Milner was probably the first theoretician in the fifties to propose explicit rules for the compositionality of assemblies. The repeated activation of a given cell assembly would reinforce synaptic links within this assembly, and in addition would "prime" a restricted number of cells, allowing future binding and thus composition with other associative processes. The latent labeled synapses would remain transiently eligible for further potentiation by the contiguous firing of other assemblies, a "tagging" concept that would find its biological counterpart only much later. Repeated sequential activation would reinforce the primed connections so that they became an integral part of the next active assembly, thereby resulting in second-order associations: their firing would thus allow the recall of a complete *phase sequence*. Similar ideas were reworded with the addition of a glue mechanism, namely temporal synchrony, acting on a much faster time scale than that initially proposed by Hebb such as to bind elementary representations into a cognitive whole (Milner, 1974) (see SYNCHRONIZATION, BINDING AND EXPECTANCY). The theoretical work fostered by von der Malsburg and colleagues showed that the combined use of "fast" and reversible Hebbian-like synaptic changes and "slow" Hebbian plasticity provides interesting compositional properties when applied to a specific type of assembly called synfire chains (see SYNFIRE CHAINS). Simultaneous recordings of cortical single-unit activity in behaving monkeys have since shown that a significant fraction of activity correlated with a specific cognitive task can be described as waves of synchrony relayed between sets of co-active neurons, at various delays ranging from a few to several hundred milliseconds. A Lego-like interlacing of dynamic assemblies can be further used to give a neuronal embodiment to abstract compositional models of cognition based on dynamical binding operations between symbols that sit at various levels of a representational hierarchy (reviewed in Frégnac and Bienenstock, 1998; see DYNAMIC LINK ARCHITECTURE).

**Figure 1.** The multiple identities of a Hebbian synapse. *A*, Monosynaptic connection between a presynaptic axon (*i*) and a postsynaptic target cell (*j*). Left, the Hebbian algorithm posits that the change in synaptic efficacy $\Delta\omega_{ij}$ is given by the product (or logical AND) of presynaptic ($x_i$) and postsynaptic ($y_j$) activities at any point in time. Right, the "covariance rule" replaces the pre- and postsynaptic terms by the departure of instantaneous pre- and postsynaptic activities from their respective mean values ($(\langle\bar{x}\rangle)$ and $\langle\bar{y}\rangle$ averaged over a certain time window. *B*, A dual excitatory/inhibitory circuit equivalent to an ideal Hebbian synapse, the gain of which varies between negative and positive boundary values. Open circle indicates an excitatory cell; open triangles indicate synapses. Solid symbols indicate inhibitory cells and synapses. *C*, A cellular analogue of classical conditioning: the Hebbian synapse transmits the neural information fed by the conditioned stimulus (CS). The unconditioned stimulus (US) activates the postsynaptic cell in an all-or-none fashion through a nonmodifiable synapse or through a depolarizing current injection directly applied by the experimenter to the postsynaptic cell. The conditioned response stems from the repeated association of the CS input followed by the US input. The phase of the association (ISI) is defined by the temporal lag between the CS and the US inputs.

## Theoretical Predictions and Neurobiological Tests of Hebb's Postulate

Ten years after the publication of his *The Organization of Behavior*, Donald Hebb was doubtful whether his theory was definite enough to be testable, not so much because of technical constraints but because of conceptual ones. Most of the premises were based on a number of postulates, each addressing a different level of integration, and failures of tests restricted to the biophysical level of the synapse would not threaten or contradict the theory in itself.

### *Hebbian Analogs of Cellular Learning*

Hebb's postulate was initially applied by cyberneticians and electrophysiologists in the context of supervised learning. In a similar way to the external teacher of the gamma-perceptron, a classifier machine developed by cyberneticians at the end of the sixties that imposes an increase in the gains of active synapses that participate in the "correct" answer (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION), electrophysiological tests of Hebbian synapses impose depolarization of the postsynaptic element concomitantly with afferent activity. The exogenous control of postsynaptic activity has been achieved using various technical means (electrical stimulation of an unmodifiable pathway, iontophoresis of excitatory neurotransmitters, intracellular current injection, uncaging of calcium at a dendritic spot) in order to elicit positive reinforcement of the modifiable test response (Figure 1*C*). This strategy has been attempted at a variety of sites in the central nervous system ranging from molluscan neuronal ganglia to the mammalian forebrain (reviewed in Brown et al., 1990; Frégnac and Shulz, 1994; Bi and Poo, 2001). Most success in demonstrating the role of postsynaptic factors has been observed in the vertebrate cortex (hippocampus, neocortex, motor cortex), where synaptic potentiation of various durations can be induced under the cooperative influence of other inputs (as is the case during high-frequency tetanus of afferent pathways) or by forcing the postsynaptic cell to an artificially high level of activity. As we will discuss later, results opposite to the Hebbian prediction have been found in the striatum, in the cerebellum, and in related structures in electric fish (reviewed in Bell, 2001; see CEREBELLUM: NEURAL PLASTICITY).

In spite of some earlier reports that invertebrate synapses possess the capacity for long-term potentiation (LTP), until recently it was assumed that nonassociative and associative forms of behavioral plasticity in *Aplysia* resulted from an activity-dependent presynaptic modulation of the efficacy of sensorimotor synapses (see INVERTEBRATE MODELS OF LEARNING: *APLYSIA* AND *HERMISSENDA*). However, later studies provided strong evidence for a postsynaptic regulation of *Aplysia* sensorimotor synapses in dissociated cell culture. These studies showed a specific influence of the appropriate motor cell in inducing spatial competition and segregation of the locus of termination of the afferent axons corresponding to different presynaptic axons. It also demonstrated that Hebbian pairing protocols induced potentiation of identified sensorimotor synapses.

By which cellular machinery does co-activity exert control over synaptic gain? In vertebrate hippocampus as well as in *Aplysia* sensorimotor co-cultures, evidence implicates the NMDA receptor and its invertebrate homologous form, respectively (see NMDA RECEPTORS: SYNAPTIC, CELLULAR, AND NETWORK MODELS). These receptors are ideally suited to operate conjunctive mechanisms, since they require concomitant presynaptic activation and depolarization of the postsynaptic neuron above a critical level to free their embedded ionophore channel from the magnesium block. However, this mechanism is certainly not unique, since Hebbian forms of plasticity can be observed even during the pharmacological APV blockade of NMDA receptors.

The use of multiple simultaneous whole-cell recordings in vitro has recently improved control of the respective timing of pre- and postsynaptic activity and the ability to patch at different distances from the soma. These experiments suggested that action potentials propagating back into dendrites serve to modify single active synaptic connections (see BACKPROPAGATION: GENERAL PRINCIPLES). Backpropagation can contribute to the induction of synaptic plasticity through three distinct mechanisms. The simplest one relies on the voltage dependency requirements of NMDA receptor activation and remains input specific. The second one, involving voltage-gated calcium channels, will apply to all parts of the dendrite in which the spike is efficiently propagated. A third mechanism involves a chain reaction and depends on the initiation of calcium spikes by otherwise subthreshold distal inputs when the EPSP follows by a 5-ms delay the invasion of the dendrite by a backpropagating action potential (reviewed in Frégnac, 1999). In all cases the backpropagating spike can be seen as the "binding signal" emitted by the soma to differentially modify synapses that are active within a precise temporal window.

## *A Theoretical Need for Synaptic Depression and Competition: Pseudo-Hebbian Rules*

Most algorithms of synaptic plasticity use rules of normalization that require depression of certain synapses in addition to Hebbian reinforcement of active connections (see POST-HEBBIAN LEARNING ALGORITHMS). The "divergence" problem caused by a straightforward application of Hebb's principle was solved by the first modelers using various ad hoc hypotheses: upper bound values (saturation) for individual synaptic weights, forgetting mechanisms slowly activated by disuse, and complementary plasticity rules that operated at the level of synapses fed both by active pathways (associative depression) and by neighboring inactive afferents (heterosynaptic depression). In the latter case, different weight normalization procedures were proposed that gave rise to what is called *competitive learning* in the modeling literature (see COMPETITIVE LEARNING). The additional decay terms introduced in the plasticity rule can depend only on local variables, or it can operate as a global constraint that maintains constant the sum (or the sum of the squares) of all the synaptic weights converging onto the same neuron. Gunther Stent proposed a biophysical mechanism inducing a selective decrease in the synaptic efficacy of afferent fibers that were inactive at the time the postsynaptic neuron was discharging under the influence of other inputs (Stent, 1973). He was probably the first theoretician to introduce the concept of a threshold in synaptic plasticity, linked to the local postsynaptic membrane potential, below which synaptic depression occurs. The prediction of this postulate found strong support from later cross-depression studies in visual pathways and from the observation of heterosynaptic depression in the CA1 field and the dentate area of the hippocampus.

The assumption of global constraints in maintaining the total synaptic weight constant onto the recipient neuron has been also made on the basis of more biological grounds, such as the theory of selective stabilization. Correlates to this model were found in simple in vitro systems that allow the culture of specified numbers of pre- and postsynaptic partners, suggesting that the total capacity of the target neuron for synaptic interaction is fixed and divided among the different input lines. Related arguments can also be found during synaptogenesis of neuromuscular junctions and of vertebrate visual pathways.

In spite of their diversity, these different rules have a common implication: they predict spatial and temporal competition between active fibers that impinge on a common target cell; they are referred to as being *pseudo-Hebbian*.

## *Experimental Support for a Generalized Hebbian Algorithm*

Most Hebbian algorithms that were used to model synaptic plasticity in self-organizing networks or behavioral learning, before the concept of spike-timing-dependent plasticity (STDP) arose, are surprisingly uniform and are based on co-activity of pre- and postsynaptic neurons. They may be summarized by the same general equation in which the change of synaptic efficacy with respect to time is equal to the product of a presynaptic term and a postsynaptic term (reviewed in Frégnac and Shulz, 1994). The so-called covariance hypothesis (in visual cortex: Bienenstock et al., 1982) replaces the pre- and postsynaptic terms by the departure of instantaneous pre- and postsynaptic activities from their respective mean values averaged over a certain time window (see Figure 1*A*). Average values in the covariance product constitute pre- and postsynaptic plasticity thresholds that determine the sign of the modification. They can be replaced by nonlinear functions of past activity (power function with an exponent greater than 1; see Bienenstock et al., 1982). Because of the particular choice of these nonlinearities, synaptic depression will be more readily induced by regimes of high activity during which the plasticity threshold increases faster than the mean postsynaptic activity. Conversely, synaptic potentiation will be promoted following low-activity regimes during which the plasticity threshold decreases slower than mean postsynaptic activity. The "floating threshold" hypothesis predictions agree with the observation of an increased rate of cortical specification in previously deprived animals that are re-exposed to a visually structured environment, when compared with the normal process observed in nondeprived animals. Although most theoretical studies have been concerned with postsynaptic thresholds, experimental evidence (priming protocols, mostly tested in hippocampal slices) suggests as well the existence of a presynaptic averaging mechanism.

The BCM covariance rule in its most general form does account for spatial and temporal competition. In addition to the straightforward Hebbian condition (positive covariance induces an increase in synaptic gain), the covariance hypothesis predicts two forms of depression. The first one is an associative heterosynaptic depression at the level of synapses whose activity was uncorrelated with that of the tetanized pathway (Levy and Steward, 1983). The second form is a homosynaptic depression, when presynaptic activity is associated with repeated failure in synaptic transmission (Frégnac et al., 1988; Frégnac and Shulz, 1999).

## Constraints on Spatial and Temporal Specificity

### *Input Specificity and Cooperativity*

A first limitation in the locality of the changes produced by learning depends on the minimal neuroanatomical convergence of input that is necessary to induce a functional change. In the case in which the activity of one afferent alone would be sufficient to induce synaptic change, convergence should be considered to be related to the density and the spatial distribution of boutons made by a single presynaptic axon onto the same target cell. Some studies based on simultaneous dual intracellular recordings failed to observe significant potentiation of individual synaptic connections, whereas their compound activation revealed an increased postsynaptic response. These results suggest the existence of a postsynaptic threshold mechanism controlling the *expression* of LTP: a critical level of depolarization has to be achieved so that the enhancement at the "primed" synapse would be revealed in response to the test input. This nonlinear behavior in the input/output curve of the postsynaptic neuron would have a major consequence: it would greatly increase the spatial input selectivity of LTP by making it conditional on the strength and the convergence of multiple inputs. It could thus prevent temporally unstructured or spatially disperse afferent information from benefiting from the potentiation.

### *Volume Plasticity*

The input specificity of Hebbian schemes of plasticity—i.e., their restriction to active synapses—might suffer strong limitations when the release of retrograde factors and the spatial diffusion of second messengers are considered. Since quantal analysis studies have implicated presynaptic factors in the maintenance of LTP, it is admitted that some feedback signal indicates to the presynaptic terminal that the correlation operation has been accomplished and that potentiation is authorized. Various retrograde messengers have been proposed, including arachidonic acid, nitric oxide, carbon monoxide, and platelet-activating factor. Taking into account the diffusion of messengers in the extracellular medium, the correlation between high levels of the released molecule and active axon terminals could then become the key factor controlling which synapses should be potentiated. This scheme accounts for the observed generalization of potentiation to neighboring synapses belonging to the axon that has initiated the retrograde messenger process, independently of the target neuron. The consequence of this "volume plasticity" is that correlation will be reinforced between elements that are co-active within a given time window and are within some critical volume without being necessarily physically connected. Reasonable estimates of the space constant on which retrograde messenger-induced changes occur are in the order of 50–150 $\mu$m, based on dual intracellular recordings of a conditioned cell and a neighbor in vitro, both of which receive parent branches from the same input fiber. More surprisingly, the postsynaptic modification also seems to spread to different presynaptic axons that have or have not been implicated in the induction of the LTP process, regardless of their own history of activation.

More advanced studies have recently been achieved at the level of identified neurons and synapses in low-density hippocampal cultures and have revealed extensive but selective spread of both LTP and long-term depression (LTD) from the site of induction to other synapses in the network (reviewed in Bi and Poo, 2001). LTD induced at synapses between two glutamatergic neurons can spread to other synapses made by divergent outputs of the same presynaptic neuron (*presynaptic lateral propagation*) or to synapses made by other convergent inputs on the same postsynaptic cell (*postsynaptic lateral propagation*). Furthermore, LTD can spread in a retrograde direction to depress synapses afferent to the presynaptic neuron (*backpropagation*). In contrast, LTP can exhibit only lateral propagation and backpropagation to the synapses associated with the presynaptic neuron. If output synapses of the paired presynaptic neuron undergo LTP/LTD, then the input synapses undergo similar changes. It is interesting to observe that the backpropagation of LTP/LTD observed in cell cultures appears to fit qualitatively the requirement for backpropagation algorithms in multilayer networks. Similar functional effects could operate on a larger scale in vivo if a permanent imbalance in activity is introduced between competing axons, for example altering the spatial grouping of bands of ocular dominance driven by the open eye in monocular deprived visual cortex.

### *Breaking the Timing Symmetry: Causality Rather than Synchrony*

Most applications of Hebbian theories based on pairing protocols indeed stressed the importance of co-activity, ignoring the few-milliseconds step that separates a presynaptic spike from the triggering of postsynaptic activation. The temporal contiguity requirement of Hebbian potentiation in cortex was first estimated in the ±50 ms range, both in vivo and in vitro, and no temporal ordering was required between pre- and postsynaptic activation. However, the wording of Hebb's principle dictates that presynaptic activity should precede the spike initiation in the postsynaptic element to which it contributes in a causal way ("A's efficiency, as one of the cells firing B"). Temporal asymmetric Hebbian and anti-Hebbian rules (Figure 2*B*) that have been introduced only in recent years agree in this respect with the original concept.

An overlooked consequence of additional pseudo-Hebbian rules is that their interplay with a purely Hebbian scheme already predicts a loss of symmetry in the temporal domain and a possible narrowing of the critical interval of association. In vitro studies of heterosynaptic plasticity in cocultures of embryonic spinal neurons and myotomal muscles show that synchronous activation of two presynaptic pathways protect them from depression, whereas a delay as short as 100 ms is sufficient to depress one or both pathways. Associative forms of LTD have been observed during contiguous dual-pathway stimulation paradigms or when the test input follows a postsynaptic depolarization induced by a brief current pulse. The exact temporal window during which a recurrent input remains eligible for potentiation depends, however, on the strength of the last unconditioned activation of the cell. These results agree partially with the temporal order requirement in associative heterosynaptic depression reported 20 years ago in the study of the crossed (weak) and uncrossed (strong) entorhinal cortex projection to the dentate gyrus, which still described much more shorter association intervals (20 ms), enabling associative LTP (Levy and Steward, 1983).

Recent work, based in most cases on dual patch recordings in vitro, has been realized in preparations as diverse as cultured hippocampal networks, the developing retinotectal system of the frog, the adult electrosensory lobe of electric fish, and the sensory neocortex of the rat. Results suggest an even tighter temporal contingency rule (10-ms range), where the temporal order of the onset of the postsynaptic subthreshold potential reflecting the arrival of the presynaptic spike and the postsynaptic spike backpropagating in the dendrite decides whether potentiation or depression occurs (re-

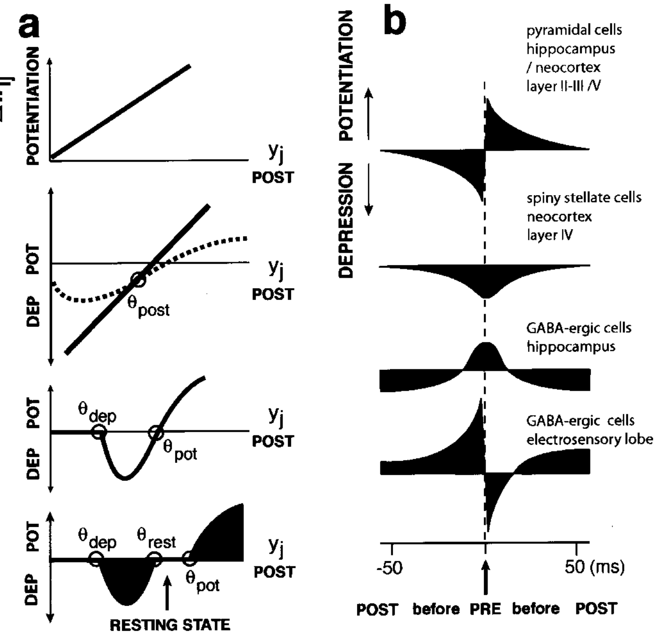

**Figure 2.** Hebbian synapses and spike-timing-dependent plasticity. *A*, A representation of Hebb's rule (top) and the most commonly observed rules of associative plasticity. Each graph expresses the relationship between the induced synaptic change $\Delta\omega_{ij}$ (positive ordinates for potentiation, negative for depression) and postsynaptic activity ($y_j$ on abscissa) at the time of the association defined by the occurrence of the presynaptic spike. The slope of Hebb's rule is proportional to presynaptic activity. The postsynaptic term (POST) has been equated successively with postsynaptic firing frequency, postsynaptic membrane potential, or calcium influx in the postsynaptic cell. In addition, many authors have confounded, rightly or wrongly, the postsysnaptic term with the presynaptic stimulus frequency applied during conditioning, which made these models more manageable in predicting the effects of various input frequencies used more specifically to induce LTD or LTP. From top to bottom: The simple Hebbian rule (top) predicts potentiation only. The covariance rule or BCM rule (second graph from the top) and ABS rule (third graph from the top) predict both depression and potentiation, respectively, with one ($\vartheta_{\text{post}}$) or two postsynaptic plasticity thresholds ($\vartheta_{\text{dep}}$, $\vartheta_{\text{pot}}$). The lower graph is derived from in vivo experiments in which the resting state of the synapse corresponds to a dead zone between depression and potentiation where information is reliably transmitted (Frégnac et al., 1988). *B*, Different forms of spike-timing—dependent plasticity rules established in vitro in cocultures and acute slices. The induced synaptic change is expressed as a function of the temporal delay separating postsynaptic firing from presynaptic firing (taken here as the zero-delay reference), imposed during the pairing protocol. From top to bottom: pyramidal cells in hippocampus or in nongranular layers in neocortex, granular spiny stellate cells in neocortex, GABAergic neurons in hippocampal cultures, GABAergic medium ganglionic layer cells in the electrosensory lobe of the electric fish. Positive ordinates indicate synaptic potentiation and negative ordinates indicate depression.

viewed in Bi and Poo, 2001; Abbott and Nelson, 2000; see Figure 2*B*). An unexpected twist in the story is the claim that the outcome of the rule itself depends on the frequency and the strength of the presynaptic inputs, which could have nontrivial consequences in vivo.

The obvious consequence is that models that incorporate STDP rules account most accurately for the emergence of causal chains within neuronal assemblies and best support phase sequence learning. It is nevertheless possible that both synchrony and causality are required to promote reverberating assemblies rather than the simple build-up of open-ended chains of feedforward activity, as exemplified by the concept of synfire chains. It is highly plausible that STDP reinforces the progressive establishment of a transmission mode through "pulse packets," since the asymmetric nature of this plasticity rule will indirectly control the jitter that could be observed in the timing spread within each pulse packet.

The most obvious cases of associative learning that depart from Hebbian co-activity or STDP rules are those requiring associations between neural events separated by long delays (see CEREBELLUM AND CONDITIONING), such as the optimal interstimulus intervals (in the range of seconds) of association in classical conditioning (see Figure 1*C*), or between the sample and choice periods in delayed-matching-to-sample comparison tasks (see CORTICAL HEBBIAN MODULES). Predictive rules have been modeled with ad hoc phase-lagged correlation functions (see REINFORCEMENT LEARNING). However, no experimental evidence has yet been obtained to account for the build-up of optimal interstimulus intervals through Hebbian mechanisms. This lack of evidence does not negate the implication of ionic mechanisms responsible for a delayed excitability change, or the slow build-up of a second-messenger-mediated intracellular response.

## From Hebbian Synapses to Behavioral Learning

This section addresses the functional and behavioral consequences that Hebbian rules of plasticity induce in biological self-organizing systems.

### *Unsupervised Learning*

Four possible applications of Hebbian processes acting on a long-term scale can be found in the early development or in the forced oriented growth of retinofugal pathways in lower vertebrates, mammals, and primates. These applications exemplify unsupervised learning, or self-organization.

1. The intrinsic synchronous bursting activity ("dark discharge") that arises prenatally from the retina before rods and cones are even formed exerts a structuring influence on the developing retinofugal pathway. The correlated firing among neighboring retinal ganglion cells within one eye and the lack of synchronous firing between ganglion cells of each eye are conditions that allow competition between geniculate afferents according to their ocularity. This correlated input is present in a still stronger way very early in prenatal life, taking the form of spatially organized waves of activity that spread intermittently in random directions across the whole retina. These synchronizing waves could provide the local correlations necessary for the sorting out and topographic refinement of retinal projections onto the lateral geniculate nucleus and, if still present after filtering through the thalamic relay, could be instrumental in the segregation of geniculate afferents in the recipient layer of visual cortex. After the first week of postnatal life in the cat, this intrinsic pattern-generating mechanism will give way to correlated inputs under the guidance of vision (see OCULAR DOMINANCE AND ORIENTATION COLUMNS).

2. Similar activity-dependent rules might apply to the development of intracortical connectivity: the validity of correlational Hebbian rules seems to hold throughout ontogenesis, if one does not restrict the choice of the postsynaptic control variable to spike activity. Indeed, free calcium activity and electrical and glial coupling could act prenatally as a substitute for synaptic transmission to ensure assembly formation in the absence of conventional fast $Na^+$ action potentials. A more classical form of Hebbian plasticity responsible for the progressive maturation of the horizontal intracortical network occurs during a few weeks following birth in the cat; the process results in a selective activity-dependent pruning and stabilization of horizontal connectivity.

3. Evidence has been obtained for the implication of Hebbian mechanisms during the functional reorganization of cortical processing following anomalous visuomotor behavior. A neuroanatomical and electrophysiological study in divergent strabismic kittens, which compensate misalignment of their eyes by alternate fixation, showed that only territories with the same ocular dominance are linked by tangential intracortical connections, and that synchronized activity is achieved only between cell groups dominated by the same eye. Furthermore, in the case of convergent strabismus, which results behaviorally in a loss of acuity through the eye that is not used for fixation, neurons dominated by the "amblyopic" eye exhibited much weaker synchronized activity than cells driven by the "good" eye. The observed correspondence between alterations in intracortical horizontal connectivity topology, the selective impairment of response synchronization, and the perceptual deficit constitutes probably the best evidence so far for a role of temporal correlation in the functional organization of cortical domains (see SYNCHRONIZATION, BINDING AND EXPECTANCY).

4. A last example illustrates the case of oriented growth of retinal axons that are artificially forced to connect the auditory thalamus after chronic deafferentation from its normal input at an early stage of development (see AUDITORY CORTEX). A combined electrophysiological and optical imaging study in the cortex, which normally should have become a primary auditory area, shows that the thalamic rewiring procedure induces the emergence of an anatomofunctional architecture similar to that observed in normal visual cortex (Sharma, Angelucci, and Sur, 2000): a normal retinotopic projection is formed, an orientation preference map is found with classical pinwheel organization, and, furthermore, the intrinsic intracortical connections show the distinctive patchy pattern along a mediolateral axis that is specific to a V1 area. Sur and colleagues further demonstrated that this rewired cortex can mediate adequate visual behavioral responses in response to visual stimuli. These findings suggest that the specificity found in the columnar organization of a given cortical area and its intrinsic horizontal connectivity are shaped by the particular temporal structure of the sensory input experienced during a critical postnatal period.

In summary, the grouping and sorting out of fibers afferent to cortex, the morphological tuning in the spatial distribution of the terminal boutons of intrinsic and extrinsic axons, the functional expression and possibly silencing of synapses, and the setting of a columnar architecture specific to the sensory modality to be processed could all, at some stage of postnatal development, be under the influence of temporal correlation between presynaptic fibers converging onto the same target, or between pre- and postsynaptic partners. This essential role of co-activity in self-organization was foreseen by theoreticians such as Linsker and Miller, who proposed a unifying role for activity, whether triggered endogenously by the nervous system or evoked by interaction with the environment (see OCULAR DOMINANCE AND ORIENTATION COLUMNS).

## *Supervised Learning and Cellular Analogues of Visual Cortical Epigenesis*

Support for a functional implication of Hebb's postulate has also been found in studies on the neuroanatomical and physiological effects of forced patterns of activity, which simulate the functional effects of anomalous visual experience during critical periods of development (epigenesis, in Frégnac et al., 1988; Frégnac and Shulz, 1999). A differential supervised association protocol was used in vivo to test specific predictions of the covariance rule by imposing opposite changes in the temporal correlation between two test parameters characterizing afferent visual activity and the output signal of the cell. Here, an external supervisor (i.e., the experimenter) helped the cell to respond to one input and blocked the cell's response to another, different input. The common outcome was that the relative preference between the two test stimulus characteristics was generally displaced toward that which had been paired with imposed increased visual responsiveness.

These pairing-induced modifications of specificity of the visual response have been considered as cellular analogues of epigenesis since they reproduce functional changes occurring during development or following early manipulation of the visual environment (monocular deprivation, rearing in an orientation-biased environment, or optically induced interocular orientation disparity). Surprisingly, the probability of inducing functional changes was found to be comparable in the kitten during the critical period and in older kittens and adults, suggesting that the cellular potential for plasticity might extend well beyond the classical extent of the critical period. Local supervised learning procedures, applied at the cellular level, might bypass the systemic control that normally blocks the expression of plasticity in the mature brain.

## *Functional Consequences of Spike-Timing-Dependent Plasticity*

It has been suggested that, with repeated experience of a sequence of sensory events, spike-timing-dependent plasticity will promote the learning of the sequence and anticipation of future events from past stimuli. Recent tests of this hypothesis have been engineered in vivo in cat primary visual cortex: repetitive sequential presentation of two stimuli, one being the orientation preferred by the recorded cell and the other being either a suboptimal orientation or an electrical stimulation of the cortex, resulted in a compensatory reorganization of orientation tuning, with the direction of the shift in orientation preference depending on the temporal order of the stimulus pair. Furthermore, similar conditioning in human subjects induced a similar shift in perceived orientation, thus mirroring the plasticity described at the single-cell level in cat visual cortex. Thus the relative timing of visual stimulation and cortical activity plays a critical role in dynamic modulations of adult cortical function. In addition, these various adaptive protocols suggest that the susceptibility to adaptive changes is not uniform throughout cortex, and that orientation pinwheel centers may obey plasticity rules differently from their surround.

## *Gating Signals and Attentional Processes*

Both Hebb and Milner were aware of the fact that the expression of synaptic changes could largely depend on the level of preactivation of nonspecific projection systems and arousal. These factors could influence the likelihood of summation at the synapse and thus could affect the amount of correlated input needed to induce synaptic changes. Because of methodological and technical difficulties, the role of the *behavioral context* (i.e., attention, reinforcement) has been often ignored in the study of the synaptic mechanisms underlying learning in mammals. Ahissar and collaborators applied cross-correlation techniques to study the plasticity of "functional connectivity" between simultaneously recorded pairs of neurons in the auditory cortex in awake monkeys performing a sensory discrimination task (reviewed in Ahissar et al., 1998). In order to control the correlation of activity between cells, the auditory stimulus preferred by the presumed postsynaptic cell was applied every time (and immediately after) the presynaptic cell fired spontaneously. The tone used to control the activity of the postsynaptic cell also signaled the reward occurrence. Under these Hebbian conditions, reversible changes in functional coupling could be induced only when the animal was attentive to the tone. These changes lasted for a few minutes and followed the covariance hypothesis predictions. The results indicate that Hebb's requirement is necessary but not sufficient for cortical plasticity in the adult monkey to occur: internal signals indicating the behavioral relevance are also required. More recently, cellular analogues of state-dependent learning have been proposed that show that the recall of a learned association in adult sensory cortex requires the application of the same neuromodulatory signals (Ach) as those present during conditioning in order for the functional changes to be expressed (Shulz et al., 2000).

## Anti-Hebbian Forms of Learning

Depending on the neural structure under study (i.e., cerebellum versus cortex) or the time course of the functional effect looked for (i.e., sensory adaptation versus learning), forms of plasticity have been observed that are contrary to the predictions of Hebb's postulate. Such changes are called anti-Hebbian (or reverse Hebbian) and should be unambiguously distinguished from pseudo-Hebbian modifications (see POST-HEBBIAN LEARNING ALGORITHMS). The best-known example of anti-Hebbian plasticity is cerebellar long-term depression (see CEREBELLUM: NEURAL PLASTICITY), which, by its time course and induction requirements, appears similar to Hebbian associative potentiation. The trigger mechanism appears to be the same in both cases: free calcium entry into the postsynaptic cell. In order to explain why in the cerebellar case depression occurs, whereas potentiation is predicted by Hebbian schemes of plasticity, it could be assumed that the sign of the change of the synaptic modification depends on the type of neurotransmission (excitatory/inhibitory) that the postsynaptic neuron will exert on other neuronal targets. Purkinje cells for which Hebbian protocols induce depression are the inhibitory output neurons of the cerebellar cortex. Although no biological basis has been found to support the hypothesis that excitatory and inhibitory cells undergo Hebbian potentiation and depression, respectively, the implications of the hypothesis are very attractive in terms of systems theory: forced co-activity would produce the same type of global positive gain control whatever the neuronal structure under study, either by increasing the transmission of the selected input through a purely excitatory loop or by reducing the excitation fed into the inhibitory efferent pathway.

Other examples of anti-Hebbian plasticity link both cerebellar LTD and fast adaptation processes in perception. In the teleost electric fishes (Mormyridae and Gymnotidae), the cerebellar-like structure that receives primary electrosensory projections is the electrosensory lobe (ELL) (see ELECTROLOCATION). The feedforward sensory input informs the fish of its electrical environment and also provides a reafferent response, owing to the sensory effect of the fish's own electric discharge (EOD). The principal cells of the ELL, like Purkinje cells in cerebellum, receive in addition a diversity of contextual inputs conveyed through parallel fibers. The context can provide a copy of the motor command responsible for the electric discharge ("efferent copy" or "corollary discharge"), proprioceptive cues about movements from the fins or the whole body, or control signals descending from higher integrative areas. The pairing of an electrosensory stimulus at a fixed phase or delay after the EOD motor command, or after the passive bend of the body tail, results, when the contextual signal is reapplied alone, in the recall of a sign-inverted image of the firing pattern evoked by the paired electrosensory stimulus. The plastic changes at the parallel fiber–principal cell synapse can be long-lasting, but the extinction of the effect is an active process depending on the frequency of the recall process. Thus, in the mormyrid ELL, the modifiable corollary discharge elicits the transient storage of a negative image of the temporal and spatial pattern of sensory input that has followed the motor command. Bell and co-workers demonstrated the synaptic nature of the change and its reversibility in GABAergic medium ganglionic cells of the ELL by replacing the sensory input (which affects the whole structure) with an intracellular current pulse affecting only the cell under study (Han, Grant, and Bell, 2000; reviewed in Bell, 2001). Similar findings have been observed with other contextual signals in other cerebellar-like structures, such as the ventilatory motor commands of the fish in the dorsal octaval nucleus of elasmobranchs (sharks and rays).

The application of sign-inverted Hebbian rules to excitatory networks has by itself a straightforward prediction: the output of the association neurons will tend to be reduced in response to input patterns to which the neural system is exposed frequently. Evidence in the visual system has been found for gain control processes acting in the range of hundreds of milliseconds. It is known, for instance, that sensory adaptation in forward masking (the fact that the first presentation of a stimulus can bias the perceived features of a second stimulus or alter its visibility) occurs on a time range too long to be accounted for by direct inhibitory action and too short to be compared with the effects of behavioral learning. Anti-Hebbian plasticity could potentially act in the vertebrate brain to filter out modification of sensory input resulting from motor exploration of the environment, and thus could optimize the detection of new events.

## Discussion

The study of memory formation benefits from the use of simple putative elementary principles of plasticity operating at a local level (the synapse) and uniformly across the cell assembly. The large number of experimental attempts to demonstrate the validity of Hebb's postulate prediction during the last 50 years should have inevitably narrowed its fields of application. Surprisingly, Hebbian schemes have survived to become the symbol of an ever-renewed concept of synaptic plasticity, open for more generalization. A variety of experimental networks, ranging from the abdominal ganglion in the invertebrate *Aplysia* to the hippocampus and visual cortex, offer converging validation of the prediction of Hebb's postulate. In these networks, similar algorithms of potentiation can be implemented using different cascades of second messengers triggered by activation of synaptic and/or voltage-dependent conductances. Classes of processes occuring on different time scales—development or epigenesis (days and weeks), learning (minutes or hours), and even perception (milliseconds)—could have similar phenomenological outcomes.

When followed literally, Hebb's postulate refers to the set of direct excitatory synaptic contacts, originating from one presynaptic neuron, onto a postsynaptic neuron that may participate in triggering its activity, and to the correlational rules that predict an increase in efficacy in synaptic transmission. Modelers have often simplified this view to the extreme, using ideal connections between pairs of neurons, and ignoring much of the complexity of different biological implementations of the so-called Hebbian synapse in invertebrates and vertebrates. Most cellular data supporting Hebb's predictions have been derived from electrophysiological measurements of composite postsynaptic potentials or synaptic currents, or from short-latency peaks in cross-correlograms, which cannot always be interpreted simply at the synaptic level. The basic conclusion of these experiments is that covariance between pre- and postsynaptic activity up- and downregulates the "effective" connectivity between pairs of functionnally coupled cells.

It may be concluded that what changes according to a correlational rule is not so much the efficacy of transmission at a given synapse but rather a more general coupling term mixing the influence of polysynaptic excitatory and inhibitory circuits linking the two cells, modulated by the diffuse network background activation. Replacing this composite interaction by a single coupling term defines an ideal Hebbian synapse and has the additional interest for the modeler of providing a weighting function of the input, which can even change sign when inhibition overcomes excitation.

# Helmholtz Machines and Sleep-Wake Learning

*Peter Dayan*

## Introduction

Unsupervised learning is largely concerned with finding structure among sets of input patterns such as visual scenes. An important example of structure occurs when the input patterns are generated or caused in a systematic way, for instance when objects with different shapes, surface properties, and positions are illuminated by lights of different characters and viewed by an observer with a digital camera at a particular relative location. Here, the inputs can be seen as living on a manifold that has many fewer dimensions than the space of all possible activation patterns over the pixels of the camera; otherwise, random visual noise in the camera would appear to be a normal visual scene. The manifold should correctly be parameterized by the generators themselves (i.e., the objects, the lights, etc.) (see Hinton and Ghahramani, 1997).

The Helmholtz machine (Dayan et al., 1995; Hinton et al., 1995) is an example of an approach to unsupervised learning called *analysis by synthesis* (see, e.g., Neisser, 1967). Imagine that we have a perfect computer graphics model that indicates how objects appear to observers. We can use this model to synthesize input patterns that look just like the input patterns the observer would normally receive, with the crucial difference that, since we synthesized them, we know in detail how the images were generated. We can then use these pairs of images and generators to train a model that analyzes new images to find out how they too were generated—that is, a model that represents them according to which particular generators underlie them. Conversely, if we have a perfect analysis model that indicates the generators underlying any image, then it is straightforward to use the paired images and generators to train a graphics model. In the Helmholtz machine, we attempt to have an imperfect graphics or generative model train a better analysis or recognition model, and an imperfect recognition model train a better generative model.

There are three key issues for an analysis by synthesis model. First is the nature of the synthetic or generative model. For the Helmholtz machine, this is a structured belief network (Jordan, 1998; see also Bayesian Networks) that is a model for hierarchical top-down connections in the cortex. This model has an overall structure (the hierarchically organized layers, units within a layer, and so on) and a set of generative parameters that determine the probability distribution the model expresses. The units in the lowest layer of the network are observable, in the sense that it is on them that the inputs are presented; units higher up in the network are latent, since they are not directly observable from inputs.

The second issue for an analysis by synthesis model is how new inputs are analyzed or recognized in light of this generative model, i.e., how the states of the latent units are determined so that the input is represented in terms of the way it would be generated by the generative model (see Graphical Models: Probabilistic Inference). For the Helmholtz machine, this is done in an approximate fashion using a second structured belief network (called the recognition model) over the latent units, whose parameters are also learned. The recognition network is a model for the standard, bottom-up connections in cortex.

The third issue is the way that the generative and recognition models are learned from data (see Graphical Models: Parameter Learning). For the sleep-wake learning algorithm for the stochastic Helmholtz machine, this happens in two phases. In the wake phase, the recognition model is used to estimate the underlying generators (i.e., the states of the latent units) for a particular input pattern, and then the generative model is altered so that those generators are more likely to have produced the input that is actually observed. In the sleep phase, the generative model fantasizes inputs by choosing particular generators stochastically, and then the recognition model is altered so that it is more likely to report those particular generators, if the fantasized input were actually to be observed.

## The Generative Model

Figure 1 shows an example Helmholtz machine, involving (for the sake of simplicity) three layers (**x**, **y**, **d**) of binary stochastic units. The generative model uses top-down biases and weights $\mathcal{G} = \{g^x, g^y, g^d, \mathsf{G}^{xy}, \mathsf{G}^{yd}\}$ to parameterize a probability distribution over the input units $\mathbf{d} = (d_1, d_2, \ldots)$. Consider an example in which the inputs are binary, pixelated, handwritten versions of the digit 9. In this case, we might contrive that $x_i$ represent some relatively abstract features of the handwritten fonts (such as high curvature for circular portions or abnormal lengths for straight portions), and $y_j$ represent some more concrete aspects of a sample character, such as tight corners at the top and bottom of the loops or elongated stems and tails.

In the standard Helmholtz machine model, the units *within* each layer are conditionally independent given the binary states of the layer above (this is called a *factorial* property). In our contrived example, across fonts, the existence of tight curvature is independent of long lengths, i.e.,

$$\mathcal{P}[\mathbf{x};\, \mathcal{G}] = \prod_i \mathcal{P}[x_i;\, \mathcal{G}] \tag{1}$$

Next, given the particular abstract properties of the font (i.e., given the state of **x**), the precise concrete realizations (i.e., the $y_j$) are individually independent:

$$\mathcal{P}[\mathbf{y}|\mathbf{x};\, \mathcal{G}] = \prod_j \mathcal{P}[y_j|\mathbf{x};\, \mathcal{G}] \tag{2}$$

Finally, given these concrete properties, pixels are independently inked:

$$\mathcal{P}[\mathbf{d}|\mathbf{y};\, \mathcal{G}] = \prod_k \mathcal{P}[d_k|\mathbf{x};\, \mathcal{G}] \tag{3}$$

In sum, by marginalizing, one can write

$$\mathcal{P}[\mathbf{d};\, \mathcal{G}] = \sum_{\mathbf{x},\mathbf{y}} \mathcal{P}[\mathbf{x};\, \mathcal{G}]\mathcal{P}[\mathbf{y}|\mathbf{x};\, \mathcal{G}]\mathcal{P}[\mathbf{d}|\mathbf{y};\, \mathcal{G}] \tag{4}$$

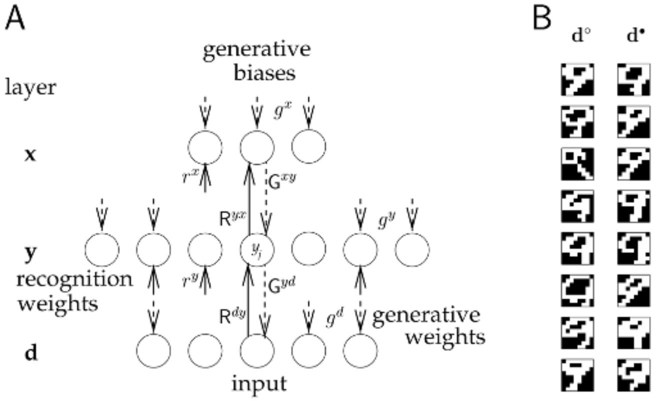

**Figure 1.** Helmholtz machine. *A*, Structure of a three-layer Helmholtz machine, with generative weights and biases $\mathcal{G}$ (dashed) and recognition weights and biases $\mathcal{R}$ (solid). *B*, Handwritten digit example. The left column shows eight samples from a training set of binarized, 8 × 8, handwritten 9s; the right column shows eight samples produced by the generative model after training. The training set is as described in Hinton et al. (1995).

For binary stochastic units,

$$\mathcal{P}[x_i;\, g_i^x] = \sigma(g_i^x)$$
$$\mathcal{P}[y_j|\mathbf{x};\, g_j^y, \mathsf{G}^{xy}] = \sigma\Big(g_j^y + \sum_i \mathsf{G}_{ji}^{xy} x_i\Big) \equiv \hat{y}_j(\mathbf{x}) \tag{5}$$

where $\sigma(u) = 1/(1 + \exp(-u))$ is the standard sigmoid function. Although the units **y** are conditionally independent given the states of the units **x** in the layer above, they are not marginally independent across all the patterns that can be generated. That is, **x** can capture statistical structure (i.e., correlations) in the states of **y**. So, for instance, the abstract curvature property captures the correlation that a tight corner at the bottom of the loop of a 9 is typically associated with a tight corner at the top of the loop. Similarly, **y** captures correlations in the states **d**. The font example is only for illustration. We actually expect the unsupervised learning algorithm itself to find the representations **y** and **x** that collectively best capture the statistical structure of **d**.

This top-down generative model is a simple example of a sigmoid belief net (or BAYESIAN NETWORKS). The conditional independence within a layer makes it very straightforward to generate a sample $\mathbf{d}^\bullet$ from $\mathcal{P}[\mathbf{d}|\mathcal{G}]$ by fantasizing a sample $\mathbf{x}^\bullet$, then $\mathbf{y}^\bullet$ given $\mathbf{x}^\bullet$ (both as in Equation 5), and then $\mathbf{d}^\bullet$ given $\mathbf{y}^\bullet$ (using a similar expression).

## The Recognition Model

When the generative model is used to create such a complete fantasy, we consider $\mathbf{x}^\bullet$ and $\mathbf{y}^\bullet$ as the *generators* of $\mathbf{d}^\bullet$. The task for the recognition model is to take a new example **d** and report the state(s) of **x** and **y** that might have generated it. In terms of our example, this implies finding a representation for a new image of a handwritten 9 in terms of the settings of the more concrete and more abstract parameters that could have generated it. Using Bayes's theorem, we know that

$$\mathcal{P}[\mathbf{x}, \mathbf{y}|\mathbf{d};\, \mathcal{G}] = \mathcal{P}[\mathbf{d}|\mathbf{x}, \mathbf{y};\, \mathcal{G}]\, \frac{\mathcal{P}[\mathbf{x};\, \mathcal{G}]\mathcal{P}[\mathbf{y}|\mathbf{x};\, \mathcal{G}]}{\mathcal{P}[\mathbf{d};\, \mathcal{G}]} \tag{6}$$

It is straightforward to calculate all the terms on the right-hand side *except* for the denominator $\mathcal{P}[\mathbf{d};\, \mathcal{G}]$, which involves a sum over all the possible states of **x** and **y** (a set that grows exponentially large as the number of elements in **x** and **y** grows). Thus, an approximation to $\mathcal{P}[\mathbf{x}, \mathbf{y}|\mathbf{d};\, \mathcal{G}]$ is usually required. The stochastic version of the Helmholtz machine (the only version we discuss here) uses for approximate recognition a bottom-up belief network (see Figure 1) over exactly the same units. This network instantiates a probability distribution $\mathcal{Q}[\mathbf{x}, \mathbf{y}|\mathbf{d};\, \mathcal{R}] = \mathcal{Q}[\mathbf{y}|\mathbf{d};\, \mathcal{R}]\mathcal{Q}[\mathbf{x}|\mathbf{y};\, \mathcal{R}]$ using a separate set of parameters, the bottom-up biases and weights $\mathcal{R} = \{\mathbf{r}^x, \mathbf{r}^y, \mathcal{R}^{dy}, \mathcal{R}^{yx}\}$. A critical approximation is that the recognition model is assumed to be factorial in the bottom-up direction, i.e., $y_1$ is independent of $y_2$ given **d**, and so forth. Over the course of learning, it is intended that $\mathcal{Q}[\mathbf{x}, \mathbf{y}|\mathbf{d};\, \mathcal{R}]$ should come to be as close to $\mathcal{P}[\mathbf{x}, \mathbf{y}|\mathbf{d};\, \mathcal{G}]$ as possible, subject to this approximation. On account of this approximation, it is as easy to generate a sample bottom-up from the recognition model, i.e., to recognize the input in terms of its generators, as it is to generate a sample top-down from the generative model, i.e., to create a fantasy.

## Sleep-Wake Learning

As for many unsupervised learning methods (see UNSUPERVISED LEARNING WITH GLOBAL OBJECTIVE FUNCTIONS), the underlying goal of sleep-wake learning is to perform maximum likelihood density estimation by maximizing the log probability of the observed data $\mathcal{D} = \{\mathbf{d}(1), \mathbf{d}(2), \ldots\}$ under the generative model, that is, $E(\mathcal{G}) = \Sigma_t \log \mathcal{P}[\mathbf{d}(t)|\mathcal{G}]$. One key idea, due to Neal and Hinton (1998) and Zemel (1994) (see MINIMUM DESCRIPTION LENGTH ANALYSIS), is to take the logarithm of both sides of Equation 4, though using the exact recognition distribution of Equation 6 to swap the order of the log and the sum:

$$\log \mathcal{P}[\mathbf{d}; \mathcal{G}] = \sum_{\mathbf{x},\mathbf{y}} \mathcal{P}[\mathbf{x}, \mathbf{y}|\mathbf{d}; \mathcal{G}] \log \mathcal{P}[\mathbf{x}, \mathbf{y}, \mathbf{d}; \mathcal{G}] + \mathcal{H}[\mathcal{P}[\mathbf{x}, \mathbf{y}|\mathbf{d}; \mathcal{G}]] \tag{7}$$

and then to introduce an approximate recognition distribution $\mathcal{Q}[\mathbf{x}, \mathbf{y}; \mathbf{d}, \mathcal{R}]$, with a bounded effect on the expression

$$\log \mathcal{P}[\mathbf{d}; \mathcal{G}] \geq \sum_{\mathbf{x},\mathbf{y}} \mathcal{Q}[\mathbf{x}, \mathbf{y}; \mathbf{d}, \mathcal{R}] \log \mathcal{P}[\mathbf{x}, \mathbf{y}, \mathbf{d}; \mathcal{G}] + \mathcal{H}[\mathcal{Q}[\mathbf{x}, \mathbf{y}; \mathbf{d}, \mathcal{R}]] \tag{8}$$

that can be quantified using a measure of the discrepancy between approximate and exact recognition distributions:

$$= \log \mathcal{P}[\mathbf{d}; \mathcal{G}] - \mathrm{KL}[\mathcal{Q}[\mathbf{x}, \mathbf{y}; \mathbf{d}, \mathcal{R}], \mathcal{P}[\mathbf{x}, \mathbf{y}|\mathbf{d}; \mathcal{G}]] \tag{9}$$

$$\equiv -\mathcal{F}[\mathbf{d}; \mathcal{R}, \mathcal{G}] \tag{10}$$

Here, $\mathcal{H}[\mathcal{A}] = -\Sigma_{\mathbf{a}}\mathcal{A}[\mathbf{a}] \log \mathcal{A}[\mathbf{a}]$ is the entropy of probability distribution $\mathcal{A}$, and, in Equation 9, $\mathrm{KL}[\mathcal{A}, \mathcal{B}] = \Sigma_{\mathbf{a}}\mathcal{A}[\mathbf{a}] \log \mathcal{A}[\mathbf{a}]/\mathcal{B}[\mathbf{a}]$ is the Kullback-Liebler (KL) divergence between two distributions $\mathcal{A}$ and $\mathcal{B}$. This KL divergence is greater than or equal to 0, with equality when $\mathcal{A}$ and $\mathcal{B}$ are essentially equal. Thus, Inequality 8 holds for an arbitrary distribution $\mathcal{Q}[\mathbf{x}, \mathbf{y}; \mathbf{d}, \mathcal{R}]$ over $\mathbf{x}$, $\mathbf{y}$, with equality if $\mathcal{Q}[\mathbf{x}, \mathbf{y}; \mathbf{d}, \mathcal{R}]$ is the true analytical distribution $\mathcal{P}[\mathbf{x}, \mathbf{y}|\mathbf{d}; \mathcal{G}]$. Expression $\mathcal{F}[\mathbf{d}; \mathcal{R}, \mathcal{G}]$ can be seen as a Helmholtz free energy; hence the name of the machine.

During the *wake* phase, a single pattern $\mathbf{d}^\circ$ is sampled from $\mathcal{D}$ and presented to the recognition model. This is executed bottom-up to produce a single sample $\mathbf{y}^\circ$ given $\mathbf{d}$ and $\mathbf{x}^\circ$ given $\mathbf{y}^\circ$. Then, the parameters $\mathcal{G}$ of the generative model are changed using stochastic gradient ascent of the lower bound to the log probability, i.e., proportionally to

$$\nabla_{\mathscr{G}} \log \mathcal{P}[\mathbf{x}^\circ, \mathbf{y}^\circ, \mathbf{d}; \mathcal{G}] = \nabla_{\mathscr{G}}\{\log \mathcal{P}[\mathbf{x}^\circ; \mathcal{G}] + \log \mathcal{P}[\mathbf{y}^\circ|\mathbf{x}^\circ; \mathcal{G}] + \log \mathcal{P}[\mathbf{d}^\circ|\mathbf{y}^\circ; \mathcal{G}]\}$$

For activation functions such as those in Equation 5, this leads to particularly simple "delta" learning rules such as

$$\Delta g_j^y \propto (y_j^\circ - \hat{y}_j(\mathbf{x}^\circ)) \quad \Delta \mathrm{G}_{ij}^{xy} \propto (y_j^\circ - \hat{y}_j(\mathbf{x}^\circ))x_i^\circ$$

in which the output of the recognition model is used as the *target* for the generative model instead of vice versa.

The ideal for the *sleep* phase would be to change the recognition weights $\mathcal{R}$ using stochastic gradient descent also of the lower bound in Equation 9. Unfortunately, this procedure is not generally computationally tractable. The second key idea in sleep-wake learning is to attempt during sleep to minimize $\mathrm{KL}[\mathcal{P}[\mathbf{x}, \mathbf{y}|\mathbf{d}; \mathcal{G}]; \mathcal{Q}[\mathbf{x}, \mathbf{y}; \mathbf{d}, \mathcal{R}]]$ instead. This is not the same, since the KL divergence is not symmetric, although they are equal at their joint minimum where $\mathcal{P}[\mathbf{x}, \mathbf{y}|\mathbf{d}; \mathcal{G}] = \mathcal{Q}[\mathbf{x}, \mathbf{y}; \mathbf{d}, \mathcal{R}]$. The KL divergence the wrong way around can be minimized by fantasizing sample $\mathbf{x}^\bullet$, $\mathbf{y}^\bullet$, and $\mathbf{d}^\bullet$ from the generative model (in the way described at the end of the section on that model), and then changing the recognition weights according to

$$\nabla_{\mathcal{R}} \log \mathcal{Q}[\mathbf{x}^\bullet, \mathbf{y}^\bullet; \mathbf{d}^\bullet, \mathcal{R}] = \nabla_{\mathscr{R}}\{\log \mathcal{Q}[\mathbf{y}^\bullet|\mathbf{d}^\bullet; \mathcal{R}] + \log \mathcal{Q}[\mathbf{x}^\bullet|\mathbf{y}^\bullet; \mathcal{R}]\}$$

For activation functions such as those in Equation 5, this leads to the same simple delta learning rules as for the generative model, except that the output of the generative model is used as the target for the recognition model.

Since sleep learning involves an approximation, it is only in very special cases (see Neal and Dayan, 1997) that it is possible to prove even that it is appropriately stable. Nevertheless, the model has been shown to work quite well in practice. Figure 1*B* shows the result of applying sleep-wake learning to a set of input patterns (left column) that are binary images of the handwritten digit 9. The right column shows fantasized samples following learning, and these can be seen to be generated by a distribution close to that in the training distribution.

## Discussion

As a directed belief network for analysis by synthesis that is trained according to maximum likelihood density estimation, the Helmholtz machine lives in what has become a rather crowded space (see UNSUPERVISED LEARNING WITH GLOBAL OBJECTIVE FUNCTIONS). In this context, the key property of the Helmholtz machine is that it uses an explicit recognition model that has its own parameters rather than performing recognition by an iterative process involving only the parameters of the generative model. In some ways this is an advantage; in particular, recognition can occur swiftly in a single pass. Learning during the sleep phase can be considered as a way of caching knowledge about how to do recognition effectively. In other ways it is a disadvantage, since the recognition model introduces an extra set of parameters that need to be learned and since, unlike the iterative mean field recognition methods that underlie most of the architectures mentioned earlier, the approximation involved in the recognition model in the Helmholtz machine cannot be tailored on-line to the particular input pattern that is presented. Another key feature is that, unlike many of these methods, the Helmholtz machine is explicitly designed to be hierarchical: units in one layer capture (i.e, both represent and generate) correlations in the layer below. Unlike INDEPENDENT COMPONENT ANALYSIS (q.v.), for instance, units within a layer are not forced to be marginally independent in the generative model, only conditionally independent *given* the activities in the layer above. This potentially allows it a much richer representation of the inputs. Also, the recognition model in the Helmholtz machine allows at least some correlations among the states of the hierarchical generators, a feature denied to mean field methods.

The Helmholtz machine also bears an interesting relationship to the Boltzmann machine (Hinton and Sejnowski, 1986; see also SIMULATED ANNEALING AND BOLTZMANN MACHINES), which can be seen as an undirected belief net. In the Boltzmann machine, which also lacks an explicit recognition model, a potentially drawn-out process of Gibbs sampling is used to recognize and generate inputs, since there is nothing like the simple, one-pass, directed recognition and generative belief networks of the Helmholtz machine. Also, the Boltzmann machine learning rule performs true stochastic gradient ascent of the log likelihood using a contrastive procedure, which, confusingly, involves wake and sleep phases that are quite different from the wake and the sleep phases of the sleep-wake algorithm. The two phases of the Boltzmann machine contrast the statistics of the activations of the network when input patterns are presented with the statistics of the activations of the network when it is running "free." This contrastive procedure involves substantial noise and is therefore slow (a problem rectified in Hinton's (2000) new approximate contrastive divergence learning rule). In the sleep-wake learning procedure for the Helmholtz machine, the wake and sleep phases are not contrastive. Rather, the recognition and generative models are forced to chase each other.

The most important open issue for the Helmholtz machine as a model of top-down and bottom-up connections in the cortex is how to weaken the approximation that the recognition and generative models are factorial within layers, without destroying the simplicity of sampling from and learning the models.

# Hemispheric Interactions and Specialization

*James A. Reggia and Svetlana Levitan*

## Introduction

Currently recognized *hemispheric specializations*, where one cerebral hemisphere performs a task better than the other, include language, handedness, visuospatial processing, emotion and its facial expression, olfaction, and attention (Hellige, 1993). For example, in roughly 95% of people the left cerebral hemisphere is dominant for language, so language is said to be *lateralized* to the left hemisphere in such individuals. Behavioral lateralization in areas such as vocalization and motor preferences has been demonstrated not only in people but also in rodents, birds, primates, and other animals.

The underlying causes of hemispheric specialization/lateralization are not well understood at present. The many anatomical, biochemical, and physiological asymmetries that exist in the brain include a larger left temporal plane in the majority of subjects, greater dendritic branching in speech areas of the left hemisphere, different distributions of important neurotransmitters such as dopamine and norepinephrine between the hemispheres, and a lower left hemisphere threshold for motor-evoked potentials. Understanding which, if any, of these asymmetries actually contribute to hemispheric specialization remains an important problem in neuropsychology and is an instance of the more general issue of how functional modularity arises in the brain (Jacobs, 1997).

Besides the underlying hemispheric asymmetries listed above, another potential factor in function lateralization is hemispheric interactions via pathways connecting the hemispheres, such as the corpus callosum. Callosal fibers are largely but not exclusively homotopic: roughly mirror-symmetric points in each hemisphere are connected to each other. Callosal connections between the hemispheres are excitatory. This, as well as clinical data and split-brain experiments, suggests that transcallosal hemispheric interactions are mainly excitatory in nature, but this hypothesis has long been quite controversial. Transcallosal monosynaptic excitatory effects are subthreshold and followed by stronger, more prolonged inhibition, suggesting to some that transcallosal inhibitory interactions are much more important (Cook, 1986). The case for interhemispheric inhibition/competition has been strengthened recently by transcranial magnetic stimulation studies indicating that activation of one primary motor cortex inhibits the opposite one.

Neural modeling provides a useful way to investigate the implications of hypotheses that complement more traditional methods. In this article, we first consider models of hemispheric interactions that do not incorporate hemispheric differences and, conversely, models examining the effects of hemispheric differences that do not incorporate hemispheric interactions. We then look in more detail at some examples of recent work that studies both hemispheric interactions and differences in the same model, demonstrating how these factors influence the emergence of lateralization in models in which lateralization is not initially present. Finally, we briefly summarize insights gained from simulated damage in these models.

## Modeling Hemispheric Interactions/Differences

A number of neural models have examined issues involving hemispheric interactions. In one group of studies, several models were developed representing homotopic left and right hemispheric regions connected via a simulated corpus callosum. For example, one early study demonstrated that oscillatory activity in a simulated hemisphere could be transferred to the other hemisphere via interhemispheric connections (Anninos and Cook, 1988). This was true regardless of assumptions about the excitatory/inhibitory nature of callosal connections, although learning was more rapid when callosal connections were excitatory. Another model, using paired neural networks representing left and right cortical regions, showed that homotopic inhibitory callosal connections produce complementary activity patterns but not lateralization in the two simulated hemispheric regions (Cook, 1986). This was done without postulating intrinsic differences between the cerebral hemispheres. These and other earlier neural models involved simulating hemispheric interactions, but none of them considered underlying asymmetric hemispheric regions or emergent lateralization.

In contrast, other models have simulated single hemispheric regions under differing conditions that are motivated by known asymmetries in the left and right cerebral hemispheres. Although these models have neither paired left and right cortical regions nor callosal connections like those above, they do examine issues related to lateralization.

One study focused on modeling hemispheric differences observed during semantic priming experiments (Burgess and Lund, 1998). Such experiments examine how the occurrence of one word facilitates the subsequent recall from memory of words with similar meanings. This model assumed that each hemisphere has the same representation of semantic information about words, but that the right hemisphere processes this information more slowly. The speed of activation of a target word for a hemisphere was also assumed to be based on a function of the semantic distance between that word and a priming word, and on the word's rate of activation decay. These word-specific quantities were derived from a large corpus of written text. Separate parameterized functions for the rate of activation of a word were determined for left and right hemispheres by evolving the parameters in these functions using a genetic algorithm. The resultant activation functions for each hemisphere, each function having different parameters, were then used successfully to predict the time course of activating word meaning in a number of priming experiments in which stimuli were presented separately to each hemisphere. These results implicitly provide a theory about the underlying differences in left and right hemisphere processing of semantic information.

Another study examining issues related to cerebral specialization without actually simulating paired hemispheric regions, corpus callosum, or the emergence of lateralization focused on the processing of spatial relations (Kosslyn et al., 1992). This investigation hypothesized that receptive field size asymmetries involving low-level visual neurons were responsible for experimental observations that the right cerebral hemisphere is faster at computing coordinate spatial relations involving precise metric information, such as judging distances, while the left hemisphere is faster in evaluating some categorical relations, such as above versus below. The coarse coding provided by error backpropagation neural networks with larger, overlapping receptive fields assumed for the right hemisphere was found to be superior for distance judgments, whereas networks with smaller, nonoverlapping receptive fields assumed for the left hemisphere were found to be superior in judging categorical relations. Conversely, training a network with adaptable receptive fields to do distance judgments led to larger receptive fields than training a network to judge categorical relations (Jacobs and Kosslyn, 1994). A separate model focusing on receptive field asymmetries from a different perspective has also been used to explain several experimentally observed visual processing asymmetries (Ivry and Robertson, 1998).

## Simulating the Emergence of Lateralization

A number of neural models of paired left and right cortical regions have been used to examine conditions under which lateralization that was not present initially might emerge during learning. These models incorporate both hemispheric interactions and hemispheric differences. Three examples are given here. The first two incorporate a simulated corpus callosum, and represent end points on a spectrum from supervised to unsupervised learning within which other models fall (Cook, 1999; Shevtsova and Reggia, 1999). The third example illustrates how noncallosal hemispheric interactions can influence lateralization.

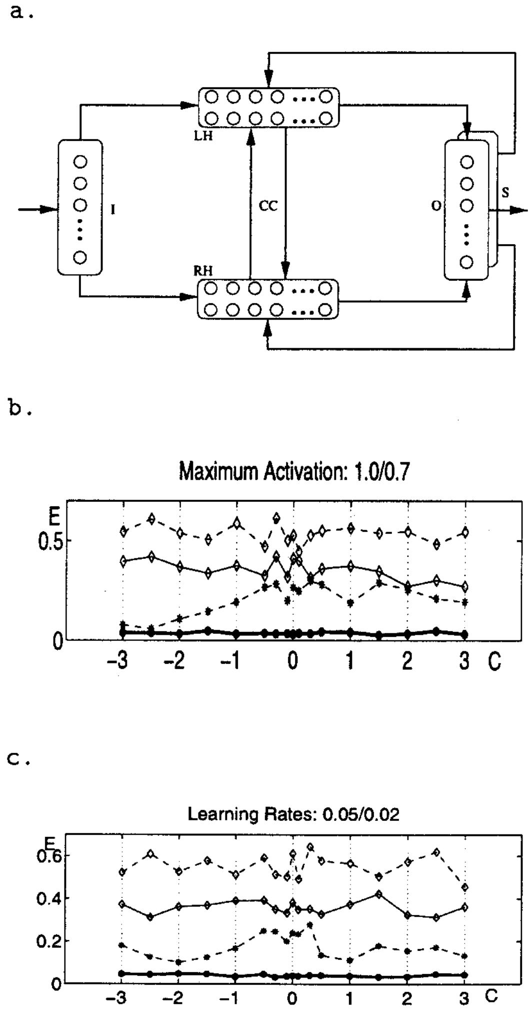

**Figure 1.** *a*, Network architecture for phoneme sequence generation. I, input elements; LH (RH), left (right) hemisphere cortex region; CC, corpus callosum; O, output elements; S, state elements. In the graphs, error (E) is plotted versus callosal strength (C) for model versions where the left hemisphere (*b*) is more excitable or (*c'*) has more potent synaptic plasticity. In each case the upper dashed curve shows pretraining error and the lowest (thick solid) curve shows post-training error for the full model's output. The two middle curves show post-training output error when the left hemisphere alone (dashed line) or the right hemisphere alone (solid line) controls output.

### *Phoneme Sequence Generation*

A phoneme sequence generation model, trained using recurrent error backpropagation, was created that takes three-letter words as input and produces the correct temporal sequence of phonemes for the pronunciation of each word as output (Reggia, Goodall, and Shkuro, 1998). Figure 1*a* schematically summarizes the network architecture, where input elements are fully connected to two sets of neural elements representing corresponding regions of the left and right hemisphere cortex. These regions are connected to each other via a simulated corpus callosum and to output elements representing individual phonemes.

The effects of different hemispheric asymmetries (relative size, excitability, learning rate parameter, etc.) on the emergence of lateralization were examined one at a time. For each hemispheric asymmetry, and for a symmetric control version of the model, the uniform value of callosal connection influences was varied over several excitatory and inhibitory values. Lateralization was measured based on the difference between the output error when the left hemispheric region alone controlled the output versus when the right hemispheric region alone did so. These simulations showed that, within the limitations of the model, it is easy to produce lateralization. For example, lateralization occurred toward the side with higher excitability (Figure 1*b*) or a higher learning rate parameter (Figure 1*c*), depending on callosal strength. Lateralization tended to occur most readily and intensely when callosal connections exerted predominantly an inhibitory influence (Figure 1*b*), but with some asymmetries significant lateralization occurred for all callosal strengths (Figure 1*c*). In this specific model, the results could be interpreted as a competitive "race-to-learn" involving the two hemispheric regions, with the "winner" (dominant side) determined when the model as a whole acquired the input-output mapping and learning largely ceased. These results suggest that lateralization to a cerebral region can, in some cases, be associated with increased synaptic plasticity in that region relative to its mirror-image region in the opposite hemisphere, a testable prediction.

### *Self-Organizing Topographic Maps*

Topographic maps representing various aspects of the environment are found in primary sensory regions of cortex. Maps in mirror-image regions of sensory cortex exhibit a rich range of patterns of asymmetries and lateralization (Bianki, 1993). A model of corresponding left and right hemispheric regions receiving sensory input has been used to study emergent map asymmetries and lateralization (Levitan and Reggia, 1999). Unlike the phoneme sequence generation model, purely unsupervised competitive learning was used. Map formation was examined while varying the underlying cortical region asymmetries and the assumed excitatory/inhibitory nature of callosal connections.

Figure 2 illustrates pairs of cortical maps appearing in this model where the centers of receptive fields of the cortical elements are plotted in the space of the sensory surface (i.e., these are *not* pictures of the cortical regions involved). Lines between plotted points indicate adjacent cortical elements. In all simulations, cortical maps were initially highly disorganized before learning, owing to randomly assigned initial synaptic strengths (Figure 2*a*). For excitatory, absent, or weakly inhibitory callosal interactions, complete and symmetric mirror-image maps appeared after learning in both hemispheric regions (Figure 2*b*). In contrast, with stronger inhibitory callosal interactions, after learning, map lateralization tended to occur (Figure 2*c*; left more organized than right), or the maps became complementary (Figure 2*d*), reminiscent of "mosaic patterns" described experimentally (Bianki, 1993). Lateralization occurred readily toward the side having higher excitability or a larger cortical region. Unlike with the phoneme sequence generation model, asymmetric plasticity had only a transitory effect on lateralization, indicating that the effects of this factor may differ substantially depending on whether supervised or unsupervised learning is used. In this model, a "phase transition" in behavior occurs at a specific inhibitory callosal strength: above this value, bilateral symmetric maps occur; below it, lateralization and complementary maps occur.

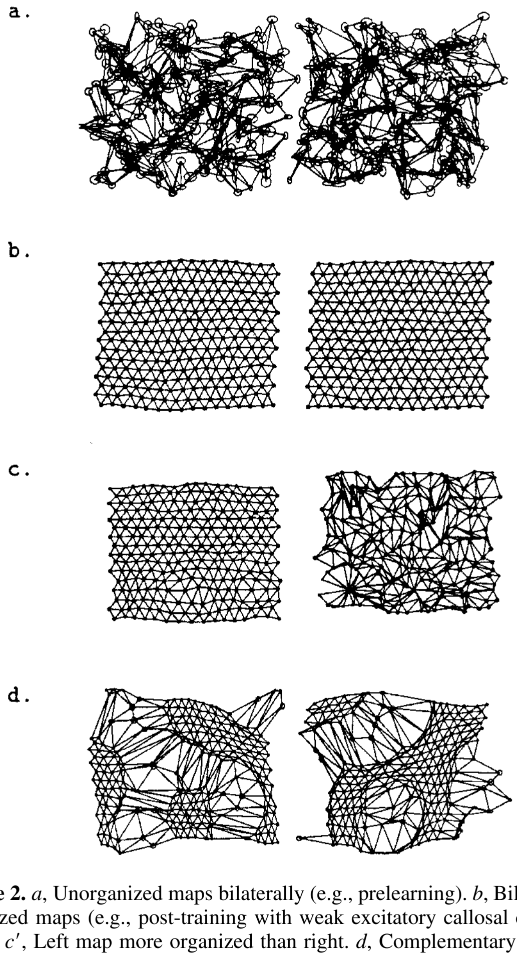

**Figure 2.** *a*, Unorganized maps bilaterally (e.g., prelearning). *b*, Bilaterally organized maps (e.g., post-training with weak excitatory callosal connections). *c*′, Left map more organized than right. *d*, Complementary mosaic maps.

### *Spatial Relations*

Asymmetries in perceptual abilities are sometimes hypothesized to be due to an underlying asymmetry in receptive field sizes in the early visual system: smaller visual receptive fields on the left than on the right. A neural model of two hemispheric regions, represented as multilayer feedforward networks having different afferent pathway receptive field sizes, was implemented to examine the plausibility of this hypothesis (Jacobs and Kosslyn, 1994). This model did not include a simulated corpus callosum but instead had an extra module called a "gating network" that determined the extent to which each hemispheric region controlled the model's output. Each hemispheric region competed to learn each output pattern, and the region whose output most closely matched the correct output pattern "won" and learned more.

In simulations performed with this model, the network was trained to perform both categorical and coordinate tasks, while the left input layer was forced to have smaller receptive field sizes. When the difference in left and right receptive field sizes was sufficiently large, the left hemispheric region became superior at the categorical task, while the right hemispheric region became superior with the coordinate task. These results are consistent with the hypothesis that asymmetric receptive field sizes contribute to hemispheric specialization in processing spatial relations.

### *Effects of Simulated Damage*

Several versions of the above models of interacting left and right hemispheric regions have been subjected to simulated focal damage (Levitan and Reggia, 1999; Shkuro, Glezer, and Reggia, 2000). For example, with the phoneme sequence generation model, an area of focal damage was introduced into an intact model by making part of one simulated hemispheric region nonfunctional. Performance errors of the full model and each hemisphere alone were measured immediately after the damage and then after further training restored the model's performance to normal. During the recovery period, in which performance eventually returned to predamage levels, the undamaged hemispheric region very often participated in and contributed to recovery, more so as the amount of damage increased. These results support the controversial hypothesis that the intact cerebral hemisphere plays a role in adult recovery from damage in the opposite hemisphere. Further, in these simulations of focal damage, when callosal influences were excitatory, the undamaged hemispheric region often had a drop in mean activation and exhibited impaired performance, representing the analog of transcallosal diaschisis (a fall in regional cerebral blood flow and glucose metabolism in the intact cerebral hemisphere following unilateral brain damage). These and other observations following model damage support the view that hemispheric interactions via callosal connections are excitatory.

## Discussion

Neural models have recently been used to investigate a variety of issues concerning whether underlying asymmetries can lead to or can explain lateralization and how assumptions about callosal influences affect lateralization. Although these models have been limited in size and scope, and although they are greatly simplified from neurobiological and behavioral reality, they have demonstrated a number of results that are relevant to current issues in brain theory.

First, any one of a variety of underlying hemispheric asymmetries can lead to hemispheric specialization in these models, including asymmetric size, excitability, receptive field sizes, and synaptic plasticity. Such a finding supports past arguments that a single underlying hemispheric asymmetry is unlikely to account for language and other behavioral lateralizations (Hellige, 1993).

Second, resolving the issue of the inhibitory versus excitatory nature of callosal influences remains elusive. Lateralization generally appeared most intensely in models with inhibitory interhemispheric interactions, lending support to past arguments that whatever the actual neurophysiological nature of callosal synaptic *connections*, callosal *influences* are apparently inhibitory in nature, producing competition between the two hemispheres. However, lateralization also occurred in some models with excitatory callosal influences and asymmetric hemispheric regions, and focal damage in these models caused a decrease in activation and sometimes performance in the opposite intact hemispheric region. These latter changes resemble those seen experimentally in stroke patients, supporting past arguments that callosal influences are predominantly excitatory. This conflicting evidence concerning the excitatory versus inhibitory nature of callosal influences may be referred to as the *callosal dilemma*. A possible resolution of this dilemma, excitatory transcallosal influences in the context of subcortical cross-midline inhibitory connections, was recently studied computationally (Reggia et al., 2001). Further examination of this issue would be a fertile topic for future research.

Finally, during the recovery period following focal damage to models, the opposite intact hemispheric region generally contributed to recovery, supporting the controversial hypothesis that the undamaged cerebral hemisphere often contributes to language recovery following unilateral brain damage in adults. This effect increased with increasing damage, suggesting that relevant future experimental studies of recovery from stroke should carefully control for this factor in interpreting data.

# Hidden Markov Models

*Hervé Bourlard and Samy Bengio*

## Introduction

Over the past 20 years, finite-state automata (FSA), and more particularly stochastic finite-state automata (SFSA) and different variants of hidden Markov models (HMMs), have been used successfully to address several complex sequential pattern recognition problems, among them continuous speech recognition, cursive (handwritten) text recognition, time series prediction, and biological sequence analysis.

FSAs allow complex learning problems to be solved by assuming that the sequential pattern can be decomposed into piecewise stationary segments, encoded through the topology of the FSA. Each stationary segment can be parameterized in terms of a deterministic or a stochastic function. In the latter case, it may also be possible that the SFSA state sequence is not observed directly but is a probabilistic function of the underlying finite-state Markov chain. This leads to the definition of the powerful HMMs, involving two concurrent stochastic processes: the sequence of HMM states modeling the sequential structure of the data, and a set of state output processes modeling the (local) stationary character of the data. The Markov model is called hidden because there is an underlying stochastic process (i.e., the sequence of states) that is not observable but that affects the observed sequence of events.

Furthermore, depending on the way the SFSA is parameterized and trained, SFSAs (and HMMs in particular) can be used either as a *production model*, in which the observation sequence is considered to be an output signal produced by the model, or as a *recognition model* (acceptor), in which the observation sequence is considered as being accepted by the model. Finally, it may also be the case that the HMM is used to explicitly model the stochastic relationship between two (input and output) event sequences, resulting in a model usually referred to as an input-output HMM.

The parameters of these models can be trained by different variants of the powerful Expectation-Maximization (EM) algorithm (Baum and Petrie, 1966; Liporace, 1982), which, depending on the criterion being used, is referred to as maximum likelihood (ML) or maximum a posteriori (MAP) training. However, even though they belong to the same family, all of these models exhibit different properties. This article compares some of the variants of these powerful SFSA and HMM models currently used for sequence processing.

## Finite-State Automata

In its more general form (Hopcroft, Motwani, and Ullman, 2000) and as summarized in Table 1, an FSA, which will be denoted $M$ in this paper, is defined as an abstract machine consisting of the following:

- A set of states $\mathcal{Q} = \{I, 1, \ldots, k, \ldots, K, F\}$, including the initial state $I$ and final state $F$, also referred to as accepting state (in the case of recognizers). Variants of this machine include machines having multiple initial states and multiple accepting states. In this article, a specific state visited at time $t$ will be denoted $q_t$.
- A set $\mathcal{Y}$ of (discrete or continuous) input symbols or vectors. A particular sequence of size $T$ of input symbols/vectors will be denoted $Y = \{y_1, y_2, \ldots, y_t, \ldots, y_T\} = y_1^T$, where $y_t$ represents the input symbol/vector at time $t$.
- A set $\mathcal{X}$ of (continuous or discrete) output symbols or vectors. A particular sequence of size $T$ of output symbols/vectors will be denoted $Z = z_1^T$, where $z_t$ represents the output symbol/vector at time $t$.
- A *state transition function* $q_t = f(y_t, q_{t-1})$, which takes the current input event and the previous state $q_{t-1}$ and returns the next state $q_t$.
- An *emission function* $z_t = g(q_t, q_{t-1})$, which takes the current state $q_t$ and the previous state $q_{t-1}$ and returns an output event $z_t$. This automaton is usually know as a *Mealy FSA*, i.e., one producing an output for each input-dependent *transition*. As a variant of this, the emission function of a *Moore FSA* depends only on the current state, i.e., $z_t = g(q_t)$, thus producing an output for each visited state. There is, however, a homomorphic equivalence between Mealy and Moore automata, given an increase and renaming of the states.

Finally, in the case of sequential pattern processing, the processed sequence is often represented as an *observed sequence* of symbols or vectors which, depending on the type of automata and optimization criterion, will sometimes be considered input events and at other times output events. To accommodate this flexibility, we also define the *observed sequence* of size $T$ as $X = x_1^T$, where $x_t$ is the observed event/vector at time $t$. For example, in the case of speech recognition, $x_t$ would be the acoustic vector resulting from the spectral analysis of the signal at time $t$, and is equivalent to $z_t$ (since in that case the observations are the outputs of the FSA).

A *deterministic FSA* is one in which the transition and emission functions $f(.)$ and $g(.)$ are deterministic, implying that the output event and next state are uniquely determined by a single input event (i.e., there is exactly one transition for each given input event and state). In comparison, a nondeterministic FSA is one in which the next state is not uniquely determined by the current previous state and input event. However, it is often possible to transform a nondeterministic FSA into a deterministic FSA, at the cost of a significant increase in the possible number of input symbols.

We will not further discuss deterministic FSAs, which have been largely used in language theory (Hopcroft et al., 2000), where FSAs are often used to accept or reject a language (i.e., certain sequences of input events).

## Stochastic Finite-State Automata

A *stochastic FSA* (SFSA) is an FSA in which the transition and/or emission functions are probabilistic functions. In the case of Markov models, there is a one-to-one relationship between the observation and the state, and the transition function is probabilistic. In the case of HMMs, the emission function is also probabilistic, and the states are no longer directly observable through the input events. Instead, each state produces one of the possible output events with a certain probability.

Depending on their structure (discussed below), transition and emission (probability density) functions are represented in terms of a set of parameters $\Theta$, which will have to be estimated on repre-

**Table 1.** Deterministic and Stochastic Finite-State Automata

| | Deterministic Finite-State Automata | Stochastic Finite-State Automata | | | |
|---|---|---|---|---|---|
| | | Markov Model | HMM | HMM/ANN | IOHMM |
| States | $k \in \mathcal{Q}$ | $x_t = k \in \mathcal{Q}$ | $k \in \mathcal{Q}$ | $k \in \mathcal{Q}$ | $k \in \mathcal{Q}$ |
| Input symbols | $y_t \in \mathcal{Y}$ | — | — | $x_t = y_t \in \mathcal{Y}$ | $x_t = y_t \in \mathcal{Y}$ |
| Output symbols | $z_t \in \mathcal{X}$ | — | $x_t = z_t \in \mathcal{X}$ | — | $z_t \in \mathcal{X}$ |
| Transition law | $q_t = f(y_t, q_{t-1})$ | Transition probabilities $p(x_t \vert x_{t-1})$ | Transition probabilities $p(q_t \vert q_{t-1})$ | Conditional transition probabilities $p(q_t \vert x_t, q_{t-1})$ | Conditional transition probabilities $p(q_t \vert x_t, q_{t-1})$ |
| Emission law | | | | | |
| Mealy | $z_t = g(q_t, q_{t-1})$ | — | Emission on transition<br>$x_t = g(q_t, q_{t-1})$<br>$p(x_t \vert q_{t-1}, q_t)$ | — | $p(z_t \vert q_t, q_{t-1}, x_t, x_{t-1})$ |
| Moore | $z_t = g(q_t)$ | — | Emission on state<br>$x_t = g(q_t)$ $p(x_t \vert q_t)$ | — | $p(z_t \vert q_t, x_t)$ |
| Training methodology | Many, often based on heuristics | Relative counts (including smoothing) | EM, Viterbi recurrence | REMAP (GEM) | GEM, EM, GD, Viterbi recurrence |
| Training criterion | Deterministic | Maximum likelihood | Maximum likelihood | Maximum a posteriori | Maximum a posteriori |

Abbreviations: HMM, hidden Markov model; ANN, artificial neural network; IOHMM, input-output HMM; EM, Expectation-Maximization algorithm; GEM, Generalized Expectation-Maximization algorithm; REMAP, recurrent estimation and maximization of a posteriori probabilities sentative training data. If $X$ represents the whole sequence of training data and $M$ its associated SFSA, the estimation of optimal parameter set $\Theta^*$ is usually achieved by optimizing a *maximum likelihood criterion*:

$$\Theta^* = \underset{\Theta}{\operatorname{argmax}}\ p(X \mid M,\Theta) \qquad (1)$$

or a *maximum a posteriori* criterion, which could be either

$$\Theta^* = \underset{\Theta}{\operatorname{argmax}}\ p(M \mid X,\Theta) = \underset{\Theta}{\operatorname{argmax}}\ p(X \mid M,\Theta)p(M|\Theta) \qquad (2)$$

or

$$\Theta^* = \underset{\Theta}{\operatorname{argmax}}\ p(M,\Theta \mid X) = \underset{\Theta}{\operatorname{argmax}}\ p(X \mid M,\Theta)p(M,\Theta) \qquad (3)$$

In the first case, we take into account the prior distribution of the model $M$; in the second case, we take into account the prior distribution of the model $M$ as well as the parameters $\Theta$.

## Markov Models

The simplest form of SFSA is a Markov model in which states are directly associated with observations (see the second column in Table 1). We are interested in modeling

$$p(X) = p(F \mid x_1^T)p(x_1 \mid I) \prod_{t=2}^{T} p(x_t \mid x_1^{t-1}, I)$$

which can be simplified, using the $k$th-order Markov assumption, by

$$p(X) = p(F \mid x_{T-k+1}^T)p(x_1 \mid I) \prod_{t=2}^{T} p(x_t \mid x_{t-k}^{t-1})$$

which leads in the simplest case to the first-order Markov model,

$$p(X) = p(F \mid x_T)p(x_1 \mid I) \prod_{t=2}^{T} p(x_t \mid x_{t-1})$$

where $p(x_1|I)$ is the initial state probability and the other terms can be seen as transition probabilities. Note that any $k$th-order Markov model can be expressed as a first-order Markov model, at the cost of possibly exponentially more states. Note also that the transition probabilities are time invariant, i.e., $p(x_t = \ell \mid x_{t-1} = k)$ is fixed for all $t$.

The set of parameters, represented by the $(K \times K)$-transition probability matrix, i.e.,

$$\Theta = p(x_t = \ell \mid x_{t-1} = k), \text{ for all } \ell, k \in \mathcal{Q}$$

is then directly estimated on a large number of possible observation (and, thus, state) sequences such that

$$\Theta^* = \underset{\Theta}{\operatorname{argmax}}\ p(X \mid M,\Theta)$$

and simply amounts to estimating the relative counts of observed transitions, possibly smoothed in the case of undersampled training data, i.e.,

$$p(x_t = \ell \mid x_{t-1} = k) = \frac{n_{k\ell}}{n_k}$$

where $n_{k\ell}$ stands for the number of times a transition from state $k$ to state $\ell$ was observed, while $n_k$ represents the number of times state $k$ was visited.

It is sometimes desirable to compute the probability of going from the initial state $I$ to the final state $F$ in exactly $T$ steps, which could naively be estimated by summing path likelihoods over all possible paths of length $T$ in model $M$, i.e.,

$$p(F \mid I) = p(x_1 \mid I) \sum_{\text{paths}} p(F|x_T) \prod_{t=2}^{T} p(x_t \mid x_{t-1})$$

although there is a possibly exponential number of paths to explore. Fortunately, a more tractable solution exists, using the intermediate variable

$$\alpha_t(\ell) = p(x_t = \ell, x_1^{t-1}, I)$$

which can be computed using the *forward recurrence*:

$$\alpha_t(\ell) = \sum_k \alpha_{t-1}(k)p(x_t = \ell \mid x_{t-1} = k) \qquad (4)$$

and can be used as follows:

$$p(F|I) = \alpha_{T+1}(F)$$

Replacing the sum operator in Equation 4 by the max operator is equivalent to finding the most probable path of length $T$ between $I$ and $F$.

Although quite simple, Markov models have many uses. For example, they are used in all state-of-the-art continuous speech recognition systems to represent statistical grammars (Jelinek, 1998), usually referred to as $N$-grams, and for estimating the probability of a sequence of $K$ words

$$p(w_1^K) \approx \prod_{k=N+1}^{K} p(w_k \mid w_{k-N}^{k-1})$$

which is equivalent to assuming that possible word sequences can be modeled by a Markov model of order $N$.

## Hidden Markov Models

In many sequential pattern processing or classification problems (such as speech recognition and cursive handwriting recognition), one of the greatest difficulties is to simultaneously model the inherent statistical variations in sequential rates and feature characteristics. In this respect, HMMs have been one of the most successful approaches used so far. As shown in Table 1, an HMM is a particular form of SFSA in which Markov models (modeling the sequential properties of the data) are complemented by a second stochastic process modeling the local properties of the data. The Markov model is called hidden because there is an underlying stochastic process (i.e., the sequence of states) that is not observable but that affects the observed sequence of events.

Although sequential signals, such as speech and handwriting, are nonstationary processes, HMMs assume that the sequence of observation vectors is a *piecewise stationary* process. That is, a sequence $X = x_1^T$ is modeled as a succession of discrete stationary states $Q = \{1, \ldots, k, \ldots, K\}$, with instantaneous transitions between these states. In this case, an HMM is defined as a stochastic FSA with a particular (generally strictly left-to-right for speech data) topology. An example of a simple HMM is given in Figure 1. In speech recognition, this could be the model of a word or phoneme that is assumed to be composed of three stationary parts. In cursive handwriting recognition, this could be the model of a letter.

Once the topology of the HMM has been defined (usually arbitrarily), the main criterion used for training and decoding is based on the likelihood $p(X \mid M, \Theta)$, i.e., the probability that the observed vector sequence $X$ was produced by Markov model $M$. In this case, the HMM is thus considered a *production model*, and the observation vectors $x_t$ are considered to be output variables $z_t$ of the HMM. It can be shown that, provided several assumptions are met (Bourlard and Morgan, 1993), the likelihood $p(X \mid M, \Theta)$ can be expressed and computed in terms of *transition probabilities* $p(q_t = \ell \mid q_{t-1} = k, \Theta)$ and *emission probabilities*, which can be of the Mealy type (emission on transitions), $p(x_t \mid q_t, q_{t-1}, \Theta)$, or

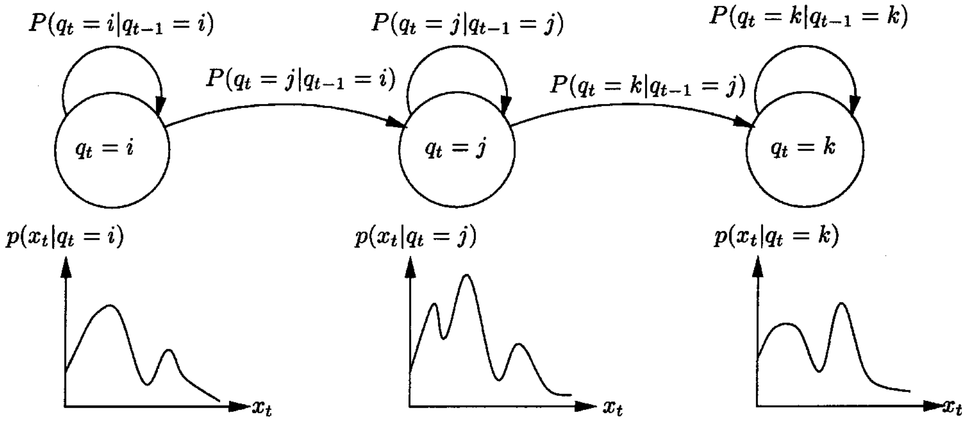

**Figure 1.** A three-state, left-to-right hidden Markov model.

of the Moore type (emission on states), $p(x_t \mid q_t, \Theta)$. In the case of multivariate continuous observations, these emission probabilities are estimated by assuming that they follow a particular functional distribution, usually (mixtures of) multivariate Gaussian densities. In this case, the set of parameters $\Theta$ comprises all the Gaussian means and variances, mixing coefficients, and transition probabilities. These parameters are then usually trained according to the maximum likelihood criterion (Equation 1), resulting in the efficient EM algorithm (Liporace, 1982; Gold and Morgan, 2000).

Given this formalism, the likelihood of an observation sequence $X$ given the model $M$ can be calculated by extending the forward recurrence (Equation 4) defined for Markov models to also include the emission probabilities. Assuming a Moore automaton (emission on states), we thus have the *forward recurrence*

$$\begin{aligned} \alpha_t(\ell) &= p(x_1^t, q_t = \ell) \\ &= p(x_t \mid q_t = \ell) \sum_k \alpha_{t-1}(k) p(q_t = \ell \mid q_{t-1} = k) \qquad (5) \end{aligned}$$

which will be applied over all possible $t$, and where $\Sigma_k$ is applied over all possible predecessor states of $\ell$, thus resulting in

$$p(X \mid M, \Theta) = \alpha_{T+1}(F)$$

Replacing the sum operator in Equation 5 by the max operator is equivalent to finding the most probable path of length $T$ generating the sequence $X$, and then yields the well-known dynamic programming recurrence, also referred to as the *Viterbi recurrence* in the case of HMMs:

$$\begin{aligned} \bar{p}(x_1^t, q_t = \ell) = p(x_t \mid q_t = \ell) \\ \times \max_{\{k\}} \{\bar{p}(x_1^{t-1}, q_{t-1} = k) p(q_t = \ell \mid q_{t-1} = k)]\} \qquad (6) \end{aligned}$$

where $\bar{p}(x_1^t, q_t = \ell)$ represents the probability of having produced the partial observation sequence $x_1^t$ while being in state $\ell$ at time $t$ and having followed the most probable path, $\{k\}$ represents the set of possible predecessor states of $\ell$ (given by the topology of the HMM), and $\bar{p}(X \mid M, \Theta)$ represents the likelihood that the most probable path is obtained at the end of the sequence and is equal to $\bar{p}(x_1^T, F)$.

During training, the HMM parameters $\Theta$ are optimized to maximize the likelihood of a set of training utterances given their associated (and known during training) HMM model, according to Equation 1, where $p(X \mid M, \Theta)$ is computed by taking all possible paths into account (forward recurrence) or only the most probable path (Viterbi recurrence). Powerful iterative training procedures based on the EM algorithm exist for both criteria and have been proved to converge to a local optimum. At each iteration of the EM algorithm, the E step estimates the most probable segmentation or the best state posterior distribution (referred to as hidden variables) based on the current values of the parameters, while the M step reestimates the optimal value of these parameters assuming that the current estimate of the hidden variables is correct.

For further reading about HMM training and decoding algorithms, see Bourlard and Morgan (1993), Deller, Proakis, and Hansen (1993), Gold and Morgan (2000), and Jelinek (1998).

### *HMM Advantages and Drawbacks*

The most successful application of HMMs is in speech recognition. Given a sequence of acoustic signals, the goal is to produce a sequence of associated phoneme or word transcriptions. To solve such a problem, one usually associates one HMM per different phoneme (or word). During training, a new HMM is created for each training sentence as the concatenation of the corresponding target phoneme models, and its parameters are maximized. Over the last few years, a number of laboratories have demonstrated large-vocabulary (at least 1,000 words), speaker-independent, continuous speech recognition systems based on HMMs.

HMMs can deal efficiently with the temporal aspect of speech (time warping) as well as with frequency distortion. They also benefit from powerful and efficient training and decoding algorithms. For training, only the transcription in terms of the speech units that are trained is necessary, and no explicit segmentation of the training material is required. Also, HMMs can easily be extended to include phonological and syntactical rules (at least when these rules use the same statistical formalism).

However, the assumptions that make the efficiency of these models and their optimization possible limit their generality. As a consequence, they also suffer from several drawbacks, including the following:

- Poor discrimination as a result of the training algorithm, which maximizes likelihoods instead of a posteriori probabilities $p(M|X)$ (i.e., the HMM associated with each speech unit is trained independently of the other models).
- A priori choice of model topology and statistical distributions, e.g., assuming that the probability density functions associated with the HMM state can be described as (mixtures of) multivariate Gaussian densities, each with a diagonal-only covariance matrix (i.e., the possible correlation between the components of the acoustic vectors is disregarded).
- Assumption that the state sequences are first-order Markov chains.
- Assumption that the input observations are not correlated over time. Thus, apart from the HMM topology, the possible temporal

correlation across features associated with the same HMM state is simply disregarded.

In order to overcome some of these problems, many researchers have concentrated on integrating artificial neural networks (ANNs) into the formalism of HMMs. In the next section we discuss some of the most promising approaches.

## ANN-Based Stochastic Finite-State Automata

The idea of combining HMMs and ANNs was motivated by the observation that HMMs and ANNs have complementary properties. HMMs are clearly dynamic and very well suited to sequential data, but several assumptions limit their generality, whereas ANNs can approximate any kind of nonlinear discriminant functions, are very flexible, and do not need strong assumptions about the distribution of the input data, but they cannot properly handle time sequences (although recurrent neural networks can indeed handle time, they are known to be difficult to train long-term dependencies, and cannot easily incorporate knowledge in their structure, as is the case for HMMs). Therefore, a number of hybrid models have been proposed in the literature.

### *Hybrid HMM/ANN Systems*

HMMs are based on a strict probabilistic formalism, making them difficult to interface with other modules in a heterogeneous system. However, it has indeed been shown (Richard and Lippmann, 1991; Bourlard and Morgan, 1993) that if each output unit of an ANN (typically a multilayer perceptron) is associated with a state $k$ of the set of states $\mathcal{Q} = \{1, 2, \ldots, K\}$ on which the SFSAs are defined, it is possible to train the ANN (e.g., according to the usual least-mean-square or relative entropy criteria) to generate good estimates of a posteriori probabilities of the output classes conditioned on the input. In other words, if $g_k(x_t|\Theta)$ represents the output function observed on the $k$th ANN output unit when the ANN is presented with the input observation vector $x_t$, we will have

$$g_k(x_t \mid \Theta^*) \approx p(q_t = k|x_t) \tag{7}$$

where $\Theta^*$ represents the optimal set of ANN parameters.

When using these posterior probabilities (instead of local likelihoods) in SFSAs, the model becomes a recognition model (sometimes referred to as a stochastic finite-state acceptor) where the observation sequence is an *input* to the system and where all local and global measures are based on a posteriori probabilities. It became necessary to revisit the SFSA basis to accommodate this formalism. In Bourlard and Morgan (1993) and Bourlard, Konig, and Morgan (1996), it is shown that $p(M|X, \Theta)$ can be expressed in terms of *conditional transition probabilities* $p(q_t|x_t, q_{t-1})$ and that it is possible to train the optimum ANN parameter set $\Theta$ according to the MAP criterion (Equation 2). The resulting training algorithm (Bourlard, Konig, and Morgan, 1994), referred to as REMAP (recursive estimation and maximization of a posteriori probabilities) is a particular form of EM training, directly involving posteriors, in which the M step involves the (gradient-based) training of the ANN and the desired target distribution (required to train the ANN) has been estimated in the previous E step. Since this EM version includes an iterative M step, it is also sometimes referred to as Generalized EM (GEM). As for standard HMMs, there is a full likelihood version (taking all possible paths into account) as well as a Viterbi version of the training procedure.

Another popular solution in using hybrid HMM/ANN as a sequence recognizer is to turn the local posterior probabilities $p(q_t = k|x_t)$ into *scaled likelihoods* by dividing these by the estimated value of the class priors as observed on the training data, i.e.,

$$\frac{p(q_t = k|x_t)}{p(q_t = k)} = \frac{p(x_t \mid q_t = k)}{p(x_t)} \tag{8}$$

These scaled likelihoods are trained discriminatively (using the discriminant properties of ANN). During decoding, though, the denominator of the resulting scaled likelihoods $p(x_t|q_t = k)/p(x_t)$ is independent of the class and simply appears as a normalization constant. The scale likelihoods can thus be simply used in a regular Viterbi or forward recurrence to yield an estimator of the global scaled likelihood (Hennebert et al., 1997):

$$\frac{p(X \mid M, \Theta)}{p(X)} = \sum_{\text{paths}} \prod_{t=1}^{T} \frac{p(x_t \mid q_t)}{p(x_t)} \, p(q_t \mid q_{t-1}) \tag{9}$$

where the sum extends over all possible paths of length $T$ in model $M$.

These hybrid HMM/ANN approaches provide more discriminant estimates of the emission probabilities needed for HMMs without requiring strong hypotheses about the statistical distribution of the data. Since this result still holds with modified ANN architectures, the approach has been extended in a number of ways, including the following:

- Extending the input field to accommodate not only the current input vector but also its right and left contexts, leading to HMM systems that take into account the correlation between acoustic vectors (Bourlard and Morgan, 1993).
- Partially recurrent ANNs (Robinson, Hochberg, and Renals, 1996) feeding back previous activation vectors on the hidden or output units, leading to some kind of higher-order HMM.

### *Input-Output HMMs*

Input-output HMMs (IOHMMs) (Bengio and Frasconi, 1995) are an extension of classical HMMs in which the emission and transition probability distributions are conditioned on another sequence, called the *input sequence*, and notated as $Y = y_1^T$. The emitted sequence is now called the *output sequence*, notated $Z = z_1^T$. Hence, in the simplest case of the Moore model (see Table 1), the emission distribution now models $p(z_t|q_t, y_t)$ while the transition distribution models $p(q_t|q_{t-1}, y_t)$.

Although this looks like an apparently simple modification, it has a structural impact on the resulting model and hence on the hypotheses of the problems to solve. For instance, whereas in classical HMMs the emission and transition distributions do not depend on $t$ (we say that HMMs are homogeneous), this is not the case for IOHMMs, which therefore are called inhomogeneous, as the distributions are now conditioned on $y_t$, which changes with time $t$.

Applications of IOHMMs range from speech processing to sequence classification tasks and include time-series prediction and robot navigation. For example, for economic time series, the input sequence could represent different economic indicators while the output sequence could be, for example, the future values of some target assets or the evolution of a given portfolio.

In order to train IOHMMs, an EM algorithm has been developed (Bengio and Frasconi, 1995) that looks very much like the classical EM algorithm used for HMMs, except that all distributions and posterior estimates are now conditioned on the input sequence. Hence we need to implement conditional distributions, either for transitions or emissions, which can be represented, for instance, by ANNs. The resulting training algorithm is thus a generalized EM, which is also guaranteed to converge. For transition probabilities, the output of the ANN would represent the posterior probability of each transition $p(q_t|q_{t-1}, y_t)$, with the constraint that all such probabilities from a given state sum to 1. For emission probabilities, the output of the ANN would represent the parameters of a unconditional probability distribution, such as a classical mixture of

Gaussians. Another implementation option would be to use an ANN to represent only the expectation $E[z_t|q_t, y_t]$ instead of the probability itself. For some applications such as prediction, this is often sufficient and more efficient.

An interesting extension of IOHMMs has been proposed in Bengio and Bengio (1996) in order to handle asynchronous input-output sequences, and thus to match input sequences that might be shorter or longer than output sequences. An obvious application of asynchronous IOHMMs is in speech recognition (or handwritten cursive recognition) where the input sequence represents the acoustic signal and the output sequence represents the corresponding phoneme transcription.

## Discussion

We have discussed the use of deterministic and stochastic finite-state automata for sequence processing and have sought to present this information in a unified framework. As a particularly powerful instantiation of SFSAs and one of the most popular tools for the processing of complex piecewise stationary sequences, we also discussed HMMs in more detail. Finally, we described a few contributions of the ANN community to improving those SFSAs, mainly the hybrid HMM/ANN systems and IOHMMs. A more extensive discussion would have taken up related areas, such as transducers, linear dynamical systems, Kalman filters, and so on—all outside the scope of this brief introduction.

# Hippocampal Rhythm Generation

*Péter Érdi and Krisztina Szalisznyó*

## Introduction

Global brain states in both normal and pathological conditions may be associated with spontaneous rhythmic activities of large populations of neurons. Experimentally, these activities can be detected by recording both from large neural assemblies (as in the EEG) or from a single neuron of the cell population. Two main global hippocampal states that occur normally are known: rhythmic slow activity, called *theta rhythm*, with the associated *gamma oscillation*, and *irregular sharp waves*, with the associated *high-frequency* (*ripple*) *oscillation*. A pathological brain state associated with *epileptic seizures* and producing epileptiform patterns also frequently occurs in the hippocampus. This article reviews the basic phenomena and their models. The main hippocampal rhythms are shown in Figure 1.

The general belief is that the different hippocampal rhythms are strongly involved in cognitive functioning. However, the functional significance of these rhythms is mentioned here only briefly (for a fuller discussion, see, e.g., Buzsáki, 1996). The first part of this article describes the most important normal and pathological hippocampal rhythms and the possible underlying mechanisms. In the second part, several different modeling strategies for studying rhythmicity in the hippocampal CA3 region are compared.

## Normal Electrical Activity Patterns

### Theta Rhythms

*The phenomenon.* The theta rhythm is a population oscillation with large (1 mV) amplitude and 4–12 Hz frequency. Theta rhythm occurs whenever an animal engages in behaviors such as walking, exploration, or sensory scanning, as well as during REM sleep (Buzsáki, 1996). Single-cell physiological studies showed different relations between the behavior of individual cells and the theta rhythm. Pyramidal cells in the hippocampus proper generally discharge with a very low frequency (0.01–0.5 Hz), although spatially sensitive "place cells" fire at 4–8 Hz when the rat is in its place field, and the position of the animal within a cell's place field may be correlated with the phase of its firing relative to the theta rhythm.

*Origin.* Discharging neurons phase locked to hippocampal theta waves have been observed in the dorsal raphe nucleus, the nucleus reticularis pontis oralis and caudalis, the supramammillary region, the septum, and the entorhinal cortex. Some of these areas are reciprocally interconnected with the hippocampal formation.

*In vitro experiments.* Population oscillation at the theta frequency can be induced pharmacologically by instillation of carbachol into

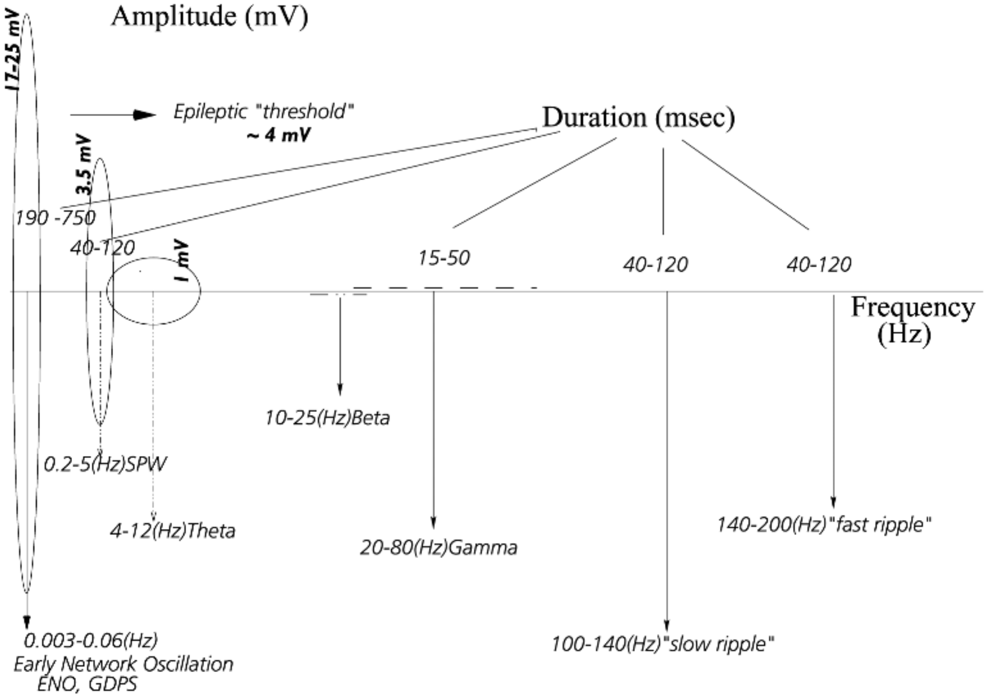

**Figure 1.** The main hippocampal rhythms occurring during physiological and pathological conditions: their frequency, duration, and amplitude.

hippocampal slices. Based on these and similar findings, it was suggested that theta rhythms may be generated not only extrahippocampally but also by the intrinsic membrane properties of the neurons of the CA3 region. The underlying single-cell firing patterns, however, may be different for in vivo and in vitro carbachol-induced oscillation: the pyramidal cells fire at a much higher frequency than in vivo. Some observations suggest a presence of two, relatively independent theta generators in the hippocampus that are mediated by the entorhinal cortex and the CA3-mossy cell recurrent circuitry, respectively. The CA3-mossy cell theta generator is partially suppressed by the dentate gyrus interneuronal output in the intact brain. Resonant properties of the CA1 neurons were found in the theta frequency range in vitro.

*Septohippocampal pathway.* The septohippocampal pathway has a cholinergic component, but it is not the only one to contribute to the generation of theta rhythm: atropin, a muscarinic antagonist of acetylcholine, does not entirely abolish the rhythmic slow activity. The GABAergic component of the septal afferents modifies the activity of the principal cells by disinhibition and is also involved in the generation of theta rhythm. These GABAergic cells are located mostly at the border of the medial and lateral septum, and terminate on the GABAergic interneurons of the hippocampus and on the non-GABAergic supramammillary cells, which are known to project to the septal complex and the hippocampus (Figure 2). The cholinergic input into the septum does not show target-selective innervation. There are some backpropagations from the hippocampus to the septum, some of them topographic.

*Entorhinal cortex.* The timing of the action potentials of pyramidal cells during the theta cycle might be determined by cooperation between the active CA3 neurons and the entorhinal input. Entorhinal excitatory transmitter-containing neurons can also depress the activity of supramammillary theta-generating/regulating cells via septal inhibitory neurons (Figure 2).

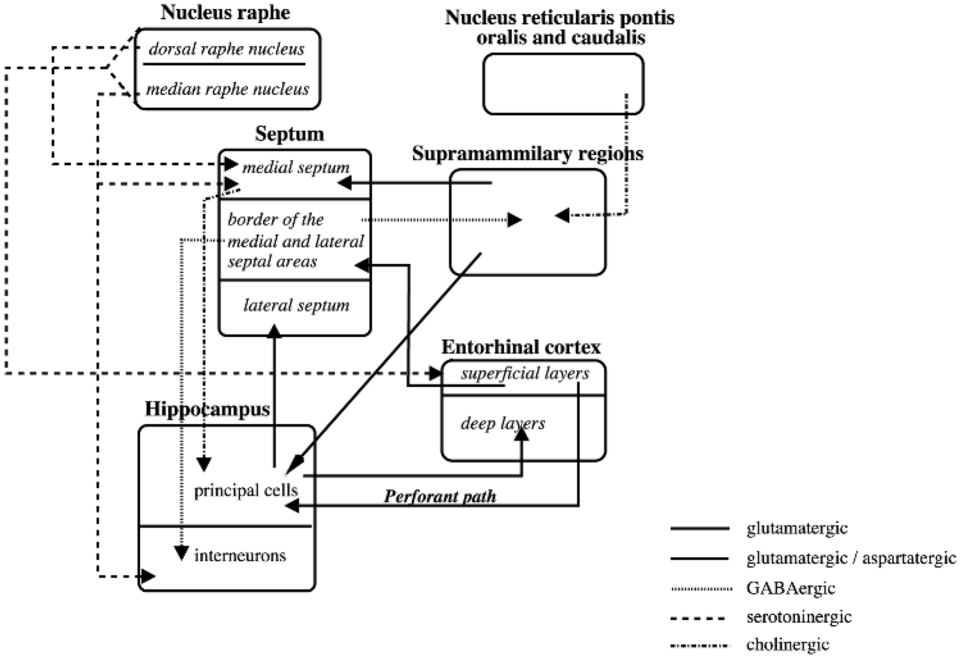
*Dorsal and medial raphe nuclei.* The main neurotransmitter of the raphe projections selectively innervates a subclass of the interneurons in the CA regions. A spatially segregated population of *serotonergic* neurons located caudally in the dorsal raphe nucleus was found to project only to the medial septum, and not to the hippocampus. In addition to the well-known serotonergic effect of the median raphe on hippocampal electrical activity, theta rhythm in the hippocampus may also be modulated by the dorsal raphe nucleus via the medial septum (Figure 2).

*Nucleus reticularis pontis oralis, caudalis.* A high degree of correlation was observed between theta waves in the nucleus reticularis pontis oralis, hippocampal fields, and nucleus reticularis pontis caudalis. The peak frequency of the theta rhythm, induced by stimulation of the reticularis pontis oralis nucleus in urethane-anesthetized rats, was decreased in aged rats compared with young and mature animals. The cholinergic system showed age-related deterioration in rats, including in the hippocampus (Figure 2).

*Supramammillary nucleus.* Neurons of the supramammillary nucleus fire phase locked to hippocampal theta rhythm. Stimulation of this area induces theta activity in the hippocampus via the medial septum and facilitates perforant pathway stimulation-evoked population spikes in the dentate gyrus even if the medial septum is inactivated. Most if not all postsynaptic targets of the supramammillary projection are principal cells in both the dentate gyrus and the CA2-CA3a subfields Figure 2).

The functional significance of the theta rhythm, including its possible role in evolution, was recently reviewed by Kahana, Seelig, and Madsen (2001). Studies in rodents have clarified the involvement of theta rhythm in synaptic plasticity and neural coding. Specifically, the phase relationship betwen theta field activity and single-cell patterns codes the location of the exploring animal. Recently, enhanced theta activity was demonstrated during both verbal and spatial memory tasks.

**Figure 2.** The interaction of the hippocampus with cortical and subcortical structures. The neurochemical character of the afferent and efferent fibers are visualized.



## *Gamma Oscillations*

*The phenomenon.* Gamma frequency field oscillations reflect synchronized synaptic potentials in neuronal populations within a range of approximately 10–40 ms. The frequency of this oscillation is in the 20–80 Hz range.

*Intrahippocampal origin.* The power of gamma oscillation in the hilus decreased significantly after bilateral removal of the entorhinal cortex but survived after surgical removal of the subcortical inputs of the hippocampus. The GABAergic perforant path input terminates exclusively on the interneurons. This pathway provides a rhythmic hyperpolarization of the interneurons, at theta frequency range, so the hypothesized voltage-dependent gamma oscillation of hippocampal interneurons will be periodically interrupted. Gamma oscillation can emerge independently in each subregion of the hippocampus, including the dentate gyrus, CA3, and CA1 regions, but it occurs with greatest power in the dentate gyrus.

*Extrahippocampal origin.* GABAergic neurons in the basal forebrain display a gamma oscillation. These GABAergic cells also project to the GABAergic reticular nucleus of the thalamus and the neocortex, where they preferentially terminate on the GABAergic interneurons. The gamma patterns are modulated by theta activity, and the dominant source of gamma activity after removal of the entorhinal input is the CA3 region.

*Underlying mechanisms.* The mechanisms underlying gamma oscillations are not fully understood. Studies of hippocampal formation have suggested that field oscillations in the gamma frequency band reflect synchronous IPSPs on the somata of principal cells. Population oscillation may emerge in interneuronal networks even when individual cells fire at remarkably higher frequencies. At least part of the gamma rhythm recorded in the extracellular space reflects synchronous membrane oscillation in the pyramidal cells brought about by the rhythmic IPSPs. Basket cells innervating the perisomatic region of pyramidal cells discharge at gamma frequency and are phase locked to the field oscillation. These findings indicate that the charges responsible for the rhythmic gamma waves are mostly carried by chloride ions that enter through $\mathrm{GABA_A}$ receptors. Extracellularly observed gamma waves reflect summation of rhythmic EPSPs by the perforant path input at the dendrites (active inward currents) and IPSPs by the oscillating interneurons at the somata (active outward currents) of the granule cell population. Given the spatial segregation of the inward and outward currents (dendrites versus somata), these active currents would summate in the extracellular space. Previous hypotheses suggested that the origin of the synchronized gamma activity may be the mutual excitation among principal cells, or at the single-cell level ("chattering cells"; Traub, Jeffreys, and Whittington, 1999). Simulation studies later showed that interneuronal networks can be synchronized by $\mathrm{GABA_A}$ synapses preferentially within gamma frequency range. Resonant properties of pyramidal cells might facilitate network synchrony in the gamma frequency range (Orbán et al., 2001).

The finding that gamma oscillation occurred in different brain regions generated considerable excitement, since gamma oscillation is supposed to be responsible for the binding of perceived and recalled attributes of aspects and events, and for forming memory traces.

## *Irregular Sharp Waves*

*The phenomenon.* Sharp waves (SPWs) have a very large amplitude (up to 3 mV), their duration is 40–120 ms, and their frequency can be between 0.2 and 5 Hz. Although maximal SPW frequencies do overlap theta frequencies, theta waves are much more regular than SPWs. SPWs also have behavioral correlates: they occur during awake immobility, drinking, eating, face washing, grooming, and slow wave sleep (Buzsáki, 1996).

*Origin.* During SPWs, pyramidal and inhibitory cells fire with increased frequency. Furthermore, there is a partial synchronous cellular activity of both pyramidal and inhibitory neurons. However, the degree of synchrony is below the threshold for induction of epileptic seizures. The amplitude and frequency of SPWs can be increased by high-frequency stimulation of the commissural system and the Schaffer collaterals, suggesting that such stimulation enhances the efficacy of the excitatory synapses. The activity of neurons in the deep layers of entorhinal cortex is also correlated with SPWs.

SPWs are thought to be formed by internal intrahippocampal processes. One important precondition for SPW generation is the occurrence of a population burst in a small set of CA3 pyramidal cells. Their synchronization is mediated by excitatory synaptic connections.

*The physiological mechanism of synchronization.* The largest degree of synchronization occurs in the adult hippocampus during an irregular sharp wave under physiological conditions. CA3 pyramidal cells have recurrent excitatory connections that terminate within the CA3 region. The autoexcitation due to these connections produces large excitatory postsynaptic potentials (EPSP), which propagate to the CA1 region through the Schaffer collaterals. Inhibitory connections control the population activity in both regions. Although sharp waves were found in rat hippocampus during consummatory behaviors and slow wave sleep, there is a normal human EEG phenomenon, called small sharp spikes (SSS), that is thought to be analogous to SPW, since it also results from partial synchronous cell firing. Not only "normal" but also epileptiform SPWs can occur. The latter are characterized an amplitude greater than 4 mV or by a less irregular pattern. Their duration is shorter than that of normal SPWs.

During irregular sharp waves, memory traces are supposed to be consolidated and transferred to neocortex.

### *High-Frequency ("Ripple") Oscillations*

*The phenomenon.* In conjunction with sharp wave bursts, CA1 pyramidal cells display a high-frequency (200 Hz) network oscillation (ripple) (Ylinen et al., 1995). Similar types of high-frequency oscillation were recorded from the entorhinal cortex and hippocampus of patients with medial temporal lobe epilepsy. The lower-frequency oscillation (80–160 Hz) was regarded as the human equivalent of normal ripples in the rat. The higher-frequency oscillation (250–500 Hz) was found in the epileptogenic regions and may reflect pathological hypersynchronous population spikes of bursting pyramidal neurons. Sleep is characterized by a structured combination of neuronal oscillations. In the hippocampus, slow-wave sleep (SWS) is marked by high-frequency network oscillations, and neocortical SWS activity is organized into low-frequency delta (1–4 Hz) and spindle (7–14 Hz) oscillations. The existence of temporal correlations between hippocampal ripples and cortical spindles is also reflected in the correlated activity of single neurons within these brain structures. This co-activation of hippocampal and thalamocortical pathways may be important for the process of memory consolidation, during which memories are gradually translated from short-term hippocampal to longer-term neocortical stores (Bragin et al., 1999).

*Origin and underlying mechanisms.* Single pyramidal cells discharge at a low frequency and are phase locked to the negative peak of the locally derived field oscillation. CA1 basket cells increase their firing rate during the network oscillation and discharged at the frequency of the extracellular ripple. These findings indicate that the intracellularly recorded fast oscillatory rhythm is not solely dependent on membrane currents intrinsic to the CA1 pyramidal cells but is a network-driven phenomenon dependent on the participation of inhibitory interneurons. One of the hypotheses was that fast field oscillation (200 Hz) in the CA1 region reflects summed IPSPs in pyramidal cells as a result of a high-frequency barrage of interneurons (Ylinen et al., 1995). The specific currents responsible for the ripple are believed to be synchronized somatic IPSPs interrupted by synchronous discharges of CA1 pyramidal neurons every 5–6 ms. Concurrent with the hippocampal sharp wave, ripples are present also in the subiculum, parasubiculum, and deep layers of the entorhinal cortex, but the ripple frequency is fastest in the CA1 region. Recent experimental and computational simulation results suggest that ripple oscillation may be mediated by direct electrotonic coupling of neurons, most likely through gap-junctional connections (Traub et al., 1999).

### *Oscillation in Developing Hippocampus*

Synchronous population activity is present both normally and in pathological conditions such as epilepsy. Low-frequency early network population oscillation (0.006–0.03 Hz), or ENO, was found in the hippocampus proper and in the gyrus dentatus region during the first few weeks of postnatal life. The underlying single-cell activity is the synchronous bursting activity, generated by pyramidal cells and interneurons, via $\mathrm{GABA_A}$, NMDA, and AMPA receptors. The oscillation is phase locked to the intracellular $\mathrm{Ca}^{2+}$ increase, and the interneuronal network exhibits a $\mathrm{Ca}^{2+}$ burst in synchrony with the ENO-associated early pyramidal $\mathrm{Ca}^{2+}$ bursts. The ENO is totally blocked by the $\mathrm{GABA_A}$ receptor antagonist bicucullin and is reduced by the glutamatergic antagonist. The developmental change of the $\mathrm{Cl}^-$ equlibrium potential is responsible for the change of the $\mathrm{GABA_A}$ $\mathrm{Cl}^-$ ion current direction. The ENO-associated $\mathrm{GABA_A}$ LTP and LTD are supposed to be partly responsible for the formation of the interneuronal network, and it is consistent with the theory that the excitatory effect–related synaptic plasticity might play a role even in inhibitory synaptic formation.

### *Epileptic Seizures*

*The phenomenon.* Epileptic activity occurs in a population of neurons when the membrane potentials of the neurons are "abnormally" synchronized. A certain degree of synchrony is necessary for normal theta and SPW behavior. However, there are some fundamental questions to be answered. Under what conditions does population firing become synchronized? What factors regulate the extent of synchronization? What are the critical factors that can influence the change from the physiological to the pathological level of the synchronization? Answers obtained in model studies are briefly summarized in the following sections.

*In vitro models.* Several in vitro models of seizures have been developed, including models invoking electrical stimulation or low calcium, low magnesium, or elevated potassium levels. (Of course, in vitro models have nothing to do with mathematical models.) The functional removal of some inhibitory interneurons from network activity might be another factor contributing to epileptic phenomena, either because of their inadequate excitatory drive or because of their depolarization blockade. Experiments with ion-selective microelectrodes revealed that a considerable activity of $\mathrm{K}^+$ ions appears temporarily in the extracellular space during enhanced neuronal activity and is removed from the extracellular space by diffusion. The elevated-potassium model of epilepsy suggests that a modest elevation in extracellular potassium ion concentration produces hypersynchronous epileptiform activity. One important element in epileptogenesis may be attenuation of the inhibitory synaptic inputs to pyramidal cells during high-$\mathrm{K}^+$ seizures. A few different epileptic phenomena are found in vitro, such as synchronized bursts, synchronized multiple bursts, and seizure-like events. Synchronized bursts last 50–100 ms, and interburst intervals are generally longer than 1 s. They are analogous to the so-called interictal events found in vivo, and can be elicited by applying a localized $\mathrm{GABA_A}$-blocking agent (e.g., picrotoxin, bicucullin, penicillin). Synchronized multiple bursts are characterized by a series of up to about ten synchronized bursts occurring at 65–75 ms intervals. The intervals between the complex events are longer than 10 s. This phenomenon can also be generated by applying $\mathrm{GABA_A}$ blocker. Seizure-like events can be generated both with and without the aid of chemical synapses. The latter was demonstrated in slices with low $\mathrm{Ca^{2+}}$ solutions. Low $\mathrm{Ca^{2+}}$ blocks spike-dependent synaptic transmission, yet spontaneous bursts of population spikes—"field bursts"—with underlying high-frequency firing of pyramidal cells are still evoked.

## Computational Models of the CA3 Region: Comparative Studies

### 1. Compartmental Models

Some detailed single-cell multicompartmental hippocampal pyramidal cell models have been established (Traub et al., 1999, p. 17). Specifically, a 19-compartment pyramidal cable model of a guinea pig CA3 pyramidal neuron was developed and incorporated in several network models. Each compartment contains six active ionic conductances: gNa, gCa, gK(DR) (where DR stands for delayed rectifier), gK(A), gK(AHP), and gK(C). The conductance gCa is of the high-voltage activated type. The model kinetics incorporate voltage-clamp data obtained from isolated hippocampal pyramidal neurons. The model predicts that CA3 pyramidal neurons in media blocking synaptic transmission should fire a burst of action potentials following antidromic stimulation. This was confirmed experimentally in hippocampal slices.

*Model reduction.* Multicompartment models could be reduced to allow questions about larger-scale brain regions to be answered while still revealing something about activity at the single-cell level. The 19-compartment Traub model has been reduced to a two-compartment model (Pinsky and Rinzel, 1994). This two-compartment model (soma, dendrite) is able to qualitatively reproduce the salient stimulus-response characteristics of the Traub-Miles (1991) single-cell model, was useful for studying the effect of intercompartmental coupling on the responses generated, and proved to be a computationally effective unit for network simulations. The "slow" and "fast" currents are segregated in the dendrite-like and the soma-like compartments, respectively.

### 2. Network Studies: Model of an in Vitro CA3 Slice

*Physiological synchronized population activities.* Traub and Miles simulated hippocampal (mostly CA3) population activity by building "bottom-up" models from data on anatomic connectivities, ionic conductances, and synaptic properties (Traub and Miles, 1991).

Three basic cell types, pyramidal cells and two types of inhibitory cells, inh(1) and inh(2) cells, were assumed. The postsynaptic effect of the inh(1) cells is mediated by perisomatic $\mathrm{GABA_A}$ receptors, while the inhibition of the inh(2) cells is mediated by the dendritic $\mathrm{GABA_B}$ receptors.

Instead of giving detailed wiring, the strategy for specifying synapses was to define the statistical properties of the topology of the neural structures. Traub and Miles defined both globally and locally random networks. The probabilities of synaptic connections for a given type of cell pair are constant in the former case and decrease with distance in the latter case.

Fully and partially synchronized bursts, multiple bursts, synchronized population oscillations, and interictal epileptic seizures were physiologically measured and reproduced by this model (Traub and Miles, 1991; Whittington, Traub, and Jeffreys, 1995).

*Epileptic interictal spikes.* A computer model was constructed of the guinea pig hippocampal region in vitro that contained 100 pyramidal neurons modeled by the 19-compartment model detailed above. This approach has contributed to the understanding of brief (usually less than 100 ms) epileptic events known as interictal spikes. The neurons were randomly interconnected with excitatory synapses, each synapse exerting a fast voltage-independent (AMPA) component and a slower voltage- and ligand-dependent (NMDA) component.

*Synchronized gamma oscillations in a hippocampus.* 1. *Gamma frequency in the interneuronal network.* Using computer simulations the hypothesis that gamma rhythm can emerge in a random network of interconnected GABAergic fast-spiking interneurons was investigated. The amplitude of spike afterhyperpolarization was above the $\mathrm{GABA_A}$ synaptic reversal potential. The ratio between the synaptic decay time constant and the oscillation period was sufficiently large; the effects of heterogeneities were modest because of a steep frequency-current relationship of fast-spiking neurons. It has been demonstrated that large-scale network synchronization requires a critical (minimal) average number of synaptic contacts per cell, and this number is not sensitive to network size. The neuronal firing frequencies could be gradually and monotonically varied by changing the $\mathrm{GABA_A}$ synaptic maximal conductance, the synaptic decay time constant, and the mean external excitatory drive to the network, but the network synchronization was found to be high only within a frequency band coinciding with the gamma (20–80 Hz) range. The model predicts that the $\mathrm{GABA_A}$ synaptic transmission provides a suitable mechanism for synchronized gamma oscillations in a sparsely connected network of fast-spiking interneurons (Wang and Buzsáki, 1996).

2. *Gamma frequency in the network of interneurons and pyramidal cells.* A network simulation was used to investigate how pyramidal cells, connected to the interneurons and to each other through AMPA-type and/or NMDA-type glutamate receptors, might modify the interneuron network oscillation. With or without AMPA receptor-mediated excitation of the interneurons, the pyramidal cells and interneurons fired in phase during the gamma oscillation. Pyramidal cells caused the interneurons to fire spike doublets or short bursts at gamma frequencies, thereby slowing the population rhythm. Rhythmic synchronized IPSPs allowed the pyramidal cells to encode their mean excitation by their phase of firing relative to the population waves. Recurrent excitation between the pyramidal cells could modify the phase of firing relative to the population waves. This model suggested that pools of synaptically interconnected inhibitory cells are sufficient to produce gamma-frequency rhythms, but the network behavior can be modified by participation of pyramidal cells (Traub, Jeffreys, and Whittington, 1997).

*High-frequency oscillation in the hippocampus.* To explore the hypothesis that gap junctions occurring between axons could explain high-frequency oscillations, a network was constructed. It has been shown that in randomly connected networks with an average of two gap junctions per cell or less, synchronized network bursts can arise without chemical synapses, with frequencies in the experimentally observed range (spectral peaks 125–182 Hz). The critical assumptions were that (1) there is a background of ectopic axonal spikes that can occur at low frequency (one event per 25 s per axon), and (2) the gap junction resistance is small enough that a spike in one axon can induce a spike in the coupled axon at short latency. The result of the simulation was that axo-axonal gap junctions, in combination with recurrent excitatory synapses, induced the occurrence of high-frequency population spikes superimposed on epileptiform field potentials.

### 3. Population Models

There is a long tradition of trying to connect the "microscopic" single-cell behavior to the global "macrostate" of the nervous system, analogously to the procedures applied in statistical physics. Global brain dynamics is handled by using continuous (neural field) description instead of the networks of discrete nerve cells. Both deterministic and statistical approaches have been developed.

*Model framework.* In a long series of papers, Ventriglia constructed a neural kinetic theory, i.e., a statistical field theory of large-scale brain activities. He assumed two types of entities, spatially fixed neurons and spatially propagating spikes ("impulses") (Ventriglia, 1994). In the deterministic field-theoretical description, each neuron is represented as a point in the neural layer or field and a neuronal density is defined, while the statistical model describes neural population activity in terms of the probability density functions (p.d.f.'s) of (1) neurons and (2) spikes traveling between the neurons.

*Synchronized population oscillation.* A different version of neural kinetic theory has been invoked to simulate a range of epileptiform and nonepileptic rhythms (Barna, Grölber, and Érdi, 1998; Gröbler, Barna, and Érdi, 1998). The synaptic strengths of excitatory and inhibitory synapses have been varied. The degree of pyramidal cell synchronization has been studied, even as single-cell activity (underlying population behavior) was monitored. Phenomena that were reproduced included fully synchronized population bursts, synchronized synaptic potentials, and low-amplitude population oscillation.

*Wave propagation.* The spatial pattern of propagation is shown in Figure 3. The model slice is shown with increasing time from top to bottom. High activity appears first in the stimulated subregion, then builds up in the neighboring regions, then propagates through the full length of the slice. The velocity of the simulated wave propagation exhibits a linear increase on the maximal synaptic conductance and is in the interval of 5–10 cm/s.

## Discussion

This article reviewed the basic physiological mechanisms and models of normal and pathological hippocampal rhythm generation. The interplay of intrinsic cell properties and synaptic interactions contributes to the generation of rhythms at both single-cell and population levels. Hippocampal rhythms are strongly involved in many areas of cognitive functioning, including navigation (see Hippocampus: Spatial Models), various memory phenomena, such as memory formation, consolidation, and amnesic syndromes.

The hippocampus has an important role in neurological diseases. Alzheimer's disease, epilepsy, and ischemia are characterized by learning and memory impairment and accompanied by selective neuronal death or characteristic changes in the hippocampal circuitry. How the various hippocampal rhythms are involved in these disorders is an open question. Understanding the electrophysiology of the hippocampal area should contribute greatly to the development of pharmacological strategies to overcome the hippocampus-dependent disorders (see Neurological and Psychiatric Disorders).

Complementary neural models are used to study the generation and control of hippocampal and other cortical rhythms. Multicompartment modeling techniques proved to be an efficient way to simulate the dynamics of even relatively large networks. Statistical population models are proper tools for describing large-scale population phenomena and wave propagation.

## Introduction

The hippocampus is the most-studied part of the brain, attracting interest because of its position (many synapses removed from sensory transducers or motor effectors), its role in human amnesia and Alzheimer's disease, and the discovery of long-term potentiation (LTP, see Hebbian Synaptic Plasticity) and of spatially coded cell firing. Bilateral damage to the hippocampus and nearby structures in patient H.M., as treatment for epilepsy, produced a profound retrograde and anterograde amnesia, prompting extensive cross-species research to uncover the specific memory deficits that result from hippocampal damage (the most prominent of which, in the rat, appears to be a deficit in spatial navigation). In short, the hippocampus has become the primary region in the mammalian brain for the study of the synaptic basis of memory and learning. Structurally, it is the simplest form of cortex. It contains one projection cell type whose cell bodies are confined to a single layer and which receives inputs from all sensory systems and association areas (Figure 1).

Attempts to model the hippocampus differ both in the level of anatomical detail and in the functionality that they seek to reproduce. Marr (1971) proposed a theory for how the hippocampus could function as an associative memory, from which have grown many extensions, usually focusing on the role of the CA3 recurrent collaterals (see, e.g., McNaughton & Nadel, 1990; for collected works, see Gluck, 1996, and Burgess, Jeffery, and O'Keefe, 1999; for a review, see Burgess et al., 2001; see also Associative Networks). However, the precise contribution of the hippocampus to memory, as opposed to the contribution of nearby structures, remains controversial. In this article we specifically consider neuronal models of spatial processing in the rat hippocampus, the domain in which the least controversial experimental data are available. We introduce data on the spatial correlates of hippocampal cell firing and the idea of the hippocampus as a spatial map, and describe some models of the firing of hippocampal place cells and their role in navigation.

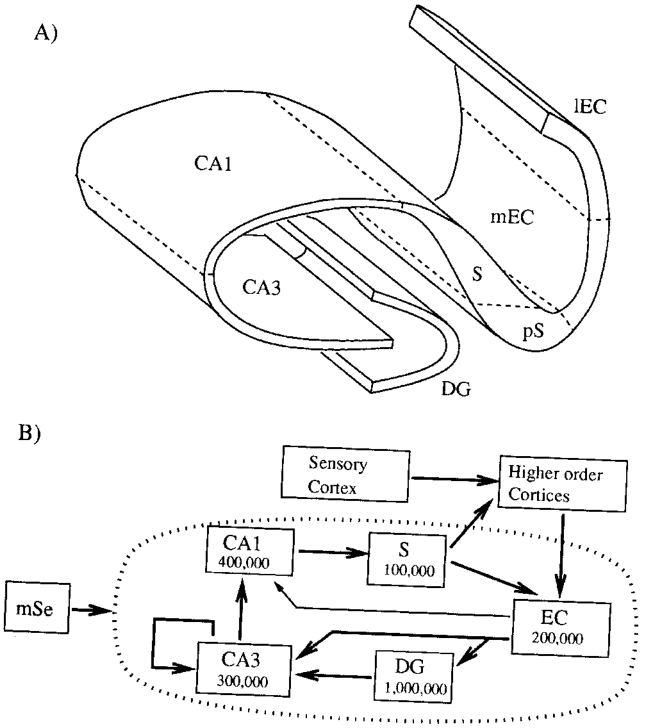

**Figure 1.** The hippocampus is formed from sheets of cells. *A*, A schematic section cut perpendicular to the longitudinal axis of the hippocampus. EC, entorhinal cortex (mEC, medial EC; lEC, lateral EC); S, subiculum; pS, pre- and parasubiculum; DG, dentate gyrus. *B*, The major projections between subfields (mSe, medial septum), and approximate numbers for the major cell type in each subfield (i.e., pyramidal cells, except for the DG, in which it is granule cells) in the rat. The human hippocampus contains one order of magnitude more cells. In the DG-CA3 projection a single mossy fiber projects from each granule cell, making very large synapses onto only 14 or so pyramidal cells. All the other projections have large divergence and convergence (many thousands to 1) and involve the type of synapse in which "Hebbian" LTP has been observed. A variety of interneurons provide feedforward and feedback inhibition. Cells in the mSe project into DG, CA3, and (less strongly) CA1, playing a role in producing the $\theta$ rhythm of the hippocampal EEG. Cells in CA3 and CA1 also project out to the lateral septum via the fornix. (Adapted with permission from B. L. McNaughton, 1989, Neuronal mechanisms for spatial computation and information storage, in *Neural Connections, Mental Computation* [L. Nadel, L. A. Cooper, P. Culicover, and R. M. Harnish, Eds.], Cambridge, MA: MIT Press.)

## Basic Data and Issues

### *Electrophysiology*

Single-unit recordings in freely moving rats have revealed "place cells" (PCs) in fields CA3 and CA1 of the hippocampus, so called because their firing is restricted to small portions of the rat's environment (the corresponding "place fields"). There is little topographic organization of PCs relating their positions in CA3 or CA1 to the positions of their firing fields. The firing properties of PCs can be manipulated by changing the rat's environment: for example, rotating the major cues in an environment can cause the place fields to rotate. In environments in which direction of movement is restricted (e.g., mazes with narrow arms), PC firing rates appear to depend on the rat's direction of travel as well as its location.

Cells in the entorhinal cortex (the main cortical input to the hippocampus; see Figure 1) also have spatially correlated firing but tend to have larger, less well-defined place fields than those in CA3 or CA1. Cells whose primary behavioral correlate is "head direction" have also been found, in the (dorsal) presubiculum (see Figure 1), anterior thalamus, and mammillary bodies. They fire when the rat points its head in a specific direction relative to the cues in the environment, and independently of its location (see Rodent Head Direction System and Zhang, 1996, and Sharp, Blair, and Brown, in Gluck, 1996, for models).

The electroencephalogram (EEG) recorded in the hippocampus is the largest electrical signal in the rat brain. One form of the EEG, called the theta ($\theta$) rhythm, is an oscillation of 7–12 Hz. O'Keefe and Nadel (1978) have suggested that in the rat, the $\theta$ rhythm coincides with displacement movements. PC firing has been found to have a systematic phase relationship to $\theta$, discovered by O'Keefe and Recce in 1993 (see Burgess and O'Keefe in Gluck, 1996): when a rat on a linear track runs through a place field, the PC tends to fire groups of spikes, with each successive group occurring at an earlier phase of the $\theta$ cycle. Consistent with these data, PCs firing at a late phase tend to have place fields centered ahead of the rat, whereas those firing at an early phase tend to have place fields centered behind the rat in open field environments (see Burgess and O'Keefe in Gluck, 1996).

There are two features of PC firing that raise immediate problems for their use in navigation: (1) information about a place in an environment (i.e., the firing of the corresponding PCs) can only be accessed locally (by actually visiting that place), and (2) place fields appear to be no more affected by the location of the goal (which is obviously essential for navigation) than by the location of any other cue. Unfortunately, there are no reports to date of cells that code for the destination of a rat's current trajectory.

### *Path Integration*

An animal may estimate its current position relative to some starting position purely on the basis of internal signals (e.g., vestibular or proprioceptive) relating to its movements in the intervening period. Such a process is often referred to as "path integration" (PI). Many animals appear to be able to use PI to return to a home location in the absence of external stimuli. Interestingly, once a rat has got its orientation from the array of cues, PCs can continue to fire in the correct places after all of the salient cues in an environment have been removed, or after the lights have been switched off (see also the role of PI in the Rodent Head Direction System). Experiments indicate that PC firing can be supported by visual, auditory, olfactory, tactile, or internal information, as available.

### *Cognitive Maps*

Cognitive maps, or mental representations of the spatial layout of an environment, were first introduced by Tolman to explain place learning in rats, including, for example, their ability to take shortcuts (see Cognitive Maps). An alternative view, suggested by Hull, is that navigation is achieved by following a list of stimulus-response-stimulus steps. O'Keefe and Nadel (1978) proposed that independent neural systems exist in the brain to support a "taxon" system for route navigation and a "locale" system for map-based navigation (for a synopsis, see O'Keefe, 1991). The "map" was taken to be a Euclidean description of the environment in an "allocentric" coordinate system (based on the world and not on some part of the animal's body). They proposed that the locale navigation system resides in the hippocampus, based on (1) the firing properties of hippocampal PCs, (2) the presence of $\theta$ rhythm during displacement movement, (3) deficits in performance of spatial tasks, including the Morris water maze and the Olton eight-arm maze, following hippocampal lesions, and (4) the interpretation of the amnesic syndrome as the loss of episodic memory (memory for specific events set in a spatiotemporal context). Note, however, that the goal independence of PC firing indicates that such cells form only part of a cognitive map, some read-out mechanism being required to guide behavior.

O'Keefe and Nadel (1978) proposed that, while the hippocampal cognitive map was clearly tied to external cues, some form of PI might support its intrinsic distance and direction metric. In their original formulation, a PC could be activated by two independent means. First, PCs could be directly activated by the sensory inputs available to an animal in a particular location. Second, activation of the set of PCs corresponding to one location, coupled with inputs indicating the rat's performance of a movement translating and rotating it by a certain amount, would lead to the activation of the set of PCs corresponding to the new location. Mismatches between the two would provide the signal for exploration, which would bring the two sets of information into correspondence by strengthening some sensory inputs and weakening others (O'Keefe and Nadel, 1978, pp. 220–230).

## Models of Place Cell Firing

### *Sensory Inputs*

In this section we describe models of how the spatial firing of PCs develops and is maintained as the rat moves around an environment. Following an earlier mathematical model of PC firing (by Zipser in 1985), Sharp used a simple network with an input layer and two layers of cells governed by "competitive learning" dynamics (see Competitive Learning and Sharp, Blair, and Brown in Gluck, 1996). In this model two types of input (or "neocortical") cells respond to cues placed around the environment: a type 1 cell that "fires" whenever a particular cue is at a given distance from the rat, and a type 2 cell that likewise responds to a particular cue at a given distance, but only if the cue is within a certain range of angles relative to the rat's head. During exploration, competitive learning leads to unsupervised clustering of the input vectors: a PC learns to fire in a portion of the environment in which the inputs (i.e., the distances and angles of cues) are similar. Interestingly, if the simulated rat's exploration is restricted to movements consistent with being in an eight-arm maze, then PC firing tends to be much more strongly correlated with the orientation of the rat (as well as its location) than in the case of unrestricted exploration, which fits well with the experimental data. The place fields in this model are robust to the removal of a subset of the environmental cues. However, the model takes some time to develop realistic place fields, whereas experiments indicate that they are present, and orientation independent, as soon as they can be measured.

### *Attractors and Path Integration*

Touretzky and Redish (in Burgess et al., 1999) proposed a model in which PCs form a coherent representation of location on the basis of estimates of the rat's location from PI and local-view information. The model investigates the interaction of frames of reference supported by different mechanisms and in different brain regions, assuming that resetting the PI system depends on the hippocampus. In a similar approach, Guazzelli, Bota, and Arbib (2001) proposed a feedforward competitive learning model that develops a PC representation by combining PI and sensory inputs, simulating in some detail the effects of darkness, and the deletion or movement of extramaze cues (see also Arbib in Burgess et al., 1999).

Samsonovich and McNaughton (1997) went much farther in placing the hippocampus at the heart of a PI system. They proposed that region CA3 of the hippocampus forms "continuous attractors" (Zhang, 1996) such that sets of place fields form preconfigured "charts," as follows. The recurrent connections between PCs fix the relative locations of place fields within a chart, and also ensure stable and coherent patterns of PC activity (i.e., activity consistent with the rat being in a single location). This system serves as the neural basis of a PI system driven by hardwired motion-related signals that shift PC activity so as to reflect the change in location of the rat corresponding to its movements. A particular chart becomes associated to the sensory stimuli in a particular environment so as to make a correspondence between locations on the chart and locations in reality. This model predicts that hippocampal lesions will impair PI, although the experimental evidence for this is controversial.

Kali and Dayan (2000) showed that continuous attractors could be formed by Hebbian learning in the recurrent connections during exploration. However, to create an attractor of equal depth across an unevenly sampled environment required that learning be mediated by novelty. Hasselmo, Wyble, and Wallenstein (in Gluck, 1996) suggest a mechanism for this. The CA3 representation reflects the expected state of the world, being influenced by the associations learned by the recurrent collaterals, while the CA1 representation reflects direct cortical input. Novelty is detected as a mismatch between the two representations, and mediates learning in CA3 by triggering the release of acetylcholine from the medial septum.

### *What Inputs Support a Place Cell's Spatially Tuned Firing?*

Recording the same PCs in boxes of varying shape and size provides insight into the environment determinants of place fields. In these experiments the location of peak firing tends to maintain a fixed distance from the nearest walls, and a symmetrical, unimodal, place field in a small box may be elongated or multimodal in a larger box. These results are qualitatively fitted by a simple model in which PC firing is a thresholded sum of up to four "boundary vector cell" (BVC) inputs, each tuned to respond maximally whenever there is a wall a given distance away along a given allocentric direction. The tuning to distance is Gaussian, with a width that increases with the distance of the peak response from the wall. (We note that the attractor models discussed earlier can show this behavior only to the extent that the behavior is determined by feedforward BVC inputs.) A random selection of hardwired BVC inputs is sufficient to model the characteristics of populations of place fields, and choosing BVCs to fit a given cell's firing in one set of environments enables prediction of its firing in a novel environment (Hartley et al., 2000).

While the model works well for the initial firing of PCs in an environment, a slow experience-dependent divergence (or "remapping") of the representations of environments of different shape (Lever et al., 2002) indicates an additional role for synaptic plasticity. Because the PC representations in the models of Kali and Dayan (2000) and Gauzzelli et al. (2001) can be incrementally modulated by learning, these models can begin to be used to address the data showing varying degrees of remapping in different experiments, although it is not yet clear what changes will be necessary to provide an accurate model of the dynamics of these data.

## Navigation

How could the hippocampus be used to enable navigation? The simplest map-based strategies are based on defining a surface, over the whole environment, on which gradient ascent leads to the goal (see Reinforcement Learning). These strategies tend to have a problem, namely, that to build up the surface, the goal must be reached many times, from different points in the environment. A new surface must be computed if the goal is moved, and multiple goals, as in the eight-arm maze, cannot be handled. Learning in these models seems slower and more goal dependent than in rats, and they are unable to perform "latent learning" (e.g., in rats, exploration in the absence of goals improves subsequent navigation). Interestingly, the performance of these models improves somewhat when a spatially diffuse representation (like place fields) rather than a punctate representation is built up during exploration (see Foster, Morris, and Dayan, 2000). Some recent models that have related navigation to the action of individual cells in the hippocampus are described in the following section.

## Using the CA3 Recurrent Collaterals

A role in navigation was proposed for the CA3 recurrent collaterals (the axonal projections by which each CA3 PC contacts approximately 5% of the other CA3 PCs) by Muller and Stead (in Gluck, 1996). Given a model of LTP in which pre- and postsynaptic firing within a short time interval leads to a small increase in synaptic "strength," the synaptic strength of a connection between two CA3 PCs can come to depend on the proximity of their place fields. This is also the condition for the formation of a continuous attractor representation, discussed earlier. After brief exploration, the synaptic strengths represent distances along the paths taken by the rat. The model proposes that the rat navigates by moving through the place fields of the cells most strongly connected to the cells with fields at the current and destination positions.

Blum and Abbott (1996) propose a related model in which the temporal asymmetry of LTP (synaptic strengthening can occur when presynaptic activity precedes postsynaptic activity; see Temporal Dynamics of Biological Synapses) is invoked to strengthen recurrent connections from one PC to another if they fire in sequence along the rat's trajectory during exploration. If synaptic modification is also weighted by how soon after the pre- and postsynaptic activity the goal was reached, then the effect of the current collaterals is to shift the location represented by PC firing from the rat's current location toward the goal. This model proposes that the rat navigates by moving from the current location (e.g., read from CA1) to the shifted location in CA3.

Neither of these models makes clear how a direction of motion is actually generated, or if it would be able to generate a shortcut or detour. To build up a true distance metric in complex environments would take a long time and might best be achieved by reinforcement learning (see Foster et al., 2000). Clear experimental support for learned asymmetric connections between PCs comes from the observation that place fields tend to become elongated backward along a path during the first few times that a rat runs along it. Asymmetric recurrent connections have also been invoked to explain the phase precession effect. In these models the spread of activation from cells with fields early in a learned trajectory to cells with fields farther along the trajectory will, later in the $\theta$ cycle, cause a PC to fire before reaching the location on the path where its original (externally driven) place field was located. However, recent evidence indicates that blocking LTP blocks the development of asymmetric place fields but does not prevent the phase precession effect.

### *Local View Model*

In 1989, McNaughton proposed that the hippocampus functions as an associative memory, as follows. As the rat explores, it learns to associate each local view and movement made with the local view from the place visited as a result of the movement. Thus, routes through an environment are stored as a chain of local view/movement associations (see McNaughton and Nadel, 1990). The model is supported by the fact that, in some situations, PC firing depends on the rat's direction (and therefore its "local view"). Some major problems with this theory are the following: (1) simple route-following strategies appear to be the kind of navigation of which hippocampectomized rats are capable (see O'Keefe and Nadel, 1978); (2) it is difficult to know which particular route will lead to the desired goal: solving this problem leads one back to the reinforcement learning approach; (3) the model is not capable of more sophisticated navigation, such as taking shortcuts; and (4) in open fields, PC firing does not seem to depend on direction. It is also not clear whether this scheme is computationally feasible; see Sharp et al. (in Gluck, 1996) for a discussion of the limitations of simple associative nets in a related situation.

### Centroid Model

O'Keefe (1991) proposed a navigational mechanism in which environments are characterized by two parameters: the centroid and the slope of the positions of environmental cues, which can be used as the origin and 0° direction of a polar coordinate framework. The firing of a PC could represent the average position of a small number of cues (their minicentroid), while head direction cells could represent the translation vector between pairs of cues. The environmental centroid and slope are then found by averaging the minicentroids and slopes. It was proposed that single cells could represent two-dimensional vectors as phasors: taking the $\theta$ rhythm of the EEG as a clock cycle, the amplitude of firing would code for proximity, and the phase of firing within a clock cycle would code for angle. Thus, summing the output of several neurons results in vector addition, and subtraction is equivalent to a phase inversion followed by addition. Thus, the summed PC activity could provide a vector $\vec{v}(t)$ continually pointing to the centroid of the environment, so that, if the "goal" was encountered at time $t_g$, storing $\vec{v}(t_g)$ (outside the hippocampus) would enable the translation vector $\vec{v}(t) - \vec{v}(t_g)$ from the rat to the goal to be calculated whenever the rat wanted to go to the goal. The advantages of this system include the ability to perform shortcuts, while the disadvantages include the sensitivity of the slope (i.e., small movements of cues could lead to reversal of the coordinate system).

## Place Cell Firing and Navigation

The population vector model (see Burgess and O'Keefe in Gluck, 1996) is implemented at the neuronal level but also generates actual movement trajectories for the simulated rat, and aims to surmount some of the difficulties discussed in the previous section. It assumes that the output stage of the hippocampal system is groups of cells that represent the distance and direction from the rat of previously encountered goal locations as it moves around the environment, and that the input to the hippocampus is a set of "sensory cells" with tuning curve responses to the distance of cues from the rat. Each goal location is represented by the firing rates of a group of "goal cells" as a population vector (i.e., the vector sum of cells' preferred directions weighted by their firing rates; see Motor Cortex: Coding and Decoding of Directional Operations), and is used to guide the rat back to a goal location (Figure 2).

The network operates in a feedforward manner. During exploration, a representation of current location is learned in the intermediate layers, entorhinal cells (ECs), PCs, and subicular cells (SCs), which map the sensory input to the population vector output. A type of competitive learning governs the dynamics of the PCs and SCs, similar to that used by Sharp (see Sharp et al. in Gluck, 1996). Latent learning during exploration is expressed as the development of large firing fields in SCs that avoids the locality of information access problem (so that goal cell firing fields cover the whole environment; see later discussion). Upon encountering a goal location, learning by modification of connections to goal cells results in each goal cell having a conical firing rate map whose peak is displaced from the goal position in a particular absolute direction (the "preferred direction" for that cell), creating the appropriate population vector.

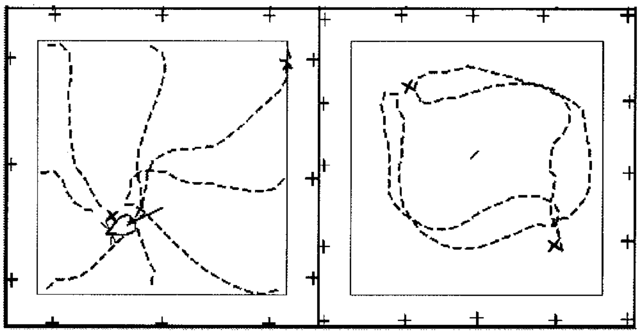

**Figure 2.** *Left*, Simulated trajectories from eight novel starting positions to a goal encountered after 30 seconds of exploration (at 60 cm/s) in a 135 × 135 cm$^2$ environment; the rat is shown to scale. *Right*, Simulated navigation between two goals with an "obstacle" in between. Cues are marked by +, goals by ×, and obstacles by /. (Adapted with permission from Burgess, N., Recce, M., and O'Keefe, J., 1994, *Neural Netw.*, 7:1065–1081.)

The model relies on the phase of firing of SCs (relative to $\theta$) being such that those firing late in a cycle have place fields centered ahead of the rat. This is achieved by making the phase of firing of ECs depend on the angle between the rat's heading direction and the direction of the centroid of the corresponding pair of cues (if the centroid is ahead, the cell fires at a late phase; if behind, it fires early). This property propagates throughout the PC and SC layers. When the rat is at the goal, the goal cell with preferred direction closest to the rat's heading direction receives a strong input, allowing connections to it to be switched on. This signal arrives at a late phase of the $\theta$ rhythm, and connections are switched on from those SCs active at that time (which tend to have firing rate maps that peak ahead of the rat). When a goal is encountered, the rat looks around in all directions, so that connections are switched on to goal cells representing each direction.

The direction and proximity (represented by the net firing of the group of goal cells) of interesting objects is the output of the hippocampal "map" and allows the simulated rat to navigate. A small number of obstacles can be avoided during navigation by subtracting the population vector of obstacle cells from the population vector of goal cells. The advantages of this model are that reasonable trajectories, including shortcuts, are performed after one visit to the goal following brief exploration, and its latent learning. The representation of directions is allocentric (e.g., north, south, etc.), and the necessary translation into left-right body turns is assumed to occur in parietal cortex (taking into account the current heading direction and the locations of obstacles) (see also Recce and Harris in Gluck, 1996; Arbib in Burgess et al., 1999; and Burgess et al., 2001).

Brown and Sharp (see Sharp et al. in Gluck, 1996) proposed a similar feedforward model of PC firing and navigation. In their model the output representation (in the nucleus accumbens) is of the egocentric directions (body turns) that lead to the goal. The association from PCs to turn cells is built up over many runs to a goal. As with Blum and Abbott's model, synaptic modification must be weighted by how soon the goal was reached after pre- and postsynaptic activity. This model would not show latent learning, and navigation would be strongly affected if stereotyped routes were used during learning. Foster et al. (2000) suggest that, in addition to a fast learning mechanism related to that used by Burgess and O'Keefe (in Gluck, 1996), a slower process of reinforcement learning might build up an explicit metric representation of the environment over the course of several trials.

## Discussion

We have reviewed several simple neuronal models of how the hippocampus takes in sensory information from environmental cues, turns it into a place cell representation of space, and uses this representation to support a spatial memory for where interesting things are located. Several of these models also consider the role of internal signals and recurrent connections in these processes. Together, these models represent some of the clearest examples of neuronal-level explanations of cognitive behavior. As noted earlier, how different environments are distinguished so that where things are in each environment can be remembered separately remains to be well understood, with data on remapping and the roles of the DG and the CA3 recurrent collaterals in providing an associative memory likely to play a part (see Marr, 1971; McNaughton and Nadel, 1990; Gluck, 1996; Burgess et al., 2001; Lever et al., 2002; and Associative Networks). A related issue is the problem of navigation in complex environments: how can local maps be patched together to guide behavior over long distances (see the "world graph" model of Arbib in Burgess et al., 1999).

With some progress made in understanding the role of the hippocampus in rat navigation, extending these models to include the role of the hippocampus in monkey and human behavior poses an exciting challenge. Recordings in monkey hippocampus that show neurons responding to the performance of actions in places (T. Ono and colleagues) or to the monkey looking in a particular place (see Rolls in Burgess et al., 1999) give an indication of how hippocampal function might generalize from rats to monkeys. In humans, there is evidence that the right hippocampus plays a role in navigation similar to the role it plays in the rat (see, e.g., Burgess et al., 1999, 2001). However, bilateral hippocampal damage in humans causes a general impairment in episodic memory. One idea relating the spatial and mnemonic roles is that a (nonverbal) episodic memory system could be formed in the right hippocampus by the addition of the human sense of linear time to the rat's spatial system; in the left hippocampus, the inputs have been supplemented by verbal information, producing memory for narratives (O'Keefe and Nadel, 1978). These issues, and the relationship between the hippocampus and the parietal cortex (generally considered the primary locus of spatial processing in primates) are explored further in Burgess et al. (1999). Finally, the need to impose an egocentric point of view on the allocentric representations in long-term memory provides a starting point for modeling the role of the hippocampus and the head-direction system in episodic retrieval (Burgess et al., 2001; see also Recce and Harris in Gluck, 1996).

# Hybrid Connectionist/Symbolic Systems

*Ron Sun*

## Introduction

There has been a great deal of research in integrating neural and symbolic processes from either cognitive or engineering standpoints. This research has led to the so-called hybrid systems. Hybrid connectionist-symbolic systems constitute a promising approach for developing more robust, more versatile, and more powerful systems for modeling cognitive processes as well as for engineering practical intelligent systems. The need for such models has been growing steadily. Events such as the 1992 AAAI Workshop on Integrating Neural and Symbolic Processes, the 1995 IJCAI Workshop on Connectionist-Symbolic Integration, and the 1998 NIPS Workshop on Hybrid Neural Symbolic Integration have brought to light many ideas, issues, controversies, and syntheses in this area. This article provides an overview and a categorization of hybrid systems.

The basic motivation for research on hybrid connectionist-symbolic systems can be summarized as follows:

- Cognitive processes are not homogeneous. A wide variety of representations and processes are likely employed. Some cognitive processes are best captured by symbolic models and others by connectionist models, just as both quantum mechanics and fluid dynamics are needed in order to model physical processes (Dreyfus and Dreyfus, 1987; Smolensky, 1988; Sun, 1994). The need for "pluralism" in cognitive modeling has led to the development of hybrid systems.
- The development of intelligent systems for practical applications would benefit greatly from a proper combination of different techniques, since currently no single technique can do everything successfully. Application domains range from loan approval to process control (Medsker, 1994).

The relative advantages of connectionist and symbolic models have been amply argued for (see, e.g., Feldman and Ballard in Waltz and Feldman, 1986; Smolensky, 1988; Sun, 1994; see also Artificial Intelligence and Neural Networks). Once the relative advantages of each model are understood, the computational benefit of the combination of models is relatively easy to justify. Naturally, one would want to take advantage of both types of models, and especially their synergy. Dreyfus and Dreyfus (1987), Sun and Bookman (1994), and Sun and Alexandre (1997) include detailed justifications for using hybrid systems.

For example, Sun and Peterson (1998) presented a model, CLARION, for capturing human skill learning that went from implicit knowledge to explicit knowledge. By integrating symbolic models (for capturing explicit knowledge) and subsymbolic models (for capturing implicit knowledge), CLARION more accurately captured human data and provided a new perspective on human skill learning.

## Issues

In developing hybrid connectionist-symbolic systems, we need to ask the following questions:

1. What types of problems are hybrid systems suitable for?
2. What are the relative advantages and disadvantages of each approach to hybridization?
3. How cognitively plausible is each approach?

Other important issues concern the architecture of hybrid systems and learning in these systems. Hybrid models likely involve a variety of different types of processes and representations, in both learning and performance. Therefore, multiple heterogeneous mechanisms interact in complex ways. Architectures, or ways of structuring these different components, thus occupy a prominent place in this area of research. Some architecture-related issues include the following:

- What type of architecture facilitates what type of process?
- Should hybrid architectures be modular or monolithic?
- For modular architectures, should different representations be used in different modules or should the same representation be used throughout?
- How does an investigator decide whether the representation of a particular part of an architecture should be symbolic, localist, or distributed?
- What are the appropriate representational techniques that bridge the heterogeneity of hybrid systems?
- How do representation and learning interact in hybrid systems? (In such systems, both aspects are likely to be more complex.)
- How should the different parts of a hybrid system be structured to achieve optimal results?

A second mattter of concern is the increased difficulty of learning. Although purely connectionist models, which are part of any hybrid system, excel in their learning abilities, hybridization makes it more difficult for a system to perform learning. Very generally, the difficulty hybrid systems have with learning comes from the symbolic side, and that difficulty dilutes the advantage that the connectionist parent brings to learning. Some of the learning-related issues include the following:

- What kind of learning can be carried out in each type of architecture?
- How can complex symbolic structures, such as rules, frames, and semantic networks, be learned in hybrid models?
- How can learning algorithms be developed for (usually knowledge-based) structured connectionist networks?
- What is the relationship among symbolic learning methods, knowledge acquisition methods, and connectionist (neural network) learning algorithms in hybrid systems?
- Can each type of architecture itself be developed with various combinations of the methods listed above?

Although many interesting hybrid models have been developed, a broader understanding of these hybrids awaits future work. Any model proposed should be examined for its cognitive plausibility, application potentials, and its strengths and weaknesses. Such an examination can lead to a synthesis of existing divergent approaches and can provide useful insight for further advances in this area. In the following sections we provide a brief categorization of different existing systems.

## Architectures and Representations

Various classification schemes of hybrid systems have been proposed (see, e.g., Sun and Alexandre, 1997). For now, we can divide hybrid systems into two broad categories: *single-module* architectures and *multimodule* architectures (Figure 1).

In single-module systems, the *representation* dimension can be of the following forms (Sun and Bookman, 1994): symbolic (as in conventional symbolic models), localist (with one distinct node for representing each concept; see, e.g., Lange and Dyer, 1989; Shastri and Ajjanagadde, 1993; Barnden in Sun and Bookman, 1994), or distributed (with a set of nonexclusive, overlapping nodes for representing each concept; see, e.g., Pollack, 1990; Miikkulainen in Sun and Bookman, 1994; Plate in Sun and Alexandre, 1997; Sperduti et al. in Sun and Alexandre, 1997; see also Connectionist and Symbolic Representations). Usually it is easier to incorporate prior knowledge into localist models, since their structures can be made to directly correspond to the structure of symbolic

1. **Single-module**
   - Representation: Symbolic, localist, distributed
   - Mapping: Direct translational, transformational
2. **Heterogeneous multimodule**
   - Components: Localist + distributed, symbolic + connectionist
   - Coupling: Loosely coupled, tightly coupled
   - Granularity: Coarse-grained, fine-grained
3. **Homogeneous multimodule**
   - Granularity: Coarse-grained, fine-grained

**Figure 1.** Classification of hybrid systems.

knowledge. (For more details on localist models, see STRUCTURED CONNECTIONIST MODELS). On the other hand, connectionist learning usually leads to distributed representation, as in the case of backpropagation. Distributed representation has some unique and useful properties. (For more details on distributed models, see PERCEPTRONS, ADALINES, AND BACKPROPAGATION and COMPOSITIONALITY IN NEURAL SYSTEMS.)

A question that may naturally arise is: Why should we use connectionist models (especially localist ones) for symbol processing, instead of symbolic models? Possible reasons for using connectionist models may include the following. (1) Connectionist models are believed to be a more apt framework for capturing a wide variety of cognitive processes (Waltz and Feldman, 1986; Sun, 1994). (2) Some inherent processing characteristics of connectionist models (such as similarity-based processing) make them more suitable for certain tasks (especially in cognitive modeling of human reasoning and learning). (3) Learning processes may be more easily developed in connectionist models, using, e.g., gradient descent and its various approximations, the Expectation-Maximization algorithm, the Baum-Welch algorithm and so on.

For multimodule systems, we can distinguish between *homogeneous* and *heterogeneous* systems. *Homogeneous* systems are similar to single-module systems except that they contain several replicated copies of the same structure, each of which can be used for processing the same set of inputs, to provide redundancy for various reasons. For example, there may be a set of competing experts for the same domain, each of which may vote for a particular solution. Or, each module can be specialized (with regard to content) for processing a particular type of input. For example, there may be different experts with the same structure but with different content knowledge for dealing with different situations.

*Heterogeneous* multimodule systems are more interesting. This category is the most hybrid of hybrid systems; CONSYDERR (Sun, 1994), SOAR/ECHO (Johnson et al. in Sun and Alexandre, 1997), and SCREEN (Weber and Wermter in Wermter, Riloff, and Scheler, 1996) belong to this category. A variety of distinctions can be made here. The first distinction has to do with *representations* of constituent modules. In heterogeneous multimodule systems, there can be different combinations of different types of constituent modules. For example, a system can be a combination of localist modules and distributed modules (e.g., CONSYDERR: Sun, 1994), or it can be a combination of symbolic modules and connectionist modules (either localist or distributed; e.g., SCRUFFY: Hendler in Barnden and Pollack, 1991). Some of these combinations can be traced to the ideas of Smolensky (1988), who argued for the dichotomy of conceptual and subconceptual processing, and Dreyfus and Dreyfus (1987), who put forward the distinction between analytical thinking and intuitive thinking.

A second distinction that can be made among heterogeneous multimodule systems has to do with the *coupling* of modules. A set of modules can be either loosely coupled or tightly coupled (Medsker, 1994). In loosely coupled situations, modules communicate with each other, primarily through message passing, shared memory locations, or shared files; an example is SCRUFFY (see Hendler in Barnden and Pollack, 1991). Loose coupling enables some loose forms of cooperation among modules. An example of cooperation is pre- and postprocessing versus main processing: while one or more modules take care of pre- and postprocessing, such as transforming input data or rectifying output data, a main module focuses on the main part of the task. Commonly, pre- and postprocessing are done using a neural network, while the main task is accomplished through the use of symbolic methods. Another form of cooperation is a master-slave relationship: while one module maintains control of the task at hand, it can signal other modules to handle some specific aspects of the task. For example, a symbolic expert system, as part of a rule, may invoke a neural network to perform a specific classification or decision making. Yet another form of cooperation is the equal partnership of multiple modules. In this form, the modules—the equal partners—may consist of (1) complementary processes, such as in SOAR/ECHO (Johnson et al. in Sun and Alexandre, 1997) or (2) multiple functionally equivalent but structurally and representationally different processes, such as in CLARION (Sun and Peterson, 1998); or (3) they may consist of multiple differentially specialized and heterogeneously represented experts, each of which constitutes an equal partner in accomplishing a task.

In tightly coupled systems, on the other hand, the constituent modules interact through multiple channels or may even have node-to-node connections across two modules, as in CONSYDERR (Sun, 1994), in which each node in one module is connected to a corresponding node in the other module. Various forms of cooperation among modules exist, in ways similar to loosely coupled systems.

Yet another distinction that can be made in multimodule systems has to do with the *granularity* of modules in such systems: they can be either coarse-grained or fine-grained. At one end of the spectrum, a multimodule system can be very coarse-grained, so that it contains only two or three modules (such as the examples cited above). At the other end, a system can be so fine-grained that it can contain numerous modules. In an extremely fine-grained system, each tiny module may contain both a (simple and tiny) symbolic component and a (simple and tiny) connectionist component, as exemplified by Kokinov's model or Stevenson's model (see their chapters in Sun and Alexandre, 1997). The computational advantage of such a microlevel integration is that a vast number of simple "processors" can exist that make up an efficient, massively parallel system.

## Learning

Learning, which can include learning content (i.e., knowledge) in a certain architecture or learning and developing an architecture itself, is a fundamental issue, and one that is clearly difficult. Learning is necessary not just because it is a fundamental aspect of cognition, but also because it is indispensable if hybrid systems are ever to be scaled up. Earlier work on hybrid models focused mostly on representational issues (see, e.g., Sun and Bookman, 1994). Such a focus might be justified at an early stage of research, since before we learn complex symbolic representations in hybrid models, we need to understand ways of representing complex symbolic structures in the first place. Over the years, some progress on learning has been made. While some have tried to extend neural learning algorithms (such as backpropagation) to learning complex symbolic representations (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION), others have instead incorporated symbolic learning methods into hybrid models.

Let us look at a few models that incorporated symbolic learning methods. Sun and Peterson (1998) presented the two-module model CLARION for sequential decision tasks. In this model, symbolic knowledge is extracted on-line from a reinforcement learning neural network and in turn is used to speed up neural learning and to facilitate transfer of learned knowledge. The work showed not only the synergy between neural and symbolic learning, but also that symbolic knowledge can be learned autonomously on-line, from subsymbolic knowledge, which is essential for developing autonomous agents.

In a similar vein, Johnson et al. (in Sun and Alexandre, 1997) developed a two-module model SOAR/ECHO for abductive reasoning through a combination of symbolic and connectionist learning (symbolic explanation-based learning in SOAR and neural learning in ECHO).

Furthermore, Thrun (1996) developed a method that integrates explanation-based learning and neural learning in a connectionist framework. In his model there is no separate symbolic and connectionist module (thus the model is a single-module one). The model uses initial domain knowledge (in the form of a trained neural network) and an explanation-based learning process to learn a complete domain theory from the initial knowledge (utilizing "explanations" based on the slopes of activation functions of the initial neural network).

There are a variety of other proposals as well (including rule extraction or insertion algorithms). Future advances in hybrid systems are likely to depend heavily on the development of new learning methods for hybrid systems and on the integration of learning and complex symbolic representations. As mentioned earlier, symbolic representation and reasoning may well emerge from subsymbolic processes through learning, and thus an intimate, synergistic combination of symbolic and subsymbolic learning is desirable and should be further pursued.

## Application Domains

To see the breadth of the hybrid systems research, let us look at a brief summary of applications.

### *Cognitive Science*

The development of hybrid systems covers most of the traditional topics in cognitive science, among them the following:

- *Reasoning*, which includes work on hybrid models for logical reasoning, case-based reasoning, and schema-based reasoning. Among existing work, Shastri and Ajjanagadde (1993) took a logic-based approach, while Barnden (in Sun and Bookman, 1994) took a case-based approach. Lange and Dyer (1989) performed reasoning based on schemas (frames). Sun (1994) combined logic-based, case-based, and schema-based approaches. These models went beyond existing nonhybrid models in capturing complex cognitive processes involved.
- *Memory*, which is an area where many models, including hybrid models, are being developed by the psychology community.
- *Classification and categorization*, which involve a variety of hybrid models, conceptual or computational (see CONCEPT LEARNING). These hybrid models often more accurately capture human data than their nonhybrid counterparts.
- *Skill learning*, including, e.g., Sun and Peterson (1998) and Johnson et al. (in Sun and Alexandre, 1997). These models have some important advantages. For example, Sun and Peterson (1998) better explained a type of skill learning than any existing nonhybrid models.
- *Word sense disambiguation*, including work by Lange and Dyer (1989), Bookman (in Sun and Bookman, 1994), and Wermter et al. (1996).
- *Natural language processing* in general, including both syntactic and semantic processing. There are many existing models. (See, e.g., Miikkulainen's and Dyer's chapters in Sun and Bookman, 1994, and all relevant chapters in Wermter et al., 1996.)

These hybrid systems use the synergy between connectionist and symbolic processes to more accurately capture human cognitive processes, either quantitatively or qualitatively.

### *Industrial Applications*

Hybrid systems of various sorts have a large variety of practical applications. Because they combine characteristics of connectionist and symbolic models, hybrid systems are often able to perform better at various tasks. For a summary of early work in this area, see Medsker (1994). See also the application-oriented chapters in Sun and Alexandre (1997), and recent issues of various *IEEE Transactions*.

## Discussion

Progress in hybrid systems is occurring steadily, if slowly. Because of the many advantages of hybrid systems, there is reason to expect further significant progress in this area. A number of possibilities exist for architectures, representations, and learning. This abundance suggests exciting possibilities in theoretical advances and in applications.

A distillation of the various extant proposals suggests two different approaches, which can be characterized as (1) incorporating symbolic mechanisms and connectionist models, and (2) stretching connectionist models all the way. In the first approach (see, e.g., Hendler in Barnden and Pollack, 1991; Sun, 1994; Wermter et al., 1996), the representation and learning techniques from both symbolic processing models and neural network models are used to tackle problems that neither type of model handles very well alone. Such problems include modeling cognition, which requires dealing with a variety of cognitive capacities. Several researchers (e.g., Smolensky, 1988; Dreyfus and Dreyfus, 1987) have argued that cognition is better captured with a combination of symbolic and neural components. The second approach, stretching connectionist models to their limit (e.g., Pollack, 1990; Giles and Gori, 1998), is predicated on the assumption that one can perform complex symbolic processing using neural networks alone, with, for example, tensor products, RAAM, or holographic models (see relevant chapters in Sun and Alexandre, 1997). Thus far, both approaches have flourished.

Despite the diversity of approaches, there is clearly an underlying theme, namely, the bringing together of symbolic and connectionist models to achieve the synthesis and synergy of two seemingly different paradigms. The various proposed methods, models, and architectures reflect the common belief that connectionist and symbolic methods can be usefully combined and integrated, and that such integration may lead to significant advances in our understanding of cognition.

# Identification and Control

*Kumpati S. Narendra*

## Introduction

System characterization and system identification are fundamental problems in systems theory. The problem of *characterization* is concerned with the mathematical representation of a system as an operator $S$ which maps input signals into output signals. The problem of *identification* is to approximate $S$ using an identification model, along with the measured inputs and outputs to the system. In the past five decades, systems theory has made major advances through a combination of mathematics, modeling, computation, and experimentation. At the same time, there has also been an explosive growth in pure and applied research related to neural networks. This article briefly explores how the concepts and methods developed in the two areas are being combined to generate general principles for the identification and control of complex nonlinear dynamical systems.

Systems can be classified as either continuous time (in which all variables of the systems are defined for all values of time $t \in R$) or discrete time (in which they are defined at integer values, i.e., $t = 0, 1, 2, \ldots$). A very general method of representing multi-input, multi-output continuous-time and discrete-time dynamical systems is by using vector differential and difference equations, as follows:

$$\begin{array}{cc} \textit{Continuous-Time Systems} & \textit{Discrete-Time Systems} \\ \dot{x}(t) = f[x(t), u(t)] & x(k+1) = f[x(k), u(k)] \\ y(t) = h[x(t)] & y(k) = h[x(k)] \end{array} \tag{1}$$

where $u(t)(u(k)) \in R^r$ is an input vector, $x(t)(x(k)) \in R^n$ is the state vector, and $y(t)(y(k)) \in R^m$ is an output vector. From Equation 1 it follows that given the state at time $t_0(k_0)$ and the input (input sequence) for $t(k) \geq t_0(k_0)$, the corresponding state and output can be determined. Equation 1 emphasizes the central role played by the state of the system, since, if the state at time $t_0$ is known, the past history of the system is not relevant, and the output is determined uniquely by the input from time $t_0$.

From the very beginning it has been realized by systems theorists that most real dynamical systems are nonlinear. However, linearizations of such systems around equilibrium states yield linear models that are mathematically tractable. For example, the linearization of Equation 1 around an equilibrium state can be described by the equations:

$$\begin{array}{ll} \dot{x}(t) = Ax(t) + Bu(t) & x(k+1) = Ax(k) + Bu(k) \\ y(t) = Cx(t) & y(k) = Cx(k) \end{array} \tag{2}$$

where $A$, $B$, and $C$ are constant $n \times n$, $n \times r$, and $m \times n$ matrices, respectively. (In this article, we confine our attention to nonlinear discrete-time dynamical systems of the form given in Equation 1, and to their linearization, given in Equation 2.) The systems given by Equation 2 are said to be time invariant and are completely parameterized by the triple $A$, $B$, $C$. The analytical tractability of the above linear models can be attributed to the fact that the superposition principle applies to them. If any two input sequences $\{u_1(k)\}$ and $\{u_2(k)\}$, when applied to the system at rest, result in output sequences $\{y_1(k)\}$ and $\{y_2(k)\}$, respectively, an input sequence $\{\alpha u_1(k) + \beta u_2(k)\}$ for $\alpha, \beta \in R$ will result in an output sequence $\{\alpha y_1(k) + \beta y_2(k)\}$. Further, in many engineering problems it has been found that most nonlinear systems can be approximated satisfactorily by such linear models in their normal ranges of operation, and this has made the latter attractive in practical contexts as well. It is this combined effect of ease of analysis and practical applicability that accounts for the great success of linear models and has made them the subject of intense study for more than four decades.

The objective of control is to influence the behavior of dynamical system in some desired fashion. The latter includes maintaining the outputs of systems at constant values (regulation) or forcing them to follow prescribed time functions (tracking). Maintaining the altitude of an aircraft or the glucose level in the blood at a constant value are simple examples of regulation; controlling a rocket to follow a given trajectory is a simple example of tracking. For the same reasons given earlier in the context of system representation, the best-developed part of control theory deals with linear time-invariant systems, for which design methods are currently well established.

The demands of a rapidly advancing technology for faster and more accurate controllers have always had a strong influence on the progress of control theory. Applications in new technologies such as robotics, manufacturing, space technology, and medical automation, as well as those in older technologies such as process control and aircraft control, are providing a wealth of new problems in which nonlinearities and uncertainties play a major role and linear approximations are no longer satisfactory. To cope with such problems, research on both identification and control using neural networks has been under way. This article describes why neural networks are attractive in this context, as well as the theoretical assumptions that have to be made when such networks are used as identifiers and controllers.

## Artificial Neural Networks

The term artificial neural network (ANN) has come to mean any computing architecture that consists of massively parallel interconnections of simple computing elements. From a systems-theoretic point of view, it can be considered as a conveniently parameterized and easily implementable class of nonlinear maps. In the early 1980s, elaborate ANNs were constructed and empirically demonstrated (using simulation studies) to approximate quite well nearly all functions encountered in practical applications. However, only after numerous authors had demonstrated that such networks are capable of universal approximation in a very precise and satisfactory sense did their study leave its empirical origins to become a mathematical discipline.

Even as these theoretical developments were in progress, empirical investigations continued, and neural networks were used not only for function approximation but also in pattern recognition and optimization problems. In 1990, Narendra and Parthasarathy suggested that feedforward neural networks could also be used as components in feedback systems. The approximation capabilities of such networks could be used in the design of both identifiers and controllers, and their analysis and synthesis could be carried out within a systems-theoretic framework. Following the publication of Narendra and Parthasarathy's paper, there was a frenzy of activity in the area of neural network–based identification and control, and a profusion of methods was suggested for controlling nonlinear systems. Although much of the research was heuristic, it provided empirical evidence that neural networks could outperform traditional methods. However, it soon became evident that more formal methods would be needed to quantitatively assess the scope and limitations of neural network–based control.

### *MLP and RBFN Networks*

The most commonly used network structures for approximating nonlinear maps are the multilayer feedforward networks, also known as the multilayer perceptron (MLP) and the radial basis function network (RBFN). These two classes of neural networks (which are described in greater detail in other articles in this *Handbook*) form the principal building blocks of the dynamical systems considered in the following sections. The $n$-layer MLP with input $u$ and output $y$ is described by the equation

$$\Gamma[w_n\Gamma[w_{n-1} \cdots\cdot \Gamma[w_1 u + b_1] + \cdots\cdot + b_{n-1}] + b_n] = y \tag{3}$$

where $w_i$ is a weight matrix in the $i$th layer and the vectors $b_i$ represent the threshold value for each node in the $i$th layer. $\Gamma[\cdot]$ is a nonlinear operator with $\Gamma(x) = [\gamma_1(x), \gamma_2(x), \ldots, \gamma_n(x)]$, where $\gamma_i(\cdot)$ is a smooth activation function (generally a sigmoid). An alternative to the MLP is the RBFN, which can be considered a two-layer network in which the hidden layer performs a nonlinear transformation on the inputs (see Radial Basis Function Networks). The output layer then combines the outputs of the first layer linearly, so that the output is described by the equation

$$y = f(u) = \sum_{i=1}^{N} w_i R_i(u) + w_0 \tag{4}$$

The functions $R_i$ are termed radial basis functions, and typically these are Gaussian functions.

In both networks, the parameters (weights) are adjusted to decrease the error between the output of the function to be approximated and that of the network, along the negative gradient. Numerous algorithms have been proposed to improve the convergence properties of MLP networks, but invariably all of them are modifications of the gradient approach. When RBFNs are used to approximate an unknown function based only on inputs and outputs, the convergence is substantially faster, since the output error is linear in the parameters.

A question that naturally arises is why neural networks should be preferred to other methods for approximating nonlinear functions in identifiers and controllers. The principal reason, already referred to, is the universal approximating capability of such networks. Empirical evidence is also available that they are fault tolerant and robust in the presence of noise. The fact that they are implementable in hardware makes them attractive in practical applications. However, a convincing theoretical argument was provided by Barron (1993), who showed that the effectiveness of MLPs (in which the output depends nonlinearly on the weights) for approximating a general class of nonlinear functions increases with the dimension of the input space, as compared to networks in which the output depends linearly on the weights. Since the dimension of the input vector used for identification and control in complex dynamical systems is generally quite high, the advantages assured by Barron are very attractive. It must be added here that other authors have taken issue with Barron on this matter by suggesting that RBFNs can enjoy the same advantages if the characteristics of the nonlinear activation functions used in them are also varied.

## Identification

If an ANN is to be used for identifying a nonlinear dynamical system, the existence of a dynamic nonlinear map relating the input and output spaces must first be established. In many practical applications, identification has to be carried out using only observed input-output data. In such cases, it is tacitly assumed that there is an underlying nonlinear dynamic map relating the two. An example of such a map is given by the state equation given in Equation 1. The objective would then be to identify the maps $f$ and $h$. If measurements on the state vector $x(k)$ of the unknown system (generally referred to as the *plant*) are available, a model of the nonlinear system can be set up as

$$\begin{aligned} \hat{x}(k+1) &= N_f[x(k), u(k)] \\ \hat{y}(k) &= N_h[x(k)] \end{aligned} \tag{5}$$

where $N_f$ and $N_h$ are neural networks approximating $f$ and $h$, respectively. Since $x(k)$ and $u(k)$ are accessible, standard approximation methods may be used to adjust the parameters of $N_f$ and $N_h$ based on the errors $\tilde{x}(k) = \hat{x}(k) - x(k)$ and $\tilde{y}(k) = \hat{y}(k) - y(k)$, respectively. It must be noted that the state/output of the system $x(k)/y(k)$, rather than $\hat{x}(k)/\hat{y}(k)$ of the network, is used in the right-hand side of the models given in Equation 5. This is generally referred to as a series-parallel model. This makes the identification procedure substantially simpler and hence practically attractive. However, a more realistic model would have the form:

$$\begin{aligned} \hat{x}(k+1) &= N_f[\hat{x}(k), u(k)] \\ \hat{y}(k) &= N_h[\hat{x}(k)] \end{aligned} \tag{6}$$

Since the estimated state of the system is used to determine $\hat{y}(k)$, we have a feedback system in this case. This implies that the model can be unstable. This model is also referred to as a recurrent network. Determining the gradient of the performance index with respect to the adjustable parameters of the network is no longer simple. Static backpropagation, used in Equation 5, has to be replaced by dynamic backpropagation, which is computationally intensive. A network described by Equation 6 is referred to as a recurrent network, and the stability properties of such networks are not well understood. Hence, the series-parallel networks described by Equation 5 are preferred in practice.

## The Nonlinear Autoregressive Moving Average (NARMA) Model

The identification problem using a state representation becomes substantially more complex when the state variables of the plant are unknown, and identification has to be carried out using only input-output data. It is well known that even in the linear case, a unique parameterization of the plant no longer exists. The success of nonlinear identification techniques therefore strongly depends on the specific parameterizations used.

For a single-input single-output (SISO) linear time-invariant system described by the state Equations 2, it can be shown that, if the system is observable, the input and output are related by the equation

$$y(k+1) = \sum_{i=0}^{n-1} \alpha_i y(k-i) + \sum_{j=0}^{n-1} \beta_j u(k-j) \qquad (7)$$

where $\alpha_i$ and $\beta_j (i, j = 0, 1, \ldots, n-1)$ are the parameters of the system. Equation 7 is known as the autoregressive moving average (ARMA) representation of the given plant and expresses the output at any instant as a linear combination of the past $n$ values of the input and the $n$ values of the output. The ARMA representation has found extensive application in linear systems theory.

Motivated by the ARMA model in the linear case, efforts were made in the early 1990s to suggest models for nonlinear system identification. If the linearized system around the equilibrium state of the system in Equation 1 is observable, it was shown (Levin and Narendra, 1993), using the implicit function theorem, that the state $x(k)$ and hence the output $y(k)$ can be determined using $n$ past values of the input and output, as follows:

$$x(k) = G[y(k), y(k-1), \ldots, y(k-n+1), u(k), \ldots, u(k-n+1)] \qquad (8)$$

and

$$y(k) = F[y(k), y(k-1), \ldots, y(k-n+1), u(k), \ldots, u(k-n+1)] \qquad (9)$$

where $G$ and $F$ are functions mapping $R^m \times R^{2n}$ into $R^n$ and $R$, respectively. Equation 9 is an exact mathematical representation of the given system (from Equation 1) in a neighborhood of the equilibrium state. It is referred to as the NARMA model and provides a rigorous mathematical basis for the synthesis of identification models using input-output data.

As mentioned in the Introduction to this article, once the existence of a nonlinear dynamic map from the input space to the output space is established, a neural network can be used to approximate the map using available data. In the present case, identification reduces to the approximation of the function $F$ in Equation 9. A neural network model of the system is then given by

$$\hat{y}(k+1) = N_F[y(k), y(k-1), \ldots, y(k-n+1), u(k), \ldots, u(k-n+1)] \qquad (10)$$

where $N_F$ is a neural network whose $2n$ inputs are the past $n$ values of the input and output, respectively. The parameters of the network are adjusted to minimize the error $e_i(k) = \hat{y}(k) - y(k)$, between the output of the network and the output of the given plant. Equation 10, approximating the NARMA model, has been used extensively for the practical identification of nonlinear systems using neural networks.

### *Comments*

The NARMA representation given in Equation 9 and the neural network approximation given in Equation 10 raise numerous theoretical and practical questions.

From a theoretical point of view, one is interested in relating the number of past values of the output and the input needed with the dimension of the state space $n$ of the system (in Equation 9 this is chosen to be $n$). Also, Equations 9 and 10 describe the evolution of two dynamical systems, and one must establish in what sense the proximity of $F$ and $N$ implies the proximity of the trajectories of the two systems.

From a practical point of view, the choice of the number of nodes and the number of layers in the network to approximate $F$ is important. However, at the present time, this is very much of an art, and the values are chosen by trial and error. There are also numerous gradient-based methods for the adjustment of parameters, but the performance criterion varies from design to design. A criterion function that has proved effective in applications is one in which the output errors as well as the incremental inputs are weighted over a finite interval of time (i.e., $\Sigma_k[e_i^2(k) + (u(k) - u(k-1))^2]$).

Recently, efforts have been made to approximate models of Equation 10 in such a manner that the input $u(k)$ appears linearly. They have the following form:

$$\hat{y}(k+1) = F_0[y(k), y(k-1), \ldots, y(k-n+1)] + \sum_{j=0}^{n-1} F_j[y(k), \ldots, y(k-n+1)]u(k-j) \qquad (11)$$

The need for such models is discussed in the following sections in the context of control.

## Control

Two distinct classes of problems that are encountered with increasing frequency in industry deserve special attention from the point of view of both the control theorist and the practicing engineer. The first is encountered in the context of systems that are already in existence and that were designed satisfactorily in a small neighborhood of the equilibrium in the state space. In this domain, linear models are used to describe the systems, and linear controllers based on them are found to perform satisfactorily. However, because of the demands of technology, the systems are required to operate in larger regions in the state space, where their characteristics are distinctly nonlinear. Both the identification model and the linear controller are then found to be inadequate to achieve the desired level of performance.

In the second class of problems, mathematical models of the plant (or process) to be controlled cannot be developed from first principles, but the process is known to be distinctly nonlinear. A finite amount of stored input-output data of the plant is available from which an adequate model of the process and a suitable controller are to be determined to satisfy stringent performance criteria.

For both classes of problems stated above, numerous decisions have to be made concerning the representation to be used, the prior information to be obtained to ensure the existence of a controller, the architecture of the identifier and controller, and the algorithms to be used in training their parameters. In the next sections we address some of the theoretical and practical questions that arise in neurocontrol.

## Regulation and Tracking

In the Introduction we noted that regulation and tracking are two control problems of general interest. Regulation involves the generalizations of a control input that stabilize the system around an equilibrium state. In the tracking problem, a reference output $y^*(k)$ is specified and the output $y(k)$ of the plant is to approximate it in some sense, e.g., lim $\sup_{k \to \infty} \|y(k) - y^*(k)\| \leq \varepsilon$. For theoretical analysis, $\varepsilon$ is assumed to be zero, so that asymptotic tracking is achieved.

In the following, we assume that linearization of the system around the equilibrium state is both controllable and observable. Controllability implies that the state of the system can be transfered to any other state by the application of a suitable control input. Observability implies that the state of the system can be determined by observing the output over a finite interval of time. If the linearized system is controllable and observable, it follows that the nonlinear system is also locally controllable and observable. Almost all control systems in operation that were designed using linear control principles satisfy the above conditions. This conclusion, in turn, implies that such systems can be controlled as described in the next section, even in regions where their dynamics are nonlinear.

## The Identification and Control Procedure

The process of identifying and controlling a plant using neural networks can be summarized as a three-step procedure. In the first step, a neural network is used to approximate the behavior of the given system. In the second step, after a sufficiently accurate model has been obtained, a neural network is designed to control the model (rather than the plant) to achieve the desired performance. In the third step, the same controller is used to control the system. If the performance does not meet specifications, the common procedure is to increase the size(s) of the neural networks used for identification and control, and repeat the entire procedure. If both identification and control are carried out concurrently, we have an adaptive system.

We first consider the dynamical system described by the state Equation 1, in which the entire state vector $x(k)$ is accessible, and attempt to regulate it around the origin. If the linearized system around the origin is controllable, it has been shown (Levin and Narendra, 1993) that $u = g(x)$ (i.e., nonlinear state feedback exists) such that the equilibrium state is stable. Hence, in principle, a neural network can be used to approximate $g(x)$. If $u(k) = N_c[x(k)]$, the overall feedback system is described by the equation

$$x(k + 1) = f[x(k), N_c[x(k)]] \tag{12}$$

The parameters of the neural network are then adjusted using dynamic back propagation. In Levin and Narendra (1993), different methods are described for accomplishing this, based on the measured state $x(k)$. Simulation results indicate that this method is far superior to that obtained using linear theory.

## Tracking

The problem of tracking a reference signal when the dynamics of the plant are unknown poses a real challenge to the control engineer. In this case, the principal question that arises is whether an input $u(\cdot)$ exists so that the output of the plant can asymptotically follow the reference input. Assuming that such an input exists, the next problem is to determine a controller structure as well as the inputs to the controller so that the output of the controller is the desired input to the plant.

Various authors have investigated the application of neural networks for tracking. In the pioneering work of Widrow (e.g., Widrow and Wallach, 1996), the nonlinear plant itself is used in place of the identification model while training the controller. In the work of Jordan (1990) and Kawato (1990), inverse modeling using neural networks is used for solving inverse kinematics and inverse dynamics problems. Qin, Su, and McAvoy (1992) have used a similar methodology for process control. More recently, Cabrera and Narendra (1999) studied in detail the conditions that a plant must satisfy for a bounded control to exist in order to achieve asymptotic tracking of any specified bounded signal in the region of interest. In the following paragraphs, we summarize the results contained in the latter that are relevant to the present discussion.

The relative degree and zero dynamics of a nonlinear discrete-time system are important concepts in attempting to determine the control input to a dynamical system to track a desired output. The definitions of relative degree and zero dynamics have been discussed by numerous authors, but the analytical issues involved are for the expert. In qualitative terms, a relative degree $d$ implies that for any arbitrary initial condition in a neighborhood of the origin, the effect of a control input $u(k)$ is felt only at time $k + d$. Hence, for the purposes of our discussion here, the *relative degree* of the system can be defined as the delay of the system. The *zero dynamics* of the system describe the behavior of the system when the input and the initial conditions are jointly chosen in such a way that the output is identically zero. One of the principal results given by Cabrera and Narendra (1999) is that if the relative degree of a dynamic system is well defined and its zero dynamics are asymptotically stable, the asymptotic tracking problem can be solved using an analytic controller of the form

$$\begin{aligned} u(k) = \gamma[&y(k), y(k-1), \ldots, y(k-n+1), u(k-1), \ldots, \\ &u(k-n+1), y^*(k), y^*(k+1) \ldots y^*(k+d)] \end{aligned} \tag{13}$$

where $y^*(k)$ is the desired output at time $k$, and $d$ is the relative degree of the system. In some cases only the reference input $y^*(k + d)$ may be needed at time $k$.

The above results have great practical significance, since the existence of a map $\gamma$ implies that a neural network $N_\gamma$ can be used to approximate it.

## Practical Considerations

Numerous difficulties are encountered when a neural network is used to control a dynamical system. These can be briefly listed as follows:

1. Since the neural network is in a feedback loop with the controlled plant, dynamic rather than static backpropagation is needed to adjust the parameters along the negative gradient. However, in practice, only static backpropagation is used.
2. From both theoretical and practical viewpoints, the best approach in the author's experience is to use the approximate model of Equation 11, in which the control input $u(k)$ can be computed algebraically. To improve the performance further, the parameters of an additional neural network may be adjusted, as in point 1.
3. Because of the complexity of the structure of an MLP neural network and the nonlinear dependence of its map on its parameter values, stability analysis of the resulting system is always very difficult and quite often intractable. However, many interesting results have been obtained by Sanner and Slotine (1992), Jagannathan and Lewis (1996), Polycarpou (1996), and Chen and Khalil (1995), most of which are applicable in specific contexts.
4. In practice, the three-step procedure described earlier is used in industrial problems, to avoid adaptation on-line and the ensuing stability problems. However, if the feedback system is stable, on-line adaptive adjustments can improve performance significantly, provided such adjustments are small.

## Conclusions

Numerous control methods have been suggested by different authors over the past decade for the practical control of dynamical systems using neural networks. These methods include supervised control, inverse control, internal model control, and model reference control. In many cases, the authors have attempted to realize identifiers and controllers as static maps using neural networks both to improve convergence and to simplify analysis. In many practical applications, such methods have performed satisfactorily. However, to our knowledge, the identification and control models described in this article are the only ones that have been rigorously derived using theoretical results from nonlinear and adaptive control.

Most of the current interest in the application of neural networks is in static systems, particularly in pattern recognition, where they have been very successful. The need for the control of nonlinear dynamical systems is, however, increasing in new technologies in which nonlinearities, uncertainties, and complexity play a major role. Neural networks are particularly attractive in such situations. However, the results obtained in nonlinear control theory, the concepts and structures provided by linear adaptive control, and the approximating capabilities of neural networks have to be judiciously combined to deal with the control problems that arise in complex dynamical systems (Chen and Narendra, 2001; Jagannathan, 2001).

The presence of a feedback loop in a system implies that stability issues have to be addressed in their design. At present, the neurocontrol problems being attempted in industry are those in which improving performance rather than ensuring stability is the main consideration. However, as faster response is required in industrial applications, stability questions are bound to become more important.

Practical systems design is driven by both cost and operational requirements. Anyone familiar with industrial problems is only too aware that bridging the gap between theoretical principles, on the one hand, and development, testing, and implementation on the other is a slow process. On the basis of theoretical advances made thus far, and the great successes that have already been reported in some cases, there is every reason to believe that neural network–based control systems will be developed in many industries in the next decade.

# Imaging the Grammatical Brain

*Yosef Grodzinsky*

## Introduction

What do students of language do? Linguists characterize linguistic knowledge; psycholinguists model the algorithms that implement this knowledge in speaking and understanding; and neurolinguists are interested in the neural mechanisms that realize these algorithms. One can imagine a research program in which these perspectives cohere, attempting to understand knowledge of language, its acquisition, processing mechanisms, and neural computation. This is the neurobiological project that attempts to characterize human language. This chapter describes attempts to reconstruct an image of language mechanisms through the analysis of lesion data and functional neuroimaging. I argue that a correct choice of the unit for functional analysis of behavior leads to a clearer image of the linguistic brain.

Innovative technologies have recently made the goal of a coherent, focused picture of the neural basis of language closer than ever before. Linguistic theory provides a sophisticated technology for the analysis of the linguistic signal; instruments that measure neural activity have become less invasive, with high resolution in both time and space; experimental ingenuity may lead to new solutions to old (and new) problems. This research enterprise must thus define brain/language relations in the form of an equation, both sides of which contain complex terms: On the one side there is linguistic behavior, described in the best theoretical vocabulary one can find, and on the other side there are brain mechanisms, interpreted by whatever techniques neuroscience can offer. The relation between the two sides is also extremely complex, and it is here that disagreements arise. Some neurolinguists study words, some study sentences, and others investigate not linguistic units, but activities, such as speaking, listening, reading, and writing. It is quite difficult to find a unit of analysis on which a consensus (one that would hopefully reflect understanding) exists. In this respect, the study of language is unique. Compare it to the study of the visual system—an uncontroversial success story. Debates in vision exist, yet none regarding the basic unit of analysis. In low-level vision, lines are lines, angles are angles, and edges are edges—elemental parts that quite clearly play a constitutive role in forming our visual experience. Likewise, in visual object recognition, some basic units of analysis—objects organized in hierarchically structured categories—also seem consensual. In the study of language, by contrast, little is agreed upon. This weakness threatens to hinder the effort to image the neural basis of language (NEUROLINGUISTICS).

The present perspective sees linguistic capacity as critically involving the pairing of sound sequences and meanings, aided by inventories of combinatorial rules, and stores of complex objects of several types, over which these rules operate as language is practiced through its various modalities. The language faculty, in this view, inheres in a cerebrally represented knowledge base (rule system), and in algorithms that instantiate it in use. It is divided into levels of representation, reflected in language processing: a level for the identification and segmentation of speech sounds (universal phonetics), and a system that enables the concatenation of phonetic units into sequences (phonology), then into words (morphology, where word structure is computed), sentences (syntax), and meaning (lexical and compositional semantics). This rich system of knowledge is cerebrally represented, and has several important properties: At every level beyond phonetics, linguistic units are taken to be discrete; the algorithms that concatenate them do so in keeping with formal rules, some of which are recursive, hence capable of handling strings of arbitrary length; these systems are universal—shared by speakers of all the world's languages. Language-particular rules are encoded in parameters that are embedded within the universal rule system (Speech Processing: Psycholinguistics).

Although not all students of language share this view, as should be evident from this handbook (see Language Processing; Past Tense Learning), there is considerable empirical evidence that supports it. This chapter thus briefly reviews some central results emanating from investigations into the brain/language juncture, which support the neural reality of linguistic rules as a constitutive element of the human language faculty. The focus here is on linguistic combinations at the sentence level; but first, some key results in two other successful areas of research are reviewed: the cerebral representation of phonological units, and of word meaning in its isolated and compositional aspects.

## Combinatorial Linguistic Systems: The Neural Representation of Sound and Meaning

A central concern of linguists who investigate the phonetic/phonology interface is the nature of the basic building blocks of speech. Rules of concatenation in language typically operate on discrete units, hence the issue of discreteness is critical. Indeed, some recent results suggest that abstracts representations of discrete linguistic objects have neural reality. Experiments in magnetoencephalography (MEG) show that auditory cortex can very rapidly construct abstract representations of discrete linguistic objects that go beyond phonetics. Specifically, representations of discrete phonological categories are available already at the earliest stages of processing. Phillips et al. (2000), for example, have shown this through an "oddball paradigm." They recorded brain activity by MEG, while subjects listened passively to synthetic speech sounds, presented in a phonological and an acoustic condition. The former contrasted stimuli from an acoustic /dæ/-/tæ/ continuum, and elicited a magnetic mismatch field in a sequence of stimuli in which phonological categories occurred in a many-to-one ratio, but no acoustic many-to-one ratio was present. Phillips et al. compared these results to the acoustic condition, where the many-to-one distribution of phonological categories was removed. No such response was elicited, although the stimuli came from an acoustic continuum identical to the phonological condition. Thus, the all-or-nothing property of phonological category membership, as opposed to phonetic stimuli, was demonstrated through MEG, supporting the existence of a neural code for a phonology with discrete categories (see also Neurolinguistics).

Another issue that neurolinguists are interested in concerns the combination of meaning-bearing units. Some hints regarding this problem may come from a comparison of neural processes involved in the recognition of words in isolation versus sentential context. Posner and Pavese (1998) tried to investigate this question through a paradigm that utilized Evoked Response Potentials (ERPs). They presented sentences like "he ate his food with a____," in which the final word was either an appropriate artifact (fork), or an appropriate natural object (fingers), or an inappropriate artifact/natural object (tub/bush). In one condition, subjects were asked to decide whether the last word referred to an artifact or a natural object (word in isolation); another condition asked whether or not the last word fit the sentential context (sentence task).

Importantly, both conditions focused more on meaning than form. When ERPs obtained in the two tasks were compared, it turned out that left frontal regions were more activated in the lexical task around 120–500 msec into the task, whereas left posterior regions were more activated in the sentence task around half a second into the task. This result suggests that lexical elements are interpreted at different times and locations than sentences, and adds to the growing literature that points to the left frontal and temporal cortices as loci of lexical semantics. It refines the picture in making an initial step toward an identification of regions in which compositional semantic processes take place.

Having discussed sound and meaning in brief, we can now move on to our main topic: how and where in the brain sentences are processed.

## Reconstructing the Image of Sentence Grammar: Lesion Data

The nineteenth-century "Connectionist" school, founded by Broca, Wernicke, and Lichtheim, and revived in our time by Geschwind (1979), began modern neuropsychology. This approach emphasized connections between brain regions (rather than the synaptic connections of present-day connectionism), and fortified belief in the existence of cerebral language centers. A clinically oriented approach, it emphasized patients' communicative skills, viewing language as a collection of *activities*, practiced in the service of communication: speaking, listening, reading, writing, naming, repetition, etc. The characterization of the language centers derived from this intuitive theory—each activity was associated with a cerebral locus. Activities are building blocks of the resulting theory of localization, and they are taken to be the essence of human linguistic capacity (Neurolinguistics).

Since the 1960s, psycholinguists have challenged this view, using theoretical and experimental tools borrowed from linguistics and psycholinguistics (e.g., Goodglass and Berko, 1960; Zurif and Caramazza, 1976). Not denying the relevance of activities, they focused on linguistic distinctions. Language became a structure-dependent piece of knowledge, divided into *levels of representation*. A variety of experiments in the 1970s proved this approach worthwhile, in that results indicated that the brain makes distinctions between types of linguistic information. Such results could not be couched in the standard view, and thus the centers were "redefined" (Zurif, 1980): each anatomical center was now said to contain devices used for the analysis and synthesis of linguistic objects. Roughly, Broca's region (Brodmann's Area BA 44, 45, 47, see Figure 1) was said to house syntax (for both receptive and productive language), while semantics was to reside in Wernicke's area (BA 22, 42, 39). Neuroanatomy also witnessed parallel advances. As large samples of patients became available, it became increasingly clear that language occupies larger areas than previously supposed. As analytic and experimental tools improved, the involvement of both hemispheres in aspects of linguistic activity was documented (cf. Ojemann, 1991).

Yet as findings accumulated—from different tasks, languages, stimulus types, and laboratories—contradictions within the behavioral data began to surface: In some cases, Wernicke's aphasics showed syntactic disturbances; Broca's patients, on the other hand, while failing certain tasks that probe syntactic abilities, succeeded in others. Serious doubts were cast on the new model, in which Broca's (but not Wernicke's) area supports receptive syntactic mechanisms. Attempts to reconcile the findings with the prevailing view argued that regions are organized not just by activities and

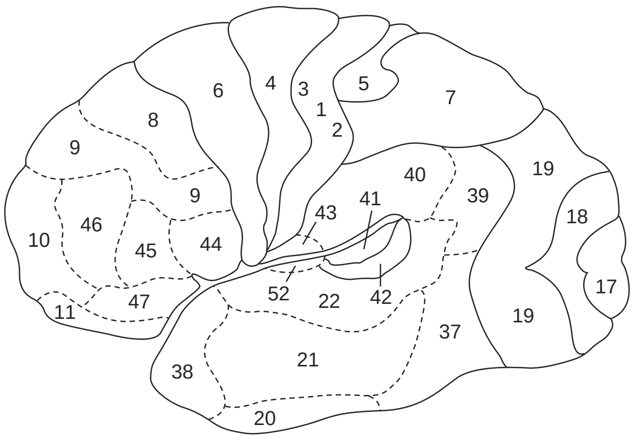

**Figure 1.** Brodmann's division of the left cortical surface into the areas referred to in the text as BA 22, BA 44, etc.

linguistic levels, but also by *tasks*, saying that "syntactic comprehension is compromised," and "grammaticality judgment is intact."

Upon examination, these analyses share a common thread: Although they were detailed in the description of tasks and activities, they were all rather holistic in their approach to the linguistic signal. Gross distinctions between form and meaning seem sufficient, and hence, less attention is paid to detailed structural properties of linguistic stimuli. Still, the amended neurological model of language could continue and prevail.

An exception to this description is the study of phonology and phonetics (cf. Blumstein (1994), Neurolinguistics). In these areas fine, theoretically motivated distinctions have long been used, and landmark discoveries of subtle distinctions that the brain makes among informational types have been made. Students working in other domains of language, however, were slower in making connections between matters neuropsychological and linguistic. Yet, when it turned out that the task-oriented approach was incorrect, the next move was to try and argue that the inconsistencies in results discussed previously were just apparent, due to our failure to make distinctions among linguistic types. It was argued that systems of grammatical knowledge are complex, and as such, can experience partial breakdown subsequent to focal brain damage. The next step, then, was to seek linguistic frameworks within which patterns of impairment and sparing in aphasia could be couched, and which in turn would give rise to a more finely grained theory of brain/language relations. This resulted in an investigation into the cerebral localization of *grammatical rule systems*. It was shown that despite the importance of channels through which language is practiced, the correct (in fact most telling) unit of analysis for the interpretation of lesion data is the particular rule type.

It is here that considerations pertaining to the structure of language began to matter heavily. As the most important aspect of our "mental organ for language" is its combinatorial nature, that is, the knowledge base and algorithms for the concatenation of linguistic sequences at all levels. Activities and tasks no doubt play a mediating role in linguistic communication, yet the defining characteristic of the language faculty is its being composed to rule systems. How these rule systems are instantiated in neural tissue thus seems the central question in neurolinguistics.

Thus it was shown that in the domain of language production, the brain makes fine distinctions among rule types: Broca's (but not Wernicke's) aphasics are deficient in producing Tense inflection, but intact in Agreement inflection (as shown in a wide variety of languages). Cross-linguistic studies further indicated that not only inflection type, but also, the position of the verb in the sentence determines its appearance subsequent to a lesion in Broca's region (Friedmann, 1998). In receptive language, the distinction between transformational and nontransformational sentences, yields a big performance contrast: aphasics with lesions in Broca's region understand active sentences, subject relatives, subject questions and the like normally, yet fail on their transformational counterparts: passives, object relatives and questions, etc. This led to the claim that in receptive language, Broca's aphasics are unable to compute transformational relations. This generalization helps localize this grammatical operation in the brain (Trace-Deletion Hypothesis, TDH, cf. Grodzinsky, 2000). Furthermore, the highly selective character of this deficit has major theoretical ramifications to linguistic theory and the theory of sentence processing. A particularly compelling argument that supports the localization of transformations in Broca's region comes from cross-linguistic comparisons: Chinese, Japanese, German, Dutch, Spanish, and Hebrew have different properties, and the performance of Broca's aphasics is determined by the TDH as it interacts with the particular grammar of each language. In English, aphasics comprehend active sentences properly. Yet the results for Japanese, which has two types of actives, are different. *Taro-ga Hanako-o nagutta* (Taro hit Hanako)—Subject Object Verb], and ***Hanako-o*** *Taro-ga nagutta*—**Object** Subject Verb. These constructions are simple, they mean the same, and they are identical on every dimension, except in that the latter is derived transformationally, with the bolded element fronted to the left edge of the sentence. Remarkably, Broca's aphasics' comprehension splits: they handle the SOV type properly, and are at chance level on the OSV.

In Chinese, an otherwise SVO language like English, (bolded) heads of relative clauses (1a, 2a) follow the (parenthesized) relative, unlike English (1b, 2b) in which they precede it. Remarkably, this reversed order correlates perfectly with the cross-linguistic results in aphasia: subject relatives (1) are comprehended at chance in Chinese and above chance in English, whereas object relatives (2) yield the opposite pattern:

(1) a. [ _ zhuei gou] de **mau** hen da *chance*
chase dog that cat very big
b. **The cat** that [ _ chased the dog] was very big *above chance*
(2) a. [mau zhuei _ ] de **gou** hen xiao *above chance*
cat chased that dog very small
b. **The dog** that [the cat chased _ ] was very small *chance*

English and Chinese thus yield mirror-image results, which correlate with a relevant syntactic contrast between the two languages. Other intriguing cross-linguistic contrasts also exist, providing further evidence that Broca's region is critically involved in transformational analysis. Moreover, reflections of the same disruption are also found in the domain of real-time processing (Zurif, 1995). This rich database is further augmented by results regarding grammatical aspects of the mental lexicon. These are also localizable, as they appear retained in Broca's aphasia, but severely disrupted after a lesion in Wernicke's area.

In sum, over the past decade or so, a new, intriguingly complex model of grammar/brain relations has emerged: Aspects of receptive syntax—those dedicated to the computation of transformational relations—are represented in Broca's region, and to some extent in Wernicke's region; the linguistic lexicon is in the latter region, whereas other parts of receptive syntax, while clearly residing in the left hemisphere, are not localizable as of yet; in productive language, Broca's region is dedicated to extremely limited aspects of structure that pertain to the upper, leftmost end of the syntactic tree (Friedmann and Grodzinsky, 2000). Most importantly, linguistic tools appear critical for the analysis of brain/

language relations (for alternative views, see NEUROLINGUISTICS; LESIONED NETWORKS AS MODELS OF NEUROPSYCHOLOGICAL DEFICITS).

## Reconstructing the Grammatical Brain: Neuroimaging

The lesion studies story may have an important lesson regarding functional neuroimaging. Early studies that used this experimental methodology grappled with many hard questions, one of which had to do with the choice of experimental materials, determined, to a large extent, by the experimenter's theoretical tastes. One would have expected neuropsychological data to play a central role in this new effort; in practice, functional imaging of language witnessed an attempt to start almost from scratch. Caught by the excitement that swept the field when neuroimaging techniques were introduced, many investigators have largely tended to dismiss aphasia data, rather than seek cross-methodological convergence. Some important mistakes were repeated as a result. Preliminary studies conducted contrastive investigations of *activities and modalities*. The first ones (Petersen et al., 1990) investigated the production versus comprehension of various linguistic stimuli in PET and then fMRI; and although they made a distinction between overt and covert sentence production, the nature of stimuli—their structure—remained unanalyzed and unspecified. No wonder, then, that anatomical overlap among studies was very limited: verb production versus comprehension, for instance, activated the cerebellum and culliculi for Petersen et al., whereas in more recent studies it was localized in the left posterior temporal lobe and the anterior insula bilaterally.

Early studies were also concerned with *cross-language comparisons*, with language once again taken as one unanalyzed whole, leading to great variation in stimuli (and subsequent anatomical variation). Thus, Mazoyer et al. (1993) conducted a PET investigation of the functional anatomy of sentence comprehension in a known (in fact, native) versus unknown language (French vs. Tamil); other authors looked at PET activations during the comprehension of active declarative sentence in spoken language, as compared to similar stimuli in sign language, finding multiple activations in the left frontal lobe, as well as in the temporal lobe bilaterally. Still others compared the fMRI activation during the comprehension of native (Japanese) versus second (English) and an unknown (Hungarian) language in the same speakers. Here, some aspects of the frontal cortex was activated bilaterally, whereas Broca's and Wernicke's regions, as well as some neighboring ones, were activated only on the left side. Similarly, the BOLD response in a comparative fMRI study of English sentences versus sentences in Mandarin Chinese resulted in bilateral activations in the inferior prefrontal cortex (BA 44, 45, 47, Figure 1), bilateral middle prefrontal cortex (BA 6, 8, 9) and secondarily in the left temporal region (BA 22, 21, 38), the left angular gyrus (BA 39), and bilateral activations in the anterior supplementary motor area (BA 8), the superior parietal region (BA 7), and in some occipital regions. So, while most of these studies demonstrated activation in the left Broca's area and around left Wernicke's area, scattered activations in many more regions—in both the left and the right hemispheres—were also recorded, thus blurring the picture, and making it much less stable than we would like it to be.

Yet, when previous neuropsychological data and linguistic considerations are taken into account, it is quite possible that activities or languages may not be the correct units of analysis for a precise characterization of brain/language relations. One possible reason for the lack of anatomical congruence among past studies, then, is that they made incorrect choices of analytic units, and as a consequence, they simply did not use appropriately minimal contrasts in their comparisons. From this perspective, a sentence in sign language is an incorrect control for a condition that contains English sentences—it may be as inappropriate a control as a Mozart symphony would be for a test for visual object recognition. Psychologists have realized this, and as a next step, set themselves to study more finely grained distinctions. Again, following the neuropsychological tradition, some have attempted to test distinctions among *levels of linguistic description*. Yet here, too, localization has been somewhat disappointing.

Friederici and her colleagues conducted a series of studies that also contrasted syntactic with semantic variables, and sought neural correlates for it, as monitored through MEG. In one study they tried to localize syntactic processes through the measurement of magnetic response during auditory exposure to "syntactically correct" and "syntactically incorrect" sentences. They found that "early syntactic parsing processes" activated temporal regions, possibly the planum polare, as well as fronto-lateral regions. They further comment that "the contribution of the left temporal regions to the early syntactic processes seems to be larger than that of the left fronto-lateral regions." Friederici (2000) summarizes the results from PET and fMRI studies: "The posterior region of the left superior temporal gyrus and the adjacent planum temporale is specifically involved in auditory language comprehension." There is also "an involvement of left inferior frontal regions in phonetic processing," and for syntax there is "maximal activation in the left third frontal convolution . . . but additional activation in the left Wernicke's area as well as some activation in the homotopic areas in the right hemisphere." Another experiment this group conducted sought to dissociate the phonological, semantic, and syntactic subsystems. They presented active declarative sentences along with sentences with the same syntactic "frame" but with nonsense words, and with unstructured word lists and non-word lists. When sentences with real and pseudo words were compared to word and non-word lists (as a reflection of syntax), certain bilateral temporal, parietal, frontal, and subcortical areas were activated.

In a similar vein, Dapretto and Bookheimer (1999) tried to dissociate syntax from semantics through fMRI. They asked subjects to make same/different judgments on sentence pairs of two types: one involving the same sentence structure but with one different word; another involving same meaning but different sentence structure (active versus passive). For both the semantic and syntactic comparisons, they report Broca's region and its vicinity (BA 44, 45, 47) and the superior and middle temporal gyri (BA 42, 22, 21) bilaterally as the main activated area in the comparison, with some more activation on the left for the syntactic comparison (BA 44).

The reader may have noticed that here, too, the anatomical overlap between studies is not very promising. Again, Broca's and Wernicke's regions are activated, providing support to the view—originating in Broca's and Wernicke's writings—that these regions are crucial parts of the language faculty. Yet this is not enough: other regions are activated in a nonoverlapping manner, and we must try and understand what this may mean. Three interpretations are imaginable: either language is widely distributed in the brain, and moreover, linguistic representations are unstable, varying from one individual to the next in a manner that affects findings; or the available imaging technology is unreliable; or experiments do not test what they purport to test.

My own tendency is optimistic, leaning toward the third possibility: while there is clearly individual variation in the precise size, location, and structure of the language areas (cf. Amunts et al., 1999, for compelling cytoarchitectonic evidence), brains appear to be relatively stable in what they represent. A large amount of functional variation and spreading, I would argue, is a consequence of the great variation among experiments at this point, caused mainly by an insufficiently refined view of linguistic structure. The fact that "syntax," "phonology," and the like are undifferentiated is likely an important reason for the wide range of anatomical loci imputed to sentence processing. A linguistic perspective—especially one that seeks to account not just for the functional imaging data, but also the rich body of knowledge that comes from lesion studies—might make matters more uniform.

An attempt to be more detailed psycholinguistically has been made by Caplan and by Just and Carpenter. These groups have attempted to view language processing in the brain from the point of view of the putative processing difficulty of different sentence types. Just et al. (1996) looked at the comprehension of three sentence types in fMRI, and found that they all activated left and right Broca's and Wernicke's regions, yet the magnitude of the effect grew with processing difficulty. Using PET, Stromswold et al. (1996) showed differential activation in left Broca's region for differentially difficult relative clauses; and study by the same group conducted a PET study with similar materials, yet with a slightly different task, and found activations in the centromedian nucleus of the left thalamus, the medial frontal gyrus, Broca's area, and the posterior cingulate gyrus. Differential processing difficulty, used as a marker that delineates the language faculty, again results in poor anatomical overlap. The similarity in the questions posed by most of these studies suggests that discrepancies in anatomical findings may either be due to different imaging devices, or choice of tasks and materials. Still, experience with the linguistic interpretation of lesion data leaves one with a gnawing sense that systematic linguistic description of functional imaging results—and subsequent planning of linguistically motivated experiments—is somewhat lacking. In the case of complexity, the blurred picture may well be due to the fact that the linguistic complexity is not a well-defined notion, and its varying construal affects the nature of experimental materials and the analysis and interpretation of results. It is perhaps advisable to go back to studying aphasia, to try and find some hints there. The strong link between grammatical transformations and the language areas may be a good place to start, if we seek to tease particular components *within* the grammar apart from others.

When transformations are separated from complexity, and tested in fMRI, a fairly clear picture emerges: left Broca's region (BA 44, 45) and to a lesser extent, both Heschl's gyri, are most strongly involved in transformational analysis. Ben-Shachar et al. (2001) have conducted this experiment in Hebrew, searching for a T(ransformational)-effect. They used minimal pairs of equally complex sentences, except that one set contained a transformation (3a) and another did not (3b):

(3) a. I helped the nurse [that John saw __ in the living room]
b. I told John [that the nurse slept in the living room]

A T-effect was found in left Broca's area (BA 44, 45): A higher BOLD signal was detected for +Transformation sentences relative to −Transformation sentences (Figure 2). These results suggest a critical role for Broca's region in the analysis of transformations in the healthy brain, and converge on the available lesion data. An ROI approach detected activations in the posterior inferior frontal gyrus and the anterior insula, the posterior superior temporal sulcus and Heschl's complex. Thus, the core computational resource for Movement structures is in areas 44, 45. Auxiliary computations occur at temporal areas bilaterally.

## Discussion

We have reviewed results that point to the neurological distinctness and locus of the transformational component of syntax. They also suggest that at least some of the results obtained in the fMRI and PET syntactic complexity experiments could be recast in transformational terms, which may lead to a radical reduction in the amount of variation, and to convergence of cross-linguistic and cross-methodological data from lesions studies, as well as from PET and fMRI.

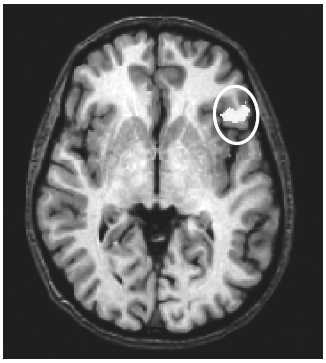

**Figure 2.** A statistical map associated with +T sentences. Left IFG is the most activated region (Ben-Shachar et al., 2001)

So what is the image of the linguistic brain? We are just beginning to reconstruct it. Whether the somewhat variable anatomy will ever permit precise localization is still an open question; and gross localization, after all, is just a small step toward understanding. Yet our best bet, it seems, is to take linguistic rules as the basic unit of functional analysis of the intricate relationship between language and the brain.

# Imaging the Motor Brain

*John Darrell Van Horn*

## Introduction

Functional imaging of the human brain during the performance of motor tasks examines one of the most basic, as well as one of the most complex, facets of brain function. Early studies assessing regional cerebral blood flow (rCBF), using positron emission tomography (PET), and investigations of blood oxygenation effects, with functional magnetic resonance imaging (fMRI), relied on simple finger opposition tasks to produce large and robust activation patterns in the motor cortex (e.g., Figure 1). However, the results of recent motor neuroimaging studies suggest that the behavioral form and context of a movement are important determinants of functional activity within cortical motor areas and the cerebellum. Unlike the consideration of higher cognitive processes (e.g., memory, learning, vision, etc.), functional imaging of the human motor system is based on the need to understand the interaction of neurological and cognitive processes with the biomechanical characteristics of the limb (e.g., reaching, grasp, rotation, flexion, etc.). This implies a dependency on other neural systems, such as vision (see Eye-Hand Coordination in Reaching Movements), to help supply information for the purposes of learning the parameters of motor tasks. Neuroimaging evidence from such studies has accumulated, indicating that multiple neural systems and their functional interactions are needed to successfully perform motor tasks, encode relevant information for motor learning, and update behavioral performance in real time. Thus, more than in any other domain, motor neuroimaging is moving beyond the concept of localization-based modularity and into that of the functional interaction of brain systems for the construction of theories of motor function.

Accompanying the rise in functional neuroimaging as a research tool has been the increase in sophistication of task paradigms employed for probing the motor system. Investigations utilizing both PET and fMRI are now examining complex sequences of finger movements and continuously generated motor behaviors to investigate in finer detail the formation of motor programs, the role of proprioceptive mechanisms, anticipation of movement, and the generation of internal models. For fMRI, in particular, this has necessitated novel approaches to how the behavioral and functional data are collected simultaneously. Also, the mathematical and statistical modeling of these data has required the careful consideration of the temporal characteristics of both the measured blood oxygenation level dependent (BOLD) signal as well as the associated motor behavioral output. These emerging experimental frameworks represent a considerable departure from the traditional "task minus control"-style experimental designs traditionally employed for fMRI. Using such methods, researchers are rapidly gaining insight into motor processes that are hugely dynamic, shaped not only by the demands of the task paradigm itself, but also on the basis of error feedback, behavioral skill acquisition, and automaticity.

In this chapter, the following aspects of the examination of the human motor system with neuroimaging will be discussed: (1) how evidence from functional imaging studies is lending support to current constructs of motor theory concerning the development of internal models of movement, (2) how this information is being functionally integrated by the brain, (3) motor automaticity, and (4) experimental design and data modeling considerations for func-

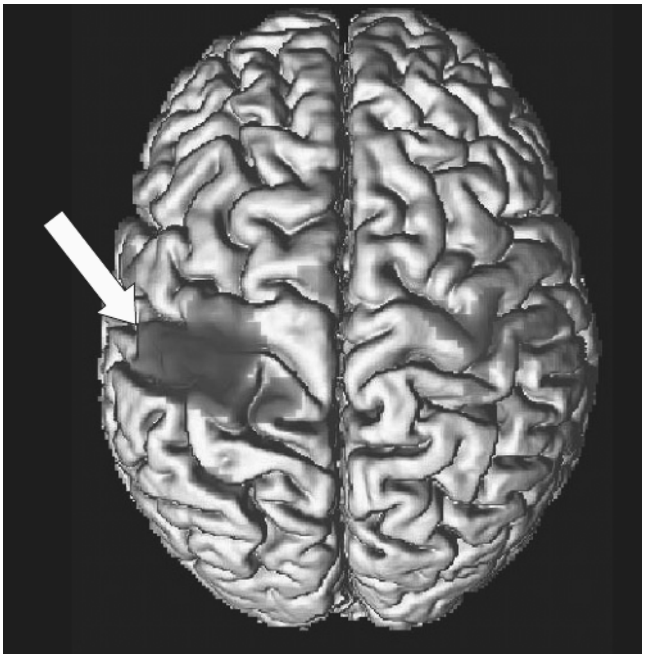

**Figure 1.** Block-design motor activation. A single male subject alternately rotates a small object in his dominant (right) hand or is at rest in 15-s intervals, over a 4.5-min functional (EPI) scanning session (General Electric Horizon 1.5 Tesla, TR =, 2000 ms, TE = 500 ms, FOV = 24 cm, 27 slices). Significant Student's *t*-test ($p < 0.001$) activation, overlaid on a rendering of the subject's cortex as measured via a high resolution spoiled gradient echo (SPGR) structural scan, is evident in motor and premotor regions, being most extensive contralateral (left; arrow) to the side of movement.

tional imaging of the motor system that bring to bear novel mathematical techniques and extends the scope of functional imaging experimentation.

## Mapping the Formation of Internal Models

The notion of internal model formation predicting future motor requirements has emerged as a dominant concept from in vivo studies of the human brain with functional neuroimaging. Reaching, grasping, and tracking objects requires the construction and execution of an internal model of the movements needed for performing the action (Desmurget and Grafton, 2000; Imamizu et al., 2000). Neuroimaging studies of visuomotor tracking, for instance, have been particularly useful for elucidating the development of internal model formation. Several such studies have identified significant changes in regional activity in a network of regions including primary and supplementary motor cortices, basal ganglia, and cerebellum during motor tasks (Grafton, Fagg, and Arbib, 1998; Grafton, Hazeltine, and Ivry, 1998; Turner et al., 1998). Each of these brain areas is directly involved in carrying out motor movements. Turner and colleagues (1998), however, examined rCBF PET images obtained while subjects moved a handheld joystick to track the movement of a target at three different rates of sinusoidal movement. Increases in rCBF during arm movement (relative to an eye tracking only baseline condition) were seen in a distributed pattern of regions, including primary sensorimotor, dorsal and mesial premotor, and dorsal parietal cortices in the left hemisphere and, though not as prominently, the sensorimotor and superior parietal cortices in the right hemisphere. Subcortical activations were observed in left putamen, globus pallidus, and thalamus, in the right basal ganglia, and in the right anterior cerebellum. Left primary motor, left globus pallidus, and right anterior cerebellum had changes in rCBF that correlated positively with the rate of movement. A particularly unique finding was the activation of the globus pallidus with increasing movement velocity. On the other hand, studies of Parkinsonian patients (Nakamura et al., 2001) have revealed increased patterns of rCBF activity in these regions, suggesting a compensation for defective basal ganglia functioning and a failure to correct errors online. This supports the notion that the basal ganglia motor circuit may be involved preferentially in controlling or monitoring the scale and/or dynamics of limb movements needed to minimize movement error. These findings hint at interdependency between distributed brains areas needed for online correction of motor errors leading to internal movement representation.

## The Emergence of Motor Automaticity

As subjects gain increased experience with motor tasks they typically display continued improvement in motor execution until those movements have become automatic. In general, motor automaticity is most likely to occur in tasks where performance errors may be readily anticipated and corrected online. Brain imaging studies have demonstrated differential changes in activity in limb motor areas during early motor skill learning, consistent with functional reorganization occurring at the level of motor output. Extensive practice and the emergence of skill automaticity resulted in decreases in the amount of activity in motor and SMA, accompanied by increases in activity in inferior parietal cortex as well as in basal ganglia. These alterations may be further modified over time presumably due to neuronal efficiency and optimization. Therefore, internal models of movements and movement automaticity are tightly linked.

On a simple level, automaticity in the motor system may be indirectly measured when contrasting performance of a motor task using the dominant and nondominant hands. Nondominant hand movements, perhaps being less automatic, appear to require greater cortical BOLD signal activity similar to complex tasks with the dominant hand, and result in greater activation of ipsilateral cortical motor areas and striatum. However, automaticity may be more rigorously examined and manipulated through the use of sensorimotor compatibility task paradigms. Experiments by Grafton, Salidis, and Willingham (2001), for example, assessed motor learning under compatible and incompatible perceptual-motor conditions to identify brain areas involved in different perceptual-motor transformations. Subjects tracked a continuously moving target that moved in a repeating sequence embedded within random movements to block sequence awareness. Psychophysical studies of behavioral transfer from incompatible (joystick and cursor moving in opposite directions) to compatible tracking established that incompatible learning was occurring with respect to target location. rCBF imaging during compatible learning identified increasing activity throughout the precentral gyrus, maximal in the arm area. Incompatible learning also led to increasing rCBF activity in the precentral gyrus, maximal in the putative frontal eye fields. When the incompatible task was switched to a compatible response and the previously learned sequence was reintroduced, there was an increase in activation of the arm region of the motor cortex. These findings indicate that learning-related increases of brain activity leading to motor automaticity are dynamic, with recruitment of multiple motor output areas, contingent on task demands.

## Feedback Monitoring

The cerebellum appears to play a critical role in the coordination of movement, being essential in the processing of motor feedback (see Cerebellum and Motor Control). Miall, Reckess, and Imamizu (2001) assessed cerebellar involvement using fMRI during visually guided tracking tasks requiring varying degrees of eye-hand coordination. BOLD signal in the cerebellum indicated greater activity during independent rather than coordinated eye and hand tracking. In subsequent tasks, they observed parametric increases in cerebellar activity as eye-hand coordination increased. This demonstrates a nonmonotonic relationship of the cerebellar BOLD signal with tracking performance, showing high activity during both coordinated and independent conditions. In another example, using $H_2{}^{15}O$ PET, Blakemore, Frith, and Wolpert (2001) examined neural responses to parametrically varied degrees of discrepancy between the predicted and actual sensory consequences of movement. Subjects used their right hand to move a robotic arm. The motion of this robotic arm determined the position of another robotic arm, which made contact with the palm of the subject's left hand. Using this interface, computer-controlled delays were introduced between the movement of the right hand and the tactile stimulation on the left. Activity in the right lateral cerebellar cortex was positively correlated with stimulation delay. These data provide provocative evidence that the cerebellum plays a key role in signaling the sensory discrepancy between the predicted and actual sensory consequences of movements, supporting motor coordination.

## Sensorimotor Integration

Sensorimotor integration is the process by which sensory input and motor output signals are combined to provide an internal estimate of the state of both the world and one's own body. Although a single perceptual and motor snapshot can provide information about the current state, computational models show that the state can be optimally estimated by an iterative process in which an internal estimate is maintained and revised by the current sensory and motor signals (see Sensorimotor Learning). These theoretical models predict that an internal state system is, indeed, stored in the brain. Reports on patients with lesions of the superior parietal lobe have shown both sensory and motor deficits consistent with an inability to maintain such an internal representation between updates (Wolpert, Goodbody, and Husain, 1998). Such behavioral findings predict that the superior parietal lobe is critical for sensorimotor integration, by maintaining an internal representation of the body's state.

Neuroimaging studies, too, have lent support to this notion. Grafton and co-workers (1992) studied visually guided movements subjects performing visuomotor tracking tasks during PET. Tracking a moving target with the index finger showed a network of focal responses of rCBF observed in the primary motor cortex, dorsal parietal cortex, precuneate cortex, SMA, and ipsilateral anterior cerebellum relative to visual tracking alone. When the temporal complexity of the tracking task was altered by introducing a "no-go" contingency that allowed for greater time for movement preparation, there was a significant increase of rCBF in the SMA. When the spatial complexity was altered by adding a secondary target that provided directional cues for the primary target, there were additional significant increases of rCBF in bilateral dorsal parietal cortex and precuneus. Performing the tracking task with different body parts produced somatotopically distributed responses in only the motor cortex. The results of this study suggest that the SMA plays a role in the sequencing of movements and that medial and dorsal parietal cortices participate in the integration of spatial attributes during movement selection.

## Measuring and Modeling the Motor System

PET and fMRI studies have provided ample evidence that activation of motor cortices and online movement error correction repeated over time result in action automaticity and sensorimotor integration. Initial attempts at movements result in widespread activation when the brain is drawing upon numerous systems to approximate the required movement, force, velocity, etc. Successive presentations of the same movements offer the motor system opportunity to tune internal model parameters on the basis of behavioral error and subsequent model updates. A process of reinforcement learning and iterative motor control optimization in this vein has been discussed extensively (see Reinforcement Learning in Motor Control). During this process, as the roles of supporting brain systems appear to be no longer required, the pattern of observed activation may be altered, diminishing in extent as the model becomes more accurate, integrated, and automatic. Ultimately, only a minimal set of brain regions necessary for carrying out the needed movement indicate BOLD response activation. Therefore, areas previously involved in the tuning of internal model parameters are now free to devote their neural resources to other cognitive problems.

From a computational point of view, this process resembles that of a control optimization problem (see Identification and Control). Initially, the parameters governing the system are ill-defined. But through an iterative process of taking errors into account, future errors are minimized as the contribution to performance accuracy from some parameters are minimized and those of others accentuated. At which time, the minimal number of parameters have been identified that minimize overall system error in the presence of system noise (i.e., model equilibrium), thereby indicating that the model has been augmented from that of a purely causal model to that of one also having the ability to forecast the next model state and required motor output (see Optimization Principles in Motor Control). This, then, forms what is often more broadly referred to in the motor control literature as a "forward model" (Desmurget and Grafton, 2000). From signal processing, such systems may be used to predict system behavior in which the parameter estimation problem involves the identification of complex poles and zeros, along with system gain terms (see also Forecasting). For example, a simplistic, finite impulse response (FIR) model is presented in Figure 2. This could be used to simulate the forward modeling of visuomotor task performance of the limb, in the presence of system noise, through the use of a switched connectivity between ocular and motor mechanisms.

To achieve the richness of functional imaging data necessary for such modeling purposes, greater sophistication in behavioral paradigms used in the scanning environment is needed. Such paradigms will involve an increased utilization of finely sampled behavioral measurements of motor speed, acceleration and higher derivatives. For example, behavioral paradigms such as that employed by Novak, Miller, and Houk (2000) might be studied with fMRI to measure the neural concomitants of rapid hand and joint movements. These authors attempted to identify overlapping submovements during a rotational target capture task by examining the zero crossings of subject acceleration traces and its derivatives, jerk and snap (the third and fourth derivatives, respectively). Movements without overlapping submovements had, on average, near symmetric, bell-shaped velocity profiles that were independent of speed and consistent with a theoretical minimum jerk velocity

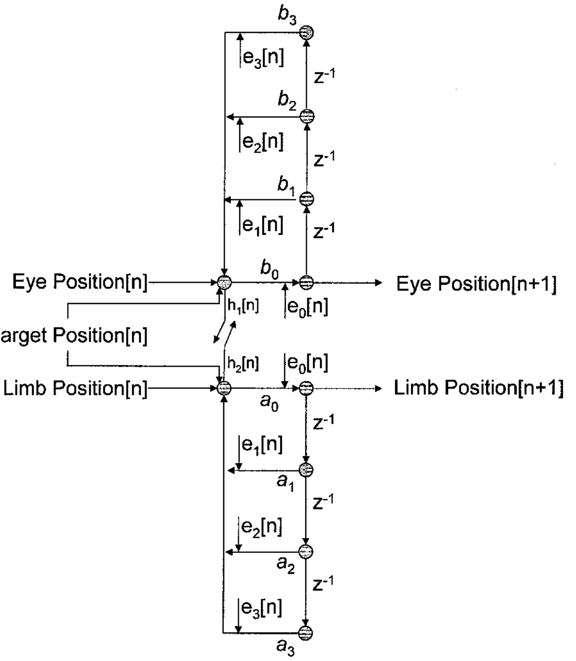

**Figure 2.** Visuomotor tracking may be modeled computationally using predictive FIR models. This figure shows a FIR model that incorporates separate, butterflied components for visual—and for motor—tracking, connected via a switched line tap. This permits both halves of the model to work independently, when the switch is open, or together using an appropriate cross-system transfer function (h), when the switch is closed. The current state of the limb position enters into the system, is scaled, delayed accordingly using discrete complex exponential delay terms (e.g., $\exp(-i2\pi/N) = z^{-1}$, where $i = \text{sqrt}(-1)$) and aggregated to form the output for the next time step. System error is present at each delay term, which when the parameter estimates have not reached equilibrium may dominate system output. Linear systems theory combined with methods for the analysis of functional and effective connectivity from neuroimaging data permit the construction of dynamic models of brain function in visuomotor control as well as other neural systems. Additionally, these models may be useful in the synthetic simulation of fMRI data as has been previously with PET (see Synthetic Functional Brain Mapping).

model. The authors propose a nonlinearly dampened mass-spring (second-order derivative) model of the wrist as a suitable model governing knob turning. Motor tasks paradigms like this, or ones that utilize a joystick, trackball, or other continuous input device permitting estimation of higher order derivatives, when conducted using whole brain fMRI would help in understanding what brain regions are dynamically involved in the construction of internal models and how they may relate to limb kinematics.

In pursuing this line of investigation, however, new thinking in fMRI experimental methods is needed. Unlike epoch- or event-related paradigms, the use of continuous performance fMRI holds considerable promise for investigation of the dynamic process of motor functioning (Figure 3). Most important in this neuroimaging framework is the performance of the subject in relation to maintaining positional, velocity, and acceleration accuracy rather than the presence or absence of perceptual stimuli. For example, Figure 4 shows the results of a reduced GLM model analysis containing only subject-generated tracking variables indicating significant effect involving visual areas (V1 and V2), cerebellum, primary and supplementary motor cortex with absolute target position; visual areas (V1 and V2), cuneus, and superior frontal gyrus with target velocity; and superior frontal and cingulated gyri with target acceleration. Activation of these visual areas has been previously implicated in attentional networks (Friston and Buchel, 2000; see also Visual Attention), underscoring the possible role for these components in visuomotor tracking performance. Subject positional error was significantly correlated with visual areas as well as activation in DLPFC, suggesting a role for the frontal cortex in the organization of action (see Prefrontal Cortex in Temporal Organization of Action). The velocity of subject positional error was significantly correlated with activity in primary motor region, consistent with the aforementioned results of Turner and coworkers (1998). These findings clearly indicate a specific collection of dynamically involved brain regions correlating with target position, velocity, acceleration, and subject-generated variables. Continued investigations of this type can examine more closely how the variables pertaining to visuomanual tracking performance are optimized by the formation of internal models of continuous movement, for instance, over a period of several weeks.

Many cognitive and behavioral models born out of human brain imaging data are often focused on the isolated brain areas associated with statistically high blood flow or BOLD signal response, rather than analyzing the cooperative computation between multiple brain regions. By contrast, the analysis of functional connec-

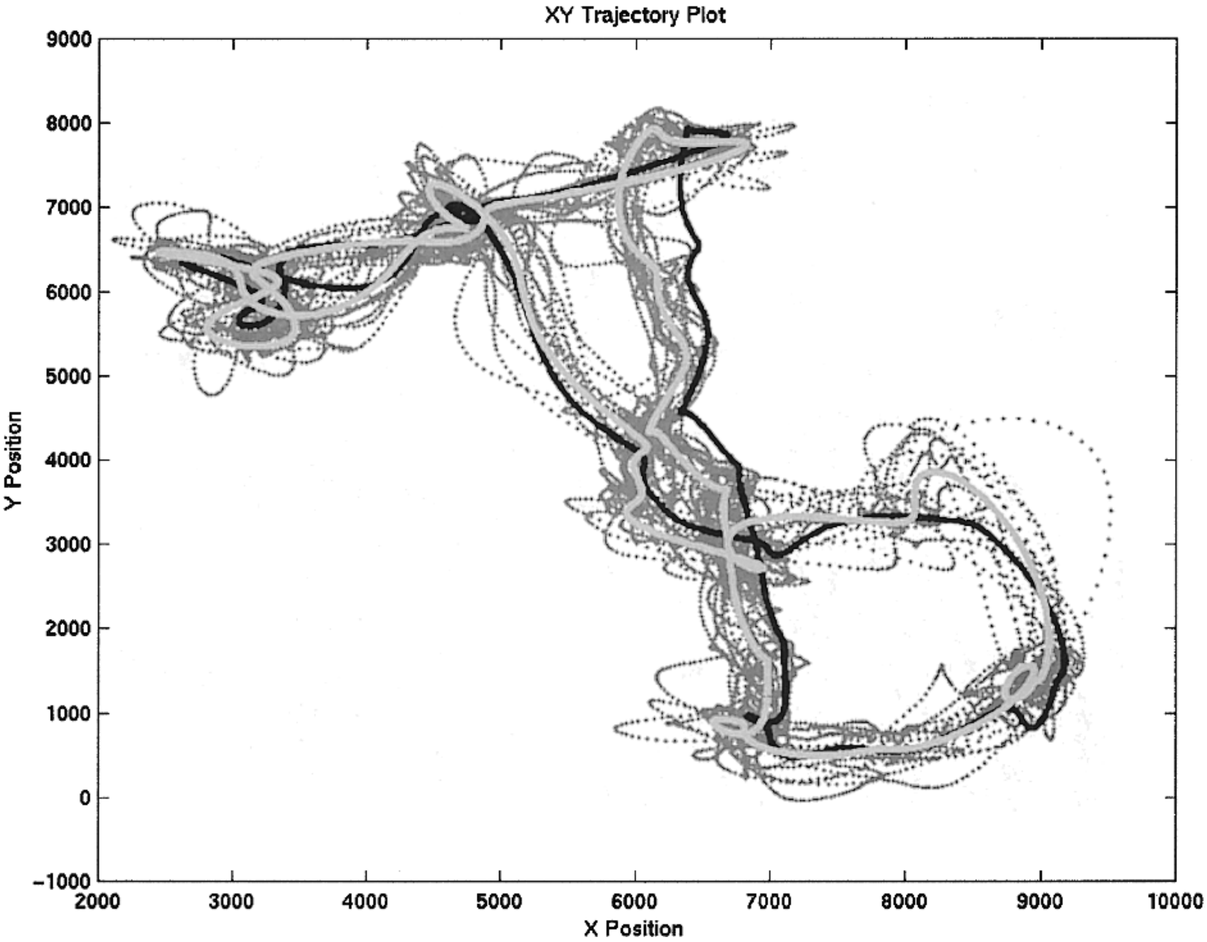

**Figure 3.** Visuomotor pursuit tracking performance obtained during fMRI in an example subject. The target trajectory presented here was constructed using a 32-point-based complex Fourier spectra having randomized phase-components. Subjects performed six versions of this trajectory, in which four were rotated versions of the same trajectory (0°, +90°, 180°, and −90°); one run was a repeat of the 0° rotated trajectory but in which a 10-time-point temporal lag was imposed on the joystick cursor; and, finally, a different trajectory, comprised of the same frequency magnitudes but having randomized phase relative to the other trajectories. The light gray dotted line represents 16 cycles of an example subject's performance, the black line represents the trajectory followed by the target, and the medium gray line the subject's mean pursuit trajectory taken over the 16 cycles.

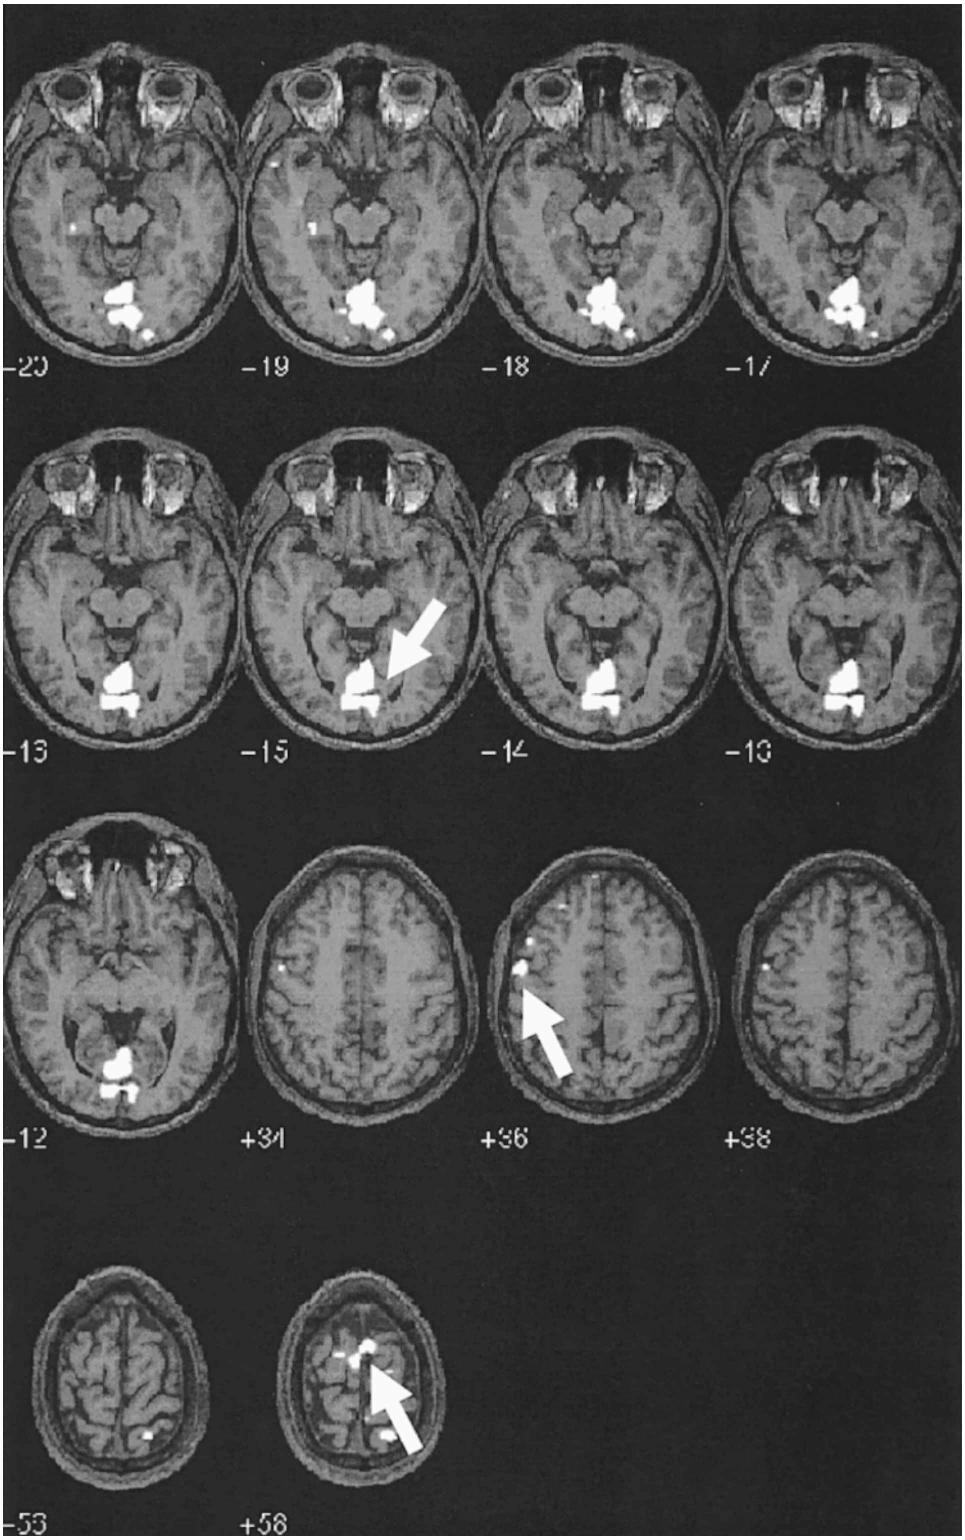

**Figure 4.** Talairach-space overlay plot of the regression of all continuous visuomotor tracking variables (Reduced Model F(12, 823), $p \leq 0.005$, uncorrected) for an example subject after the removal of run-to-run, linear trend, eye movement, and physiological effects. An all-plastic fiberoptic joystick was specially fabricated for use in the MRI scanner. Subject visuomotor tracking performance, eye position, heart rate, and respiration was continuously measured during collection of BOLD EPI time series (General Electric Horizon 1.5T scanner, TR = 2000 ms, TE = 500 ms, FOV = 24 cm). Scanner and task timing were synchronized using the acquisition of the MR scanner unblank TTL signal from which slice acquisition information was obtained. This information was used to sort both the subject's tracking performance data, as well as physiological monitoring and eye tracking data, into a slice-based experimental design matrix. Additional variates were included in the design matrix to account for run-to-run shifts in baseline as well as within-run linear trends. Voxels from each slice were then subjected to linear regression via the GLM and effects were tested against the Wilk's Lambda criterion and converted to F-statistics. A reduced regression model of only those variables related to subject task performance was obtained after regressing out the effects of physiological, eye tracking, and run-to-run effects. Principle effects of the performance-related variables alone are noted in visual and motor cortices (arrows) as well as in middle frontal gyrus. These results demonstrate the successful activation of principle neural systems during continuous visuomotor tracking in fMRI. Further detail on the relative roles of each of the individual performance variables is the subject of a manuscript in preparation.

tivity provides insight into the functional relationships between distributed brain areas (see Covariance Structural Equation Modeling). Figure 5 shows a three-dimensional representation of the pattern of inter-regional correlations between BOLD time course activity during visuomotor tracking, indicative of strong connectivity between visual, motor, and subcortical regions. Such strong interaction between these areas would be expected from current models of internal model formation. The combination of functional connectivity modeling methods for neuroimaging may be combined with techniques for forecasting system behavior thereby

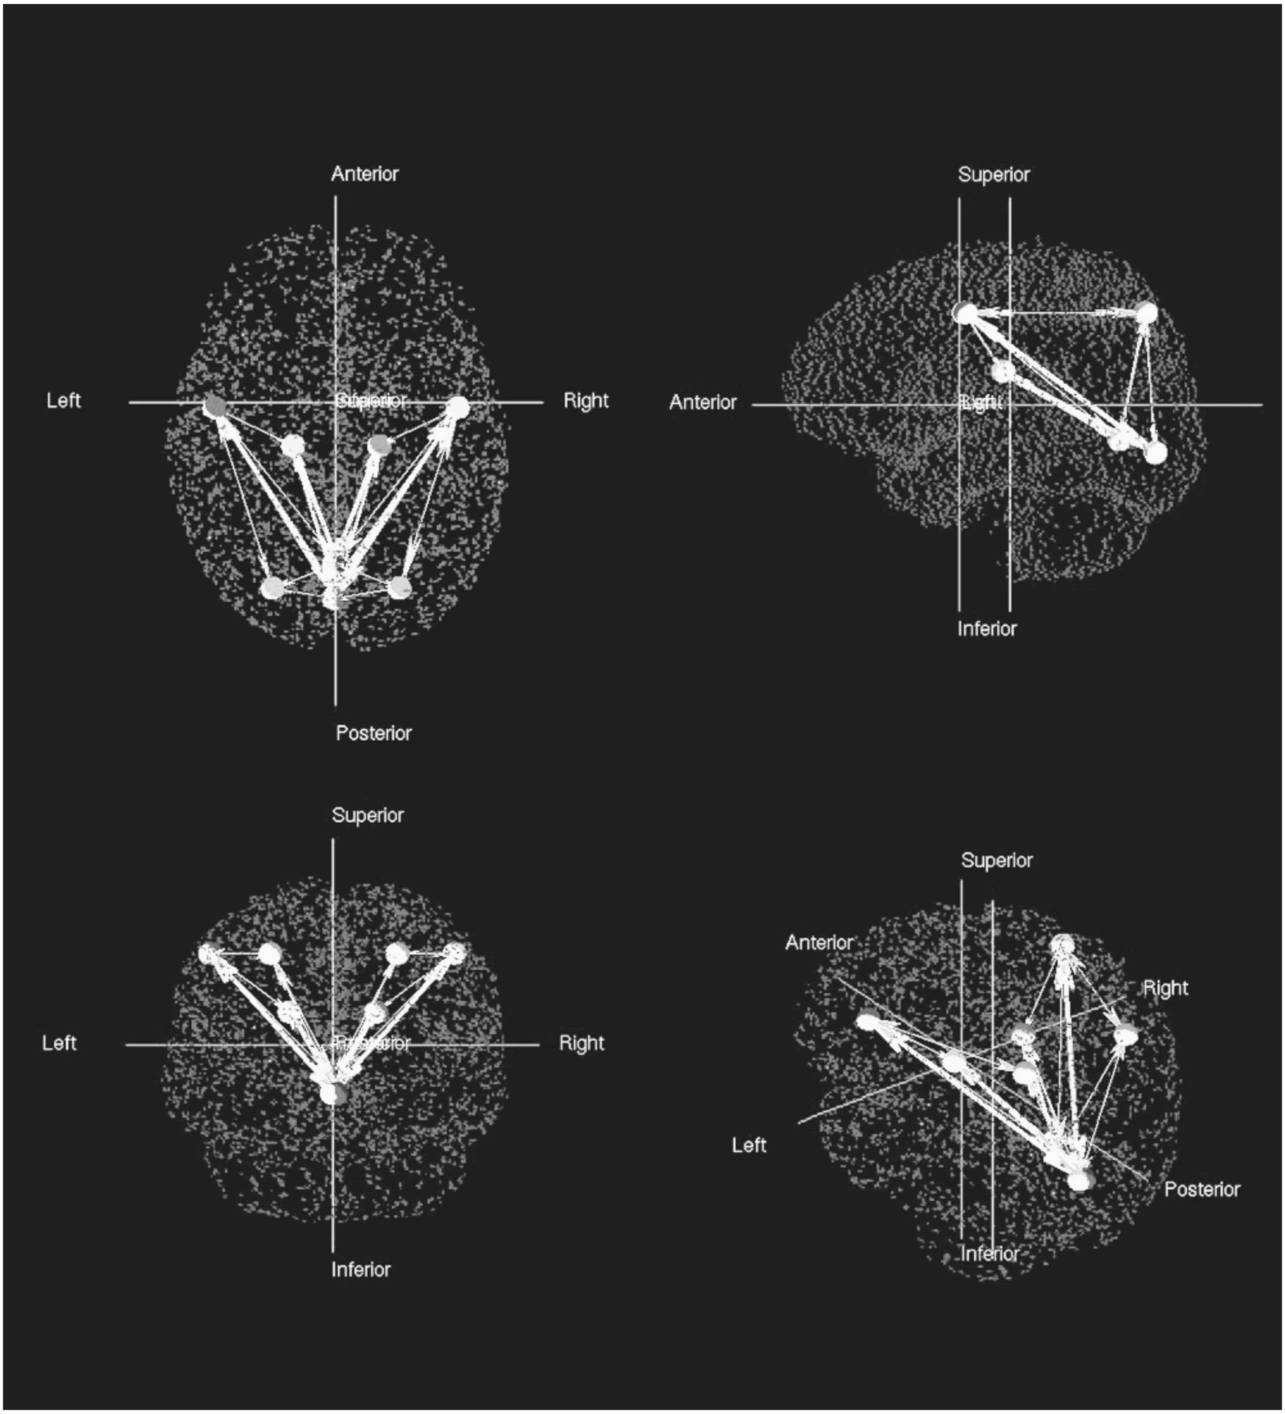

**Figure 5.** In this figure, multiple views (axial, sagital, coronal, and perspective) of brain regions identified during continuous visuomotor tracking are shown as spheroids in 3D standardized Talairach space. The strength of the correlation is indicated by line thickness and no connectivity is evident where a path connecting two brain regions is not present. The resulting paths indicate bidirectional paths connecting the visual regions, subcortical, parietal, and primary motor regions, with stronger correlations existing between primary visual and motor regions as well as from visual to subcortical regions. Further decomposition of the correlational structure between regions (PCA, structural equation modeling, etc.) can be used to identify the independent contributions that each connection contributes to the region-wise covariance matrix. Inclusion of causal and anticausal lag terms (e.g., as in Figure 2) increases the generality of the model giving it a temporal component similar to that of the hemodynamic lag between stimulus presentation and the BOLD response in fMRI. Moreover, in a connected network it is often useful to identify optimal routes between nodes by which to propagate information through the system. Analytical techniques are available for the assessment of the minimum-cost path (the path in which information loss is minimal or that propagation delay is smallest) between a node in a connected network to other surrounding nodes. For example, Djikstra's minimum-cost path algorithm can be employed to examine the minimum-cost path from V1 to, for instance, the primary motor cortex. The minimum cost path may be further constrained by restricting the number of other regions (nodes) through which it must pass (e.g., the number of hops).

providing an empirically based model for the temporal characteristics of inter-regional connectivity involved during tracking and online error correction. Since the resulting FIR-connectivity model includes temporal delay terms, both causal and anticausal, then feedback and feedforward connections may be estimated. The examination of how the strength of connectivity is altered between regions over time as internal models of motor behavior are formed would also be possible. The analysis of how signals are propagated through the network would identify optimum paths of information flow (see figure caption for discussion). In this manner, the responsibilities of the parietal lobe and cerebellum (Desmurget et al., 2001), as well as the role the basal ganglia (see BASAL GANGLIA), in the formation of internal models and automaticity could be assessed via this modeling process.

## Conclusions

The framework of online error correction, automaticity, and integration, gaining support from in vivo functional brain imaging, is helping to explain changes in motor system activation magnitude and spatial extent often accompanying practice and increased skill. In visuomotor tracking, in particular, it is difficult to envision how such behavioral alterations can result in the absence of a predictive internal model. Empirical results from brain imaging have given credence to previously postulated theoretical models of visuomotor coordination (Gauthier et al., 1988) that anticipated such dynamic interaction between motor and visual systems. One can readily expect that the levels of sophistication for examining the domain of the motor system using neuroimaging will continue to improve. In presenting these key examples from the field of neuroimaging, it is clear that there has been and will continue to be much gained from studies imaging the motor brain.

# Imaging the Visual Brain

*Robert L. Savoy*

## Introduction

This article describes some of the progress made in functional brain imaging of visual processes and highlights the challenges and opportunities for future progress, especially in the context of testing models and theories. A few key attributes of modern brain-imaging tools are compared. A subset of the many applications to visual processing is described. The primary technology used in the selected studies is functional magnetic resonance imaging (fMRI), which is currently the dominant volumetric imaging technology for studying human brain function. But the emphasis is to describe, independent of the imaging technology, the relevance of particular experimental designs to problems in visual perception and associated issues in higher-level (i.e., necessarily top-down) processing of visual information.

The key features of modern brain-imaging tools as presented here are those features that determine the potential strengths and weaknesses of each tool when the tool is applied to problems in human brain theory. These features include current and likely future limits in spatial and temporal resolution, constraints on subject participation, and trade-offs in experimental design. Within a given imaging modality, such attributes of the various imaging tools are not independent of each other. Lesion data will be mentioned briefly, but as it is not a usable experimental tool with humans, it will not be emphasized, despite its great theoretical and historical importance.

Functional imaging tools have been applied to a wide range of problems associated with low-level and higher-level visual processing. This article will focus on retinotopy (a low-level aspect of the brain's visual architecture), visual motion perception and visual object representation (intermediate-level aspects of vision), and voluntary modulation of attention and visual imagery (higher-level processes that necessarily have top-down components). This list does not come close to covering the full range of applications to the visual system, but it emphasizes some of the areas where modeling and brain theory might be testable using current imaging tools.

## Imaging Technologies

Functional imaging technologies can be divided into three categories based on the kind of physical phenomena they can measure. In one group are technologies (EEG, MEG, TMS/rTMS, intracranial electrode recordings) that measure, disrupt, or stimulate the human nervous system by interacting with the electrical properties of active neurons. In a second group are technologies (SPECT, PET, fMRI, NIRS) that measure aspects of blood flow and blood chemistry that change in response to local neural activity. The third category (DOT) may ultimately be able to respond to both aspects of human brain function. For a general overview, see Savoy (2001).

### *Spatial and Temporal Resolution Limits*

Table 1 summarizes the approximate spatial and temporal resolutions for various brain imaging modalities. However, it should be understood that one-number summaries are highly misleading, for at least three reasons. First, the physical resolution limits of the *tool* may be different from the resolution limits implied by the biophysical phenomenon being measured. For example, MRI can collect images in a few milliseconds, and optical techniques like NIRS can collect information in microseconds, but both of these technologies, when applied to functional brain mapping, are constrained by the slower temporal resolution of the neuronally triggered hemodynamic changes. Similar statements can be made about spatial resolution. The second way in which one-number summaries can be misleading is that, for several modalities (notably fMRI), the numbers are moving targets that are changing quickly as improvements are made to the hardware and associated analysis software. Finally, there are often explicit trade-offs available when using these technologies. For example, if one is willing to spend an entire MRI session collecting one brain volume, it is possible to improve the spatial resolution. More generally, there are trade-offs between imaging time, spatial resolution, and signal-to-noise ratio in all modalities, but most dramatically in MRI.

**Table 1.** Critical Attributes of Current Imaging Modalities

| Modality | Spatial Resolution | Temporal Resolution | Temporal Design Types | | | | Many Sessions with Single Subject |
|---|---|---|---|---|---|---|---|
| | | | BLK | SST | RST | IST | |
| $O^{15}$-PET | 8–12 mm | ~30–60 s | √ | — | — | — | No |
| SPECT | 3–8 mm | ~20 s | √ | — | — | — | No |
| TMS, rTMS | ~cm | 10 s | √ | √ | — | — | Yes |
| MEG/EEG | ~cm | 1 ms | √ | √ | NA | — | Yes |
| NIRS | ~cm | 1 ms | √ | √ | √ | √ | Yes |
| iEEG | $\mu$m | 1 ms | √ | √ | NA | √ | No |
| fMRI | 1–8 mm | 1,000 ms | √ | √ | √ | √ | Yes |

Abbreviations: BLK: block design; SST: spaced single trials; RST: rapid single trials; IST: individual single trials; PET: positron emission tomography; SPECT: single-photon emission computed tomography; TMS, rTMS: (rapid) transcranial magnetic stimulation; NIRS: near infrared spectroscopy; MEG/EEG: magneto- and electroencephalography; iEEG: intracranial EEG; fMRI: functional magnetic resonance imaging; NA: not applicable.

Table 1 lists the current resolutions for typical uses of the modalities in functional brain imaging. At least one specific application is mentioned in the section on retinotopy within which substantially greater spatial resolution is achieved.

### *Experimental Design and Data Analysis*

In addition to the trade-offs with respect to imaging hardware, there are related constraints on available experimental designs. Table 1 includes several columns related to these issues. Most important is the column associated with multiple testing of a single subject. The ability to return, again and again, to the same brain with additional tests is one of the great practical strengths of the minimally invasive technologies that do not use ionizing radiation. This attribute is likely to be of particular importance in testing theories and models in the future.

The information on temporal design types is included in the table to indicate some constraints imposed on experimental design by the various modalities. In block design tests ("BLK"), the subject performs a given task for an extended period of time (say, 1 minute) to get the brain and its associated blood flow in a given state before an image is collected. Other design types refer to the use of single trials. In spaced single trials ("SST"), the responses to individual stimulus presentations are collected and averaged together. SST designs in the domain of blood-based imaging have intertrial intervals on the order of 10–20 s; SST designs in the domain of electrical modalities have intertrial intervals that are much shorter (between 250 and 2,000 ms). Rapid single trial ("RST") designs refer to the use of stimuli that elicit overlapping hemodynamic changes, which are separated via deconvolution during data analysis. This technique is specific to fMRI. Its advantages are the more efficient use of imaging time and the more rapid presentation of stimuli to keep subjects awake and engaged in the tasks; its disadvantages are greater complexity in specifying the design and analyzing the data, as well as less sensitivity. Note that the electrical modalities actually use stimuli that are more "rapid" in the sense that they can be presented at shorter intertrial intervals, but the electrical signals thus stimulated are over much faster than the hemodynamic changes, so they are not generally overlapping, and therefore the term SST is perhaps more appropriate. Both SST and RST, collectively called *event-related designs*, involve the combining of data from different trials within a given trial type. The ultimate, in terms of experimental resolution, is the individual single trial ("IST"), in which data from each individual stimulus presentation are analyzed independently from the rest. In theory, any modality could accomplish this; in practice, only those with sufficient signal-to-noise ratio can be used this way.

## Applications in Vision

### *Retinotopy*

The first application of fMRI-based research was in the domain of the early stages of visual processing. Indeed, the very first human fMRI study involved the demonstration that a region of the brain associated with early visual processing, occipital cortex in the calcarine fissure, yielded an NMR signal that varied as flashing lights were presented (or not) to a subject.

This demonstration was exciting, but the excitement was limited, for several reasons. First, nothing new had been demonstrated about human visual cortex. Second, there were a host of technical concerns which, had they been correct, would have meant that the spatial resolution obtainable with fMRI would be seriously compromised. And finally, most of the next simple advances would not go beyond what we already know from (invasive) single-cell recordings in nonhuman primates.

However, the development of fMRI in the ensuing years for the study of early visual processing addressed all these concerns, and went far beyond them. First, retinopy was demonstrated for area V1 at a level of spatial resolution that exceeded any previously demonstrated with a noninvasive technique. Second, retinotopy was used to delineate multiple visual areas. Differences between the layout of human visual areas as compared with other primate species were demonstrated, and new visual areas apparently unique to humans were described.

The ability to routinely map retinotopically defined regions of the human brain has enabled progress in number of areas. In one clinically relevant application (Hadjikhani et al., 2001) the visual auras of a migraine headache were mapped for an individual subject as the headache progressed and the auras moved through different portions of the visual field. The ability to objectively observe the physiology underlying what had previously been considered to be purely subjective effects is of obvious practical consequence, especially in the context of evaluating drug treatments and other therapies. In a context perhaps more directly relevant to testing theories and models, several groups have claimed to detect ocular dominance columns in human visual cortex (Cheng, Waggoner, and Tanaka, 2001; Menon et al., 1997). This achievement uses MRI techniques that push the spatial resolution (with associated tradeoffs in temporal resolution). If functional imaging of cortical columns in other brain areas is achieved (which is not a trivial extension, as the ocular dominance columns are some of the largest in cerebral cortex), the ability to test increasingly rich and detailed models will be likely.

### Motion Processing and the Motion Aftereffect

One of the most robust findings in functional brain imaging is the activation of the cortical area known as V5 or MT by the visual presentation of moving stimuli. This area has been important in at least two types of studies: the popular visual illusion known as the motion aftereffect (MAE), and the documentation of changes in cortical activity in response to voluntary changes of attention.

Virtually concurrent with the earliest studies of retinotopy using fMRI, a classic psychological effect, the MAE, was seen to be associated with detectable brain activity localized to specific parts of the cortex associated with visual motion processing. When subjects looking at moving patterns reported a subjective MAE, specific brain areas—notably area MT/V5—showed increased activity. This initial finding has been extended using behavioral variants of the basic effect to demonstrate particularly tight correlation of MT activity and the subjective perception of the effect. Two studies made use of the fact that the MAE lasts longer (after adaptation) if it is not elicited by the presentation of a stationary test pattern. In one study, subjects were kept in the dark after adaptation. Activity in MT decreased when the subject was in the dark, and returned during subsequent viewing of a stationary target that elicited the subjective impression of motion. In another study, the MAE was generated in only part of the visual field, and MT activity was elicited only when the stationary target was presented to the adapted portion of the field (see Moore and Engel, 1999, for a summary). This collection of work gives some idea of the potential for hypothesis testing associated with functional brain imaging in vision.

### Visual Object Representation: General Issues, and Are Faces a Special Case?

One of the most active areas of experimental research and theoretical analysis in the context of functional brain imaging of vision has to do with visual object representation. Numerous imaging and clinical reports have documented localization of cortical function associated with particular classes of visual objects. The category of human faces has received by far the most attention in this regard, but many other categories (from general classes such as living versus inanimate or tools versus animals to highly specific classes such as cows versus horses) have been studied.

One focus of the debate is the meaning of these localized activations per se. Specifically, it has been documented that, for example, the "fusiform face area" responds best to faces in a number of contexts, but the area responds (statistically significantly) to numerous other categories of objects (e.g., Ishai et al., 1999). The question of whether it is best to think of this area as somehow face specific or, alternatively, as specific to any overpracticed category is one of the heated debates in the field. Lesion data are particularly relevant here. There is the relatively rare but well-documented phenomenon of prosopagnosia (a specific impairment of the visual perception of faces), and there is the even rarer case study of an otherwise healthy subject who lost the visual face-processing area of cortex in infancy and continued to show face-specific deficits as an adult. But disentangling the specificity for faces from the possible specificity for a more general overpracticed category has not yet been achieved.

A growing number of quantitative studies are attempting to understand and utilize this cortical specificity to study visual object representation. Discriminating the brain activation responses to different categories has been refined to demonstrating varying degrees of specificity even in areas that are not the best ones for the individual categories. So, for example, it is possible to discriminate houses from scissors even when the imaging data are restricted to areas that are maximally responsive to faces (Haxby et al., 2001).

Independent of the ultimate resolution of these concerns, these cortical areas of reasonable specificity can be exploited to test longstanding questions of theoretical interest in cognitive neuroscience and brain modeling. The following two sections discuss two aspects of visual processing that are necessarily top-down phenomena: voluntary modulation of attention, and imagery. In both cases, the ability to functionally specify an a priori region of interest for analysis (based on the object- or motion-selective specificity outlined above) is crucial for tight experimental and statistical tests.

### Visual Attention

*Attention* is an intensively studied area of cognitive psychology and has been very popular for imaging studies. There are many reviews of visual attention in the context of imaging (e.g., Kanwisher and Wojciulik, 2000). The following discussion focuses on one aspect of this area.

A classic PET study (Corbetta et al., 1990) contrasted the activation of different cortical areas depending on whether the subject needed to attend to a single attribute of the stimuli (size/shape, color, or speed of motion) or to *any* of those three attributes when performing a discrimination task. A more recent study of visual attention took advantage of the known localization of function associated with three categories (motion processing, face processing, and place/building processing) to test an explicit theoretical question of long standing in cognitive psychology and neuroscience. Both of these studies required changes in voluntary attention, with (in some cases) associated changes in behavioral performance measures. But, independent of whether there were detectable changes in behavioral performance on the associated tasks, there were detectable and statistically significant changes in the activity of specific cortical areas. By dint of clever experimental design, these changes were relevant to specific theoretical questions, as elaborated below.

One early fMRI-based study demonstrated that the use of voluntary attention (deciding whether to attend to a subset of moving dots or to a subset of stationary dots in a field of moving and stationary dots) caused detectable changes in MR signals associated with a visual motion-processing area in cortex (O'Craven et al., 1997). This study did not have an overt behavioral measure to provide external evidence that subjects were actually performing their assigned tasks. But the data were sufficiently clean and unambiguous that this study was published and gained considerable attention.

Over the ensuing years the study was replicated and extended in a number of ways by different laboratories around the world. The initial basic demonstration of attentional modulation became the starting point for more subtle experiments, experiments that were more tightly tied to behavioral measures. Importantly, both the qualitative and the quantitative measures of attentional modulation were replicated. For instance, the motion-processing area was active whenever visual movement was present, but that activity increased by about 50% when the subject was attending to the movement, in contrast to when the subject was not attending to the movement. The studies that used analogous tasks as part of their design found quantitatively similar changes.

Taking advantage of the findings that other parts of the brain showed localized activity in response to certain classes of objects (e.g., the so-called fusiform face area [FFA] and parahippocampal place area [PPA]) one study (O'Craven, Downing, and Kanwisher, 1999) addressed the question of whether there was increased processing of the irrelevant attributes of attended objects relative to unattended objects. Stimuli were designed that mixed the attributes of faces, places, and motion on each trial. The discrimination task on a given trial depended on only one of these attributes. Not surprisingly, the three relevant cortical areas (MT/V5, FFA, and PPA) each showed increased activation when the discriminating attribute (motion, faces, or places) was the relevant one for that cortical area. More interestingly, contrasting the imaging data from those trials distinguished by an irrelevant attribute of the stimulus (e.g., whether or not an image was moving in a face discrimination task) led to the demonstration of increased activity in the area responsible for that attribute (e.g., the motion-processing area in the example above), even though the presence or absence of that attribute (motion, in this example) was irrelevant to the discrimination task. This finding was interpreted as supporting models of attentional processing that had an "object-based" component: once the subject is attending to an object for whatever reasons, all attributes of the attended object are enhanced in processing, including those that are not functionally relevant at the time. Thus, brain imaging experiments are being applied to theoretical questions of longstanding interest in cognitive psychology.

### *Visual Imagery*

There have been numerous studies of visual imagery attempting to document changes in brain activity while subjects "imagine," i.e., recreate in their minds, some approximation to the brain state elicited by the physical presentation of various visual stimuli, in the absence of those stimuli. Continuing the thread started with the studies of voluntary visual attention in the previous section, *imagery* shares the property of being necessarily a top-down phenomenon. In at least one study involving the visual imagery of familiar faces or familiar locations, the strength and functional localization of the imagined visual images were sufficient to permit a data analyst looking only at two regions of the cortex (previously localized as being particularly responsive to faces or places, respectively) to estimate, with far greater than chance accuracy, whether the subject was imagining one or the other of the two classes of stimuli *on individual stimulus presentation trials*. That is, it was not necessary to average across a collection of trials of a given type (e.g., imagining a face) in order to be able to do the discrimination (O'Craven and Kanwisher, 2000). Studies such as this one have obvious potential for both practical applications and the testing of theoretical models of brain function.

## Discussion

The present article described some of the lowest-level applications (using the regular retinotopic mapping of multiple visual areas to distinguish those areas), some of the middle-level applications (connected to functional localization associated with object and motion processing), and some of the highest, necessarily top-down applications associated with voluntary attention and imagery. Visual stimulus processing has probably been the most intensively pursued application of functional brain imaging. One reason for this popularity is the wealth of data on the primate visual system, obtained largely through invasive, single-cell recordings and lesion studies. The early dependence on connection to known primate neurophysiology is, in recent times, being turned around. Several laboratories are now developing functional MRI suites designed specifically to study nonhuman primates. The idea is to use the invasive technologies like single-cell recording, adapted for the MR environment, and get a deeper understanding of both the functional brain structures and the relationship between neural activity and hemodynamics, using methods that would be unethical in human subjects.

This article has reviewed some applications in functional brain imaging of the visual modality in which *quantitative* measures of activity were obtained. In analogy with a classic observation in experimental psychology by Paul Meehl (1967), it should be understood that increasing the statistical power of the experimental tool (whether by increasing the number of subjects or by increasing the strength and sensitivity of the imaging hardware) is generally not sufficient to distinguish interesting models of brain function and organization. The fact that brain area *X* shows a different level of activity in response to task 1 than in response to task 2 has been amply demonstrated for many *X*s and pairs of tasks. Increasing the power of the tools will only increase the set of *X*s and task pairs for which those differences become statistically significant (Savoy, 2001). Quantitative and parametric observations must be obtained to help functional brain imaging live up to its potential, specifically, the potential to create tight, quantitative tests of theory and causal models. Many experimentalists understand this challenge and the associated dilemmas, and an increasing number of studies go beyond the "boxology" sometimes disparagingly applied to functional imaging studies. Increased communication between brain theorists and functional neuroimagers can only improve the situation.

# Imitation

*Aude G. Billard*

## Introduction

*Imitation*—the ability to recognize and reproduce others' actions—is a powerful means of learning and developing new skills. Species endowed with this capability are provided with fundamental abilities for social learning. In its most complex form, imitation provides fundamental capabilities for social cognition, such as the recognition of conspecifics, the attribution of others' intentions, and the ability to deceive and to manipulate others' states of mind.

Research on imitation builds a bridge between biology and engineering, and between the study and use of imitation. Biology seeks to better understand the cognitive and neural processes behind the different forms of animal imitation, and how these relate to the evolution of social cognition. Engineering uses studies of the biological processes of human imitation to design robot controllers and computational algorithms enabling learning and imitative skills similar in robustness and flexibility to human skills.

There are three major levels of modeling of imitation. *Theoretical modeling* derives models of the cognitive mechanisms behind imitation based on behavioral studies of humans' and other animals' imitation. *Computational modeling* builds models of the neural mechanisms, and their brain correlates, behind imitation learning in human and other animals. *Robotics modeling* designs algorithms for imitation learning, implementable in hardware systems, that allow a robot to be taught by demonstration. Next we briefly describe key findings and issues faced by each of the three levels of imitation modeling.

## Theoretical Modeling

The study of animal imitation encompasses a large range of disciplines, including ethology, neuroscience, psychology, and linguistics.

For ethologists, the major issue is to define what behaviors the term *imitation* refers to and in which species these behaviors are exhibited (for reviews, see Whiten, 2000; Heyes, 2001). Animal imitation seems best described in terms of levels of complexity. Imitation (or "true" imitation) is contrasted to mimicry or copying. True imitation is the ability to replicate and, by so doing, learn skills that are not part of the animal's prior repertoire, by observation of those performed by others. Mimicry, in contrast, is the ability to replicate a behavior that is usually part of the usual animal repertoire.

Simple forms of imitation that probably require no understanding of intention or theory of mind are found in, e.g., rats and monkeys. These species' copying ability is considered to be an instance of *social facilitation*, in which the correct behavior is prompted by the social context. This simple imitative behavior relies on a form of associative learning that accepts temporal delays, imprecise timing, and incomplete cues (Heyes, 2001). In this form of imitation, the act of observing enhances learning of a skill by reducing the number of incorrect associations.

More complex forms of imitation are demonstrated by apes and dolphins. Chimpanzees and orangutans can master simple sequential, manipulatory tasks. They are capable of replicating part of the observed behavior in a different context than that in which it was observed. Dolphins can be trained to copy long sequences of body movements following human demonstration, showing an ability to map different body structures to their own (they respond to the demonstrator's movements of the legs and arms with similar movements of their tail and fins, respectively).

These more complex forms of imitation are set apart from simpler ones because they encompass the ability to reproduce *sequences* of actions and the ability to *transform* the actions so as to produce variations (subparts) of the observed behavior in the same or a different context (see, e.g., Byrne and Russon, 1998).

The ability to imitate reaches its fullest complexity in humans. Humans can imitate any actions of the body based on a variety of purposes or goals, such as the goal of reproducing the aesthetic (e.g., dance), efficiency (e.g., sport), or precision (e.g., surgery) aspect of the movement. Imitation can be *immediate* or *deferred*, depending on whether the replication occurs within a short (few minutes) or long (hours, days) time after the demonstration. It may be partial or selective (when only part of the imitative behavior is replicated), goal-directed (when only the means-end of the demonstration is perfectly reproduced), or exact (Bekkering and Prinz in Dautenhahn and Nehaniv, 2002). Imitation in humans extends to verbal and facial expression, and from there to high-level cognitive and behavioral skills. It is a fundamental means to relate socially to others, and people who are impaired in their imitative skills, such as people with autism, also show general impairment in other social skills.

For psychologists, imitation is crucial to the child's growing capacity for representation and symbolization. Meltzoff and colleagues' work contributed to redefining the developmental stages of children's imitation proposed by Piaget in *Play, Dreams and*

*Imitation* (see Meltzoff and Moore, 1999). In infants, immediate imitation of facial expression appears soon after birth, suggesting an "innate" kinesthetic-visual mapping.* Deferred imitation appears as early as 9 months, implying a growing capacity for internal representation of others' movements. Generalized imitation involving numerous modalities, such as vocal and verbal imitation and the ability to imitate a great variety of actions, begins around 15 to 18 months.

An important body of research in linguistics studies vocal and verbal imitation in birds, with the goal of understanding the role that hearing plays in tuning speech production and how this can relate to similar developmental processes in human infants (see Doupe and Kuhl, 1999). Young birds' songs mature in the presence of a tutor (usually the parent bird) and are species and region specific. Parrots and mynah birds are particularly intriguing because of their ability to reproduce segments of human speech.

Studies of animal imitation show that imitation results not from a single mechanism but from several cognitive mechanisms that are multimodal (audiomotor, visuokinesthetic-motor) in essence and are used for other (nonimitative) behaviors. Visuomotor imitation is better understood at this stage than is vocal imitation, as it can profit from the large body of literature on perception and production of motion. Findings from these studies directly relevant to the study of imitation are briefly summarized next.

### *Motion Perception*

Since Johansson's landmark study in 1973, an abundance of literature has demonstrated the capacity of humans to recognize biological (especially human) motions from a limited number of cues (these studies use point-light display techniques that allow the viewer to see only one point for each moving limb) (for a review, see Dittrich, 1999). Humans can easily make out the general features of the motion, distinguishing the type of gait or the type of action, as well as specific features, such as the weight of an object being lifted or the age and sex of the walker. More important, humans are quite capable of distinguishing between biological and nonbiological motions. This ability relies on powerful visual mechanisms for quickly extracting relevant features from the kinematics of multiple-joint motion. Some of these features are the phase or relationship across limb motion, the orientation, and the speed of limb movement.

### *Motor Control*

Although there is evidence that the brain can recognize motion from a limited number of clues, it is not yet understood which information is used to recognize and to reproduce the motion. Because of the redundancy of multiple-joint motion, the information offered in point-light display experiments is usually not sufficient to lead to a single plausible solution. It seems, therefore, that the mechanisms humans use to assist in visual reconstruction of motion rely on models of the structure of the human body and the dynamics of its possible motion.

Evidence that the central nervous system (CNS) uses models of body dynamics to direct motion also comes from purely motor control studies (see MOTOR CONTROL, BIOLOGICAL AND THEORETICAL). The idea is that, rather than relying on sensory feedback (which is too slow to reach the CNS in time for the next motor command), the CNS uses *feedforward control* to control movements; that is, it uses *inverse forward* models to predict the expected outcome of a command as well as to estimate the current position and velocity of the moving limbs.

In summary, evidence from psychophysical studies of motion perception and from motion studies suggest that, to achieve a good replication of movements from a paucity of visual cues, the brain uses models of human kinematics and dynamics of motion. Moreover, it is likely that visual and motor representation of movements bear a close relationship for the mapping to be immediate and precise. It is not yet understood how the CNS builds these representations.

## Computational Modeling

The challenge faced by computational modeling is to construct a model that can account for all the instances of imitation reported in the literature. The model should provide a means of naming and distinguishing animal imitative abilities, following a list of fundamental cognitive components. Ideally, this hierarchical representation of animal imitation should follow the evolutionary tree, such that the different cognitive processes can be linked to the evolution of specific neural structures. We review next the evidence for neural structures specific to imitation.

### *Neural Structures Behind Visuomotor Imitation*

For a long time imitation has been a topic of research primarily in the cognitive and psychological sciences; only recently has imitation become the explicit topic of a number of neuroscience studies. This new trend started with the discovery of the *mirror neuron* system (Rizzolatti et al., 1996), a neural circuit in F5 area of monkey premotor cortex that is active both when the monkey observes another monkey or a human grasping or manipulating objects and when the monkey performs the same manipulation. The mirror neuron system has been proposed as the link between visual and motor representation that is necessary to learn from the observation and imitation of others' actions. Evidence from brain imaging studies (e.g., Decety et al., 2002) suggests the existence of a similar system in humans involving predominantly Brodmann's areas 44 and 45 (Broca's areas), 40 (parietal lobe), and 21 (superior temporal sulcus).

Evidence that specific areas of the human brain contribute to imitation also comes indirectly from lesion studies. Studies of abnormal imitative behavior can be separated in two groups:

1. Patients suffering from a lack of or strong deficiency in the ability to imitate. Patients with ideomotor apraxia after parietal lesion are unable to make symbolic gestures or to act out the use of an object in response to an oral request (DeRenzi, Motti, and Nichelli, 1980). It is unclear whether ideomotor apraxia results from a deficit in motor imagery mechanisms or in motor execution. Apraxic patients are sometimes also incapable of recognizing a correctly produced gesture when given a stationary (photograph) or moving visual presentation. This suggests that the parietal lobe provides the locus of a neural network responsible for the translation of mental representation into movement production. However, the absence of systematic co-occurrence of ideomotor apraxia and impairment in gesture recognition indicates that motor imagery and motor execution remain two separate processes, even if closely interconnected.

2. Patients displaying obstinate imitation behavior, that is, a compulsive imitation behavior that cannot be stopped easily by command. Patients with frontal lobe damage sometimes display imitation behavior in which they imitate the examiner's gestures without being so instructed (Lhermite, Pillon, and Serdaru, 1986). This type of disorder supports the view that the frontal lobe modulates (mainly inhibits) a subcircuit that continually interprets vi-

*Unsuccessful replications of the work led to a large debate that seems now quasi-resolved, thanks to several consecutive successful replications.

sual observation of movements through the activation of motor patterns that would produce the same movements (a typical mirror neuron circuit).

Taken together, evidence from lesion studies and brain imaging suggests a major role for parietomotor connectivity as a basic circuit (possibly the mirror neuron system) behind movement imitation, and it also highlights the importance of frontoparietal connectivity in regulating this circuit.

Since its discovery, the mirror neuron system has led to a number of speculations about its role in imitation. However, evidence to support these hypotheses is still lacking. Research on the human mirror system is still in its early stage and has addressed only simple actions of the arms and hands (fingers). It remains to be shown that mirror neurons exist for driving motion of other limbs, and to understand their role in driving imitation and imitation learning of complex actions (so as to qualify as "true imitation").

Computational modeling investigates some of the possible implications of a high-level representation of movements common to both visual and motor systems (a mirror neuron system) for imitation learning. In this quest, Oztop and Arbib developed a computational model of monkey mirror neuron system (see Arbib et al., 2002, and LANGUAGE EVOLUTION: THE MIRROR SYSTEM HYPOTHESIS). The model accounts for the role of the parietal lobe and F5 area in recognition and control of grasping. In particular, it gives a description of how, through learning of performing grasps, visuomotor (from parietal lobe to F5) connectivity can be built.

At a higher level of abstraction, computational models of the neural and cognitive correlates to human imitation are developed. Demiris and Hayes's model (in Dautenhahn and Nehaniv, 2002) gives an account of the cognitive processes behind imitation, in which the motor system is either active (active imitation) or passive (passive imitation) during perception. The active imitation mode encompasses a motor imagery mechanism (a type of mirror system) in which the same motor structures used in producing motion are used during visual perception for classification and recognition of motion.

Billard's (1999) model gives a high-level, comprehensive, but simplified representation of the visuomotor pathway behind learning by imitation, from processing real video data to directing a dynamic simulation of a humanoid or an actual robot (Figure 1). The model has composite modules whose functionalities were inspired by those of specific brain regions, incorporating abstract models of the superior temporal sulcus (STS), the spinal cord, the primary motor cortex (M1), the dorsal premotor area (PMd), and the cerebellum. Each part is implemented at a connectionist level, where the neuron unit is modeled as a *leaky integrator*. Neurons in the PMd module respond both to visual information (from STS) and to corresponding motor commands produced by the cerebellum. The STS-PMd-M1 interconnection is a simplified model of a mirror neuron system. The biological plausibility of the model was validated against kinematic recording of human motion (Billard, 1999) and functional magnetic resonance imaging (fMRI) data of human imitation of finger motion (Arbib et al., 2000).

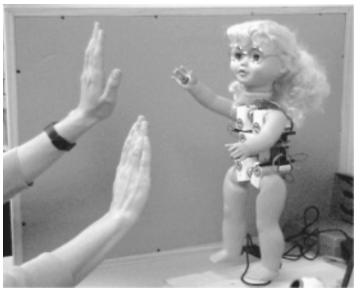

**Figure 1.** Robota, a minihumanoid, doll-like robot, can mirror the arm and head motion of a human demonstrator by visual tracking of the optical flow. Researchers are investigating its use as an educational toy for normal and handicapped children. (From Billard in Dautenhahn, K., and Nehaniv, C., Eds., 2002, *Imitation in Animals and Artifacts*, Cambridge, MA: MIT Press, Reproduced with permission.)

## Robotics Modeling

Robotics investigates the potential of imitation learning as a user-friendly means of human-robot interaction. The goal is to provide robots with the capacity for being reprogrammed in a nonexplicit fashion, that is, through demonstration. The challenge is to determine learning algorithms that are flexible across tasks and across platforms (robots).

An important issue dealt with by computational and robotic modeling is that of determining a measure of the similarity across demonstrator and imitator motions (Schaal, 1999; Dautenhahn and Nehaniv, 2002). For instance, when imitating grasping an object, one can reproduce one, a few, or all characteristics of the movements, and one can in principle reproduce (1) the goal of the movement (grasping the object with any effector following any path), (2) the goal of the movement and the correct effector (grasping the object with the correct hand), and (3) the detail of each joint movement, the motion of subsegments, and even the overall speed of movement. In each case, a different measure of the similarity between demonstrator and imitator movements must be used to account for the correctness of the reproduction. The measure should, in some cases, be qualitative, comparing the relationships across objects (which hand, which object), whereas in other cases it is quantitative, comparing the paths followed by each hand or comparing the angular trajectories of each joint.

In construction imitations of joint motion, the problem is how to transfer human motions into robot motions, insofar as humans and robots have very different dynamics. In other words, the problem is how to compute the inverse kinematics (if working in eccentric coordinates, such as when using visual tracking) or the inverse dynamics (when working in intrinsic coordinates such as when using manipulandum; see ROBOT LEARNING and ROBOT ARM CONTROL).

A large part of robotics research follows a purely engineering perspective, solving assembly task learning from observation (e.g., Friedrich et al., 1996). Typically, the demonstrator's movements are measured either as torques and joint angle displacements through the use of a manipulandum or from visual tracking. The robot is then controlled using classical planning techniques.

More recent efforts, inspired by computational modeling of human imitation, are oriented toward analyzing the underlying mechanisms of imitation in natural systems and modeling those mechanisms in artificial ones. The goal here is to design robot controllers showing similar robustness and adaptability as natural systems. Biologically inspired models of the ability to imitate have been tested in experiments in which the robot could replicate movements of the head and arms of a human (see Schaal, 1999, for a review).

## Discussion

Imitation is a concept heavily debated in the biological literature. Modeling can eliminate some of the debate by defining what minimal computation is necessary for each type of imitation. Several theoretical models have been proposed to distinguish between each level of computation, e.g., by differentiating between purely associative imitation (low-level imitation) and sequential imitation (high-level imitation). Although conceptual distinctions are important, they are hard to validate through behavioral studies only. Computational models play a key role in validing these theories by offering an explicit functional description of the computation required for each level of imitation. Realistic modeling that uses real data as input (e.g., video recording of human or animal motion) and physical devices (e.g., robots) or realistic simulation as output is essential to gain a fuller understanding of the mechanisms underlying sensorimotor coordination in imitation.

At this point, there are very few computational or robotic models of imitation. However, the field is currently popular and is bound to grow rapidly within the next years. Its popularity is in part due to recent technological development in robotics that have allowed the design of humanoid robots whose joint complexity approaches that of humans. Modeling of imitation has also benefited from a recent spate of neurological data on human and monkey imitation. Computational and robotic modeling are expected to fill in the gaps between modeling of low-level information (from neurological studies) and modeling of high-level information (from behavioral studies). Modeling of imitation should lead to a better understanding of the neural mechanisms at the basis of social cognition and offer new perspectives on the evolution of animals' ability for social representation.

# Independent Component Analysis

*Anthony J. Bell*

## Introduction

Independent component analysis (ICA) is a linear transform of multivariate data designed to make the resulting random vector as statistically independent (factorial) as possible. Despite its relatively short history, it is rapidly becoming a standard technique in multivariate analysis. In signal processing it is used to attack the problem of the blind separation of sources (Haykin, 2000), for example of audio signals that have been mixed together by an unknown process. In the area of neural networks and brain theory, it is an example of an information-theoretic unsupervised learning algorithm, and one that provides one of the most compelling accounts of how early sensory processing may self-organize. That is, when an ICA network is trained on an ensemble of natural images, it learns localized oriented receptive fields (see FEATURE ANALYSIS) qualitatively similar to those found in area V1 of mammalian visual cortex (Bell and Sejnowski, 1997). Finally, in the increasingly important area of analyzing multivariate brain data (multielectrode recordings, electroencephalography, functional magnetic resonance imaging), ICA has been used to pull recordings apart into components of interest to researchers attempting to understand task-related spatial and temporal brain dynamics (Jung et al., 2000; BRAIN SIGNAL ANALYSIS).

Thus we have the pleasingly ironic situation in which the same neural network algorithm is being used both as an explanation of brain properties and as a method of probing the brain.

The idea is as follows. We are given an $N$-dimensional random vector, $\mathbf{x}$, which could be the instantaneous output of $N$ microphones, $N$ time points of an audio signal, $N$ pixels of an image, the output of $N$ electrodes that record brain potentials, or any other multidimensional signal. Typically there will be many correlations between the elements of the vector $\mathbf{x}$. ICA, like PRINCIPAL COMPONENT ANALYSIS (PCA) (q.v.), is a method of removing those correlations by multiplying the data by a matrix, as follows:

$$\mathbf{u} = \mathbf{W}\mathbf{x} \tag{1}$$

(Here, we imagine the data are zero-mean; see the next section for details on preprocessing.) But whereas PCA merely uses second-order statistics (the covariance matrix), ICA uses statistics of all orders. PCA attempts to decorrelate the outputs (using an orthogonal matrix $\mathbf{W}$), while ICA attempts to make the outputs statistically independent, and places no constraints on the matrix $\mathbf{W}$. Statistical independence means the joint probability density function (p.d.f.) of the output *factorizes:*

$$p(\mathbf{u}) = \prod_{i=1}^{N} p_i(u_i) \tag{2}$$

while decorrelation means only that $\langle \mathbf{u}\mathbf{u}^T \rangle$, the covariance matrix of $\mathbf{u}$, is diagonal ($\langle \cdot \rangle$ means average).

Another way to think of the transform in Equation 1 is as follows:

$$\mathbf{x} = \mathbf{W}^{-1}\mathbf{u} \tag{3}$$

In this, the data are formed by linear superposition of *basis functions* (columns of $\mathbf{W}^{-1}$), each of which is activated by an independent component, $u_i$. We call the rows of **W** *filters* because they extract the independent components. In orthogonal transforms such as PCA, the Fourier transform, and many wavelet transforms, the basis functions and filters are the same (because $\mathbf{W}^T = \mathbf{W}^{-1}$), but in ICA they are different.

The usefulness of a nonorthogonal transform sensitive to higher-order statistics can be seen in Figure 1. Here we plot PCA and ICA basis functions (axes) for a two-dimensional data distribution. Clearly, the ICA axes capture the structure of the data much better. Although this data distribution may look strange, it is actually very common in natural data, much more common than those who like to model data with Gaussians, or mixtures of Gaussians, might suppose. It comes from the nonorthogonal "mixing together" of highly sparse independent components, where by *sparse* we typically mean much peakier than a Gaussian, with longer tails. A more technical term for sparse is super-Gaussian. The ICA algorithm we will describe is ideally suited for extracting these sparse independent components.

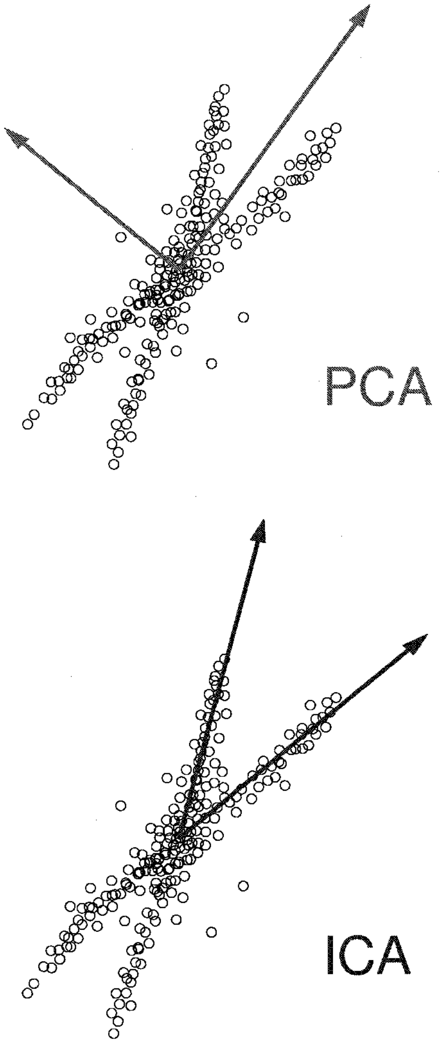

**Figure 1.** The difference between PCA and ICA on a nonorthogonal mixture of two distributions that are independent and highly sparse (peaky with long tails). An example of a sparse distribution is the Laplacian $p(x) \propto e^{|-x|}$. PCA, looking for orthogonal axes that are ranked in terms of maximum variance, completely misses the structure of the data. Although these distributions look strange, they are very common in natural data. (Courtesy of T.-P. Jung.)

Before describing the algorithm, we make some remarks regarding the origin of the various algorithms and the relations between them, with pointers to tutorial literature. This is necessary for a balanced treatment, as there is no one ICA algorithm.

The ICA problem was introduced by Herault and Jutten (1986). The results of their algorithm were poorly understood and led to Comon's 1994 paper defining the problem, and to his solution using fourth-order statistics. Much work took place in this period in the French signal processing community, including the maximum likelihood approach (Pham, Garrat, and Jutten, 1992), which subsequently formed the basis of Cardoso and Laheld's (1996) EASI method. These methods are very close to the Infomax approach (Bell and Sejnowski, 1995) so we will refer to this algorithm as Infomax/ML-ICA. Cichocki, Unbehauen, and Rummert (1994) had proposed an algorithm that motivated Amari (1997) and colleagues to show that its success was due to its relation to a "natural gradient" modification of the Infomax/ML-ICA gradient. This modification greatly simplified the algorithm, and made convergence faster and more stable.

This algorithm, which we might, rather clumsily, call NatGrad-Infomax/ML-ICA, is thus derived from multiple authors and is the most widely used adaptive, or on-line (i.e., stochastic gradient), method for ICA. It is also the most neural-network-like. It is the one we will describe in the body of this article, at the risk of underrepresenting other approaches. Useful batch algorithms also exist, such as Hyvärinen's FastICA and many cumulant-based techniques.

Helpful review papers comparing the different algorithms are Lee et al. (1998) and Hyvärinen (1999). The edited collection of Haykin (2000) contains excellent survey papers from many of the authors mentioned above, and the edited collection of Girolami (2000) contains more recent theoretical work and examples of many applications. There have been two international workshops on the topic (ICA 1999 and 2000), the proceedings of which contain much additional material.

## An Algorithm for ICA

This section provides enough information for the reader to implement ICA. To follow the full derivations, readers will have to consult the original sources. There is only space here to highlight the mathematics.

### *Preprocessing*

To start with, the linear transform of Equation 1 should actually be an *affine* transform: $\mathbf{u} = \mathbf{W}\mathbf{x} + \mathbf{w}$, where $\mathbf{w}$ is an $N \times 1$ "bias" vector that centers the data on the origin. But if we assume the independent component p.d.f.s, $p_i(u_i)$, are roughly symmetric, then it is simpler to make the data zero-mean beforehand. An additional preprocessing step, one that speeds convergence, is to "sphere" the data beforehand, that is, to diagonalize its covariance matrix. These preprocessing steps are achieved as follows:

$$\mathbf{x} \leftarrow 2\langle \mathbf{x}\mathbf{x}^T \rangle^{-1/2}(\mathbf{x} - \langle \mathbf{x} \rangle) \tag{4}$$

by which we mean that we subtract the mean of the data, then multiply by twice the inverse square root of its covariance matrix. This yields a decorrelated data ensemble whose covariance matrix satisfies $\langle \mathbf{x}\mathbf{x}^T \rangle = 4\mathbf{I}$, where $\mathbf{I}$ is the identity matrix. This is a useful starting point for further training with the *logistic*-ICA algorithm, which we will describe below. Note that this sphering method is not PCA. It is another decorrelation method called zero-phase whitening, which we have empirically found to be a better starting point for training than PCA-style decorrelation. In fact, there are many decorrelating, or second-order independent transforms, and extra constraints are needed to choose one of them. Zero-phase whitening constrains the matrix **W** to be symmetric, while PCA constrains it to be orthogonal. ICA, also a decorrelation technique, but without any constraints on **W**, finds its constraints in the higher-order statistics of the data.

### *Natural-Gradient Infomax/ML ICA*

Most neural network algorithms have an objective function. ICA is no different. Its objective is to minimize the *redundancy* between the outputs. This is a generalization of the mutual information and is written as follows:

$$I(\mathbf{u}) = \int p(\mathbf{u}) \log \frac{p(\mathbf{u})}{\prod_{i=1}^{N} p_i(u_i)} \, d\mathbf{u} \tag{5}$$

It is easily verified that this redundancy measure has the value of 0 when the p.d.f. $p(\mathbf{u})$ factorizes as in Equation 2.

This is actually a difficult function to minimize directly. The insight that led to the Infomax-ICA algorithm was that $I(\mathbf{u})$ is related to the joint entropy, $H(\mathbf{g}(\mathbf{u}))$, of the outputs passed through a set of sigmoidal nonlinear functions, **g**. The relation is as follows:

$$I(\mathbf{u}) = -H(\mathbf{g}(\mathbf{u})) + E\left[\sum_i \log \frac{|g_i'(u_i)|}{p_i(u_i)}\right] \tag{6}$$

Thus, if the absolute values of the slopes of the sigmoid functions, $|g_i'(u_i)|$, are the same as the independent component p.d.f.s, $p_i(u_i)$, then Infomax (maximizing the joint entropy of the $\mathbf{g}(\mathbf{u})$ vector) will be the same as ICA (minimizing the redundancy in the **u**-vector). The principle of matching the $g_i'$s to the $p_i$s is illustrated in Figure 2, where a single Infomax unit attempts to match an input Gaussian distribution to a logistic sigmoid unit, for which

$$g(u) = \frac{1}{1 + e^{-u}} \tag{7}$$

The match cannot be perfect, but it does approach the maximum entropy p.d.f. for a distribution bounded between 0 and 1—in other words, the unit distribution—and this is done by maximizing the expected log slope, $E[\log|g'(wx)|]$. The generalization of this idea to $N$ dimensions leads to maximizing the expected log determinant of the Jacobian matrix $[\partial g_i(u_i)/\partial x_j]_{ij}$. This optimization attempts to map the input vectors uniformly into the unit $N$-cube (assuming that the $g$-functions are still 0–1 bounded). Intuitively, we can see the following: If our outputs are spread evenly in a cube, then telling you the value along one axis does not tell you anything about the values along the other axes. This is the intuition behind statistical independence.

To cut a long story short, the exact stochastic gradient descent algorithm that maximizes $H(\mathbf{g}(\mathbf{u}))$ is:

$$\Delta \mathbf{W} \propto \mathbf{W}^{-T} + \mathbf{f}(\mathbf{u})\mathbf{x}^T \tag{8}$$

where $-T$ denotes inverse transpose, and the vector function, **f**, has elements

$$f_i(u_i) = \frac{\partial}{\partial u_i} \ln g_i'(u_i) \tag{9}$$

When $g_i'(u_i) = p_i(u_i)$ for all $i$, then, according to Equation 6, we have an exact ICA algorithm.

This leaves us with the tricky problem. Either we have to estimate the functions **g** on-line during training or we have to hope that the final term in Equation 6 does not interfere with Infomax performing ICA. This is one occasion where hoping actually works, because of the following *robustness conjecture: Any super-Gaussian prior*, $\mathrm{p_i(u_i)}$, *will suffice to extract super-Gaussian in-*

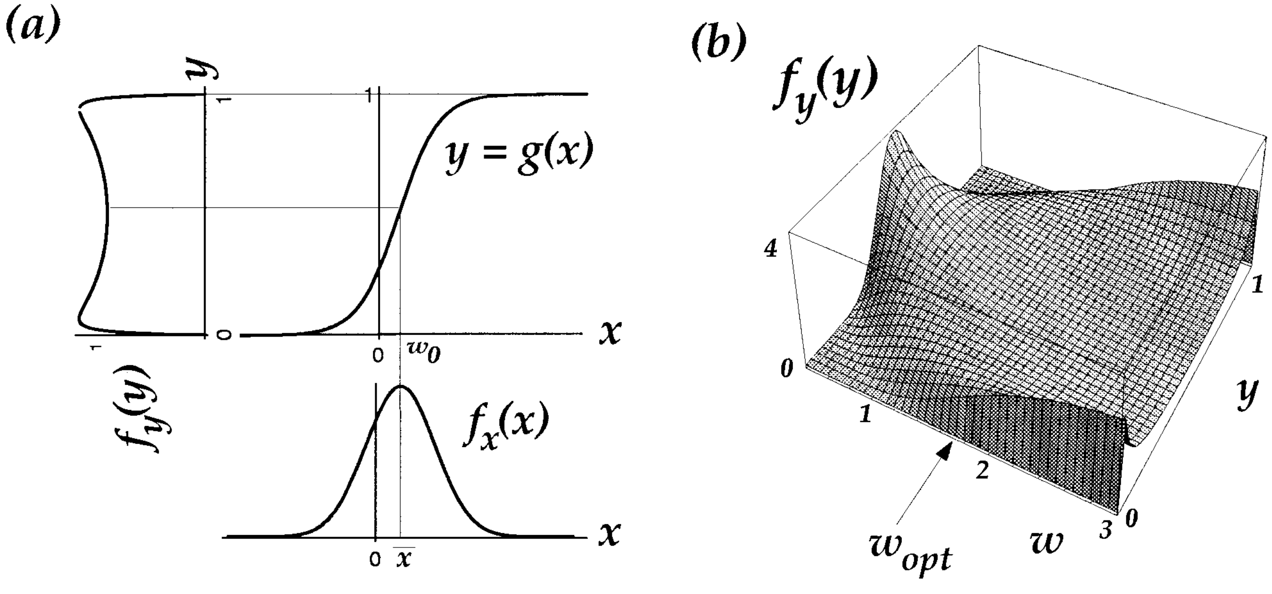

**Figure 2.** Optimal information flow in sigmoidal neurons. *A*, Input $x$, having probability density function $f_x(x)$ (note: this is $p(x)$ in the text), in this case a Gaussian, is passed through a nonlinear function $g(x)$. The information in the resulting density, $f_y(y)$, depends on matching the mean and variance of $x$ to the threshold, $w_0$, and slope, $w$, of $g(x)$ (Nicol Schraudolph, personal communication). *B*, $f_y(y)$ is plotted for different values of the weight $w$. The optimal weight, $w_{\text{opt}}$, transmits most information. (From Bell, A. J., and Sejnowski, T. J., 1995, An information maximization approach to blind separation and blind deconvolution, *Neural Computat.*, 7:1129–1159. Reproduced with permission.)

*dependent components. Any sub-Gaussian prior will suffice to extract sub-Gaussian independent components.* Super-Gaussian means peakier than Gaussian, sometimes called *sparse*, and usually signifying positive kurtosis. There are no solid proofs yet of this conjecture; it is more something that has been empirically observed, but it leads to generally successful "extended ICA" algorithms (see Lee et al., 1998) that do on-line switching of the priors, $\hat{p}_i(u_i)$, between super- and sub-Gaussian functions. In practice, because of this robustness, this switching may be all the estimation we need to do. This is also the insight behind "negentropy" approaches to ICA, which maximize the distance of the $p_i(u_i)$ from Gaussian, as described in Hyvärinen (1999) and Lee et al. (1998).

For most natural data (images, sounds, etc.), the independent component p.d.f.s are all super-Gaussian, and many good results can be achieved with what is called logistic ICA, in which our super-Gaussian prior is the slope, $g'(u_i)$, of the common logistic sigmoid function (Equation 7) so often used in neural networks. For this choice of $g$, the function $f$ in Equation 8 evaluates as $f(u) = 1 - 2g(u)$.

The Infomax-ICA algorithm is almost identical to the maximum likelihood approach (Pham et al., 1992). In maximum likelihood density estimation, we maximize a parameterized estimate of the log of the p.d.f. of the input, $\log\hat{p}(\mathbf{x}|\mathbf{W}, \mathbf{g})$. A simple argument shows that the determinant of the Jacobian matrix, $\det [\partial g_i(u_i)/\partial x_j]_{ij}$, is exactly such a density estimate (for much the same reason that $|g'_i(u_i)|$ is a density estimate for $p_i(u_i)$ in Equation 6). Infomax maximizes this log likelihood, and therefore inherits the useful properties of maximum likelihood methods, while preserving an information-theoretic perspective on the problem.

The final twist in the Infomax/maximum likelihood ICA algorithm comes from Amari and colleagues (Amari, 1997). They observed that a simpler learning rule with much faster and more stable convergence was obtained by multiplying the Infomax gradient of Equation 8 by $\mathbf{W}^T\mathbf{W}$ to obtain the following much simpler rule:

$$\Delta\mathbf{W}_{\text{NatGrad}} = (\Delta\mathbf{W})\mathbf{W}^T\mathbf{W} \propto (\mathbf{I} + \mathbf{f}(\mathbf{u})\mathbf{u}^T)\mathbf{W} \qquad (10)$$

Since $\mathbf{W}^T\mathbf{W}$ is positive definite, it does not change the minima and maxima of the optimization, it just scales the gradient. As luck would have it, it scales the gradient in an optimal fashion, which may be explained by an appeal to information geometry (Amari, 1997) or to equivariance: the gradient vector local to $\mathbf{W}$ is normalized so that it always behaves as it does when $\mathbf{W}$ is close to $\mathbf{I}$. For explanations, see the relevant chapters in Haykin (2000).

Both interpretations reflect the fact that the parameter space of $\mathbf{W}$ is not truly Euclidean, since its axes are entries of a matrix. Technically speaking, the parameter space has the structure of a Lie group.

Equation 10 can be clearly seen to be a nonlinear decorrelation rule, stabilizing when $\langle -\mathbf{f}(\mathbf{u})\mathbf{u}^T \rangle = \mathbf{I}$ (the minus sign is there because the $\mathbf{f}$ functions are typically decreasing). The Taylor series expansion of the $\mathbf{f}$ functions provide information about higher-order correlations necessary to perform the ICA task.

## Applications

The blind source separation problem in signal processing has often been considered synonymous with the ICA problem, but ICA can be applied in many situations where there is no clear notion of what constitutes a source. Some of the most interesting results have been achieved in such situations. Here we consider a few.

### *ICA on Natural Images*

From the point of view of computer vision and computational neuroscience, perhaps the most interesting result was the ICA basis vectors obtained for a data set of small image patches drawn from natural images (Bell and Sejnowski, 1997). These basis vectors consisted of oriented, localized, contrast-sensitive functions, sometimes refered to as edges (though an edge is really something to do with object boundaries).

Figure 3 shows a selection of basis functions (columns of $\mathbf{W}$) and filters (rows of $\mathbf{W}$) obtained from training on 18 × 18 patches.

The reason why this is interesting is that both the classic experiments of Hubel and Wiesel on orientation-selective neurons in visual cortex and several decades of theorizing about feature detection in vision have left open a question most succinctly phrased by Horace Barlow: "Why do we have edge detectors?" In other words, were there any coding principles that could have predicted the formation of localized, oriented receptive fields?

Barlow was the first to propose that our visual cortical feature detectors might be the end result of a *redundancy reduction* process, in which the activation of each feature detector is supposed to be as statistically independent from the others as possible. Algorithms based on second-order statistics had failed to give clear, robust local filters. In particular, the principal components of natural images are Fourier filters ranked in frequency, quite unlike oriented localized filters.

Several authors proposed projection pursuit-style approaches, culminating in Olshausen and Field's (1997) demonstration of the self-organization of local, oriented receptive fields using a sparseness criterion.

By identifying sparseness with super-Gaussianity (which Olshausen and Field implicitly did), we can readily see why an Infomax/ICA net with the logistic nonlinearity for its $g_i(u_i)$s would produce the filters that produced the sparsest activation distributions when passed over the images. These distributions, furthest from Gaussian on the super-Gaussian side, were the most likely to be as statistically independent as possible, through the central limit theorem argument that any mixture of two independent distributions produces a distribution that is closer to Gaussian. As stated before, it is remarkable that none of the independent components of natural images are sub-Gaussian. This has been verified by using the extended ICA algorithm.

The assumption implicit in both approaches has been that the first layer of visual processing should attempt to invert the simplest possible image formation process, in which the image is formed, just as in Equation 3, by linear superposition of basis vectors (columns of $\mathbf{W}^{-1}$), each activated by independent (or sparse) causes, $u_i$.

Impressive results have been obtained by van Hateren and Ruderman (1998) on the *basis movies* of moving images. This 1,728-dimensional transform (viewable at http://hlab.phys.rug.nl/demos/ica) is one of the largest ICA applications to date. The resulting spatiotemporal bases are localized, oriented, and moving perpendicular to their orientation direction, just as in monkey visual cortex. And significantly, there are many more with the much lower spatial frequency required to match the profile of monkey visual receptive fields. This helps to answer the complaint that the ICA bases of natural images were clustered around high-frequency (sharp) contrast filters.

### *Biomedical Applications*

This section reports briefly on the work of S. Makeig, T.-P. Jung, M. McKeown, and their colleagues (see Jung et al., 2000, and Brain Signal Analysis).

Electroencephalographic (EEG) data are a measure of the brain's electric fields, which are linearly mixed by volume conduction at scalp electrodes with negligible time delays and thus are perfect for ICA analysis. If there were 14 electrical dipoles in the brain, each with independently fluctuating charges, and 14 noiseless electrodes on the scalp, then the dipole signals could be perfectly recovered by ICA. This is, of course, not the case. But the results are interesting nonetheless.

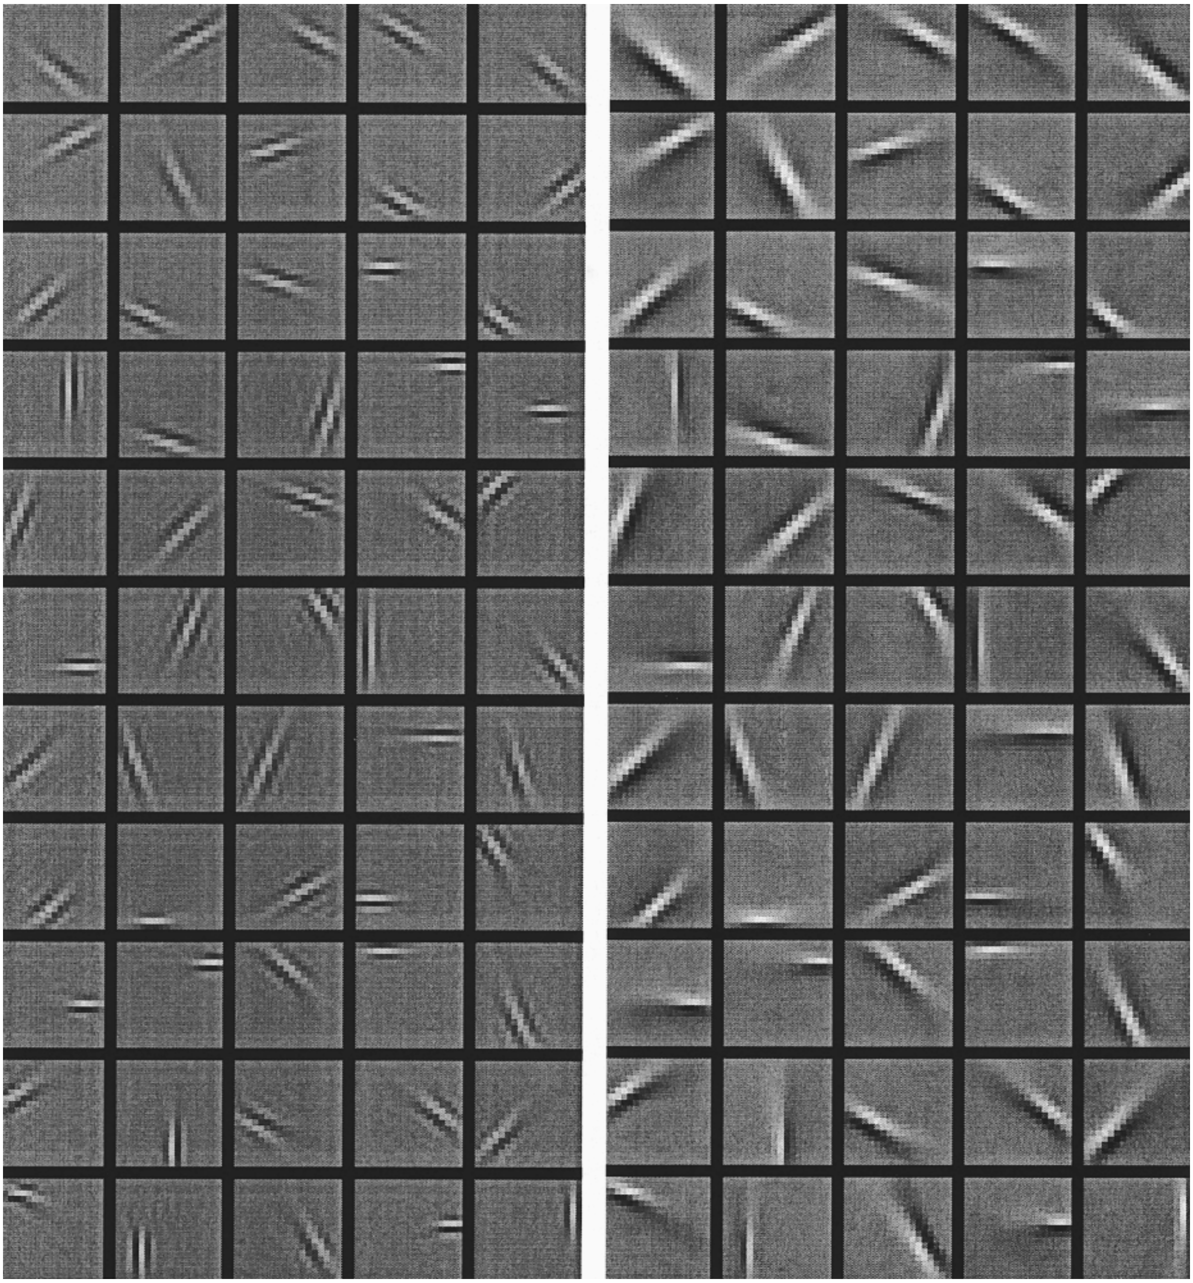

**Figure 3.** A selection of the 324 independent basis functions (left) and filters (right) obtained by training on $18 \times 18$ patches drawn from natural images. The results were obtained by van Hateren and van der Schaaf using Hyvärinen's (1999) FastICA method and are similar to those found using Bell and Sejnowski's (1997) Infomax/ML-ICA. (From van Hateren, J. H., and vander Schaaf, *Proc. R. Soc. Lond. B*, 265:359–366. Reprinted with permission.)

As well as decomposing correlated alpha wave activity across electrodes into prominent rhythms in different components with different time courses, many ICA outputs are easy to identify with artifacts known to contaminate brainwave data. In Figure 4, five of these are displayed, corresponding to eye blinks, localized scalp muscle movements, 60-Hz electrical line noise, heartbeat, and a horizontal eye movement. Both their time courses and their scalp maps help support these interpretations. The EEG data can then be cleansed of these artifacts, by zeroing the columns in $\mathbf{W}^{-1}$ corresponding to the artifacts and reconstructing the data using Equation 3.

Another kind of brain recording, functional magnetic resonance imaging (fMRI), monitors humans during the performance of psychomotor tasks and produces a three-dimensional picture of their brain activity with a spatial resolution of about 5 mm$^2$ and a temporal resolution of about 2 s. The subject is typically asked to alternate between performing a given task and a control task, so that researchers can identify which regions of the brain are differently activated. One of the independent components of the fMRI data studied by McKeown and colleagues was a pattern of spatial brain activation that was activated with a square-wave time course exactly corresponding to the execution of the task. This was true

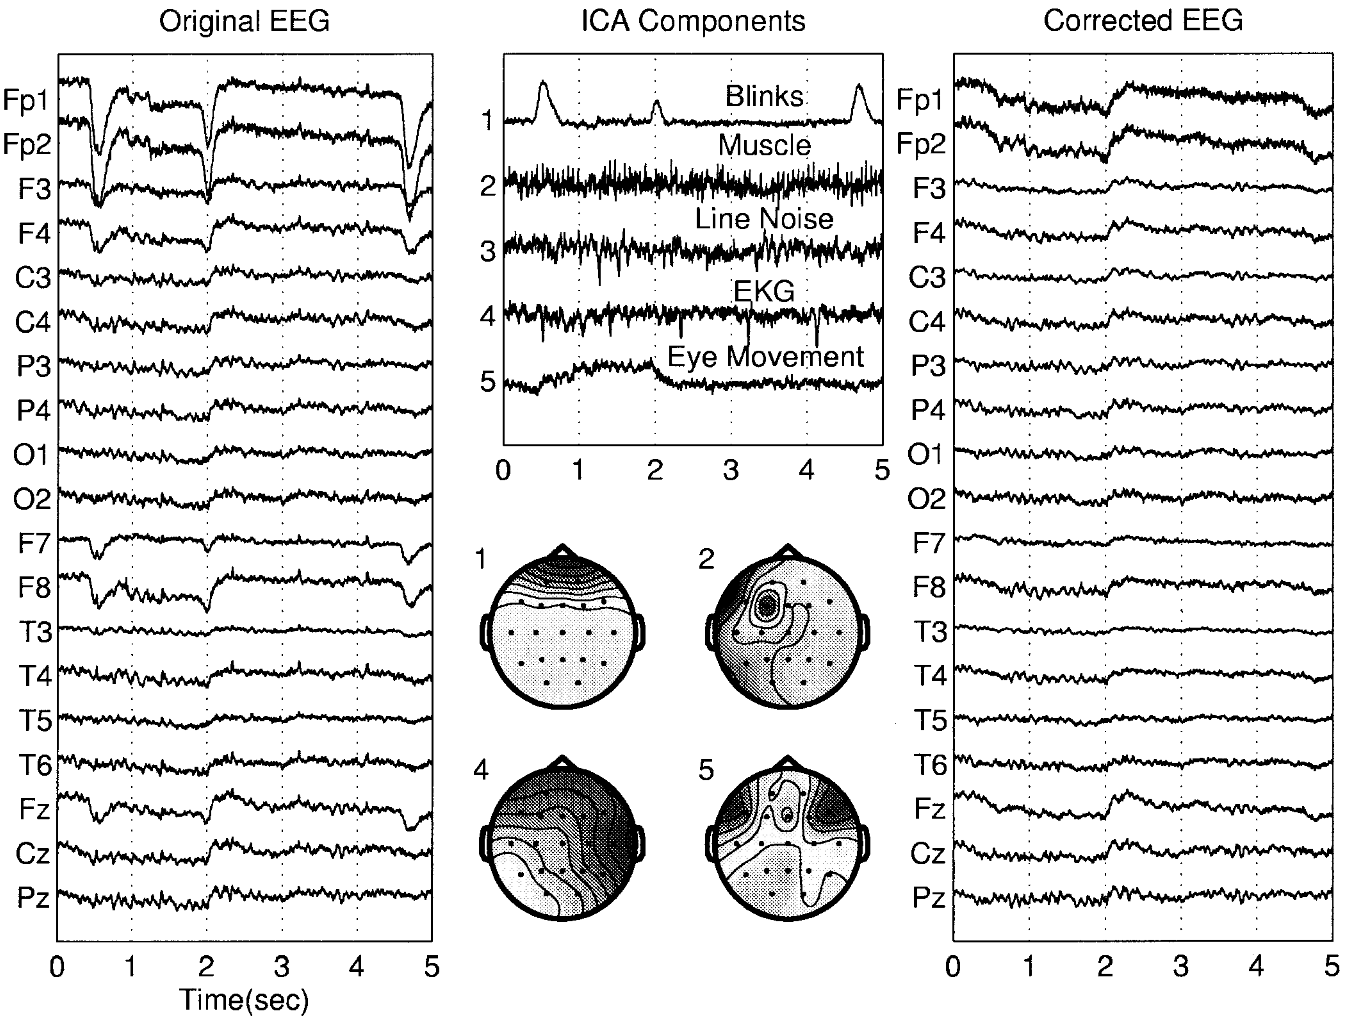

**Figure 4.** A 5-s portion of the EEG time series (left), ICA components accounting for eye movements, cardiac signals, and line noise sources (center), and the EEG signals corrected for artifacts by removing the five components (right). (From Jung, T.-P., et al., 1998, *Adv. Neural Inf. Process. Syst.*, 10:894–900. Reprinted with permission.)

over six trials with two subjects. When the independent components were ranked in terms of their strength in the original signal, this time course was ranked between 14th and 41st out of 146, so it was by no means a strong signal in the original data. The brain map associated with it contained activations in relevant areas of the brain corresponding mainly to vision and visual association, but also some in a motor area, and some in prefrontal cortex.

In each case, in focusing on individual time courses, we are looking at on the order of 1/146th of the brain activation data. Thus, the vast majority of the possibly confusing and irrelevant brain activation is stripped away for us, because its brain maps are statistically independent from the ones that concern us.

## Discussion

With these descriptions of the application of ICA to image processing and brain recordings, we hope to move the reader away from toy problems to a realization that algorithms of this kind have many applications. In almost every case, the algorithm has yielded surprises. Applications at the ICA 2000 workshop ranged from clustering World Wide Web documents to extracting the earthquake signal on the volcanic island of Stromboli.

On the theoretical side, ICA is in many ways much more interesting than its cousin, PCA, and this success comes from the simultaneous relaxation of two assumptions. The first is geometrical: that coordinate systems in signal transforms should be orthogonal. The second is statistical: that anything interesting in the probability distribution can be captured by the covariance matrix. Progress in this field will be made by further combined statisticogeometrical innovations, such as the identification of group-theoretic symmetries in probability distributions with the subspaces that they are embedded in, but that's another story.

# Information Theory and Visual Plasticity

*Nathan Intrator*

## Introduction

The relevance of information theory to neural networks has become more apparent in recent years. This theory has become important in analyzing and understanding the nature of the neuronal code that is relayed between cortical layers and the nature of the learning goals that guide neuronal learning and synaptic modification. Rapid advances in single- and multiple-electrode recording and other noninvasive techniques have provided a clearer view on neuronal activity and synaptic modification. However, the puzzle is still unsolved. We do not know what neuronal learning goals are, how they are being incorporated, and, most importantly, the nature of the neuronal code and how it is formed and interpreted by successive layers.

Information theory is an excellent tool that tells us how to code the information we want to relay. When studying the brain, we do not exactly know what the brain is coding at a local neuronal neighborhood and, thus, we cannot rely entirely on information theory to understand what neurons do. However, under various assumptions regarding the role of neuronal activity, one can test whether a certain code is optimal. When we try to understand the nature of synaptic learning rules, we should be concerned with possible goals that may underlie synaptic changes. It is conceivable that knowing what could be a useful goal under different input environments could serve for distinguishing between synaptic plasticity theories. Only after this distinction between goals has been achieved can one continue on and distinguish between learning rules aimed at achieving the same objective, on the basis of their detailed mathematical or computational properties. In this article, we briefly indicate possible neuronal goals resulting from various information-theoretic considerations. We are not making a statement about the nature of information relay in the brain or about the nature of information representation, where possible candidates may be action potentials, single spikes, spikes averaged along a time window of few milliseconds, or spike activity averaged over few cells.

For a book on information theory, see *Elements of Information Theory* (Cover and Thomas, 1991). Useful relevances to neuronal activity can be found in Rieke et al. (1996).

## Brief Review of Information Theory

Information theory was developed about 50 years ago for the study of communication channels (Shannon, 1948). Shannon considered information as a loss of *uncertainty* and defined it as a function of the probability distribution of the code words. If, for example, the probability distribution $P(X)$ is concentrated on a single value, then the information we can transmit, when choosing values from such distribution, is zero, since there is only one value to transmit. Thus, the amount of information is a function of the variability of the distribution and actually the exact shape of the distribution. This information quantity, which we denote by $H(X)$, should satisfy an additivity constraint, which states that when two random variables are independent, the information contained in both of them should be the sum of the information contained in each of them, namely

$$P(X_1, X_2) = P_1(X_1)P_2(X_2) \Rightarrow H(X_1, X_2) = H(X_1) + H(X_2) \quad (1)$$

Shannon has shown that the only function that is consistent with this condition (and with a few other simple constraints) is the Boltzmann entropy of statistical mechanics. The connection between information theory, statistics, and statistical mechanics is demonstrated in Jaynes (1957). The entropy in continuous and in discrete cases respectively is given by

$$\begin{aligned} H(X) &= -\int_K P(x) \log P(x)dx \\ H(X) &= -\sum_{i=1} p(x_i) \log p(x_i) \end{aligned} \quad (2)$$

where $p(x_{\mathrm{i}})$ is the probability of observing the value $x_{\mathrm{i}}$ out of possible $K$ discrete values of the random variable $X$. (In information theory, it is customary to neglect the Boltzmann constant, which sets up the units correctly, and to use the logarithm of base 2, so that the information is measured in bits.) An intuitive way to look at this function is by considering the average number of bits that is needed to produce an efficient code. It is desirable to use a small number of bits for sending those words that appear with high probability and to use a larger number of bits for sending words that appear with lower probability. In the special case of $n$ words arriving with the same probability, the number of bits that are required for each word is $\log_2 n$.

Shannon formulated this idea for the problem of information flow through a bottleneck, having to optimize the code so as to send the smallest number of bits on average. This led to questions such as how the receiver, given only the transmitted information, maximizes his knowledge about the data available at the sender's end. For our purpose, we formulate the mutual information idea in terms of a neural network of a single layer. Let $\mathbf{d}^i \in R^n$ be an input vector to the network occurring with a probability distribution $P_{\mathbf{d}}$, and let $\mathbf{c}^i \in R^k$ be the corresponding $k$-dimensional network activity with its probability distribution $P_c$. The *relative entropy* or the *Kullback-Leibler distance* between the two probability distributions is defined as

$$
\begin{aligned}
D(P_{\mathbf{d}} \| P_{\mathbf{c}}) &= \sum_{\mathbf{d}_i} P_d(\mathbf{d}_i) \log \frac{P_d(\mathbf{d}_i)}{P_c(\mathbf{c}_i)} \\
&= E_{P_d}[\log(P_d) - \log(P_c)] \qquad (3)
\end{aligned}
$$

Note that this is not symmetric and does not satisfy the triangle inequality.

Consider now the joint probability distribution of the input and output random variables $P(\mathbf{d}, \mathbf{c})$ such that $P_{\mathbf{d}}$ and $P_{\mathbf{c}}$ are the corresponding marginal distributions. The *mutual information* $I(\mathbf{d}, \mathbf{c})$ is the relative entropy between the joint distribution and the product distribution, namely,

$$
\begin{aligned}
I(\mathbf{d}, \mathbf{c}) &= D(P(\mathbf{d}, \mathbf{c}) \| P(\mathbf{d})P(\mathbf{c})) \\
&= \sum_{\mathbf{d}^i} \sum_{\mathbf{c}^j} P(\mathbf{d}^i, \mathbf{c}^j) \log \frac{P(\mathbf{d}^i, \mathbf{c}^j)}{P(\mathbf{d}^i)P(\mathbf{c}^j)} \\
&= \sum_{\mathbf{d}^i} \sum_{\mathbf{c}^j} P(\mathbf{d}^i, \mathbf{c}^j) \log \frac{P(\mathbf{d}^i | \mathbf{c}^j)}{P(\mathbf{d}^i)} \\
&= H(\mathbf{d}) - H(\mathbf{d}|\mathbf{c}) \qquad (4)
\end{aligned}
$$

Additional properties of mutual information can be found in Cover and Thomas (1991). For example, $I(\mathbf{d}, \mathbf{c}) = H(\mathbf{c}) - H(\mathbf{c}|\mathbf{d})$, and $I(\mathbf{d}, \mathbf{c}) = H(\mathbf{c}) + H(\mathbf{d}) - H(\mathbf{d}, \mathbf{c})$.

By maximizing the mutual information, we effectively minimize $H(\mathbf{d}|\mathbf{c})$. Namely, we reduce the uncertainty about the input $\mathbf{d}$ by knowing the output $\mathbf{c}$. Thus, given a constrained situation in which the output $\mathbf{c}$ carries less data than the input $\mathbf{d}$, information theory tells us what the optimal output should be for a given input so as to have, on average, maximal knowledge about the input. Synaptic modification rules can be derived from solving the mutual information maximization problem under various assumptions about the probability distribution of the inputs. The solution to such a learning rule is based on gradient ascent, or other more sophisticated optimization algorithms.

### *Distributions That Maximize Entropy under Various Constraints*

When we observe a certain distribution, it is natural to ask if this distribution represents a redundant coding or if it maximizes entropy under certain constraints. In some cases, we may be interested to recover the constraints under which the distribution maximizes the entropy. This section mentions some of the most common constraints and the distributions that are naturally connected with these constraints. Entropy maximization (or, as it is sometimes called, the MAX-ENT principle) is a powerful statistical inference tool. Given a certain set of constraints on a random variable, it suggests the *only possible* unbiased underlying distribution for the process. If the observed distribution is different, this implies that there are additional or different constraints governing the process. An excellent review with connection to statistical mechanics can be found in Jaynes (1957). Applications of this inference tool are many (see, e.g., Skilling, 1989).

*Bounded distributions.* The uniform distribution maximizes the entropy of a random variable with bounded values. Note that when discretizing a random variable, its distribution becomes automatically bounded, but it is the nondiscretized distribution that governs the process. Thus, we would expect a maximal entropy distribution of 8-bit gray-level pictures to have a Gaussian and not a uniform distribution.

*Positive valued random variables.* Distributions that take only positive values or, more generally, that are bounded from below are a special and important case. They include, for example, distributions of spike counts over a certain measurement window. It turns out that under mean value constraint, the Poisson distribution maximizes the entropy. Under a variance constraint (of positive-valued distribution), the Gibbs distribution maximizes the entropy. This distribution occurs often when a quadratic functional (also called an energy or a Hamiltonian) can be associated with a configuration state of a physical system. A famous example is the annealing process (Brillouin, 1956) and a numerical algorithm called simulated annealing (Kirkpatrick and Gelatt, 1983).

*Fixed variance constraint.* Under a fixed mean and variance, an unbounded random variable has a normal distribution for entropy maximization. This makes a strong connection between minimizing entropy and searching for distributions that are far from Gaussian. It also shows that a linear layered network receiving Gaussian distributed inputs should extract the projections that maximize the variance, namely, find the principal components of the data in order to maximize the entropy of the projections.

## Minimal Description Length

We have seen how information theory can suggest an optimal coding $\mathbf{c}$ for a given input $\mathbf{d}$ based on the probability distribution of the inputs. In this case, the code is transmitted through the bottleneck transmission line to the receiver, which then tries to reconstruct the original inputs. This formulation does not take into account the complexity of the code that is being sent and the complexity of constructing or decoding this code. A different information-theoretic formulation, one that is more appropriate for supervised learning, does take the above considerations into account. This formulation is based on the *minimal description length* (MDL) principle (Rissanen, 1984), which states that the way to choose a better model for data is by minimizing concurrently the cost of describing the model and the cost of describing the misfit between the model and the data. In terms of the information bottleneck (described earlier), we can view the current situation as a teacher-student network in which the teacher is trying to send the student the network to solve a certain problem. Under a supervised setup, the assumption is that both the student and the teacher can see the input data (zero cost), but only the teacher knows what the output should be. For the student to reconstruct the output, he would need to have a good model (network), namely, a small misfit between network output and desired output, and for quick learning, the model should be simple. Both of these properties can be measured by the entropy of sending the information about data misfit and about the model. In classical information theory, it is often assumed that the cost of learning a model can be neglected, as learning takes place only once, whereas data are sent continuously. However, when modeling learning, it is clear that the cost of learning plays an important role and should not be neglected. Hinton and colleagues have presented a formulation based on MDL principles for learning in neural networks (see Zemel and Hinton, 1995). It remains to be seen whether measuring the model (or learning) cost using the cost of sending the model parameters (entropy of the weight distribution) will turn out to be a useful constraint and a useful neuronal learning goal.

Note that measuring model cost by the entropy of its parameters may be radically different from measuring model cost by the actual or effective number of parameters, as has been proposed before (Akaike, 1974).

### Projection Pursuit and Cortical Plasticity

Thus far we have discussed maximization of entropy under various conditions. At times, however, minimization of entropy is more relevant. This occurs, for example, when classification is sought and small ambiguity of the outputs is desired. It also occurs when one is searching for independent components (Comon, 1994) and, especially, when one is looking for structure in the data by searching for interesting projections. To see the connection between independent components and the search for structure in the projections, we note that when two (or more) independent components are added together, their combined distribution is more Gaussian than is each of the component's distributions. Thus, seeking projections that are far from Gaussian can find the original distributions, assuming they were non-Gaussian to start with. More generally, the central limit theorem implies that given a list of independent random variables, their mean is normally distributed. Thus, a random projection of high-dimensional data would yield a single-dimensional Gaussian distribution unless there was a strong dependency between the projection vector and the data. A theoretical analysis of properties of projections was done by Diaconis and Freedman (1984). They have shown that for most high-dimensional clouds (of points), most low-dimensional projections are approximately Gaussian. Since entropy is maximized for a Gaussian distribution, searching for minimal entropy amounts to searching for maximal deviation from a Gaussian distribution. In practice, calculating the entropy is computationally expensive and requires knowledge (or robust estimation) of the projected distribution. Therefore, approximations to the entropy are used that rely on polynomial moments. The general framework of exploratory projection pursuit (Friedman, 1987) suggests various ways to seek such non-Gaussian projections. Its supervised version is called *projection pursuit regression* (Friedman and Stuetzle, 1981). It turns out that polynomial moments that are not approximating the entropy are also good candidates for measuring deviation from Gaussian distribution. For example, skewness and kurtosis, which are functions of the first four moments of the distribution, are frequently used in the search for independent components or non-Gaussian projections.

Intrator and Cooper (1992) have shown that a BCM neuron can find structure in the input distribution that exhibits deviation from Gaussian distribution in the form of multimodality in the projected distributions. Since clusters cannot be found directly in the data, owing to its sparsity, this type of deviation, which is measured by the first three moments of the distribution, is particularly useful for finding clusters in high-dimensional data, and thus is useful for classification or recognition tasks. This learning rule has been compared with skewness and kurtosis measures for the purpose of extracting simple-cell receptive fields from natural images (Blais et al., 1998).

### Summary

We have demonstrated some features of information theory that are relevant to information relay in cortex. We have presented cases in which information theory considerations led people to seek methods for Gaussianizing the input distribution and, in other cases, led people to seek learning goals for non-Gaussian distributions. The MDL principle was presented as a learning goal that takes into account the complexity of the decoding network. In particular, we have made the connection of entropy-based methods, projection pursuit, and cortical plasticity. Further details on the extraction of information in visual cortex can be found in FEATURE ANALYSIS.

# Integrate-and-Fire Neurons and Networks

*Wulfram Gerstner*

### Introduction

Most biological neurons communicate by short electrical pulses called *action potentials* or *spikes*. In contrast to the standard neuron model used in artificial neural networks, integrate-and-fire neurons do not rely on a temporal average over the pulses. In integrate-and-fire and similar spiking neuron models, the pulsed nature of the neuronal signal is taken into account and considered as potentially relevant for coding and information processing. In contrast to more detailed neuron models, integrate-and-fire models do not explicitly describe the form of an action potential. Pulses are treated as formal events. This is no real drawback, since, in a biological spike train, all action potentials of a neuron have roughly the same form. The time course of an action potential, therefore, does not carry any information.

Integrate-and-fire and similar spiking neuron models are phenomenological descriptions on an intermediate level of detail. Compared to other Single-Cell Models (q.v.), they offer several advantages. In particular, coding principles can be discussed in a transparent manner. Moreover, dynamics in networks of integrate-and-fire neurons can be analyzed mathematically. Finally, large systems with thousands of neurons can be simulated rather efficiently. Reviews of integrate-and-fire networks can be found in Maass and Bishop (1998) and in Gerstner and Kistler (2002).

## Spiking Neuron Models

### *Integrate-and-Fire Model*

In its simplest form, an integrate-and-fire neuron $i$ consists of a resistor $R$ in parallel to a capacitor $C$ driven by an external current $I_i$. The voltage $u_i$ across the capacitor is interpreted as the membrane potential. The voltage scale is chosen so that $u_i = 0$ is the resting potential. The temporal evolution of $u_i$ is

$$\tau_m \frac{du_i}{dt} = -u_i + RI_i(t) \tag{1}$$

where $\tau_m = RC$ is the membrane time constant of the neuron.

Spikes are formal events. We say that neuron $i$ has fired a spike if $u_i$ reaches at a time $t = t_i^f$ a threshold $\vartheta$. The form of the action potential is not described explicitly. Immediately after spike firing, the potential $u_i$ is simply reset to a value $u_{\text{reset}} < \vartheta$. Integration of Equation 1 is then resumed with $u_{\text{reset}}$ as the initial condition (Stein, 1967). Because the spatial structure of the neuron is neglected, such a model is also called a point model (see Single-Cell Models).

In a network of neurons, the input $I_i$ to neuron $i$ is due to the spikes of presynaptic neurons $j$. Detailed models of synaptic input can be found in Synaptic Interactions. In the simplest model of a synapse, each presynaptic spike arrival evokes a postsynaptic current with a standard time course $\alpha$. The total input to neuron $i$ is then

$$I_i = \sum_{j,f} w_{ij}\alpha(t - t_j^f) \tag{2}$$

where the sum runs over all firing times $t_i^f$ of all presynaptic neurons. The factor $w_{ij}$ is the synaptic efficacy of a connection from a presynaptic neuron $j$ to a postsynaptic neuron $i$. Choices for the postsynaptic current include a delayed $\delta$-pulse, $\alpha(s) = \delta(s - \Delta^{\text{ax}})$, or a double exponential, $\alpha(s) = [e^{-(s-\Delta^{\text{ax}})/\tau_1} - e^{-(s-\Delta^{\text{ax}})/\tau_2}]/(\tau_1 - \tau_2)$, where $\Delta^{\text{ax}}$ is the axonal transmission delay and $\tau_1$, $\tau_2$ are synaptic time constants.

### *Spike Response Model*

The integrate-and-fire equation (Equation 1) with the synaptic current (Equation 2) can be integrated, either numerically or analytically. Since it is a linear equation, the analytical integration can be done for each term in the sum of Equation 2 separately. The total membrane potential is then the sum of all the postsynaptic potentials (PSPs) caused by presynaptic firing, plus the refractory effect of a negative reset potential. Given the last firing time $\hat{t}_i$ of neuron $i$, the result of the integration is therefore of the form ($t > \hat{t}_i$)

$$u_i(t) = \eta(t - \hat{t}_i) + \sum_{j,f} w_{ij}\varepsilon(t - \hat{t}_i, t - t_j^f) \tag{3}$$

The next firing of $i$ occurs if the membrane potential $u_i$ approaches the threshold $\vartheta$ from below. Equation 3 defines the dynamics of the spike response model (SRM). It was introduced above as an integrated version of the integrate-and-fire model, but the SRM is in fact more general (Figure 1). The function $\eta$ describes the action potential at $\hat{t}_i$ and the spike afterpotential that follows. The function $\varepsilon$ describes the voltage response of neuron $i$ to a presynaptic spike at $t_j^f$. Let us suppose that the last spike of the postsynaptic neuron $i$ was far back in the past ($t - \hat{t}_i \to \infty$). Then $\varepsilon(\infty, s)$ as a function of $s$ describes the time course of the PSP caused by a presynaptic spike. If the postsynaptic neuron $i$ has been active in the recent past, then a presynaptic spike is less effective in exciting a postsynaptic response. The first argument of $\varepsilon(t - \hat{t}_i, t - t_j^f)$ describes the dependence on the recent firing history of the postsynaptic neuron. With an appropriate choice of the functions $\varepsilon$ and $\eta$, about 90% of the firing times of the Hodgkin-Huxley model with time-dependent input can be correctly predicted by the SRM, with a precision of ±2 ms (Kistler, Gerstner, and van Hemmen, 1997). Moreover, the spatial structure of neurons with a linear dendritic tree can be incorporated by an appropriate choice of $\varepsilon$. For synapses that are farther out on the dendritic tree, the PSP, and hence the function $\varepsilon$, rise more slowly.

## Noise

Biological neurons that are driven by a time-dependent intracellular current exhibit a reliable, (nearly) deterministic behavior, just as the models in Equations 1 or 3. On the other hand, neurons that are part of a cortical network emit spikes at irregular intervals. Since the exact spike times cannot be controlled by the experiment, the irregularity is interpreted as noise.

Formally, noise can be introduced into the integrate-and-fire model by adding a fluctuating input $\sigma\xi_i(t)$ on the right-hand side of Equation 1, where $\sigma$ is a parameter controlling the amplitude of the noise and $\xi$ is a normally distributed random variable with zero mean (see Diffusion Models of Neuron Activity). In the presence of noise, we may ask the following question: Given the last firing time $\hat{t}_i$ of neuron $i$ and the input current $I_i(t')$ for $t' > \hat{t}_i$, what is the probability that the next spike occurs around time $t$? The answer is given by the conditional interval distribution $P(t|\hat{t}_i, I(\cdot))$. The calculation of $P(t|\hat{t}_i, I(\cdot))$ for the diffusion model is equivalent to the solution of a first-passage-time problem. The general solution to this problem is not known.

Noise can also be introduced into spiking neuron models in a different manner. The voltage $u_i(t)$ is calculated according to Equation 1 or 3. Even before $u_i$ reaches the threshold $\vartheta$, neuron $i$ may fire with an "escape rate," $\rho(t)$, that depends on the momentary distance from threshold and possibly also on the current input $I$,

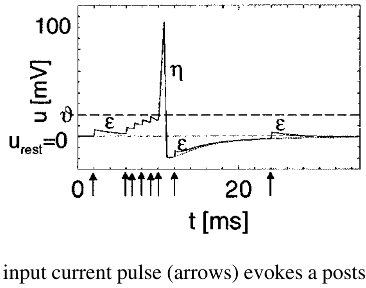

**Figure 1.** Each input current pulse (arrows) evokes a postsynaptic potential with time course $\varepsilon$. If the sum of the postsynaptic potentials reaches the threshold $\vartheta$, an action potential with time course $\eta$ is triggered. An input current pulse immediately after the action potential evokes a reduced response because of refractoriness.

viz., $\rho(t) = h(u(t) - \vartheta; I(t))$. In this case, an explicit expression for the conditional interval distribution is known, viz.,

$$P(t|\hat{t}_i, I(\cdot)) = \rho(t) \exp\left[-\int_{\hat{t}_i}^{t} \rho(t')dt'\right] \tag{4}$$

With an appropriate choice of the escape function $h$, the diffusion model can be approximated by the escape model to a high degree of accuracy For a review of noise models, see Gerstner and Kistler (2002, chap. 5).

## Network Dynamics and Population Equations

In many areas of the brain, neurons are organized into groups of cells with similar properties, e.g., pools of motor neurons or columns in the visual cortex. Instead of looking at the firings of individual neurons, we may simply be interested in the fraction of neurons that are active in the population. In each small time window $\Delta t$, let us count the number of spikes $n_{\mathrm{sp}}(t; t + \Delta t)$ that are emitted across the population, and divide by the number $N$ of neurons and $\Delta t$. This procedure defines the population activity or population rate

$$A(t) = \lim_{\Delta t \to 0} \frac{n_{\mathrm{sp}}(t; t = \Delta t)}{N\Delta t} = \frac{1}{N} \sum_{j,f} \delta(t - t_j^f) \tag{5}$$

where $\delta$ is the Dirac $\delta$ function and the sum runs over all spikes of all neurons in the population. The population activity has units of 1 over time and can be seen as the rate at which the total spike count increases. Note that the definition of the population rate (Equation 5) does not involve a temporal average, only a spatial average. What is the temporal evolution of $A(t)$ in a (homogeneous) network of spiking neurons?

The state of each neuron depends on its input *and* on the time $\hat{t}$ of its last spike (see Equation 3). We define a *homogeneous* population by the conditions that (1) lateral coupling has a fixed value $w_{ij} = w_0/N$, and (2) external inputs $I^{\mathrm{stim}}(t)$ are the same for all neurons. The total input to any neuron in the network is therefore

$$I(t) = w_0 \int_0^{\infty} \alpha(s)A(t - s)ds + I^{\mathrm{stim}}(t) \tag{6}$$

Even though they all receive the same input, different neurons will, in general, have different firing times $\hat{t}$. A neuron that has fired its last spike at $\hat{t}$ and has received an input $I(t')$ for $t' > \hat{t}$ will contribute with weight $P(t|\hat{t}, I(\cdot))$ to the population activity at time $t$. Hence the expected value of the population activity at time $t$ is

$$A(t) = \int_{-\infty}^{t} P(t|\hat{t}, I(\cdot))A(\hat{t})d\hat{t} \tag{7}$$

For spiking neurons with escape noise $\rho(t)$, $P(t|\hat{t}, I(\cdot))$ is given by Equation 4 and therefore is highly nonlinear. Equation 7 is implicitly contained in Wilson and Cowan (1972) and Knight (1972), and is formally derived in Gerstner (2000) for a homogeneous, fully connected network of spiking neurons in the limit of $N \to \infty$.

In their 1972 paper, Wilson and Cowan proposed transforming the integral Equation 7 into a differential equation of the form

$$\tau \frac{d}{dt} A(t) = -A(t) + g\left[w_0 \int_0^{\infty} \alpha(s)A(t - s)ds + I^{\mathrm{stim}}(t)\right] \tag{8}$$

where $\tau$ is a time constant, $w_0$ is the neuronal coupling strength, $I^{\mathrm{ext}}(t)$ is a stimulus, and $g$ is a nonlinear transfer function. One of the problems of Equation 8 is that the time constant $\tau$ is the result of a process of "time coarse graining," which is necessary for the transition from Equation 7 to Equation 8. Since the time window of coarse graining has to be defined somewhat arbitrarily, the time constant $\tau$ is basically ad hoc. Because of the problems inherent in Equation 8, it is preferable to work directly with Equation 7.

For the diffusion noise model, Equation 7 is valid but not very useful, because the conditional interval distribution $P(t|\hat{t}, I(\cdot))$ is not known. As an alternative to Equation 7, the state of the population can be described by the distribution of membrane potentials $P(u, t)$ (Abbott and van Vreeswijk, 1993; Brunel, 2000; Nykamp and Tranchina, 2000). At each moment of time $P(u, t)\Delta uN$ gives the number of neurons in the population with a membrane potential between $u$ and $u + \Delta u$. The equation of the integrate-and-fire model (Equation 1) with additive diffusion noise $\sigma\xi(t)$ can be transformed into a Fokker-Planck equation for the distribution of membrane potentials:

$$\tau \frac{\partial P(u, t)}{\partial t} = \frac{\sigma^2}{2\tau} \frac{\partial^2 P(u, t)}{\partial u^2} + \frac{\partial}{\partial u} \{[u - RI(t)]P(u, t)\} \tag{9}$$

The threshold is treated as an absorbing boundary, so that the probability density vanishes for $u \geq \vartheta$. The probability current across threshold equals the population activity

$$A(t) = \frac{\sigma^2}{2\tau^2} \left.\frac{\partial P(u, t)}{\partial u}\right|_{u=\vartheta} \tag{10}$$

Since the membrane potential of active neurons is immediately reset to $u_{\mathrm{reset}}$, the population activity $A(t)$ acts a source of probability current at $u = u_{\mathrm{reset}}$. For a review, see Gerstner and Kistler (2002, chap. 6).

## Application to Coding

Integrate-and-fire models can be used to discuss potential principles of coding and dynamics in a transparent manner (Maass and Bishop, 1998, chaps. 1, 2, 10–14). Before we turn to networks, let us start with two examples of coding on the single-neuron level.

### *Signal Encoding by Single Neurons*

Coherent input is more efficient than incoherent spikes in driving a postsynaptic neuron. To see why, let us consider the SRM (Equation 3). For the sake of simplicity, we assume that the postsynaptic neuron $i$ was inactive in the recent past ($t < 0$) and receives, for $t > 0$, input from two presynaptic neurons $j = 1, 2$, both firing at 100 Hz. We set $w_{i1} = w_{i2} = w_0$. According to Equation 3, each input spike evokes a postsynaptic potential $\varepsilon(-\infty, t - t_j^f)$, where $t_j^f$ is one of the firing times of neuron $j$. If the two spike trains are out of phase, the summed postsynaptic potential is lower than in the synchronous case (Figure 2). By an appropriate choice of the threshold $\vartheta$, an output spike of the postsynaptic neuron $i$ occurs therefore only in the coherent (or "coincident") case. Quite generally, coincidence detection is possible if the threshold of the postsynaptic neuron is slightly above the mean value, the membrane potential would take for asynchronous input (König, Engel, and Singer, 1996; Kempter et al., 1998). In the auditory system, it is

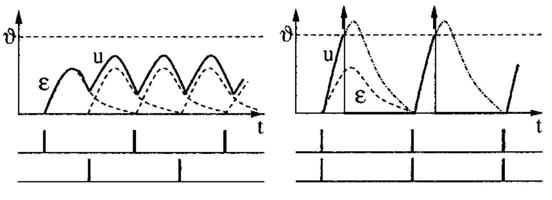

**Figure 2.** *Left,* Spike trains from two different presynaptic neurons are phase shifted with respect to each other. The summed potential $u$ does not reach the threshold. *Right,* Spikes from the same presynaptic neurons arrive synchronously, so that $u$ reaches the threshold $\vartheta$ and evokes the generation of output spikes (arrows). Afterwards, $u$ is reset (schematic figure).

commonly accepted that coincidence detection is used for the localization of sound sources. On the other hand, it is an open question whether *cortical* neurons operate in the regime of coincidence detection (König et al., 1996; see also SINGLE-CELL MODELS).

### *Coding by Homogeneous Populations*

Spiking neurons connected to each other by excitatory or inhibitory synapses exhibit nontrivial dynamical properties. The population may respond rapidly to external signals. The network activity may explode or die away. Neurons may spontaneously develop a tendency to fire synchronously or in groups. All of these phenomena, which can potentially be the basis of various coding schemes, can be understood from an analysis of Equations 6 through 10. Some of the fundamental questions are highlighted in the following.

First, is it possible, in the absence of an external stimulus, to stabilize a population of spiking neurons at a reasonable level of spontaneous activity? For $N \rightarrow \infty$, spontaneous activity corresponds to a stationary solution $A(t) \equiv A_0$ of the population dynamics described by Equation 7 or 10. Spontaneous asynchronous firing seems to be a generic feature of cortical tissue, but its role is still unclear. A stability analysis shows that without noise, asynchronous firing is never stable. Thus, the apparent noisiness of cortical neurons is a necessary feature of the system.

Even in the presence of noise, neurons often tend to synchronize their firings and develop collective oscillations. This observation leads to the second question: How is the frequency of collective oscillations related to neuronal parameters? It turns out that there are different oscillatory regimes, depending on the form of the postsynaptic potential, the axonal delay, and the value of the threshold (Abbott and van Vreeswijk, 1993; Brunel, 2000; Gerstner, 2000). The frequency of the collective oscillation may be low (about that of individual neurons) or several times faster. Collective oscillations and synchronization (Maas and Bishop, 1998, chaps. 10 and 11; Gerstner and Kistler, 2002, chap. 12) have been suggested as potential coding schemes in cortex and hippocampus (see SYNCHRONIZATION, BINDING AND EXPECTANCY).

Third, how rapidly does the population activity $A(t)$ respond to changes in the input? An analysis of Equation 7 shows that the response time is not limited by the membrane time constant of the neurons, but can be much faster (Gerstner, 2000). The fast response is due to the fact that, during spontaneous activity, there are always some neurons with a membrane potential just below threshold. A slight increase in the input will make those neurons fire immediately. The fast response of populations of spiking neurons to a new input could be important for an explanation of reaction time experiments (Thorpe, Fize, and Marlot, 1996; cf. FAST VISUAL PROCESSING). The same type of argument also shows that populations of spiking neurons can reliably transmit signals that vary on a time scale that is short compared to the interspike intervals of a neuronal spike train, as is the case in the auditory pathway, for example.

All of the above results hold true for homogeneous networks with either excitatory or inhibitory coupling. Formally, the theory is valid for full connectivity in the limit of $N \rightarrow \infty$. It also yields an excellent approximation for networks with random connectivity if the density of connections is either very high or very low. An extension to mixed excitatory/inhibitory populations as found in the cortex is possible (Brunel, 2000).

### *Coding in Structured Networks*

Structure in neuronal networks may arise from a spatial arrangement of neurons or from specific patterns stored in a distributed manner in the network.

In networks with local (or distance-dependent) excitatory connections, traveling waves may occur. In two-dimensional sheets of neurons, wave fronts may have planar or spiral shapes, similar to the ones found in reaction-diffusion systems. Collective oscillations and asynchronous firing are other possible network states. These effects can be described by a direct generalization of the theory of homogeneous systems to a spatially continuous population. Replace $A(t)$ in Equation 7 by $A(x, t)$ where $x$ is the spatial location. Instead of Equation 6, we use $I(x, t) = \int dx' w(|x - x'|) \int ds\, \alpha(s)\, A(x', t - s)$, where $w(\cdot)$ is the distance-dependent coupling strength. Activity waves have been reported in slice cultures. It has also been suggested that similar activity waves could account for some of the trial-to-trial variability in cortical spike train recordings.

In the previous example, neurons that are strongly connected are located next to each other. Activity spreads from one group of neurons to its neighbors, which is easily recognizable by an external observer as a traveling wave of activity. Let us now keep the connections between the same neurons as before, but move all neurons to a new random location on the two-dimensional sheet. Apart from the fact that connection lines are longer, nothing has changed. What used to be a propagating wave in the original spatial arrangement now looks like asynchronous firing of neurons all over the sheet. Nevertheless, it is a specific, nearly deterministic spatiotemporal spike pattern. These "hidden" waves of activity have been termed SYNFIRE CHAINS (q.v.) (Abeles, 1991). Although the existence and stability of synfire chains can be shown by simulation or analysis of model networks, this does not necessarily imply that real brains make use of synfire chains for coding.

## Discussion

What is the code used by cortical neurons? What is signal, what is noise in neuronal spike trains? Although the final answers to these questions have to come from additional experiments, modeling on the level of integrate-and-fire networks can contribute to answering, because models allow researchers to explore potential coding schemes and to identify relevant operating regimes.

In populations of integrate-and-fire neurons, a rate code can be a very fast code, if rate is defined by a population average ("population activity") rather than by a temporal average (Knight, 1972; Gerstner, 2000). In contrast to widespread belief, the speed of signal transmission is not limited by the membrane time constant of the neuron. Moreover, with appropriate spike-based learning rules (Maass and Bishop, 1998, chap. 14), spiking neurons can work, in principle, at a very high temporal precision (Abeles, 1991). Large-scale simulations of integrate-and-fire networks provide a link between theory and experiments.

One of the points that has been stressed in recent models of integrate-and-fire neurons in the relevance of the subthreshold regime. If neuronal and network parameters are chosen so that the mean membrane potential stays just below threshold, then several interesting properties emerge. First, neurons act as coincidence detectors. They are sensitive to fluctuations in the input and can therefore "read out" the coherent aspects of the input signal (König et al., 1996; Kempter et al., 1998). Second, neurons in this regime respond rapidly to changes in the input (Gerstner, 2000). This might be relevant for explaining fast reaction times (Thorpe et al., 1996). Third, to stabilize a highly recurrent network of spiking neurons in the subthreshold regime, a certain amount of noise is necessary (Abbott and van Vreeswijk, 1993; Gerstner, 2000). From that point of view, it comes as no surprise that cortical neurons appear to be noisy. Whether this apparent noisiness is due to intrinsic noise sources in the neuronal dynamics, to noise in the synaptic transmission, or to deterministic chaos in a network is not clear. Model studies have shown that noise itself can arise as a network effect if neurons are in the subthreshold regime. Although individual neurons behave more or less deterministically, the same neurons show large firing variability when part of a random network of excitatory and inhibitory neurons with sparse connectivity (Brunel, 2000). Such networks can represent past input in their spatiotemporal firing pattern (see TEMPORAL INTEGRATION IN RECURRENT MICROCIRCUITS). Thus, the study of integrate-and-fire networks may shed new light on the burning questions of brain theory.

# Invertebrate Models of Learning: *Aplysia* and *Hermissenda*

*John H. Byrne and Terry Crow*

## Introduction

Certain invertebrates lend themselves to the study of learning and memory because of their relatively simple central nervous systems. In many cases, a fairly complete "wiring diagram" can be specified and modeled. Many neurons are relatively large and can be uniquely identified, which permits the examination of the functional properties of an individual cell and the ability to correlate those properties with a specific behavior mediated by the cell. Biophysical and molecular events underlying the changes in cellular properties can then be elucidated and mathematically modeled. This chapter summarizes the progress that has been made toward a mechanistic analysis of learning in the gastropod mollusks *Aplysia* and *Hermissenda*.

## Nonassociative Modifications of Defensive Siphon and Tail Withdrawal Reflexes in *Aplysia*

### *Behaviors and Neural Circuits*

The siphon-gill and tail-siphon withdrawal reflexes of *Aplysia* have been used to analyze the neuronal mechanisms contributing to nonassociative and associative learning (see Carew, 2000; Kandel, 2001; Byrne, 2002). The siphon-gill withdrawal reflex is elicited when a stimulus is delivered to the siphon and results in withdrawal of the siphon and gill (Figure 1*A*). The tail-siphon withdrawal reflex is elicited by stimulation of the tail, which results in a coordinated set of defensive responses composed of a reflex withdrawal of the tail and the siphon (Figure 1*B*).

Defensive reflexes in *Aplysia* exhibit three forms of nonassociative learning: habituation, dishabituation, and sensitization. Habituation is defined as a decrement in response caused by repeated delivery of a stimulus (see HABITUATION). Dishabituation is defined as a restoration of a habituated (decremented) response by delivery of another stimulus. Finally, sensitization is defined as an enhancement of a nondecremented response by delivery of another stimulus to the animal. With repeated stimulation, the reflexes undergo both short-term (minutes) and long-term (days) habituation. Applying a noxious stimulus to the head or tail can produce restoration of a habituated response (dishabituation) or sensitization of a nonhabituated response. Short-term sensitization lasts minutes, whereas long-term sensitization lasts days to weeks depending on the type of sensitization training. Although not described here, *Aplysia* also exhibits forms of associative learning such as classical conditioning and operant conditioning, which have been analyzed at the mechanistic level. Some of these mechanisms have been mathematically modeled and simulated by using a series of coupled ordinary differential equations (Byrne et al., 1990).

The afferent limb of the siphon-gill withdrawal reflex consists of sensory neurons with somata in the abdominal ganglion. The sensory neurons monosynaptically excite gill and siphon motor neurons, which are also located in the abdominal ganglion. Excitatory, inhibitory, and modulatory interneurons in the withdrawal circuit have also been identified.

The afferent limb of the tail-siphon withdrawal reflex consists of a cluster of 200 sensory neurons located in the pleural ganglion. These sensory neurons make monosynaptic excitatory connections with motor neurons in the adjacent pedal ganglion (Figure 2). The motor neurons produce withdrawal of the tail. In addition to their connections with tail motor neurons, sensory neurons form synapses with various identified interneurons. Some of these interneurons provide a parallel pathway to activate the tail motor neurons. These same interneurons activate motor neurons in the abdominal ganglion that control reflex withdrawal of the siphon (Figure 2). Several additional neurons modulate the reflex (not shown in Figure 2). Aspects of the neural circuit controlling tail withdrawal and its plasticity have been mathematically modeled and simulated us-

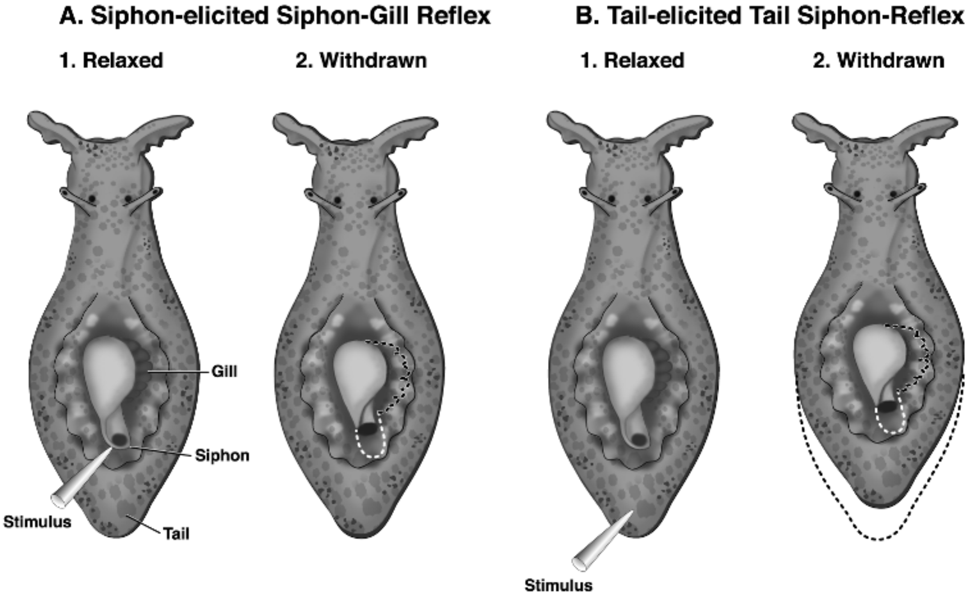

**Figure 1.** Siphon-gill and tail-siphon withdrawal reflexes of *Aplysia. A*, Siphon-gill withdrawal. Dorsal view of *Aplysia*. (1) Relaxed position. (2) A stimulus (e.g., a water jet, brief touch, or weak electric shock) applied to the siphon causes the siphon and the gill to withdraw into the mantle cavity. *B*, Tail-siphon withdrawal reflex. ing the conductance-based simulator package SNNAP (White et al., 1993; see also Neurosimulation: Tools and Resources).

The sensory neurons for both the siphon-gill and tail-siphon withdrawal reflexes are similar and appear to be key plastic elements in the neural circuits. Changes in their membrane properties and synaptic efficacy are associated with sensitization and the procedures that mimic short- and long-term sensitization training (see below).

### *Cellular Mechanisms in Sensory Neurons Associated with Short- and Long-Term Sensitization in Aplysia*

*Short-term sensitization.* Short-term sensitization is induced when a single brief train of shocks to the body wall results in the release of modulatory transmitters such as serotonin (5-HT) from facilitatory neurons that innervate the sensory neurons. The binding of 5-HT to receptors activates adenylyl cyclase, raising the level of the second messenger cAMP in sensory neurons. The increase in cAMP activates cAMP-dependent protein kinase (protein kinase A, PKA), which adds phosphate groups to specific substrate proteins and consequently alters their functional properties. One result of this protein phosphorylation is an alteration of the properties of membrane channels. Specifically, the increased levels of cAMP lead to a modulation of the S-$K^+$ current ($I_{K,S}$), the delayed $K^+$ channel ($I_{K,V}$), and the calcium-activated $K^+$ current ($I_{K,Ca}$). These changes in membrane currents lead to depolarization of the membrane potential, enhanced excitability, and an increase in the duration of the action potential. Cyclic AMP also appears to activate a membrane-potential- and spike-duration-independent process of facilitation, which may be due to the translocation of transmitter vesicles from a storage pool to a releasable pool. This process would result in more vesicles available for release with subsequent action potentials in the sensory neuron. These combined effects contribute to the short-term cAMP-dependent enhancement of transmitter release. Serotonin also appears to act through another receptor to increase the level of second messenger diacylglycerol (DAG), which in turn activates protein kinase C (PKC). Like PKA, PKC modulates the delayed $K^+$ channel ($I_{K,V}$) and activates the spike-duration-independent process of facilitation. This modulation of $I_{K,V}$ also contributes to the increase in duration of the action potential. Serotonin can also activate mitogen-activated protein kinase (MAPK). One substrate for MAPK is the synaptic-vesicle-associated protein synapsin, which tethers synaptic vesicles to cytoskeletal elements and thus helps to control the reserve pool of vesicles in synaptic terminals. Of general significance is the observation that a single modulatory transmitter (i.e., 5-HT) activates at least three kinase systems. The consequences of the activation of these multiple messenger systems and multiple modulations of cellular processes occur when test stimuli elicit action potentials in the sensory neuron at various times after the presentation of the sensitizing stimuli. The enhanced release of transmitter from the sensory neuron leads to an enhanced activation of follower interneurons and motor neurons and an enhanced behavioral response (i.e., sensitization).

Aspects of the modulation of membrane channels and the dynamics of second messenger systems, calcium regulation, and

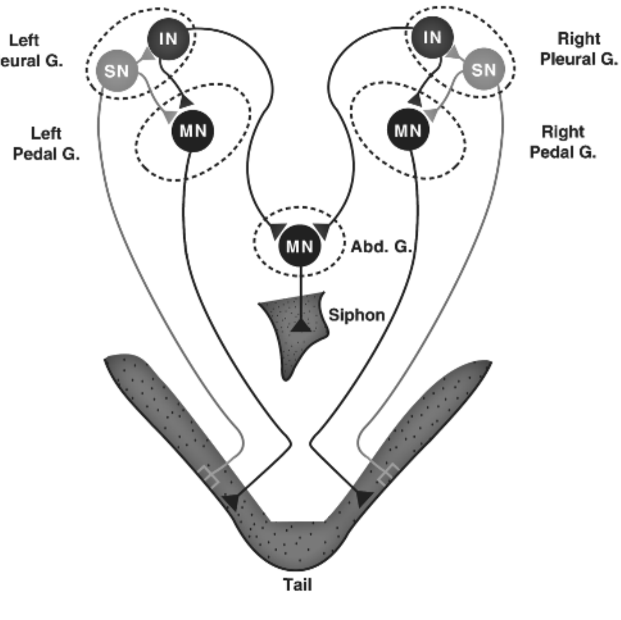

**Figure 2.** Simplified circuit diagram of the tail-siphon withdrawal reflex (see text for details).

transmitter storage and release have been mathematically modeled and simulated (Gingrich and Byrne, 1987; Baxter et al., 1999). The details of these biophysical and biochemical processes were necessary to simulate the features of the empirical data, which could not be captured by less detailed models (see Baxter and Byrne, 1993).

*Long-term sensitization.* Repetition of the sensitizing stimuli leads to the induction of long-term facilitation. Repeated training leads to a translocation of PKA to the nucleus, where it phosphorylates the transcriptional activator CREB1 (cAMP-responsive element-binding protein). CREB1 binds to a regulatory region of genes known as the cAMP-responsive element (CRE). Next, this bound and phosphorylated form of CREB1 leads to increased transcription. cAMP also leads to the activation of MAPK, which phosphorylates the transcriptional repressor CREB2. Phosphorylation of CREB2 by MAPK leads to a derepression of CREB2 and therefore promotes CREB1-mediated transcriptional activation. The combined effects of activation of CREB1 and derepression of CREB2 lead to changes in the synthesis of specific proteins.

One protein whose synthesis is regulated in this manner is *Aplysia* tolloid/BMP-like protein (ApTBL-1). Tolloid and the related molecule BMP-1 appear to function as secreted $Zn^{2+}$ proteases. In some preparations, they activate members of the transforming growth factor $\beta$ (TGF-$\beta$) family. Indeed, in sensory neurons, TGF-$\beta$ mimics the effects of 5-HT in that it produces long-term increases in synaptic strength of the sensory neurons. Interestingly, TGF-$\beta$ activates MAPK in the sensory neurons and induces its translocation to the nucleus. Thus, ApTBL-1 and TGF-$\beta$ could be part of an *extracellular* positive feedback loop possibly leading to another round of protein synthesis to further consolidate the memory.

Prolonged stimulation and increased cAMP also activate a process that decreases the level of PKA regulatory subunits, further prolonging PKA activation (Greenberg et al., 1987). With fewer regulatory subunits to bind to catalytic subunits, the catalytic units would be persistently active and could contribute to long-term facilitation of transmitter release through the same cAMP-dependent processes that are seen in the short term. Some of these cAMP-PKA-induced changes include a decrease in $I_{K,S}$ and enhanced excitability, perhaps as well as a change in the synthesis of an $I_{K,S}$ channel protein or protein associated with the channel.

The downregulation of a homolog of a neuronal cell adhesion molecule (NCAM) ApCAM also plays a key role in long-term facilitation. This downregulation has two components. First, the synthesis of ApCAM is reduced. Second, preexisting ApCAM is internalized via increased endocytosis. The internalization and degradation of ApCAM allow for the restructuring of the axon arbor. The sensory neuron can now form additional connections with the same postsynaptic target or make new connections with other cells. As with short-term sensitization, the enhanced release of transmitter from existing contacts of sensory neurons onto motor neurons and interneurons contributes to the enhanced long-term responses of the animal to test stimuli (i.e., sensitization). However, unique to long-term sensitization, increases in axonal arborization and synaptic contacts may contribute to the enhanced activation of follower interneurons and motor neurons (e.g., Figure 2).

In addition to the cellwide changes in protein synthesis described above, recent work by Martin, Kandel, and their colleagues indicates that protein synthesis also occurs at the sites of synaptic contacts between sensory neurons and motor neurons. This local protein synthesis appears to be important in synapse-specific changes in synaptic efficacy.

*Other temporal domains for the memory of sensitization.* Historically, memory has been divided into two temporal domains: short term and long term. It has become increasing clear from studies of a number of memory systems that this distinction is overly simplistic. For example, in *Aplysia*, Carew and his colleagues and Kandel and his colleagues have recently discovered an intermediate phase of memory that has distinctive temporal characteristics and a unique molecular signature. The intermediate-phase memory for sensitization is expressed at times approximately 30 minutes to three hours after the beginning of training. It declines completely prior to the onset of long-term memory. Like long-term sensitization, its induction requires protein synthesis, but unlike long-term memory, it does not require mRNA synthesis. The expression of the intermediate-phase memory requires the persistent activation of PKA.

## Associative Learning in *Hermissenda*

### *Pavlovian Conditioning*

Pavlovian (or classical) conditioning of *Hermissenda* involves changes in light-elicited locomotion and foot length (conditioned responses, CRs) produced by stimulation of the visual and vestibular systems with their adequate stimuli (see Sahley and Crow, 1998). The Pavlovian conditioning procedure consists of pairing light, the conditioned stimulus (CS), with high-speed rotation, the unconditioned stimulus (US). After conditioning, the CS suppresses normal light-elicited locomotion and elicits foot shortening (see Figure 3). Retention of conditioned behavior persists for several days to weeks depending on the number of conditioning trials used in initial acquisition (Alkon, 1989; Sahley and Crow, 1998). Pavlovian conditioning in *Hermissenda* exhibits CS specificity and is dependent on the association of the two sensory stimuli involving both contiguity and contingency. Nonassociative contributions to behavior are expressed in the initial trials of the conditioning session and decrement rapidly following the termination of multiple-trial conditioning. In addition to multiple-trial conditioning of suppression of light-elicited locomotion and foot contraction, one-trial conditioning also modifies light-elicited locomotion (Crow and Forrester, 1986). Pairing the CS with direct application of 5-HT (nominal US) to the exposed nervous system of otherwise intact *Hermissenda* produces suppression of light-elicited locomotion when the animals are tested 24 hours after the one conditioning trial. One-trial conditioning also produces enhanced excitability of type B photoreceptors (see Figure 4), a component of the CS pathway that expresses cellular plasticity produced by multiple-trial Pavlovian conditioning (see below).

### *Cellular and Synaptic Plasticity Associated with Pavlovian Conditioning*

Certain sites of intrinsic modifications of cellular and synaptic plasticity in classically conditioned animals are associated with both enhanced excitability and synaptic facilitation, which have been localized to the primary sensory neurons (photoreceptors) of the pathway mediating the CS (Alkon, 1989; Frysztak and Crow, 1994). Enhanced excitability in identified photoreceptors of conditioned *Hermissenda* is expressed by a significant increase in spike activity elicited by the CS or extrinsic current, an increase in the input resistance, an alteration in the amplitude of light-elicited generator potentials, decreased spike frequency accommodation, and a reduction in the peak amplitude of voltage-dependent ($I_A$, $I_{Ca}$) and $Ca^{2+}$-dependent ($I_{K,Ca}$) currents (for reviews, see Alkon, 1989; Sahley and Crow, 1998). The enhanced excitability, expressed by an increase in both the amplitude of CS-elicited generator potentials and the number of action potentials elicited by the CS, may be a major contributor to changes in the duration and amplitude of CS-elicited complex postsynaptic potentials (PSPs) and enhanced CS-elicited spike activity observed in postsynaptic targets. Pseudorandom or random presentations of the CS and US do not result in the development of suppression of either light-elicited locomotion or CS-elicited foot shortening.

ever, changes in the strength of synaptic connections between type B photoreceptors and other components of the CS pathway have also been detected following conditioning. Facilitation of the amplitude of monosynaptic inhibitory postsynaptic potentials (IPSPs) elicited by single spikes in type B photoreceptors is detected in type A photoreceptors and type I interneurons of conditioned animals (Figures 4*C* and 4*D*). A second site of cellular plasticity in conditioned animals is the type A photoreceptor. Lateral type A photoreceptors of conditioned animals exhibit an increase in CS-elicited spike frequency, a decrease in generator potential amplitude, and enhanced excitability and decreased spike frequency accommodation to extrinsic current (for a review, see Sahley and Crow, 1998). The evidence for localization of cellular changes in the CS pathway indicates that multiple sites of plasticity involving changes in excitability and synaptic strength exist in the type B photoreceptors of conditioned animals (see Figure 4). Anatomical studies of type B photoreceptors indicate the existence of spatially segregated compartments (Alkon, 1989). Phototransduction occurs in the soma-rhabdomeric compartment, spike generation in the distal axon, and synaptic interactions in the axon terminal regions within the cerebropleural neuropil. Therefore, a decrease in K$^+$ conductances of type B photoreceptors could contribute both directly and indirectly to enhanced excitability by increasing the amplitude of CS-elicited generator potentials and increasing CS-elicited spike activity in the spike-generating zone by modification of conductances that influence the interspike interval.

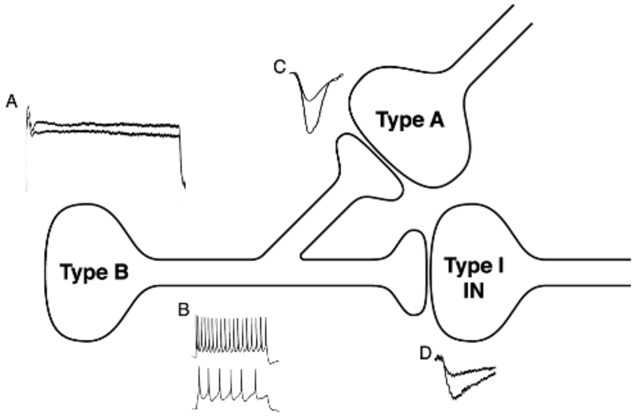

**Figure 4.** Components of the CS pathway that express plasticity in conditioned *Hermissenda. A*, The CS elicits a larger amplitude generator potential (upper trace) recorded from type B photoreceptors of conditioned animals as compared to pseudorandom controls (lower trace). *B*, An extrinsic current pulse elicits more action potentials in type B photoreceptors from conditioned preparations as compared to pseudorandom controls. *C*, Conditioning results in facilitation of the synaptic connections between type B photoreceptors and type A photoreceptors and type B photoreceptors and type I interneurons (*D*) as compared to control animals that received pseudorandom presentations of the CS and US.

## *Mechanisms of Pavlovian Conditioning*

Recent modeling studies utilizing a Hodgkin-Huxley type analysis of membrane conductances and the SNNAP simulator (see NEUROSIMULATION: TOOLS AND RESOURCES) have shown that modulation of several K$^+$ currents ($I_A$, $I_h$, $I_{K,Ca}$) can account for both the enhanced excitability of type B photoreceptors and enhancement of monosynaptic IPSPs detected in conditioned animals (Cai, Baxter, and Crow, 2001; see also Fost and Clark, 1996). In addition, modeling studies incorporating an analysis of membrane conductances in the phototransduction compartment, spike-generating zone, and synaptic terminals are providing insights into determining the relative contribution of changes in excitability and synaptic strength to modifications of complex PSP amplitude in postsynaptic neurons of the CS pathway.

Studies of the signal transduction pathways responsible for the modification of diverse $K^+$ currents of type B photoreceptors of conditioned animals have identified several second messenger systems. Both protein kinase C (PKC) and extracellular signal-regulated protein kinase (ERK) contribute to the conditioned modification of excitability and synaptic efficacy of *Hermissenda* (Alkon, 1989; Sahley and Crow, 1998; Muzzio et al., 2001).

Studies of one-trial conditioning have provided insights into the mechanisms of memory consolidation. One-trial conditioning (see above) produces short-, intermediate-, and long-term memory for enhanced excitability in identified type B photoreceptors. Associated with intermediate memory is the phosphorylation of a 24-kDa protein (CSP24) that exhibits a sequence identity to the $\beta$-thymosin family of actin-binding proteins (Crow and Xue-Bian, 2000). The regulation of CSP24 by one-trial conditioning occurs in neurons of the CS pathway and not in either the pedal or cerebropleural ganglia. Cytoskeletal-related proteins such as CSP24 may contribute to long-term structural remodeling in the CS pathway by regulating the turnover of actin filaments during the intermediate-term transition period between short- and long-term memory.

## Discussion

The possibility of relating cellular changes to complex behavior in invertebrates is encouraged by the progress that has already been made in examining the neural mechanisms of simple forms of nonassociative and associative learning. The results of these analyses have shown that (1) learning involves changes in existing neural circuitry (at least for the short-term, the growth of new synapses and the formation of new circuits for learning and memory are not necessary); (2) learning involves the activation of second messenger systems; (3) the second messenger affects multiple subcellular processes to alter the responsiveness of the neuron (at least one locus for the storage of memory is the alteration of specific membrane currents); (4) long-term memory requires new protein synthesis, whereas short-term memory does not; and (5) long-term memory may be associated with structural changes in the nervous system.

# Ion Channels: Keys to Neuronal Specialization

*José Bargas, Lucía Cervantes, Elvira Galarraga, and Andrés Fraguela*

## Introduction

Neurons code information and communicate by firing voltage spikes called action potentials (APs). Firing of APs is due to the presence of voltage-gated ion channels. Charge movement through them produces transient electrical currents that generate spikes. Ligand-gated ion channels activated during synaptic functioning produce patterns of voltage changes (see TEMPORAL DYNAMICS OF BIOLOGICAL SYNAPSES) that bring membrane voltage to the activation range of different sets of voltage-gated ion channels. The latter promote or restrain the firing of APs following certain patterns (coding). Patterning is nonlinear and is not the simple summation of excitatory and inhibitory influences. This article summarizes why: the operation of voltage-gated channels.

Hodgkin and Huxley (1952) established a model to explain how ion channels generate APs (see AXONAL MODELING). APs link cellular and systems neurophysiology: they are the feature extracted to design formal neurons (Arbib, 1964) (see Canonical Neural Models); they encode the physical properties of stimuli, motor commands, and working memory, and they correlate with behavior and perception (see section on Mammalian Brain Regions and Cognitive Development). However, diverse combinations of different voltage-gated ion channels are possible. Each neuron is endowed with a different combination (Llinás, 1988; Huguenard and McCormick, 1994). Therefore, each cell responds with a distinct set of firing patterns on synaptic activation: plateaus with repetitive firing, bistability, frequency adaptation, tonic firing, bursting, spontaneous pacemaking, etc. There is a "neuronal specialization" that reflects different functions of neural nets (locationism) supported by variations in firing (Llinás, 1988), morphology (Cajal, 1899), and the distribution of afferents with transmitters and modulators (Nicoll, 1988) (see Biophysical Mosaic of the Neuron) (Fig. 1).

More than 50 genes encode the pore-forming domains ($\alpha$-subunits) of $K^+$ channels (KCN). More than 10 genes encode $Na^+$ channels (SCN), and at least 10 genes encode pores for $Ca^{2+}$ channels (CACN). Five genes encode cation or pacemaking channels (HCN). And $\alpha$-subunits are not alone. Auxiliary subunits, $\beta$, $\gamma$, $\alpha_2\delta$, and $\delta$, encoded by other genes, change the kinetics and voltage dependence of channels. Thousands of channel types can theoretically arise from subunit combination and alternative splicing (proteomics from genomics). How can we make functional sense of this complexity? One way is to take *firing* as the crucial property. Since neurons are specialized, we should extract, as simply as possible, their different firing properties (e.g., Suri, Bargas, and Arbib, 2001). We need to know which are the main ion channels that contribute to different firing patterns.

The roles for ion channels are (1) to generate APs and (2) to set a particular pattern, rhythm, oscillation, threshold, adaptation, pacemaking, bursting, etc. for the firing of APs. This is the coding process that produces a distinct input-output function (I/O function) for a neuron in a certain condition (see Single-Cell Models).

## Operation of Ion Channels

Figure 2 simplifies the operations of an ion channel, and Figure 3 illustrates basic firing patterns. Ion currents through channels follow Ohm's law,

$$I_i = (G_{\text{MAX}} \cdot m^n h) \cdot (V - E_i) \qquad (1)$$

where $I_i$ = current, $G_{\text{MAX}} m^n h$ = conductance ($g(V)$), and $V - E_i$ = voltage ($\Delta$V). Channels can be closed ($C$), open ($O$), or inactive ($I$) (Figure 2). Only the O-state produces an $I_i$. To be in any state, $C$, $O$, or $I$, depends on voltage and time: $I(V, t)$. A voltage change ($\Delta$V) modifies the probability of being in any state. But velocity of change, or *time dependence*, is a main difference between ion channels, which is assessed by extracting time constants ($\tau_s$) from current ($I_i$) records represented by (for example):

$$I_i(t) = r_1(1 - \exp(-t/\tau_m))^n \exp(-t/\tau_h) + r_2 \qquad (2)$$

where $\tau_{\text{m}}$ is an activation time constant, $\tau_h$ is an inactivation time constant, $r_1$ and $r_2$ are constants, and $n$ is the exponent that fits nonlinear kinetics (Figure 2). $\tau_{\text{s}}$ ($h$ or $m$ above) depend on voltage. Fitting $I_i$ records for different voltages ($I$-$V$ plots) with Equation 2 produces a family of $\tau_{\text{s}}$ (Figure 2) where $\tau \approx 1/(\alpha + \beta)$ and $\alpha$ is the forward rate constant, whereas $\beta$ is the backward rate constant for changing state (Figure 2). Differences in *time dependence* dictated by $\tau_{\text{s}}$ make currents *transient, fast, slow, persistent*, or *slowly inactivating*.

Conductance, $g(V)$, measurements are also obtained from $I$-$V$ plots, where Equation 1 is applied to each record to obtain $g(V)$,

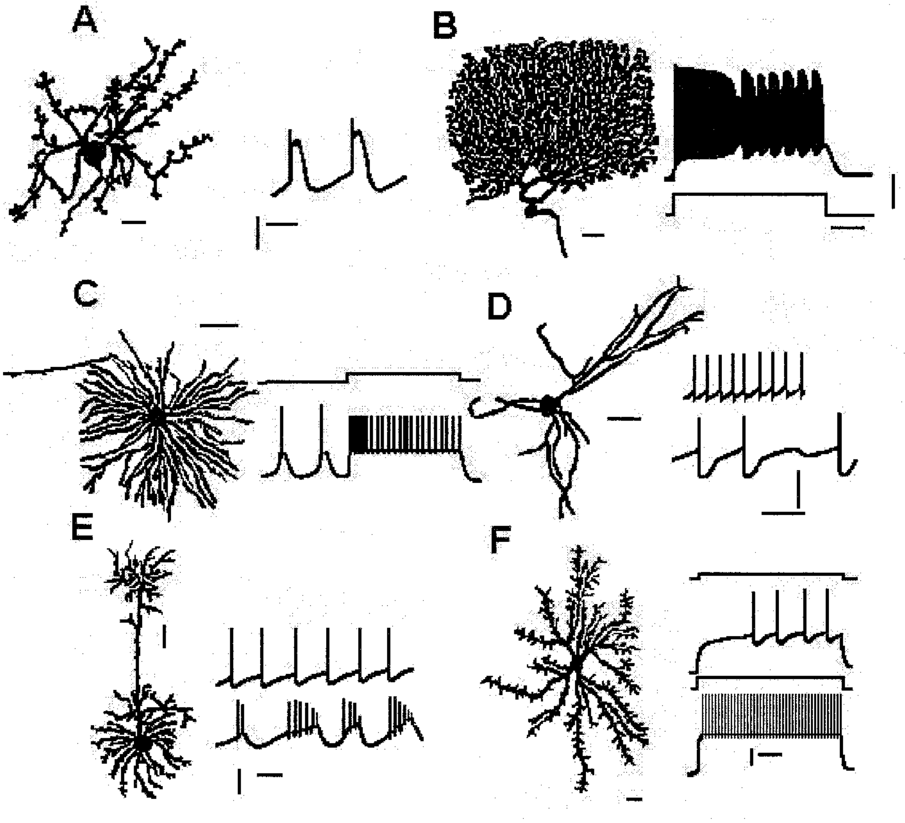

**Figure 1.** Neurons differ in morphology and firing pattern (see NEOCORTEX-BASIC NEURON TYPES). *A*, Inferior olive neuron. *B*, Cerebellar Purkinje cell. *C*, Thalamic relay neuron. *D*, Subtantia nigra compacta neuron. *E*, Cortical pyramidal neuron. *F*, Spiny neuron of the neostriatum.

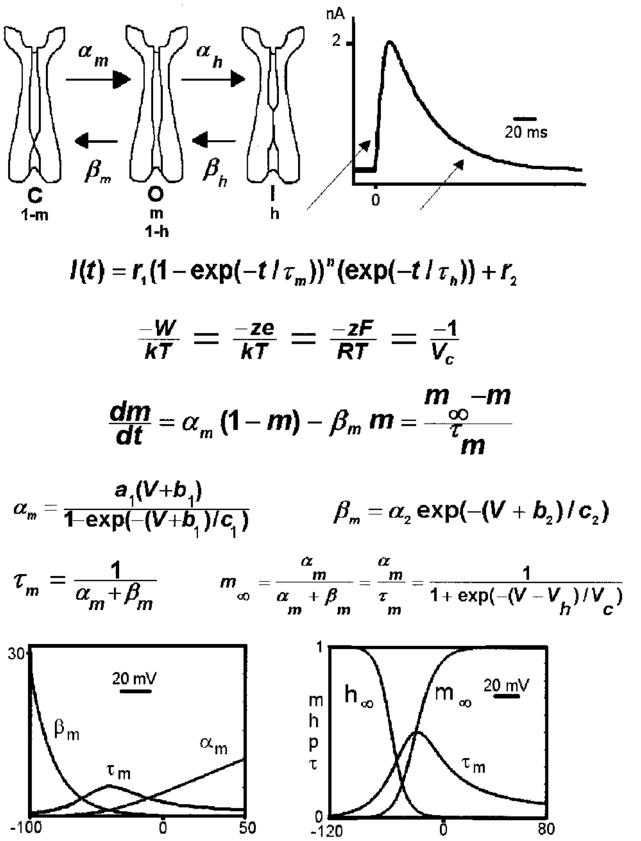

$$I(t) = r_1(1 - \exp(-t/\tau_m))^n(\exp(-t/\tau_h)) + r_2$$

$$\frac{-W}{kT} = \frac{-ze}{kT} = \frac{-zF}{RT} = \frac{-1}{V_c}$$

$$\frac{dm}{dt} = \alpha_m(1-m) - \beta_m m = \frac{m_\infty - m}{\tau_m}$$

$$\alpha_m = \frac{a_1(V+b_1)}{1-\exp(-(V+b_1)/c_1)} \qquad \beta_m = \alpha_2 \exp(-(V+b_2)/c_2)$$

$$\tau_m = \frac{1}{\alpha_m+\beta_m} \qquad m_\infty = \frac{\alpha_m}{\alpha_m+\beta_m} = \frac{\alpha_m}{\tau_m} = \frac{1}{1+\exp(-(V-V_h)/V_c)}$$

**Figure 2.** Channel function. At the top, a closed channel (C) may open (O) following rate constant $\alpha_{\mathrm{m}}$ (below). The channel may close again following rate constant $\beta_{\mathrm{m}}$ or may inactivate (I) following rate constant $\alpha_h$. Deinactivation follows rate constant $\beta_h$. $\tau_{m,h} \approx 1/\alpha + \beta$. Activation ($m_\infty$) and inactivation ($h_\infty$) functions can be obtained by plotting the conductance obtained from I-V plots. The bottom graph depicts relations between $\mathrm{m}_\infty$, $\tau$, $\alpha$, and $\beta$. Once $\alpha$ and $\beta$ are obtained, a differential equation (*dm*/*dt*) describes the kinetics of a channel. Channels differ in voltage and time dependence.

which, plotted against *V*, forms a sigmoid function (Figure 2) called the *activation* (or *inactivation*) function ($m_\infty$ and $h_\infty$). $g(V)$ dictates the *voltage dependence* of the current and is the other main difference between ion channels, which are then *threshold, subthreshold*, or *suprathreshold* in respect to firing. $g(V)$ can be fitted to:

$$g(V) = G_{\mathrm{MAX}}/(1 + \exp(\pm(V - V_h)/V_c)) \tag{3}$$

(activation: $-$; inactivation $+$ sign). Where $G_{\mathrm{MAX}} = g$ when all channels are open, *V* denotes voltage, $V_h$ is the voltage at which half the channels are open, and $\mathrm{V_c}$ is the slope factor of the sigmoid equivalent to a Boltzmann exponent (RT/F or kT/e -in mV; ≈ 26 mV at 25°C), *z* denotes valence, $V - V_h$ is ΔV, and *F*, *R*, *T*, *k*, *T*, and *e* have their usual meaning (Figure 2). $g(V)$ is a cumulative Boltzmann distribution (Figure 2) but, normalizing $G_{\mathrm{MAX}} = 1.0$, becomes a probability (P) function where *m* is the P to open and $1 - m$ is the *P* to close (Figure 2). *Inactivation* is denoted by *h* (Figure 2 uses *p* for both).

$\alpha$ and $\beta$ define first-order kinetics: simple exponential solutions multiplied by constants (Figure 2) (Jack, Noble, and Tsien, 1975) or Boltzmann distributions. $g(V)$ is proportional to permeability ($P(I, V)$), which can be obtained transforming *I-V* plots with the Goldman-Hodgkin-Katz equation for current,

$$P(I, V) = \frac{I}{V} \cdot \frac{RT}{(zF)^2} \cdot \left(\frac{\exp(-zFV/RT) - 1}{[C]_o \cdot \exp(-zFV/RT) - [C]_i}\right) \tag{4}$$

where $[C]_i$ denotes internal ion concentrations, $[C]_o$ denotes external ion concentrations, *I* is current, and *V* is voltage. $g(V)$ can also be obtained by differentiating the *I-V* plot or by using instantaneous *I-V* plots (tail currents).

In summary, $V_h$, $V_c$, and $\tau_{\mathrm{s}}$ *characterize* ion conductances, i.e., $g(V)/\tau_m = \alpha_m$, etc., giving their time and voltage dependence. Neurons use an array of ion conductances differing in time, voltage dependence, and the ion carried. The concerted work of them makes up the firing properties or coding.

The activation function *m* (Equations 1 and 3) is raised to an *n* power, where *n* is the order of the kinetic reaction. Thus, nonlinearity arises by the parallel action of *n* first-order processes. Each represents the movement of a protein (channel) subunit or domain. All of them move for the whole channel molecule to change state. The sigmoidal delay to change may be viewed as the many "closed states" ($C_1$, $C_2$, . . . , $C_{\mathrm{n}}$) that have to be crossed before entering the "open state." Note that, since each channel is composed of several domains, nonlinearity arises at the molecular level. Imagine then what happens when many of such molecules combine to produce a firing pattern, when neurons possessing different arrays of these channels combine to form a neural net, and when nuclei possessing different nets arrange to produce a nervous system.

Inward or outward ion currents depend on the value of $E_i$ or equilibrium potential of the ion (Equation 1). If $E_i$ is less than firing threshold, *I* is a hyperpolarizing outward current that will tend to arrest firing (Figure 3). If $E_i$ is greater than firing threshold, *I* is a depolarizing inward current that will promote firing. When a neuron increases firing, there is no a priori way to know whether an inward current was facilitated or an outward current was restrained.

## Neuronal Specialization

Each neuronal class has a different set of ion conductances. The original HH model (see Axonal Modeling), consisting of a transient inward current (Figures 3*B*1, 3*C*1), a persistent outward current (Figures 3*B*3, 3*C*2), and a leak current (Figure 3*A*2) ($I_{Na}$, $I_K$, and $I_{leak}$), gives a *basic firing mechanism* (BFM). Leak currents are made up of a family of $\mathrm{K}^+$ channels with a double pore-forming domain in tandem (KCNK1-7, 9, 10, 12, 13, 16, 17) with 13 members. These channels make up the electrotonic structure or cable properties.

A good exercise using a simulator (e.g., Huguenard and McCormick, 1994) is to begin with the BFM (Figure 3*A*3) and then add one class of conductance at a time to see how the BFM is modified (column *A* in Figure 3). From top to bottom, the records in column *A* of Figure 3 show the BFM (Figure 3*A*3) with one auxiliary current at a time (Figures 3*A*4–9). Any firing pattern is due to a sum of conductances,

$$C\frac{Vd}{dt} = -\sum_i^n (I_i) = -(I_{Na} + I_k + I_{leak} + I_{to} + I_{so} + I_{ti} + I_{si} + \cdots + I_n) \tag{5}$$

where *to* denotes transient outward, *so* denotes slowly inactivating outward, *ti* denotes transient inward, *si* denotes slowly inactivating inward, and so on; *C* denotes capacitance. Column *D* shows a modeling experiment adding several auxiliary conductances in sequence.

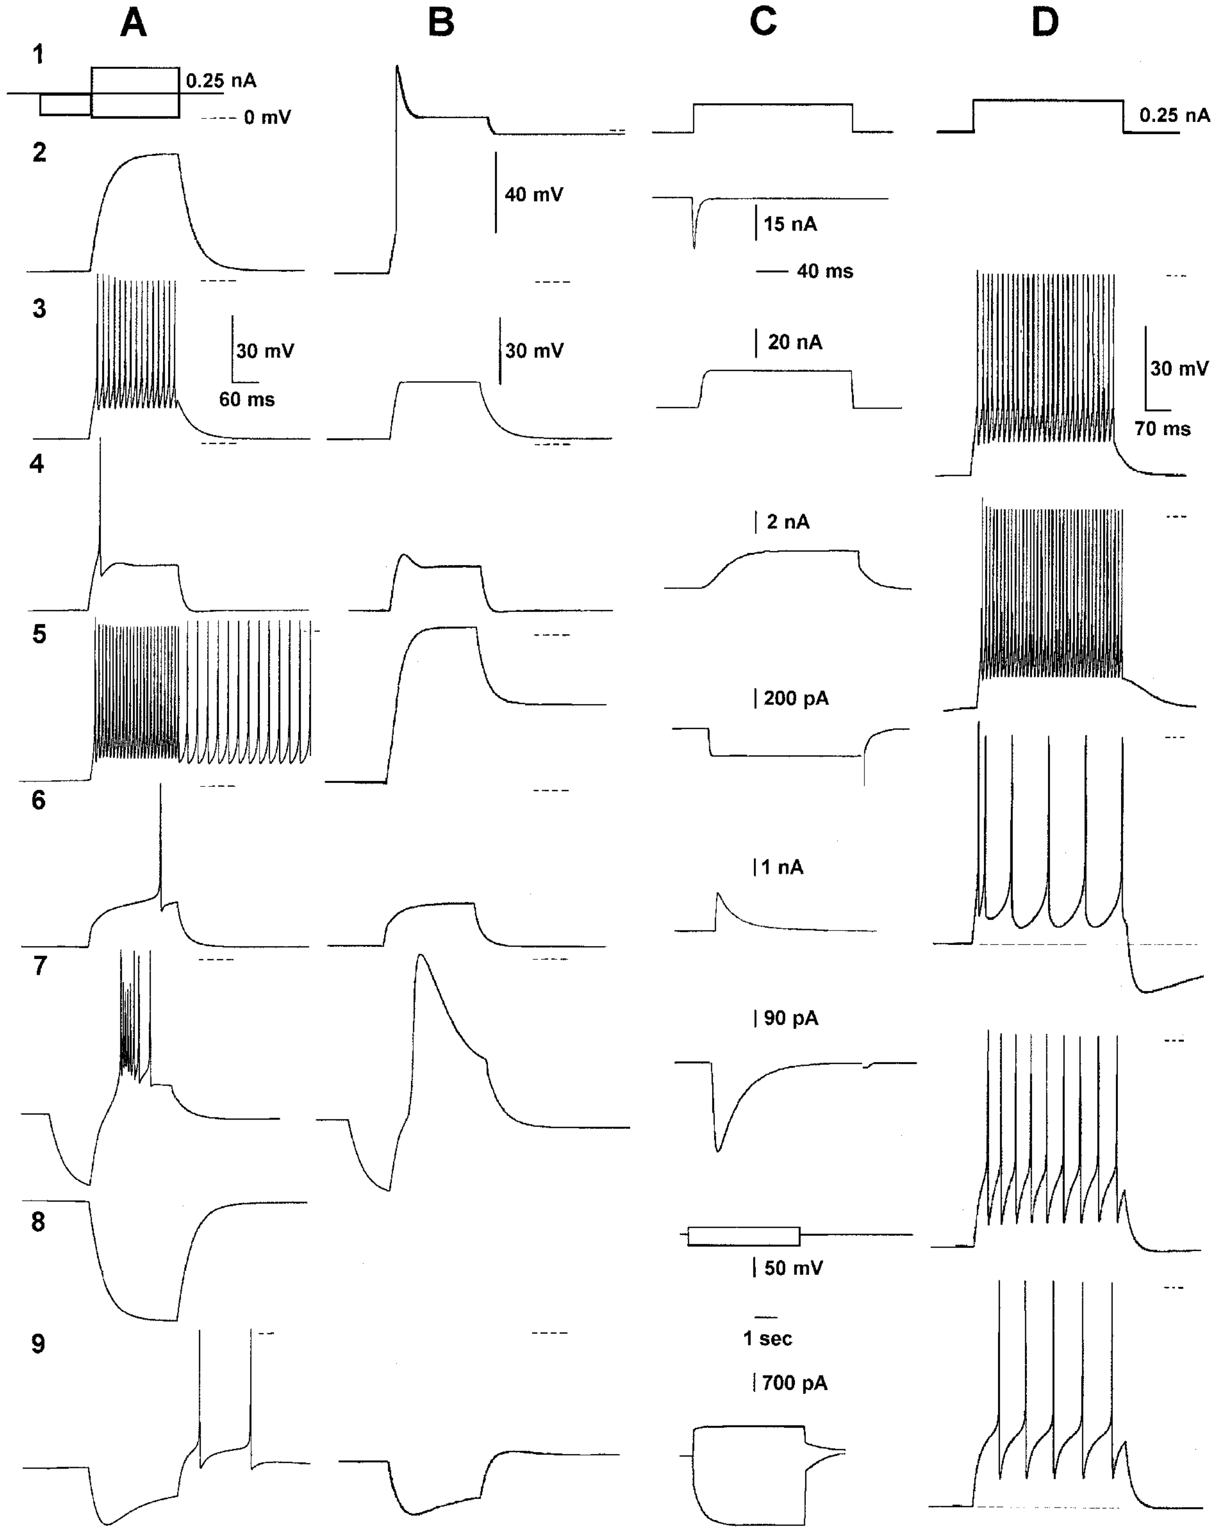

**Figure 3.** Firing patterns. Columns *A*, *B*, and *D* are voltage recordings; column *C* shows current recordings. *A*1, Stimuli. The main stimulus is a depolarizing current step. *A*2, $I_{leak}$ produces RC responses. *A*3, $I_{Na}$ and $I_K$ are added to produce a basic firing mechanism (BFM). *A*4, BFM plus $I_{SO}$ produces adaption. *A*5, BFM plus $I_{SI}$ produces a plateau potential and increases firing. *A*6, BFM plus $I_{TO}$ delays firing. *A*7, BFM plus $I_{TI}$ produces bursting after a hyperpolarization. *A*8, Hyperpolarizing RC response (cf. *A*2). *A*9, BFM plus $I_h$ produces rebound excitation. *B*, RC response plus-$I_{Na}$(*B*2), $I_K$(*B*3), $I_{SO}$(*B*4), $I_{SI}$(*B*5), $I_{TO}$(*B*6), $I_{TI}$(*B*7), and $I_h$(*B*9). *C*, A depolarizing command (*C*1) evokes $I_{Na}$(*C*2), $I_K$(*C*3), $I_{SO}$(*C*4), $I_{SI}$(*C*5), $I_{TO}$(*C*6), $I_{TI}$(*C*7), and hyperpolarizing and depolarizing commands (*C*8) elicit $I_h$(*C*9). *D*, BFM after a depolarizing step (*D*3), plus subthreshold $I_{Ca}$ (firing increases: *D*4–5), $I_{SK}$ (AHP and adaptation increase while frequency decreases: *D*6), $I_{BK}$ (frequency increases and there is less adaptation: *D*7–8), and $I_D$ (frequency decreases and becomes regular; AHPs look smaller than *D*9) added in sequence.

## Functional Classification

- Activated by depolarization
  - Inward
    - Transient ($I_{ti}$)
    - Slowly or incompletely inactivating ($I_{si}$)
  - Outward
    - Transient ($I_{to}$)
    - Slowly or incompletely inactivating ($I_{so}$)
- Activated by hyperpolarization
  - Inward
    - Cationic currents (pacemaking) ($I_h$)
  - Outward
    - Inward rectifiers ($K_{ir}$)

*Transient inward* ($l_{it}$) currents are sodium currents ($I_{Na}$ in Figure 3*C*2; Goldin, 2001) that inactivate quickly and produce the depolarizing phase of the spike (Figures 3*A*3, 3*B*2). One class, Nav1.1 to 1.9 or SCN1–11, is blocked by tetrodotoxin and saxitoxin, although some of them need high concentrations (SCN10, 11). A second class, Nav2.1 (SCN6, 7: SNS and NaN), is tetrodotoxin resistant. Certain types allow a small percentage of the current ($<10\%$) without inactivation, generating a persistent current (e.g., Nav 1.6).

Another $I_{ti}$ are calcium "T-currents" ($\alpha_{1G,H,I}$, $I_T$, or CACNA, blocked by kurtoxin) (Randal and Benham, 1999), which produce "low-threshold spikes" (sinoatrial node) (Figure 3*B*7) that trigger sodium spikes (in neurons), producing bursts (Figure 3*A*7). A previous hyperpolarization—an afterhyperpolarization (AHP) or an inhibitory synaptic potential (IPSP)—de-inactivates T-channels (Figure 3*A*7). Thalamic, nigral, pallidal, pontine, cortical, and many other neurons use $I_T$ to fire in bursts after an IPSP, producing rebound excitation, postinhibitory afterdischarges, augmentation responses, and slow rhythmic bursting, like that seen in spindle waves (see OSCILLATORY AND BURSTING PROPERTIES OF NEURONS). At depolarized potentials, T-channels are inactive.

Thus, neurons are able to respond differently depending on previous membrane potential. This allows a net to behave differently at different moments, while using the same neuronal elements (multitask networks). Since APs can be evoked from two different membrane potentials, the neuron has two functionally different firing thresholds. A neuron may have more than one threshold, and different firing patterns may be evoked from each threshold.

*Transient outward* ($I_{to}$) currents are potassium currents or $I_A$ (e.g., Kv1 and Kv4 families, or KCN1,4, blocked by dendrotoxin and aminopyridines) (Figure 3*C*6). They oppose $I_T$. Inactivating between spikes, they set a stereotyped behavior between APs pacing tonic firing (Figure 3*D*9) at low frequencies. When subthreshold, they oppose any depolarization (Figure 3*B*6), so that membrane potential reaches threshold with a delay: $I_A$ "retards" membrane trajectory toward threshold (Figure 3*A*6). A "conditioning" stimulus inactivates $I_A$, increasing responses with time, so that a previous subthreshold stimulus may reach threshold after a delay (*facilitation*).

A number of genes, differing in $\tau_h$, code for $I_A$ (Shieh et al., 2000). Hence, firing latency and rhythmic firing depend on voltage and time, expanding the I/O function (see column *D* of Figure 3).

*Slowly inactivating inward* ($I_{si}$) currents inactivate after several hundreds of milliseconds or seconds. On a short time scale they may be viewed as persistent. They are calcium currents, or persistent components of some sodium currents, or cationic currents. Their activation produces a depolarization that adds to the stimulus, enhancing it (Figure 3*B*5; cf. Figure 3*A*2) and increasing firing (Figure 3*A*5). Calcium channels come in two families, L ($\alpha_{1S,C,D,F}$ or CACNA-S,C,D,F) and non-L ($\alpha_{1A,B,E}$ or CACNA-A,B,E). L channels are blocked by calciseptine and dihydropyridines. Their inactivation depends on intracellular $Ca^{2+}$ and voltage: $Ca^{2+}$ enters and shuts down the channel (feedback). Inactivation of the non-L family depends mainly on voltage (except for P).

$I_{si}$ produce "plateau potentials" that sustain repetitive firing (Figure 3*D*5; cf. Figure 3*D*3) and bistable properties, i.e., two stable membrane potentials that alternate. There is a gain in the I/O function during plateaus. In the dendrites, slow synaptic depolarizations (NMDA) boost plateaus produced by $I_{si}$.

Activated during the spike, $I_{si}$ contribute to it and to activating the potassium conductances that generate the AHP (Figure 3*D*6). Plateau potentials, bistability, dendritic spikes, and activation of outward currents are only some roles of $I_{si}$. Calcium entry has many other roles: in transmitter release, muscle contraction, cytoskeleton function, enzyme and gene activation, and so on.

*Slowly inactivating outward* ($I_{so}$) potassium currents (Figure 3*C*4) consist of (1) Kv channels as Kv2,3 or KCNA–D, 1–4; (2) KvLQT or KCNQ1–5, HERG or KCNH1–4, which are blocked by TEA, noxiustoxin, etc. (Shieh et al., 2000); (3) SK and IK channels or KCNN1–3 and KCNN4, respectively, which are blocked by apamin and charybdotoxin and activated by intracellular calcium; and (4) slow channels, BK or KCNMA1, which are blocked by TEA, iberiotoxin, and charybdotoxin (Shieh et al., 2000) and activated by voltage and intracellular calcium. All tend to maintain a quiet membrane-opposing depolarizing stimulus (Figure 3*B*4), spikes, inward currents, and plateau potentials. They decrease excitability, decrease or arrest firing frequency, and augment firing threshold. Depolarization activates $I_{so}$, it hyperpolarizes the membrane and then shuts down again (feedback). The BFM (Figure 3*A*3) becomes adapting firing (Figure 3*A*4) if a slow outward current (Figure 3*C*4) is superimposed. Conversely, when $I_{so}$ is blocked, a frequency gain occurs. Note that several $I_{so}$ depend on calcium accumulation. $Ca^{2+}$ enters with each spike, allowing a short-time memory. Calcium-dependent gating of AHP opens a fraction of channels, depending on the number of spikes fired (digital to analog conversion) (Figure 3*D*6). The AHP fixes the time interval between spikes or trains of spikes and ends episodes of increased excitability, sets the pace for rhythmic firing and bursting, and allows frequency control and adaptation (see THALAMUS). Firing depends on calcium dynamics (see column *D* in Figure 3) because all neurons posses some variety of a calcium-dependent $I_{so}$. Thus, firing mechanisms have to simulate calcium dynamics to be realistic.

*Inward currents activated by hyperpolarization* ($I_h$) or HCN1–4 blocked by cesium (Kaupp and Seifert, 2001) activate when the membrane potential hyperpolarizes below firing threshold, producing voltage "sags" ($E_i \approx -35$ mV) that oppose the same hyperpolarization (Figure 3*B*9). They contribute to rebound "humps" that may attain firing (Figure 3*A*9) when the hyperpolarization is over. $I_h$, $I_T$, and $I_A$, acting in concert, produce rhythmic bursting (see SLEEP OSCILLATIONS). $I_h$ are "pacemaking currents" that allow spontaneous firing: an AP produces an AHP; the AHP activates $I_h$, which then depolarizes the membrane back to fire another AP, which is followed by another AHP that repeats the cycle, keeping the cell firing. When $I_h$ reaches the threshold for T-channels during rebound, a low-threshold Ca spike and bursting may ensue. Since the cycle (e.g., the orbit in the phase plane) is initiated by a hyperpolarization, the cell has a "threshold" going in the hyperpolarizing direction (an unstable singular point that initiates the entire orbit).

*Outward currents activated by hyperpolarization* ($K_{ir}$*s*) are inward rectifier potassium channels composed of four domains, each with only two transmembrane segments. Strong activation by a hyperpolarization produces inward potassium currents ($K_{ir}$ or KCNJ1–15, blocked by cesium and barium) (Shieh et al., 2000), but no physiological stimulus hyperpolarizes the cell beyond $E_K$. Thus, the role of these channels is to *close* when the cell is depolarized. At rest, some channels are open and participate in the resting membrane potential and cable properties. When synaptic entries depolarize the cell, $K_{ir}$ current shuts down and all inputs increase their value abruptly, since electrotonic length has shrink.

The threshold is dynamic. It depends on $K_{ir}s$, which act as a gate, requiring a convergence of inputs to pass the signal. A sum of synaptic inputs is not responsible for firing, but a complex interaction of intrinsic and synaptic conductances change the I/O function. Activation of $K_{ir}s$ depends on the potential and on extracellular potassium, which depend on the excitability level (synchronicity).

## Discussion

Brain neuronal circuits are complex and dynamic. Ion channels endow neurons with properties such as multiple thresholds, different firing patterns associated with each threshold, the possibility of switching between different firing patterns, timing, multiple time constants for spike frequency adaptation, a changing electrotonic length, pacemaking, intrinsic facilitation, gating, bistable properties, short memory traces, etc. Each ion current contributes to a set of properties. Many ion conductances modify the BFM. Different firing patterns are shaped by previous activity and modulation. Accordingly, neuronal nets dynamically switch between different firing states and different configurations of synaptic weights: *n* thresholds and *n* firing levels due to *n* ion conductances activated at each level. A different pattern at each level will reach synaptic terminals differently. Each pattern encompasses a different I/O function. An I/O function may favor learning, while others may favor consolidation. Some would be preferred by sensory neurons, others by intermediate or motor neurons. Some net-states induce resonance between a set of nuclei. Other net-states decouple these nuclei but may couple other nuclei.

The simple picture used here to hint into this complexity is an abstraction. Nonlinearities produce many counterintuitive outcomes. One example is shown in column *D* of Figure 3, in which several conductances were added in sequence (from top to bottom) to the BFM (in Figures 3*D*3–4): a subthreshold Ca current (Figures *D*4–5)-enhanced evoked discharge, a Ca-activated SK-type current (Figure 3*D*6) decreased firing frequency and increased AHPs and adaptation, but addition of a BK type of current did not decrease firing (Figure 3*D*8) but, surprisingly, increased firing and produced less adaptation. The addition of $I_A$ (with a rather slow $\tau_h$) produced tonic firing with very low firing frequencies never reached by BFM alone (e.g., as in a neostriatal spiny neuron). Comparing the AHPs of records in Figure 3*D*6 and Figure 3*D*9, one would not imagine that the firing in Figure 3*D*9 involved more outward current.

# Kalman Filtering: Neural Implications

*Simon Haykin*

## Introduction

The time-domain description of a system by a *state-space model*, depicted in Figure 1, is of profound importance. The notion of state plays a key role in the formulation of this model. The *state*, denoted by the vector $\mathbf{x}(n)$, is defined as any set of quantities that would be sufficient to uniquely describe the unforced dynamic behavior of the system at discrete time *n*. The model of Figure 1 is not only mathematically convenient, it also offers a close relationship to physical/neurobiological reality and a basis for accounting for the statistical behavior of the system.

The state-space model of Figure 1 embodies two basic equations:

1. *Process equation*

$$\mathbf{x}(n + 1) = \mathbf{F}(n + 1, n)\mathbf{x}(n) + v_1(n) \quad (1)$$

where $\mathbf{F}(n + 1, n)$ is a transition matrix and the vector $v_1(n)$ is an additive dynamic noise.

2. *Measurement equation*

$$\mathbf{y}(n) = \mathbf{C}(\mathbf{n})\mathbf{x}(n) + v_2(n) \quad (2)$$

where the vector $\mathbf{y}(n)$ is the *observation*, $\mathbf{C}(n)$ is a *measurement matrix*, and the vector $v_2(n)$ is an additive *measurement noise*.

Typically, the state $\mathbf{x}(i)$ is hidden and therefore unknown, and the requirement is to estimate it using a sequence of observations $\mathbf{y}(1), \mathbf{y}(2), \ldots, \mathbf{y}(n)$. The sequential estimation problem is called *filtering* if *i = n, prediction* if $i > n$, and *smoothing* if $1 \leq i < n$. Unlike smoothing, both filtering and prediction are real-time operations. In this article, we only consider prediction and filtering, which are closely related.

## Kalman Filters

In a classic paper, Kalman (1960) derived a general solution for the *linear* filtering problem, and with it the celebrated *Kalman filter*

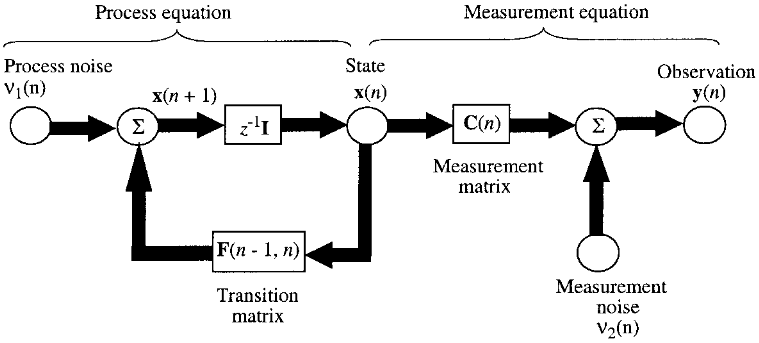

**Figure 1.** Signal-flow graph representation of a linear, discrete-time dynamical system.

was born. Assuming that the dynamic noise $v_1(n)$ and measurement noise $v_2(n)$ are independent, white, and Gaussian processes, the Kalman filter is a recursive estimator that is optimum in the minimum mean-square error or, equivalently, maximum likelihood sense (Jazwinski, 1970).

Let $\mathbf{Y}_{n-1}$ denote the subspace spanned by the observations $\mathbf{y}(1)$, $\mathbf{y}(2), \ldots, \mathbf{y}(n-1)$. Given the new observation $\mathbf{y}(n)$, the current estimate of the state denoted by $\hat{\mathbf{x}}(n|\mathbf{Y}_{n-1})$ is recursively updated as follows:

$$\hat{\mathbf{x}}(n+1|\mathbf{Y}_n) = \mathbf{F}(n+1, n)\hat{\mathbf{x}}(n|\mathbf{Y}_{n-1}) + \mathbf{G}(n)\alpha(n) \quad (3)$$

where $\mathbf{G}(n)$ is the *gain matrix*, and the vector

$$\alpha(n) = \mathbf{y}(n) - \mathbf{C}(n)\hat{\mathbf{x}}(n|\mathbf{Y}_{n-1}) \quad (4)$$

is the *innovation*, representing the part of $\mathbf{y}(n)$ that is new. Equations 3 and 4 show that the underlying structure of the Kalman filter is in the closed-loop form of a *predictor-corrector*, consisting of two steps:

1. *Measurement update*, which uses the current observation $\mathbf{y}(n)$ to compute the innovation $\alpha(n)$.
2. *Time update*, which uses $\alpha(n)$ to update the past estimate $\hat{\mathbf{x}}(n|\mathbf{Y}_{n-1})$.

In addition to Equations 3 and 4, the Kalman filter involves three other basic steps (Haykin, 2002):

1. *Computation* of the gain matrix $\mathbf{G}(n)$ in terms of an error covariance matrix $\mathbf{K}(n, n-1)$, where the error refers to the difference between the true state $\mathbf{x}(n)$ and the current estimate $\hat{\mathbf{x}}(n|\mathbf{Y}_{n-1})$.
2. *Time updating* of the error covariance matrix $\mathbf{K}(n, n-1)$ via the so-called *Riccati equation*.
3. *Initialization* of the filter by setting $\hat{\mathbf{x}}(1|\mathbf{Y}_0) = \mathbf{0}$ and $\mathbf{K}(1, 0) = \Pi_0$, where $\mathbf{0}$ is the null vector and $\Pi_0$ is a prescribed diagonal matrix.

The computational complexity of the Kalman filter is of order $M^2$, where $M$ is the dimensionality of the state space.

A serious limitation of the standard Kalman filter is that it is prone to unstable behavior that may arise due to model mismatch and use of finite-precision arithmetic. The origin of the problem is traced to the fact that in situations of this kind, the Riccati equation may *not* result in a non-negative definite solution for the error covariance matrix $\mathbf{K}(n, n-1)$, which is unacceptable. (An important property of a covariance matrix is that it must be non-negative definite.) The unstable behavior of the Kalman filter is referred to as the *divergence phenomenon*.

To overcome this phenomenon, we may use *square-root filtering*, whereby the square root of the error covariance matrix rather than the error covariance matrix itself is propagated through the filter. According to the *Cholesky factorization*, we may write

$$\mathbf{K}(n, n-1) = \mathbf{K}^{1/2}(n, n-1)\mathbf{K}^{T/2}(n, n-1) \quad (5)$$

where $\mathbf{K}^{1/2}(n, n-1)$ is a lower triangular matrix (i.e., all the elements above the main diagonal are zero), and $\mathbf{K}^{T/2}(n, n-1)$ is its transpose. The important thing to note here is that the product of a lower triangular matrix and its transpose is unlikely to become indefinite.

The discussion up to this point rests on the premise that the state-space model of Equations 1 and 2 is linear. What if the model is nonlinear, as shown by the equations

$$\mathbf{x}(n+1) = \mathbf{f}(n, \mathbf{x}(n)) + v_1(n) \quad (6)$$

$$\mathbf{y}(n) = \mathbf{c}(n, \mathbf{x}(n)) + v_2(n) \quad (7)$$

where $\mathbf{f}$ and $\mathbf{c}$ are time-varying, vector-valued functions? The explicit dependence on time $n$ accounts for a possibility that the equations are time varying. To deal with this new situation, we may extend the use of the standard Kalman filter. Specifically, the nonlinear process equation (Equation 6) and the nonlinear measurement equation (Equation 7) are linearized at each iteration of the filter around most recent estimates of the state, which is achieved by retaining the first-order terms in the Taylor series expansions of the nonlinear functions $\mathbf{f}$ and $\mathbf{c}$. For obvious reasons, the resulting filter is referred to as the *extended Kalman filter*, or EKF (Jazwinski, 1970; Haykin, 2002).

## Supervised Training of Neural Networks

The Kalman filter offers two important properties: (1) estimation of the state using the entire past sequence of observations, and (2) use of second-order information in the form of an error covariance matrix. These two properties make the Kalman filter into a powerful tool for the supervised training of neural networks. The issue of concern here is how to proceed with this approach in a computationally feasible manner without compromising the application of Kalman filter theory. The answer lies in using a *decoupled* form of the extended Kalman filter, in which the computational complexity is made to suit the requirements of a particular application and available computational resources (Puskorius and Feldkamp, 2001).

In this article, we consider the supervised training of a recurrent multilayer perceptron (RMLP), for which the decoupled extended Kalman filter (DEKF) has established itself as an enabling technology by solving some difficult signal processing and control problems.

Let the vector $\mathbf{w}(n)$ denote the synaptic weights of the entire RMLP at iteration $n$. With adaptive filtering in mind and $\mathbf{w}(n)$ viewed as a state of the RMLP, we may formulate the state-space model of the network as (Haykin, 1999)

$$\mathbf{w}(n+1) = \mathbf{w}(n) + v_1(n) \quad (8)$$

$$\mathbf{d}_0(n) = \mathbf{c}(\mathbf{w}(n), \mathbf{u}(n), \mathbf{v}(n)) + v_2(n) \quad (9)$$

Equation 8 describes a diffusion process. The vector-valued function **c** accounts for the overall nonlinearity from the input layer to the output layer of the RMLP. The arguments **u**($n$) and **v**($n$) of the function **c** denote the signal vector applied to the input layer and the vector of recurrent activation potentials at internal nodes of the RMLP, respectively. The vector $v_1(n)$ denotes noise *artificially* introduced into the process equation, and the vector $v_2(n)$ denotes additive noise in the measured data. The vector $\mathbf{d}_0(n)$ is the desired response of the RMLP.

There are two contexts in which the term "state" is used here:

- The network's weights, **w**($n$), which are adjusted during training.
- The recurrent activation functions, **v**($n$), which continue to evolve nonlinearly with time once the training ends.

By comparing the model of Equations 8 and 9 for the RMLP with the linear dynamical model of Equations 1 and 2, we see that the difference between these two models is in the nonlinear form of the measurement equation (Equation 9). This matter is taken care of through linearization, thereby facilitating application of the EKF. This linearization requires the partial derivatives of the output(s) of the RMLP with respect to its weights. (Backpropagation through time provides an efficient algorithm for computing these partial derivatives.) Decoupling is introduced into the extended Kalman filtering algorithm by assuming that the interactions between the estimates of certain weights in the RMLP can be ignored, the effect of which is to introduce zeros into the error covariance matrix. If the weights are decoupled so that certain subgroups of weights are mutually exclusive of one another, then the error covariance matrix can be arranged into a block-diagonal form, thereby reducing the computational burden of the algorithm (Puskorius and Feldkamp, 2001).

Two noteworthy points on the use of Kalman filtering for the supervised training of recurrent networks are:

1. Introduction of the artificial noise $v_1(n)$ in the process equation (Equation 8) has the desirable effects of accelerating the convergence process and enhancing the likelihood of reaching a global minimum of the error performance surface. Through the use of an annealing procedure, the effect of $v_1(n)$ can be gradually reduced as the network approaches an equilibrium condition.
2. The presence of second-order information in the form of error covariance matrix has the desirable effect of overcoming the vanishing gradients problem that arises when a recurrent network is trained with a gradient-based algorithm such as the real-time recurrent learning algorithm (Haykin, 1999).

## Dynamic Model of Visual Recognition

The visual cortex is endowed with two key anatomical properties:

- *Abundant use of feedback*. The connections between any two connected areas of the visual cortex are bilateral, thereby accommodating the transmission of forward as well as feedback signals between the interconnected cortical areas.
- *Hierarchical multiscale structure*. The receptive fields of lower-area cells in the visual cortex span only a small fraction of the visual field, whereas the receptive fields of higher-area cells increase in size until they span almost the entire visual field. It is this constrained network structure that makes it possible for the fully connected visual cortex to perform prediction in a high-dimensional data space with a reduced number of free parameters and therefore in a computationally efficient manner.

Rao and Ballard (1997) exploit these two properties of the visual cortex to build a dynamic model of visual recognition, recognizing that vision is fundamentally a nonlinear dynamic process. The motivation for building the model was to explain the way in which the responses of cells in the visual cortex are significantly modulated by stimuli from beyond the classical receptive field. This modulation can be exerted from multiple sources, including the higher-level systems that are activated when an animal views a natural scene.

The Rao-Ballard model of visual recognition is a hierarchically organized neural network, with each intermediate level of the hierarchy receiving two kinds of information: bottom-up information from the preceding level, and top-down information from the higher level. For its implementation, the model uses a multiscale estimation algorithm that may be viewed as a hierarchical form of the extended Kalman filter. In particular, the EKF is used to simultaneously learn the feedforward, feedback, and prediction parameters of the model using visual experiences in a dynamic environment. The resulting adaptive processes operate on two different time scales:

- A *fast* dynamic state-estimation process, which allows the dynamic model to anticipate incoming stimuli.
- A *slow* Hebbian learning process, which provides for synaptic weight adjustments in the model.

In a subsequent study, Patel, Becker, and Racine (2001) studied the use of an RMLP trained with the DEKF algorithm to deal with high-dimensional signals, namely, moving visual images. The particular problem dealt with is the tracking of objects that vary in both shape and location, which is a challenging problem. By making use of short-term continuity, Patel et al. show that their model is capable of tracking a mixture of different geometric shapes (circles, squares, and triangles). As with the Rao-Ballard dynamic model of visual recognition, the Patel-Becker-Racine model is designed with a hierarchical structure; specifically, the first hidden layer of neurons in the RMLP was connected to relatively small, local regions of the visual field applied to the input layer, and a subsequent hidden layer spanned the entire visual field. The Patel-Becker-Racine model may be viewed as a first step toward modeling the dynamic mechanism by which the human brain might be simultaneously recognizing and tracking moving stimuli.

## Hypothesis That the Cerebellum Is a Neural Analog of a Dynamic State Estimator

The cerebellum has an important role to play in the control and coordination of movements, which are ordinarily carried out in a very smooth and almost effortless manner. The fundamental issue to be resolved here is whether the cerebellum plays the role of a controller or a dynamic state estimator, in light of what we know about modern control theory. Unfortunately, this issue cannot be resolved solely on the basis of the evidence that cerebellar damage or disease causes inaccuracy or instability of movements.

The key point in support of the dynamic state-estimation hypothesis is embodied in the following statement, the validity of which has been confirmed by decades of work on the design of automatic tracking and guidance systems: *Any system, be it a biological or artificial system, required to predict and/or control the trajectory of a stochastic multivariate dynamic system, can only do so by using or invoking the essence of Kalman filtering in one way or another.*

Building on this key point, Paulin (1997) presented several lines of evidence that favor the hypothesis that the cerebellum is a neural analog of a dynamic state estimator. A particular line of evidence presented therein relates to the vestibulo-ocular reflex (VOR), which is part of the oculomotor system. The function of the VOR is to maintain visual (i.e., retinal) image stability by making eye rotations that are opposite to head rotations. This function is mediated by a neural network that includes the cerebellar cortex and vestibular nuclei. Now, from modern control theory we know that a Kalman filter is an optimum linear system with minimum mean-square error for predicting the state trajectory of a dynamic system using noisy measurements; it does so by estimating the particular state trajectory that is most likely, given an assumed model for the underlying dynamics of the system. A consequence of this strategy is that when the dynamic system deviates from the assumed model, the Kalman filter makes estimation errors of a predictable kind, which may be attributed to the filter believing in the assumed model rather than the actual sense data. According to Paulin (1997), estimation errors of this kind are observed in the behavior of the VOR.

The important point to note, in this brief discussion of the hypothesis that the cerebellum is a neural analog of a Kalman filter, is that the hypothesis is *not* to be taken to imply that the cerebellum physically resembles a Kalman filter. Rather, the cerebellum may provide information in the nervous system, which is analogous to state estimation in a Kalman filter.

## From Kalman Filters to Particle Filters

Many dynamical phenomena, whether biological or physical, that are encountered in practice are inherently very complex, involving one or more of the following elements: nonlinearity, non-Gaussianity, and high dimensionality. The EKF deals with the first two elements by doing two things:

- Localized linearization of the nonlinear functions in the process and measurement equations by retaining first-order terms in their Taylor series expansions.
- Approximations of the process and measurement processes by Gaussian processes that are propagated analytically through the first-order approximations of the nonlinear functions.

The practical limitation of this approach is that it may produce large errors in the state estimates.

An analytic approach to circumvent this problem is to use the unscented Kalman filter, which builds on the *unscented transformation* due to Julier, Uhlmann, and Durrant-Whyte (1995). In this new transformation, the input stochastic process is again approximated by a Gaussian process, but the nonlinear transformation is treated in a special way involving a carefully chosen set of sample points. To be specific, let the vector $\bar{\mathbf{x}}$ and the matrix $\mathbf{K}_{\mathbf{x}}$ respectively denote the mean and covariance of a stochastic process $\mathbf{x}(n)$ whose dimensionality is $M$. Let $\mathbf{x}(n)$ be propagated through a nonlinear function: $\mathbf{y} = \mathbf{f}(x)$. To calculate the mean and covariance of the output vector $\mathbf{y}(n)$, we first form a set of $2M + 1$ *sigma vectors*, defined by

$$\left.\begin{aligned} \chi_0 &= \bar{\mathbf{x}} \\ \chi_i &= \bar{\mathbf{x}} + \sqrt{M + \lambda}(\mathbf{K}_{\mathbf{x}}^{1/2})_i \quad i = 1, 2, \ldots, M \\ \chi_i &= \bar{\mathbf{x}} - \sqrt{M + \lambda}(\mathbf{K}_{\mathbf{x}}^{1/2})_i \quad i = M + 1, M + 2, \ldots, 2M \end{aligned}\right\} \tag{10}$$

where $\lambda$ is a scaling factor under the designer's control, and $(K_{\mathbf{x}}^{1/2})_i$ is the $i$th column of the square root of matrix $\mathbf{K}_{\mathbf{x}}$ (i.e., lower triangular matrix in the Cholesky factorization of $\mathbf{K}_{\mathbf{x}}$). The mean and covariance of the nonlinearly transformed vector $\mathbf{y}(n)$ are obtained by using weighted sums of a new vector $\mathbf{y}_i$ related to the sigma vectors as

$$\mathbf{Y}_i = \mathbf{f}(\chi_i), \quad i = 1, 2, \ldots, M$$

For an arbitrary nonlinearity, the deceptively simple unscented transformation produces approximations that are accurate to third order for Gaussian inputs, and at least second order for non-Gaussian inputs. The *unscented Kalman filter* (UKF) is a straightforward extension of the unscented transformation (Wan and van der Merwe, 2001). It is a derivative-free state estimator in that, by using multiple forward propagations, the need for explicit computation of Jacobians is avoided; hence, differentiable nonlinear functions are no longer a necessary requirement. The computational complexity of the UKF is, in general, $O(M^3)$; but under special conditions the computation can be restructured to be $O(M^2)$, which is essentially the same as that for the EKF.

The EKF and UKF rely on the use of approximations to ensure mathematical tractability. To avoid approximations, we have to sacrifice mathematical tractability. This is precisely what is done in particle filters, which are rooted in Bayesian theory (Bernardo and Smith, 1998) and Monte Carlo simulation (Robert and Casella, 1999).

*Particle filters* provide a tool for recursive computation of a stochastic point-mass approximation to the posterior distribution of the hidden states of a nonlinear dynamic system, given a set of observations related to the states. These filters are based on the following stochastic model (Andrieu, Doucet, and Punskaya, 2001):

1. The hidden states are described by the initial distribution $p(\mathbf{x}(0))$ and transition distribution $p(\mathbf{x}(n)|\mathbf{X}_{n-1})$.
2. The observations $\mathbf{y}(1), \mathbf{y}(2), \ldots, \mathbf{y}(n)$ are conditionally independent, given the likelihood $p(\mathbf{y}(n)|\mathbf{Y}_{n-1}, \mathbf{x}(n))$.

The goal of particle filtering is to recursively estimate the *posterior distribution* $p(\mathbf{X}_n|\mathbf{Y}_n)$, the *filtering distribution* $p(\mathbf{x}(n)|\mathbf{Y}_n)$, and certain expectations such as the conditional mean and conditional covariance of $\mathbf{x}(n)$, where $\mathbf{X}_n$ denotes the sequence $\mathbf{x}(0), \mathbf{x}(1), \ldots, \mathbf{x}(n)$, and $\mathbf{Y}_n$ denotes the sequence $\mathbf{y}(1), \mathbf{y}(2), \ldots, \mathbf{y}(n)$. Note that the model described under points 1 and 2 defines a generic dynamic model, embodying hidden Markov models as a special case.

In Monte Carlo simulation, a set of weighted, independent, and identically distributed particles (i.e., samples) is drawn from the posterior distribution, thereby mapping integrals to discrete sums. Typically, it is not possible to sample directly from the posterior distribution; hence the recourse to *importance sampling* from an arbitrary *proposal distribution*. The choice of the proposal is a major design issue. In this context, we may use approximations based on the EKF or UKF to generate Gaussian proposal distributions. Basically, the use of UKF here leads to the formulation of the unscented particle filter (Wan and van der Merwe, 2001). Some nice results on image tracking using the unscented particle filter are reported in Rui and Chen (2001).

A limitation of importance sampling is that it does not lend itself to recursive estimation. To get around this problem, we may use a constrained version of importance sampling known as *sequential importance sampling*. The use of this approach yields a set of parameters known as *normalized importance weights*; they are involved in recursively computing the conditional expectations of interest.

Unfortunately, sequential importance sampling has a serious limitation of its own: The variance of the normalized importance weights increases stochastically over time. Typically, after a few iterations the normalized weights of a large number of particles (samples) become practically insignificant, with the result that they are removed from the sample set, in which case the algorithm no longer adequately represents the posterior distribution of interest. This degeneracy problem is avoided by using a *bootstrap filter*, which involves the elimination of samples with small weights and the multiplication of samples with large weights. The bootstrap filter is essentially modular in extent and therefore simple to implement.

A particle filter may be made highly efficient (i.e., the variance of the estimation error is reduced) by using the so-called Rao-Blackwellization procedure (Robert and Casella, 1999). In so doing, each particle is replaced by a Gaussian distribution propagated through a Kalman filter. The Rao-Blackwellized particle filter represents a stochastic bank (i.e., mixture) of standard Kalman filters (de Freitas, 2002).

To sum up, particle filters offer a powerful tool for sequential state estimation under full nonlinear and non-Gaussian conditions. Although it is computationally intensive, it lends itself to straightforward implementation on a parallel computer.

## Discussion

Kalman filtering is a powerful idea rooted in modern control theory and adaptive signal processing; it has withstood the test of time since 1960. Under the ideal conditions of linearity and Gaussianity, the Kalman filter produces an estimate of the hidden state of a dynamic system, with the estimate being optimum in the mean-square-error sense or, equivalently, the maximum likelihood sense. The state-estimation procedure is recursive, which makes it well suited for implementation on a digital computer.

In practical terms, the Kalman filter provides an indispensable tool for the design of automatic tracking and guidance systems, and an enabling technology for the design of recurrent multilayer perceptrons that can simulate any finite-state machine. In the context of neurobiology, Kalman filtering provides invaluable insight into visual recognition and motor control.

The classic Kalman filter and its extensions, namely, the extended Kalman filter and the unscented Kalman filter, offer mathematical tractability by invoking certain approximations and Gaussian assumptions. When the issue of approximations and Gaussian assumptions is of serious concern, we may resort to another powerful tool, particle filters, which are rooted in Bayesian theory and Monte Carlo simulation. Again, particle filters are computationally intensive, but with a parallel computer, they can be implemented in a straightforward modular fashion.

# Laminar Cortical Architecture in Visual Perception

*Stephen Grossberg*

## Introduction

The cerebral cortex is the seat of the highest forms of biological intelligence in all sensory and cognitive modalities. Neocortex has an intricate design that exhibits a characteristic organization into six distinct cortical layers. Differences in the thickness of these layers and in the sizes and shapes of neurons led the German anatomist Korbinian Brodmann to identify more than 50 divisions, or areas, of neocortex. This classification has been invaluable as a basis for classifying distinct functions of different parts of neocortex. The functional utility of the laminar organization itself in the control of behavior has, however, remained a mystery until recently. Several models of visual cortex (e.g., Li, 1998; Stemmler, Usher, and Niebur, 1995; Somers et al., 1998; Yen and Finkel, 1998) have clarified aspects of cortical dynamics, but have not articulated how the laminar architecture of cortex contributes to visual perception. A LAMINART model has recently proposed clear functional roles for these layers for the purposes of visual perception (Grossberg, 1999a; Grossberg and Raizada, 2000). The present article uses this model as an organizing theme with which to integrate the analysis and explanation of a variety of data about visual perception and neuroscience. Additional recent research suggests that the functional roles for cortical layers that are proposed by the model may also generalize, with appropriate specializations, to other forms of sensory and cognitive processing.

Bottom-up, top-down, and horizontal interactions are well known to occur within and between the cortical layers. The model proposes how these interactions help the visual cortex to realize (1) the binding process whereby cortical groups distributed data into coherent object representations, (2) the attentional process whereby cortex selectively processes important events, and (3) the developmental and learning processes whereby cortex shapes its circuits to match environmental constraints. It is suggested that the mechanisms that achieve the third property imply the first and second properties. That is, constraints that control stable cortical self-organization in the infant seem to strongly constrain properties of learning, perception, and attention in the adult.

## Perceptual Grouping and Attention

During visual perception, the visual cortex can generate perceptual groupings and can focus attention on objects of interest. *Perceptual grouping* is the process whereby the brain organizes image contrasts into emergent boundary structures that segregate objects and their backgrounds in response to texture, shading, and depth cues in scenes and images. Perceptual grouping is a basic step in solving the "binding problem," whereby spatially distributed features are bound into representations of objects and events in the world. Vivid perceptual groupings, such as illusory contours, can form over image positions that do not receive contrastive bottom-up inputs from an image or scene. Perceptual groupings can form *preattentively* and automatically, without requiring the conscious attention of a viewing subject.

*Attention* enables humans and other animals to selectively process information that is of interest to them. In contrast to perceptual grouping, top-down attention typically does not form visible percepts over positions that receive no bottom-up inputs. Attention can modulate, sensitize, or prime an observer to expect an object to occur at a given location or with particular stimulus properties. But were attention by itself able to routinely generate fully formed perceptual representations at positions that did not receive bottom-up inputs, then we could not easily tell the difference between external reality and internal fantasy, and we would experience hallucinations all the time. In fact, it has been proposed that a breakdown in this modulatory property of attention can give rise to hallucinations in patients with mental disorders like schizophrenia.

Despite the fact that perceptual grouping and attention make opposite requirements on bottom-up inputs, many recent experiments have shown that perceptual grouping and attention can occur simultaneously within the same circuits of the visual cortex, notably cortical areas V1 and V2 (see Grossberg, 1999a, and Grossberg and Raizada, 2000, for reviews). How is this possible? How does cortical circuitry form perceptual groupings that can complete a boundary grouping over locations that receive no bottom-up visual inputs, whereas top-down attention cannot do so? Why should attention be deployed throughout the visual cortex, including cortical areas that previously were thought to accomplish purely preattentive processing? An answer can be found by exploring the link between attention and learning.

### *Attention and Learning*

Top-down attention has been proposed to be a key mechanism whereby the brain solves the *stability-plasticity* dilemma (Grossberg, 1999b). The stability-plasticity dilemma concerns that fact that our brains can rapidly learn enormous amounts of information throughout life, without just as rapidly forgetting what they already know. Brains are *plastic* and can rapidly learn new experiences, without losing the *stability* that prevents catastrophic forgetting. How are attentive processes realized within neocortex in order to stabilize the learning process?

An improper solution to this problem could easily lead to an infinite regress. This is true because perceptual groupings can form preattentively and provide the substrate on which higher-level attentional processes can act. How can the preattentive grouping mechanisms develop in a stable way, before higher-order attentional processes can develop with which to stabilize them? How can you use attentional mechanisms to stabilize the formation of preattentive grouping circuits, if these attentional mechanisms cannot develop until the preattentive grouping mechanisms do? This is called the *attention-preattention interface problem*. Below we discuss the possibility that the laminar circuits of visual cortex enable preattentive grouping processes to use some of the same circuitry that attentive mechanisms use, even before attentive mechanisms come into play, in order to stabilize their own cortical development and learning. Preattentive grouping uses top-down *intra*cortical feedback between the layers, whereas attention uses top-down *inter*cortical feedback between them. Both feedback processes converge on a shared decision circuit that helps to determine which perceptual groupings will be perceived.

A solution to the attention-preattention interface problem can be derived from earlier efforts to understand how attention helps to solve the stability-plasticity dilemma: bottom-up signals activate top-down expectations, whose signals are matched against bottom-up data. Both the bottom-up and the top-down pathways contain adaptive weights, or long-term memory traces, that can be modified by experience. The learned top-down expectations "focus attention" on information that matches them. They select, synchronize, and amplify the activities of cells within the attentional focus while suppressing the activities of irrelevant cells, which could otherwise be incorporated into previously learned memories and thereby destabilize them. The cell activities that survive such top-down attentional focusing rapidly reactivate bottom-up pathways. The amplified, synchronized, and prolonged activation of cells within the bottom-up and top-down signal exchanges form a *resonant* state. Such resonances rapidly bind distributed information at multiple levels of brain processing into context-sensitive representations of objects and events. The greater activity, duration, and synchrony of these resonances can support slower processes of learning; hence the term *adaptive* resonance. Adaptive Resonance Theory (q.v.), or ART, has been developed to quantitatively explain how processes of learning, expectation, attention, synchronization, memory search, and consciousness are linked in both healthy subjects and clinical patients. A rapidly growing body of neurobiological data has begun to confirm the predicted links between learning, top-down matching, attention, synchronization, and consciousness.

Learning can easily lead to catastrophic forgetting in response to a changing world. Many popular neural models experience such catastrophic forgetting, notably feedforward models such as back-propagation. ART shows how top-down attention can stabilize learning if it satisfies four properties that together are called the ART matching rule:

1. *Bottom-up automatic activation:* A cell, or cell population, can become active enough to generate output signals if it receives a large enough bottom-up input, other things being equal. Such an input can drive the cell to supraliminal levels of activation.
2. *Top-down priming:* A cell becomes subliminally active if it receives only a large top-down expectation input. Such a top-down priming signal can sensitize, or modulate, the cell and thereby prepare it to react more quickly and vigorously to subsequent bottom-up inputs that match the top-down prime. The top-down prime by itself, however, cannot generate supraliminal output signals from the cell.
3. *Match:* A cell is activated if it receives large convergent bottom-up and top-down inputs. Such a matching process can generate enhanced activation as resonance takes hold.

4. *Mismatch:* A cell's activity is suppressed, even if it receives a large bottom-up input, if it also receives only a small, or zero, top-down expectation input.

Recent data analyses have suggested that variants of the simplest circuit (Figure 1), a top-down on-center off-surround network, is used by the brain (Grossberg, 1999b). In such a circuit, when only bottom-up signals are active, all cells can fire that receive large enough inputs. When only top-down attention is active, cells in the off-surround that receive inhibition but no excitation can be strongly inhibited, while cells in the on-center that receive a combination of excitation and inhibition can become at most subliminally activated, owing to the balance between excitation and inhibition. When bottom-up and top-down inputs match (pathway 2 in Figure 1*C*), the two excitatory sources of excitation (bottom-up and top-down) that converge at the cell can overwhelm the one inhibitory source; it is a case of two against one. When bottom-up and top-down inputs mismatch (pathway 1 in Figure 1*C*), the top-down inhibition can neutralize the bottom-up excitation; it is a case of one against one.

**Figure 1.** *A*, Patterns of activation, or short-term memory (STM), on a lower processing level send bottom-up signals to a higher processing level. These signals are multiplied by adaptive weights, or learned long-term memory (LTM) traces, which influence which cells are activated at the higher processing level. These latter cells, in turn, activate top-town expectation signals that are also multiplied by learned LTM traces. These top-down expectations are matched against the STM pattern that is active at the lower level. *B*, This matching process selects, amplifies, and synchronizes STM activations that are supported by large LTM traces in an active top-down expectation, and suppresses STM activations that do not get top-down support. The size of the hemidisks at the end of the top-down pathways represents the strength of the learned LTM trace that is stored in that pathway. *C*, The ART matching rule can be realized by a modulatory top-down on-center off-surround network, as discussed in the text. (From Grossberg, S., 1999a, How does the cerebral cortex work? Learning, attention, and grouping by the laminar circuits of visual cortex, *Spatial Vision*, 12:163–185. Reprinted with permission.)

### *Attention Is Modulatory*

The ART matching rule predicted that top-down attention is part of a modulatory *priming* and *matching* process. By itself, attention cannot supraliminally activate cells, so they cannot generate output signals. Data compatible with this prediction have gradually been reported over the years. For example, Zeki and Shipp (1988, p. 316) wrote that "backward connections seem not to excite cells in lower areas, but instead influence the way they respond to stimuli." Likewise, the data of Sillito et al. (1994) on attentional feedback from V1 to the lateral geniculate nucleus (LGN) led them to conclude that "the cortico-thalamic input is only strong enough to exert an effect on those dLGN cells that are additionally polarized by their retinal input . . . the feedback circuit searches for correlations that support the 'hypothesis' represented by a particular pattern of cortical activity." Their experiments demonstrated all of the properties of the ART matching rule, since they found in addition that "cortically induced correlation of relay cell activity produces coherent firing in those groups of relay cells with receptive-field alignments appropriate to signal the particular orientation of the moving contour to the cortex . . . this increases the gain of the input for feature-linked events detected by the cortex." In other words, top-down priming by itself cannot fully activate LGN cells; it needs matched bottom-up retinal inputs to do so, and those LGN cells whose bottom-up signals support cortical activity get synchronized and amplified by this feedback. In addition, anatomical studies have shown that the top-down V1 to LGN pathway realizes a top-down on-center off-surround network.

## How to Stabilize Cortical Development and Learning

The preceding discussion suggests that top-down attentional mechanisms should be present in *every* cortical area in which self-stabilizing learning can occur, since without top-down learned expectations that focus attention, any such learned memories could easily be degraded due to catastrophic forgetting.

These analyses should, in particular, apply to the perceptual grouping process, because the cortical horizontal connections that support perceptual grouping in cortical areas like V1 develop through a learning process that is influenced by visual experience (e.g., Calloway and Katz, 1990; Antonini and Stryker, 1993). It is also known that many developmental and learning processes, including those that control horizontal cortical connections, are stabilized dynamically and can be reactivated by lesions and other sources of cortical imbalance (Das and Gilbert, 1995); and that adult learning uses the same types of mechanisms as the infant developmental processes on which it builds (Kandel and O'Dell, 1992). What cortical mechanisms ensure this type of dynamical stability?

This is a particularly challenging problem for perceptual groupings because they can generate suprathreshold responses over positions that do not receive bottom-up inputs. They therefore seem to violate the ART matching rule. How, then, can the horizontal connections that generate perceptual groupings maintain themselves in a stable way? Why are they not washed away whenever an illusory contour grouping forms over positions that do not receive a bottom-up input? The LAMINART model proposes an answer to this question that clarifies how attention, perceptual grouping, development, and perceptual learning work and interact within the laminar circuits of visual cortex.

## Preattentive Mechanisms of Perceptual Grouping

Four circuit properties summarize this proposal of how the visual cortex, notably areas V1 and V2, uses its laminar design to generate coherent perceptual groupings that maintain their analog sensitivity to environmental inputs, the so-called property of *analog coherence*. Four additional circuit properties will then be summarized whereby attention, development, and learning may be integrated into this laminar design. Each of these design constraints is supported by neurophysiological, anatomical, and psychophysical data.

### *Analog Sensitivity to Bottom-Up Sensory Inputs*

Bottom-up inputs from the retina go through the LGN on their way to cortex. LGN outputs directly excite layer 4. LGN inputs also excite layer 6, which then indirectly influences layer 4 via an on-center off-surround network of cells, as in Figure 2*A*. The net effect of LGN inputs on layer 4 cells is thus via an on-center off-surround network. Such a feedforward on-center off-surround network of cells can preserve the analog sensitivity of, and normalize, the activities of target cells if these cells obey the membrane equations of neurophysiology. Such a network can preserve the analog sensitivity of layer 4 cells in response to LGN inputs that may vary greatly in intensity.

### *Bipole Boundary Grouping*

The active layer 4 cells input to pyramidal cells in layer 2/3. These cells initiate the formation of perceptual groupings. They generate excitatory signals among themselves using monsynaptic long-range horizontal connections, and inhibition using short-range disynaptic inhibitory connections, as in Figure 2*B*. These interactions support inward perceptual groupings between two or more boundary inducers, as in the case of illusory contours, but not outward groupings from a single inducer, which would fill the visual field with spurious groupings.

These grouping properties may be ensured as follows. When a single active pyramidal cell sends horizontal monosynaptic excitation to other pyramidal cells, this excitation is inhibited by the disynaptic inhibition that it also generates; this balance between excitation and inhibition is a case of one against one. Model simulations have shown that such an approximate balance between excitation and inhibition is needed to stabilize the development of horizontal connections. A different result obtains when two or more pyramidal cells are activated at positions that are located at opposite sides of a target pyramidal cell, and all the cells share approximately the same orientation preference and are approximately collinear across space. Then the excitation from the active pyramidal cells summates at the target cell, thereby generating a larger total excitatory input than a single pyramidal cell could. In addition, the active cells excite a single population of disynaptic inhibitory interneurons, which generates a saturating, or normalized, inhibitory output to the target cell. Thus, excitation is bigger than inhibition in this case, so that grouping can occur; it is a case of two against one. This combination of constraints is called the *bipole* property. Layer 2/3 pyramidal cells may thereby become active either because of direct inputs from layer 4, or because of bipole boundary groupings that form in response to other active layer 2/3 cells.

### *Folded Feedback and Analog Coherence*

The active cells in layer 2/3 can form groupings on their own in response to unambiguous visual inputs. In response to scenes wherein multiple groupings are possible but only a few of them are correct, intracortical feedback helps to select the correct cells, and also binds them together in a coherent way. This selection happens when active cells in layer 2/3 send excitatory feedback signals to layer 6 via layer 5, as in Figure 2*C*. Layer 6 then activates the on-center off-surround network from layer 6 to 4. This feedback process is called *folded feedback*, because feedback signals from layer 2/3 to layer 6 get transmitted in a feedforward fashion back to layer 4; that is, feedback is “folded” back into the feedforward flow of bottom-up information within the laminar cortical circuits.

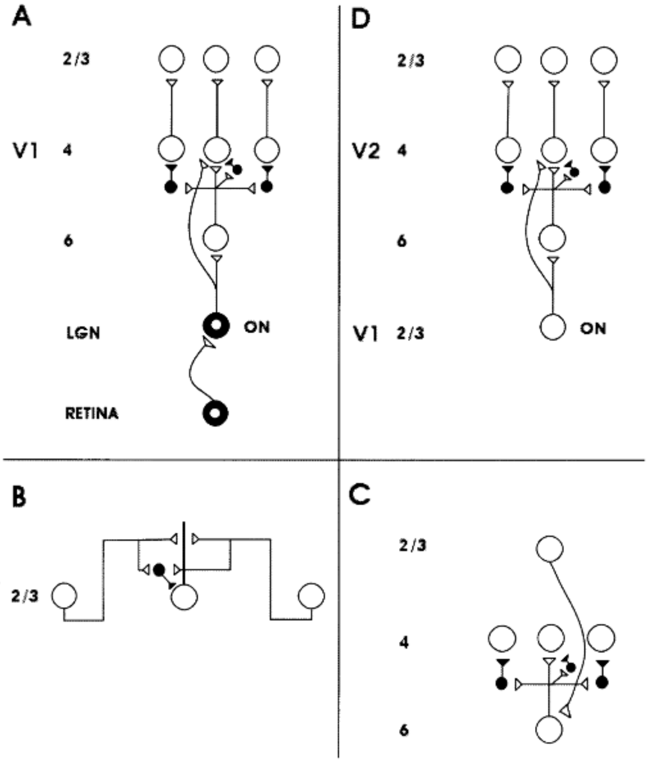

**Figure 2.** *A* model circuit of retinal, lateral geniculate nucleus (LGN), and cortical V1 interactions. Open symbols indicate excitatory interactions and closed symbols indicate inhibitory interactions. *A*, Feedforward circuit from retina to LGN to cortical layers 4 and 6. Retina: Retinal ON cells have an on-center off-surround organization. Retinal OFF cells have an off-center on-surround organization. LGN: The LGN ON and OFF cells receive feedforward ON and OFF cell inputs from the retina. Layer 4: Layer 4 cells receive feedforward inputs from LGN and layer 6. LGN ON and OFF cell excitatory inputs to layer 4 directly establish oriented simple-cell receptive fields. Layer 6 cells excite layer 4 cells with a narrow on-center and inhibit them using inhibitory interneurons that span a broader off-surround, which includes cells in the on-center (not shown). Like-oriented layer 4 simple cells with opposite-contrast polarities compete (not shown) before generating half-wave rectified outputs that converge on layer 2/3 pyramidal (complex) cells. Layer 2/3: The converging simple cell outputs enable complex cells to respond to both polarities. They thereby full-wave rectify the image. *B*, Horizontal grouping interactions in layer 2/3: After being activated by inputs from layer 4, layer 2/3 pyramidal (complex) cells excite each other monosynaptically via horizontal connections, primarily on their apical dendrites. They also inhibit one another via disynaptic inhibition that is mediated by model smooth stellate cells. Multiple horizontal connections share a common pool of stellate cells near each target pyramidal cell. This ensures that boundaries form inwardly between pairs or greater numbers of boundary inducers, but not outwardly from a single inducer. *C*, Cortical feedback loop from layer 2/3 to layer 6: Layer 6 cells receive excitatory inputs from layer 2/3. The long-range cooperation thereby engages the feedforward layer 6-to-4 on-center off-surround network, which then reactivates layer 2/3 cells. This “folded feedback” loop can select winning groupings without a loss of analog coherence. *D*, Outputs from layer 2/3 to area V2 directly excite layer 4 cells and layer 6 cells, which indirectly influence layer 4 cells via an on-center off-surround network, as in area V1. (From Grossberg, 1999a).

Folded feedback turns the cortex into a feedback network that binds the cells throughout layers 2/3, 4, and 6 into functional columns. The on-center off-surround network also helps to select the strongest groupings that are formed in layer 2/3 and to inhibit weaker groupings, while preserving the analog values of the selected groupings. In particular, the on-center signals from layer 6-to-4 support the activities of those pyramidal cells in layer 2/3 that are part of the strongest horizontal groupings. The off-surround signals can inhibit inputs to layer 4 that were supporting less active groupings in layer 2/3. In this way, signals from layer 4 to the less active groupings in layer 2/3 are removed, and thus these groupings collapse.

### *Self-Similar Hierarchical Boundary Processing*

Converging evidence suggests that area V2 replicates aspects of the structure of area V1, but at a larger spatial scale. Thus, layer 2/3 in area V1 sends bottom-up inputs to layers 4 and 6 of area V2, much as LGN sends bottom-up inputs to layers 4 and 6 of area V1, as in Figure 2*D*. This input pattern from V1 to V2 can preserve the analog sensitivity of layer 4 cells in V2 for the same reason that the LGN inputs to V1 can preserve the analog sensitivity of layer 4 cells in V1. The shorter perceptual groupings in layer 2/3 of area V1 are proposed to group together, and enhance the signal-to-noise ratio of, nearby V1 cells with similar orientation and disparity selectivity. The longer perceptual groupings in area V2 are proposed to build long-range boundary segmentations that separate figure from background; generate 3D groupings of the edges, textures, shading, and stereo information that go into object representations; and complete boundaries across gaps in bottom-up signals due to the retinal blind spot and veins (Grossberg, 1994).

## Attention, Development, and Learning

The following four circuit properties are proposed to integrate top-down attention into the preattentive grouping process in a way that solves the attention-preattention interface problem and enables grouping circuits to develop and learn in a stable way.

### *Top-Down Feedback from V1 to LGN*

As noted above, layer 6 of area V1 sends a top-down on-center off-surround network to the LGN, as in Figure 3*A*. This top-down pathway automatically gain-controls and focuses attention on those LGN cells whose activities succeed in activating V1 cells. Data of Sillito et al. (1994) are compatible with the hypothesis that this feedback obeys the ART matching rule, and thus can only subliminally activate, or modulate, LGN cells. Matched bottom-up inputs are needed to supraliminally activate LGN cells while top-down signals are active. This process is predicted to help stabilize the development of receptive fields in V1, including disparity-tuned complex cells, during the visual critical period.
