### *Folded Feedback from Layer 6 of V2 to Layer 4 of V1*

A similar top-down process seems to occur at all stages of visual cortex, and probably beyond. Layer 6 in a given cortical area, such as V2, generates top-down cortical signals to layer 6 of lower cortical areas, such as V1, where they activate the layer 6-to-4 folded feedback network in the lower area (Figure 3*B*). One such known top-down pathway exits layer 6 in V2 and activates V1 via layer 1, then layer 5, then layer 6, as in Figure 3*C*. Top-down feedback can thereby activate a top-down on-center off-surround circuit, as required by the ART matching rule. Intercortical attention is herewith suggested to use outputs from layer 6 of a given cortical area to activate layer 4 of a lower cortical area via layer 6-to-4 folded feedback.

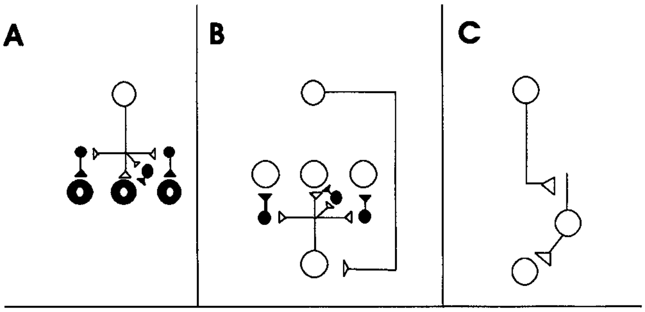

**Figure 3.** *A*, Top-down corticogeniculate feedback from layer 6: LGN ON and OFF cells receive topographic excitatory feedback from layer 6 in V1, and more broadly distributed inhibitory feedback via LGN inhibitory interneurons that are excited by layer 6 signals. The feedback signals pool outputs over all cortical orientations and are delivered equally to ON and OFF cells. Cortiogeniculate feedback selects, gain-controls, and synchronizes LGN cells that are consistent with the cortical activation that they cause, thereby acting like a type of automatic attentional focus. *B*, Attentional feedback from V2 to V1: Layer 6 in V2 activates layer 6 in V1, which then activates the layer 6-to-4 on-center off-surround network that attentionally primes layer 4 cells. *C*, One feedback pathway arises from layer 6 cells in V2 and activates apical dendrites in layer 1 of V1. Cells in layer 5 are activated through these apical dendrites and thereupon activate layer 6 cells. Layer 6 in V2 can also modulate layer 2/3 of V1 by activating layer 1 dendrites of both excitatory and inhibitory cells in layer 2/3. (From Grossberg, 1999a).

### *Layer 6-to-4 Signals Are Subliminal*

The ART matching rule predicts that this top-down pathway subliminally activates, or modulates, cells in layer 4. This modulatory property is predicted to be due to the fact that the excitatory and inhibitory signals within the on-center from layer 6-to-4 are approximately balanced, so that at most, a weak excitatory effect occurs after activating the circuit via top-down feedback. Consistent data show that "feedback connections from area V2 modulate but do not create center-surround interactions in V1 neurons" (Hupé et al., 1997, p. 1031) and that top-down connections have an on-center off-surround organization (Bullier et al., 1996). Model simulations have shown that that this approximate balance is needed to achieve stable development of interlaminar 6-to-4 connections.

Although it is modulatory, this top-down circuit can have a major effect on cortical cell activations when the cortex is activated bottom-up by visual inputs: it can strongly inhibit activities of layer 4 cells whose layer 2/3 cell projections are not bound into strong groupings, and amplify the strongest groupings until they can resonate. A competitive effect of top-down attention has been reported in the neurophysiological experiments of Reynolds, Chelazzi, and Desimone (1999). Its laminar substrates have not yet been tested, however. By using such an attentional mechanism, higher-level influences such as figure-ground separation or even learned object prototypes can bias the cortex to select consistent groupings at lower cortical levels. In this way, automatic early vision filtering, 3D boundary and surface processing, and higher-order knowledge constraints can mutually influence one another.

### *Two Bottom-Up Input Sources to Layer 4*

A simple functional explanation can now be given of a ubiquitous cortical design; namely, why there are direct bottom-up inputs to layer 4, as well as indirect bottom-up inputs to layer 4 via layer 6 (e.g., Figures 2*A* and 2*D*). Why are these two separate input pathways not just a gigantic waste of wire? In particular, why is the indirect layer 6-to-4 pathway not sufficient to fully activate layer 4 cells *and* to maintain their analog sensitivity using its on-center off-surround network? The proposed explanation is that the indirect layer 6-to-4 inputs need to be modulatory to preserve the stability of cortical development and learning. Direct inputs to layer 4 are therefore also needed to fully activate layer 4 cells.

Taken together, these eight cortical design principles lead to the circuit diagram in Figure 4 for perceptual grouping, attention, development, and learning within and between areas LGN, V1, and V2. The generality of the constraints that lead to this design poses the intriguing possibility that the same cortical circuits may explain data at multiple levels and modalities of neocortical sensory and cognitive processing.

## The Preattentive Perceptual Grouping Is Its Own Attentional Prime

These circuit constraints suggest how the horizontal connections within cortical area V1 and V2 can develop and learn stably in response to visual inputs, and thereby solve the preattention-attention interface problem: both preattentive perceptual groupings within V1 and attentive feedback from V2 to V1 generate feedback signals to layer 6 of V1, one via intracortical pathways from layer 2/3 of the same cortical area, and the other via intercortical pathways from layer 6 of a higher cortical area. Both types of feedback activate the folded feedback circuit from layer 6-to-4. Top-down attention uses this circuit to focus attention within V1 by inhibiting layer 4 cells that are not supported by excitatory 6-to-4 feedback. Perceptual grouping uses it to select the correct grouping by inhibiting layer 4 cells that would otherwise form incorrect groupings. In both cases, folded feedback prevents the wrong combinations of cells in layers 4 and 2/3 from being active simultaneously. In the adult, this selection process defines perceptual grouping properties. In the infant, and also during adult perceptual learning, it prevents incorrect horizontal connections from being learned, since "cells that fire together wire together." This sharing of the layer 6-to-4 selection circuit by both grouping and attention clarifies how attention can propagate along a boundary grouping and can thereby selectively prime an object representation (Grossberg and Raizada, 2000; Roelfsema, Lamme, and Spekreijse, 1998).

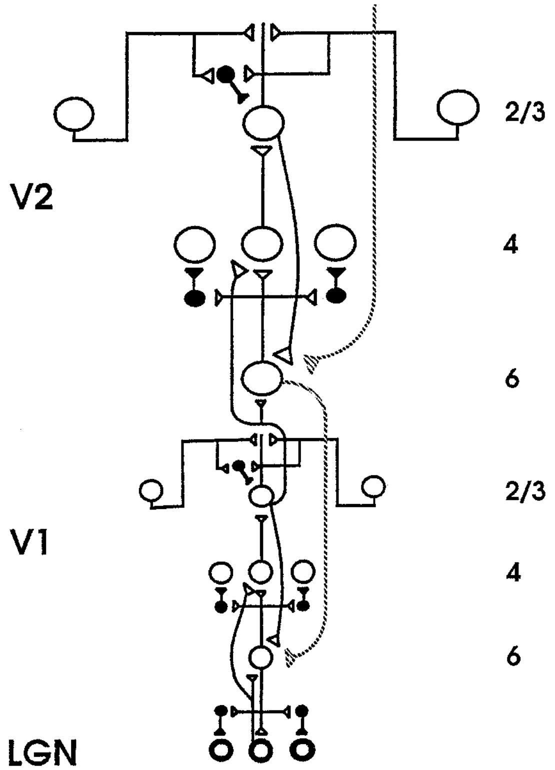

**Figure 4.** A model synthesis of bottom-up, top-down, and horizontal interactions in LGN, V1, and V2. Cells and connections with open symbols denote preattentive excitatory mechanisms that are involved in perceptual grouping. Closed symbols denote inhibitory mechanisms. Gray denotes top-down attentional mechanisms. (From Grossberg, 1999a).

The folded feedback circuit from layer 6-to-4 gets activated by perceptual grouping signals from layer 2/3 at *all* positions of the grouping, even positions that do not receive bottom-up inputs. The ART matching rule is thus satisfied at all positions, and the source of the "top-down expectation" is intracortical top-down signals from the perceptual grouping itself. In summary, the *preattentive perceptual grouping is its own attentional prime* because it can use the modulatory 6-to-4 circuit to stabilize its own development using *intra*cortical feedback, even before attentional *inter*cortical feedback can develop.

## Discussion

All sensory and cognitive neocortical areas share key laminar properties. For example, long-range horizontal connections are known to occur in many areas of neocortex, such as the auditory and language areas of the human temporal cortex. Ongoing research suggests that the above principles of how to achieve stable cortical development and learning, to bind together distributed cortical data through a combination of bottom-up adaptive filtering and horizontal associations, and to modulate it with top-down attention generalize to other neocortical areas.

# Language Acquisition

*Brian MacWhinney*

## Introduction

Language is a uniquely human achievement. All of the major social achievements of human culture—architecture, literature, law, science, art, and even warfare—rely on the use of language. Although there have been attempts to teach language to primates, the ability to learn language is a distinctive mark of the human species. This view of language led Chomsky (1965) to voice this assessment:

> It is, for the present, impossible to formulate an assumption about initial, innate structure rich enough to account for the fact that grammatical knowledge is attained on the basis of the evidence available to the learner. Consequently, the empiricist effort to show how the assumptions about a language acquisition device can be reduced to a conceptual minimum is quite misplaced. The real problem is that of developing a hypothesis about initial structure that is sufficiently rich to account for acquisition of language, yet not so rich as to be inconsistent with the known diversity of language.

To address this challenge, neural network researchers have explored a wide variety of network architectures and linguistic problems. This work has shown how children can learn language without relying on specifically linguistic, innate initial structure. However, several problems must be addressed before we can say that neural networks have answered Chomsky's challenge.

## An Example

Let us consider, as an example of this type of research, the neural network developed by MacWhinney et al. (1989). This model was designed to explain how German children learn to select one of the six different forms of the German definite article. In English, we have a single word "the" that serves as the definite article. In German, the article can take the form *der*, *die*, *das*, *des*, *dem*, and *den*, as indicated in Table 1. The choice of a particular form of the article depends on three additional features of the noun: its gender (masculine, feminine, or neuter), its number (singular or plural), and its role within the sentence (subject, possessor, direct object, prepositional object, or indirect object). There are 16 cells in the paradigm for the four cases and four genders (masculine, feminine, neuter, plural), but there are only six forms of the article. This means that a given form of the article, such as *der* can be used for either masculine-nominative-singular or feminine-genitive-singular, and so on.

To make matters worse, assignment of nouns to gender categories in German is quite nonintuitive. For example, the word for "fork" is feminine, the word for "spoon" is masculine, and the word for "knife" is neuter. Acquiring this system of arbitrary gender assignments is particularly difficult for adult second language learners. Mark Twain expressed his consternation at this aspect of German in a treatise entitled "The aweful German language" in which he accuses the language of unfairness and capriciousness in its treatment of young girls as neuter, the sun as feminine, and the moon as masculine. Along a similar vein, Maratsos and Chalkley (1980) argued that, because neither semantic nor phonological cues can predict which article accompanies a given noun in German, children could not learn the language by relying on simple surface cues.

These relations are so complex that a careful linguistic description of the system occupies well over 200 pages. However, MacWhinney et al. (1989) show that it is possible to construct a connectionist network that learns this system from the available cues (see Figure 1). The model uses a simple feedforward architecture. The input is structured into two pools of units. The first pool has 143 phonological units and 5 token meaning units. The second pool has 17 case cues from syntactic structure and 11 phonological cues from endings on the noun. These two input pools feed into two separate pools of collector units that then feed together into a second level of hidden units. The output is a set of six nodes for the six possible forms of the German article. It is important to remember that each of these six articles must serve several functions to fill up the 16 cells of the declensional paradigm.

The network was trained using the backpropagation algorithm. After 40 epochs of training on a set of 102 real German nouns, the network was able to choose the correct article 98% of the time. This meant that it not only succeeded in getting the gender of the noun right, but also figured out how to use the case cues to correctly select one of the 16 cells of the paradigm. To test the network's generalization abilities, we presented it with old nouns in new case roles. In these tests, the network chose the correct article in 92% of trials. This type of cross-paradigm generalization provides clear evidence that the network went far beyond rote memorization during the training phase. In fact, the network quickly succeeded in learning the whole of the basic formal paradigm for the marking of German case, number, and gender on the noun.

In addition, the simulation was able to generalize its internalized knowledge to solve the problem that had so perplexed Mark Twain—guessing at the gender of entirely novel nouns. We presented the network with 48 new high-frequency German nouns in a variety of sentence contexts. On this completely novel set, the simulation chose the correct article from the six possibilities in 61%

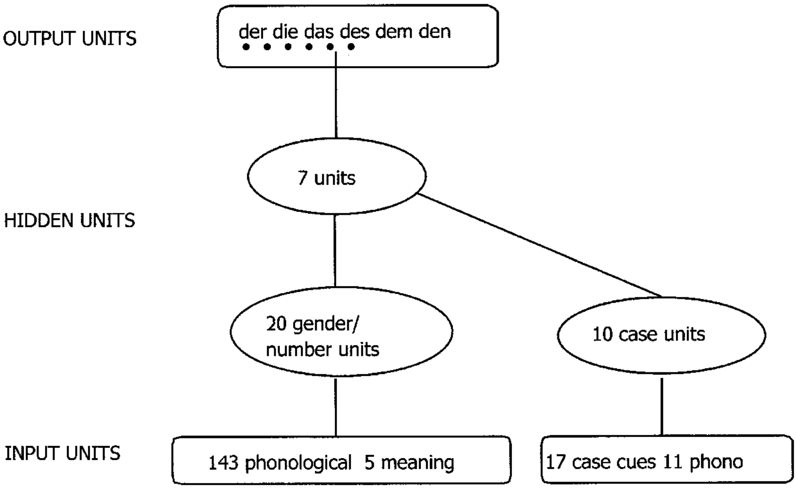

**Figure 1.** A network model of the acquisition of German declensional marking

of trials, versus 17% expected by chance. Thus, the system's learning mechanism, together with its representation of the noun's phonological and semantic properties and the context, produced a good guess about what article would accompany a given noun, even when the noun was entirely unfamiliar. In a subsidiary simulation, we showed that, when the model only has to guess the gender of the noun, and not its position in the paradigm, it achieves over 70% accuracy on new nouns. This is a level that comes close to that achieved by native speakers.

The network's learning paralleled children's learning in a number of ways. Like real German-speaking children, the network tended to overuse the articles that accompany feminine nouns. The reason for this is that the feminine forms of the article have a high frequency, because they are used both for feminines and for plurals of all genders. The simulation also showed the same type of overgeneralization patterns that are often interpreted as reflecting rule use when they occur in children's language. For example, although the noun "Kleid" (clothing) is neuter, the simulation used the initial "kl" sound of the noun to conclude that it was masculine. Because of this, it invariably chose the article that would accompany the noun if it were masculine. Interestingly, the same article-noun combinations that are the most difficult for children were also the most difficult for the network.

Demonstrations of this type illustrate how children can acquire linguistic knowledge without relying on stipulated, hard-wired constraints of the type envisioned by Chomsky. Similar demonstrations have been produced in a wide variety of areas including: the English past tense, Dutch word stress, universal metrical features, German participle acquisition, German plurals, Italian articles, Spanish articles, English derivation for reversives, lexical learning from perceptual input, deictic reference, personal pronouns, polysemic patterns in word meaning, vowel harmony, historical change, early auditory processing, the phonological loop, early phonological output processes, ambiguity resolution, relative clause processing, word class learning, speech errors, bilingualism, and the vocabulary spurt.

## Challenges

Researchers have contested the logic underlying these demonstrations. Some of the problems that have been raised relate only to minor implementational features of the earliest models (MacWhinney and Leinbach, 1991), but others are more fundamental. The five most fundamental challenges are:

*Dual route*. Neural networks provide a good account of associative processes, but fail to account for the learning of regular rules.

*Lexical learning*. Neural networks have problems learning large numbers of words.

*Syntax*. Neural networks have problems dealing with the compositional aspects of complex syntax.

*Neuronal realism*. Some neural network architectures make inappropriate assumptions regarding neural processing.

*Embodiment*. Neural networks have not been able to model the ways in which the mind is linked to the body.

Let us look at responses to each of these five challenges in greater detail.

### Dual Route

Pinker (1999) has been a key proponent of the application of a dual-route model to language acquisition. He contends that irregular forms, such as *fell*, *went*, *feet*, or *broken*, are processed through an associative memory grounded on neural networks, but that regular forms, such as *jumped*, *wanted*, *cats*, and *dropped*, are produced by rule. Pinker views his defense of the psychological reality of linguistic rules as a part of a general defense of the linguistic theory of generative grammar.

The fact that irregulars are processed differently from regulars does not prove the existence of symbolic rules. Neural networks have no problem representing both regular and irregular patterns in a single network. For example, the network developed by Kawamoto (1994) encodes regular forms as nodes in competition with less regular nodes. In that homogeneous recurrent network architecture, regular and irregular forms display quite different temporal activation patterns, in accord with empirical observations. Kawamoto's model also accords with the fact that even the most regular patterns display phonological conditioning and patterns of gradience (Bybee, 1995) of the type modeled by neural networks.

### Lexical Learning

Neural networks have problems learning large numbers of words. Typically, neural network architectures have been used primarily as methods for extracting and classifying patterns. Word learning differs from classification in two ways. First, the association between a word's meaning and its sound is almost entirely arbitrary. There is nothing in the specific sounds of *table* that depicts the shape or purpose of a table. This means that the learning of words cannot rely on the methods for pattern detection that are so important in neural network research. Second, the number of words that a speaker must learn is extremely large. If we look just at word stems, adult English speakers control between 10,000 and 50,000 words. Many of these words have multiple meanings and many can be further combined into compounds and rote phrases. Thus, the effective lexicon of an adult English speaker is from 20,000 to 80,000 words.

Self-organizing maps (SOMs) (Farkas and Li, 2001) offer a promising framework for dealing with the encoding of lexical items. Precision of encoding can be obtained by increasing the dimensionality of the coding space and then recompressing the additional dimensions. Conflicts between related words that are close on the lexical map can trigger a process of focused learning that concentrates specifically on words that are being confused. Catastrophic interference can be avoided by adding new nodes without forgetting older patterns (Hamker, 2001).

Because SOMs provide a relatively local encoding of words, they then allow us to address four additional problems that stem from problems of representing words in neural networks.

*U-shaped learning.* Children often produce a form like *went* correctly for several weeks or months and then shift to occasionally saying *go-ed*. Later, they move back to saying *went* consistently. This pattern, known as *U-shaped learning*, requires an ability to learn some forms first by rote. Backpropagation networks are good at producing overgeneralizations like *go-ed* but weak at producing and holding on to a rote form like *went* (Plunkett and Marchman, 1993). By default, SOMs place an emphasis on early rote learning and are slower to generalize out the regular patterns.

*Homophony.* Because most neural network models do not have discrete representations for lexical items, they have problems distinguishing homophonous forms. Consider what happens to the three homophones of the word *ring* in English. We can say *the maid wrung out the clothes*, *the soldiers ringed the city*, or *the choirboy rang the bell*. These three different words all have the same sound /rIN/ in the present, but each takes a different form in the past. In SOMs, these three words have clearly different representations in semantic space.

*Compounds.* Without discrete representations for lexical items, neural networks have problems with compound words. The fact that the past tense of *undergo* is *underwent* depends on the fact that *undergo* is a variant of the stem *go*. When the compound itself is high enough in frequency, the network can learn to treat it as an irregular. Networks have problems learning the past tense of low-frequency irregular compounds. However, if the network can detect the present of "go" inside "undergo," it can solve this problem.

*Derivational status.* Neural networks have problems utilizing information regarding the derivational status of lexical items. In English, the past tense forms of denominal verbs always receive the regular past tense suffix. For example, the word *ring* can be used as a verb in *the groom ringed her finger*, but we would never say *the groom rung her finger*. Without an ability to know that a word derives from a noun, neural networks cannot encode this pattern. German provides even clearer examples of the importance of derivational status. All German nouns that derive from verbs are masculine. For example, the noun *der Schlag* ("blow"; "cream") derives from the verb *schlagen* ("to hit"). However, there is no motivated way of indicating this in the model. In general, the model includes no independent way of representing morphological relationships between words. Thus, no distinction is made between true phonological cues such as final /e/ or initial /kn/ and derivational markers for the diminutive, such as *-chen* or *-ett*. This leads to some very obvious confusions. For example, masculines such as *der Nacken* ("neck") and *der Hafen* ("harbor") end in phonological /en/, whereas neuters such as *das Wissen* ("knowledge") and *das Lernen* ("learning") end in the derivational suffix *-en*. Confusion of these two suffixes leads to inability to correctly predict gender for new nouns ending in /en/. Without having a way of representing the fact that derivational morphemes have an independent lexical status, neural networks cannot process these patterns.

These four difficulties reflect a single core problem. By working with neural networks that flexibly encode lexical items, we can begin to address these additional features of word structure.

## *Syntax*

Elman (1990) has provided demonstrations of the ability of neural networks to process complex syntactic structures. His model uses recurrent connections to update the network's memory after it listens to each word. The network's task is to predict the next word. This framework views language comprehension as a highly constructive process in which the major goal is trying to predict what will come next. Psycholinguists recognize the importance of prediction, but they view the major task of language processing as the construction of mental models. It is not clear how understanding prediction will help us understand the construction of mental models, although the two processes are certainly related.

An alternative to the predictive framework relies on the older neural network mechanisms of spreading activation and competition. For example MacDonald, Perlmutter, and Seidenberg (1994) have presented a model of ambiguity resolution in sentence processing that is grounded on competition between lexical items. Models of this type do an excellent job of modeling the temporal properties of sentence processing. Such models assume that the problem of lexical learning in neural networks has been solved. They then proceed to use localist representations to control interactive activation during sentence processing. Until we have indeed solved the problem of lexical learning, this is a very effective way of advancing the research agenda.

Another approach that makes similar assumptions uses a linguistic framework known as Construction Grammar. This framework emphasizes the role of individual lexical items in early grammatical learning (Tomasello, 2000). Early on, children learn to use simple frames such as *my* + *X* or *his* + *X* to indicate possession. As development progresses, these frames are merged into general constructions, such as the possessive construction. In effect, each construction emerges from a lexical gang. Sentence processing then relies on the child's ability to combine constructions online. When two alternative constructions compete, errors appear. An example would be **say me that story*, instead of *tell me that story*. In this error, the child has treated *say* as a member of the group of verbs that forms the dative construction. In the classic theory of generative grammar, recovery from this error is supposed to trigger a learnability problem, since such errors are seldom overtly corrected and, when they are, children tend to ignore the feedback. Neural network implementations of Construction Grammar address this problem by emphasizing the direct competition between *say* and *tell* during production. The child can rely on positive data to strengthen the verb *tell* and its link to the dative construction, thereby eliminating this error without corrective feedback. In this way, models that implement competition provide solutions to the logical problem of language acquisition.

These various approaches to syntactic learning must eventually find a way of dealing with the compositional nature of syntax (Valiant, 1994). A noun phrase such as "my big dog and his ball" can be further decomposed into two segments conjoined by the "and."

Each of the segments is further composed of a head noun and its modifiers. Our ability to recursively combine words into larger phrases stands as a major challenge to connectionist modeling. One likely solution would use predicate constructions to activate arguments that are then combined in a short-term memory buffer during sentence planning and interpretation. To build a model of this type, we need to develop a clearer mechanistic link between constructions as lexical items and constructions as controllers of the on-the-fly process of syntactic combination.

### *Neuronal Realism*

Some researchers have criticized neural network models in the area of language acquisition for a failure to properly represent basic facts about the brain. To the degree that the backpropagation algorithm relies on reciprocal connections between units, this criticism is well founded. However, work in this area has begun to rely on models such as self-organizing feature maps, adaptive resonance, and Hebbian learning that have closer mappings to the features of neural organization. In fact, Elman (1999) has shown how the imposition of biologically realistic assumptions, such as the brain's preference for short connections, can lead to more effective language learning. Thus, this particular challenge to neural network theory may end up being more of a searchlight than a barrier.

Neural networks must also achieve a closer match to what we are now learning about functional neural circuitry. We know that auditory cortex, Broca's area, temporal word storage, and frontal attentional areas are all involved in various ways in language processing. However, we have not yet figured out exactly how these separate brain structures map onto separate aspects of lexical and syntactic processing.

### *Embodiment*

The final challenge to neural network modeling comes from researchers who have begun to explore the ways in which the mind is grounded on the body. This relatively new line of research emphasizes the importance of findings that mental imagery makes use of the reactivation of perceptual systems to recreate physically grounded images. A convergence of work in neuroscience, psychology, and cognitive linguistics points to the view of language use not as disembodied symbol processing, but as indirectly grounded on basic mechanisms for perception and action, which themselves operate on the human body. Neural network models have just begun to deal with this new challenge. One approach emphasizes the ways in which distal learning processes can train action patterns such as speech production on the basis of their perceptual products (Plaut and Kello, 1999). Another approach, adopted by the NTL (Neural Theory of Language) group (Bailey et al., 1997) relies on the higher-order formalism of Petri nets to represent the control structure of body motions such as *pull* or *stumble*. The architecture then includes transparent methods of linking the higher-level representation to a neural network implementation.

One trend that will facilitate this work, as well as all modeling of language acquisition is the increasing availability of transcript and multimedia data from children interacting with their caretakers. The Child Language Data Exchange System (CHILDES) at http://childes.psy.cmu.edu now provides thousands of hours of transcripts of child language data, much of it linked to audio and some to video. In the context of the broader TalkBank Project at http://talkbank.org, this data is being recoded in XML format and linked to a variety of computational tools for analyzing gestural, phonological, morphological, and syntactic structure. This growing database provides increasingly rich targets for neural network modeling.

## Conclusions

Neural networks have addressed many aspects of Chomsky's challenge. They have been used to develop useful models of virtually all aspects of language learning and processing. However, further challenges lie ahead. Of these, the most pressing is the need to develop methods for simulating the learning of a realistically sized lexicon of several thousand words. If this problem can be solved, it will have further positive consequences for models of syntactic development that emphasize the importance of item-based learning. It is likely that a good solution to this problem will need to rely on an improved understanding of the ways in which the brain stores and processes lexical items. An even greater challenge will be developing models that express the ways in which language processing is grounded on embodied cognition. Together, these challenges guarantee vitality in this area for years to come.

# Language Evolution and Change

*Morten H. Christiansen and Rick Dale*

## Introduction

No direct evidence remains from before the emergence of writing systems to inform theories about the evolution of language. Only as evidence is amassed from many different disciplines can theorizing about the evolution of language be sufficiently constrained to remove it from the realm of pure speculation and allow it to become an area of legitimate scientific inquiry. To go beyond existing data, rigorously controlled thought experiments can be used as crucial tests of competing theories. Computational modeling has become a valuable resource for such tests because it enables researchers to test hypotheses about specific aspects of language evolution under controlled circumstances (Cangelosi and Parisi, 2002; Turner, 2002). With the help of computational simulations, it is possible to study various processes that may have been involved in the evolution of language, as well as the biological and cultural constraints that may have shaped language into its current form (see Evolution and Learning in Neural Networks).

Connectionist models have played an important role in the computational modeling of language evolution. In some cases, the networks are used as simulated agents to study how social transmission via learning might give rise to the evolution of structured communication systems. In other cases, the specific properties of neural network learning are enlisted to help illuminate the constraints and processes that may have been involved in the evolution of language. This article surveys this connectionist research, starting from the emergence of early syntax and continuing to the role of social interaction and constraints on network learning in subsequent evolution of language and to linguistic change within existing languages.

## Emergence of Simple Syntax

Models of language evolution focus on two primary questions: how language emerged, and how languages continue to change over time. An important feature of the first question is the emergence of syntactic communication. Cangelosi (1999) studied the evolution of simple communication systems, but with an emphasis on the emergence of associations not only between objects (meaning) and symbols (signal), but also between the symbols themselves (syntax). In particular, the aim was to demonstrate that simple syntactic relations (a verb-object rule) could evolve through a combination of communicative interactions and cross-generational learning in populations of neural networks.

In Cangelosi's simulations, populations of networks evolved based on their ability to forage in an environment consisting of a two-dimensional 100 × 100 array of cells. About 12% of the cells contained randomly placed mushrooms that served as food. Three types of mushrooms were edible, increasing a network's fitness if collected, whereas another three types were poisonous, decreasing the network's fitness if collected. The networks had a standard feedforward architecture with a single hidden unit layer and were trained using backpropagation (see Backpropagation: General Principles). Input was represented in terms of three sets of input units encoding the location of a mushroom, the visual features of the mushroom, and words naming objects or actions. The output contained sets of units representing actions (*approach, avoid, discriminate*) and words with the latter units organized into two winner-take-all clusters (object and verb). Populations consisted of 80 networks, each with a life span of 1,000 actions. The 20 networks with the highest fitness level were selected for asexual reproduction, each producing four offspring through random mutation of 10% of its starting weights. During the first 300 generations, the populations evolved an ability to discriminate between edible and poisonous mushrooms without the use of words. In subsequent populations, parents provided teaching input for the learning of words denoting the different mushrooms (objects) and the proper action to take (verbs). The simulations were repeated with different random starting populations. Sixty-one percent of the simulations resulted in optimal vocabulary acquisition, with different "verb" symbols used with edible (*approach*) and poisonous (*avoid*) mushrooms, and different "noun" symbols used for the different types of mushrooms.

The simulations indicate how a simple noun-verb communication system can evolve in a population of networks. Because the features of a mushroom were perceived only 10% of the time, paying attention to the parental language input provided a selective advantage with respect to foraging, thus reinforcing successful linguistic performance.

Another approach to the emergence of elementary syntax has been offered by Batali (1998). He suggested that a process of negotiation between agents in a social group may have given rise to coordinated communication. Whereas Cangelosi's model involved the emergence of rudimentary verb-object syntax in a foraging environment, Batali's networks were assigned the task of mapping meaning onto a sequence of characters for the purpose of communication in a social environment. The networks in this simulation did not start out with a predetermined syntactic system. Instead, a process of negotiation across generations engendered the evolution of a syntactic system to convey common meanings.

Each agent in the simulation was a simple recurrent network (SRN; Elman, 1990), capable of processing input sequences consisting of four characters and producing an output vector representing a meaning involving a subject and a predicate. In a negotiation round, one network was chosen as a learner, and ten randomly selected teachers conveyed a meaning converted into a string of characters. The learner then processed the string produced by the teacher, and was trained using the difference between the teacher's and the learner's meaning vectors. Batali described this interaction between learners and teachers as a kind of negotiation, since each must adjust weights in accordance with its own cognitive state and that of others. At the start of the simulations the networks generated only very long strings that were unique to each meaning. After several thousand rounds of negotiation, the agents developed a more efficient and partially compositional communication system, with short sequences of letters used for particular predicates and referents. To test whether novel meanings could be encoded by the communication system, Batali omitted ten meanings, and reran the simulations. After training, networks performed well at sending and processing the omitted meaning vectors, demonstrating that the rudimentary grammar exhibited systematicity capable of accommodating a structured semantics.

Batali's model offers illuminating observations for the evolution of language. An assumption of this model was that social animals can use their own cognitive responses (in this case, translating meaning vectors into communicable signals) to predict the cognitive state of other members of their community. Batali compared this ability to one that may have arisen early in hominids and contributed to the emergence of systematic communication. Once such an elementary communication system is in place, migration patterns may have promoted dialectical variations. The next section explores how linguistic diversity might arise as a result of geographical separation between groups of communicating agents.

## Linguistic Diversity

The diversity of the world's many languages has offered puzzling questions for centuries. Computational simulations allow for the investigation of factors influencing the distribution and diversity of language types. An intuitive approach, considered in the next section, is that languages assume an adaptive shape governed by various constraints in the organism and environment. Livingstone and Fyfe (1999) have proposed an alternative perspective based on simulations in which linguistic diversity arises simply as a consequence of spatial organization and imperfect language transmission in a social group.

The social group in the simulation consisted of networks with two layers of three input and output units, bidirectionally connected and randomly initialized. As in Batali's simulations, agents were given the task of mapping a meaning vector onto an external "linguistic" signal. For each generation, a learner and a teacher were randomly selected. The output of the teacher was presented to the learner, and the error between meaning vectors was used to change the learner's weights. Each successive generation had agents from the previous generation acting as teachers. The agents were spatially organized along a single dimension and communicated only with other agents within a fixed distance. By comparing agents across this spatial organization, performance akin to a dialect continuum was observed: small clusters of agents communicated readily, but as the distance among them increased, error in communication increased. When the simulation was implemented without spatial organization (i.e., each agent was equally likely to communicate with all others), the entire population quickly negotiated a global language, and diversity was lost. This model supports the position that diversity is a consequence of spatial organization and imperfect cultural transmission.

The results of Livingstone and Fyfe's as well as Batali's simulations may not rely directly on the properties of neural network learning, but rather on the processes of learning-based social transmission. However, when it comes to explaining why certain linguistic forms have become more frequent than others, the specific constraints on learning in such networks come to the fore. The next section discusses how limitations on network learning can help explain the existence of certain so-called linguistic universals.

## Learning-Based Linguistic Universals

Despite the considerable diversity that can be observed across the languages of the world, it is also clear that languages share a number of relatively invariant features in the way words are put together to form sentences. Spatial organization and error in transmission cannot account for these widespread commonalities. Instead, the specific constraints on neural network learning may offer explanations for these consistent patterns in language types. As an example, we can consider heads of phrases, that is, the particular word in a phrase that determines the properties and meaning of the phrase as a whole (such as the noun *boy* in the noun-phrase *the boy with the bicycle*). Across the world's languages, there is a statistical tendency toward a basic format in which the head of a phrase consistently is placed in the same position—either first or last—with respect to the remaining clause material. English is considered to be a head-first language, meaning that the head is most frequently placed first in a phrase, as when the verb is placed before the object noun-phrase in a transitive verb phrase such as *eat curry*. In contrast, speakers of Hindi would say the equivalent of *curry eat*, because Hindi is a head-last language.

Christiansen and Devlin (1997) trained SRNs with eight input and eight output units encoding basic lexical categories (i.e., nouns, verbs, prepositions, and a possessive genitive marker) on corpora generated by 32 different grammars with differing amount of head-order consistency. The networks were trained to predict the next lexical category in a sentence. Importantly, these networks did not have built-in linguistic biases; rather, they were biased toward the learning of complex sequential structure. Nevertheless, the SRNs were sensitive to the amount of head-order inconsistency found in the grammars, such that there was a strong correlation between the degree of head-order consistency in a given grammar and the degree to which the network had learned to master the grammatical regularities underlying that grammar. The higher the inconsistency, the more erroneous the final network performance was. The sequential biases of the networks made the corpora generated by consistent grammars considerably easier to acquire than the corpora generated by inconsistent grammars. Christiansen and Devlin further collected frequency data concerning the specific syntactic constructions used in the simulations. They found that languages incorporating fragments that the networks found hard to learn tended to be less frequent than languages the network learned more easily. This suggests that constraints on basic word order may derive from nonlinguistic constraints on the learning and processing of complex sequential structure. Grammatical constructions incorporating a high degree of head-order inconsistency may simply be too hard to learn, and would therefore tend to disappear.

More recently, Van Everbroeck (1999) presented network simulations in a similar vein in support of an explanation for language-type frequencies based on processing constraints. He trained recurrent networks (a variation on the SRN) to produce the correct grammatical role assignments for noun-verb-noun sentences that were presented one word at a time. The networks had 26 input units, providing distributed representations of nouns and verbs as well as encodings of case markers, and 48 output units, encoding the distributed noun-verb representation according to grammatical role. Forty-two different language types were used to represent cross-linguistic variation in three dimensions: word order (e.g., subject-verb-object), and noun and verb inflection. The results of the simulations coincided with many observed trends in the distribution of the world's languages. Subject-first languages, both of which make up the majority of language types (51% and 23%, respectively), were easily processed by the networks. Object-first languages, on the other hand, were not well processed and have very low frequency among the world's languages (object-verb-subject: 0.75%; object-subject-verb: 0.25%). Van Everbroeck argued that these results were a predictable product of network processing constraints. Not all results, however, were directly proportional to actual language-type frequencies. For example, verb-subject-object languages account for only 10% of the world's language types, but the model's performance on these exceeded performance on the more frequent subject-first languages. Van Everbroeck suggested that making the simulations more sophisticated (incorporating semantics or other aspects of language) might allow network performance to better approach observed frequencies. Together, the simulations by Van Everbroeck and by Christiansen and Devlin provide preliminary support for a connection between learnability and frequency in the world's languages based on the learning and processing properties of connectionist networks. The next section discusses additional simulations that show how similar network properties may also help explain linguistic change within a particular language.

## Linguistic Change

The English system of verb inflection has changed considerably over the past 1,100 years. Simulations by Hare and Elman (1995) demonstrate how neural network learning and processing constraints may help explain the observed pattern of change. The morphological system of Old English (ca. 870) was quite complex, involving at least ten different classes of verb inflection (with a minimum of six of these being "strong"). The simulations involved several "generations" of neural networks, each of which received as input the output generated by a trained net from the previous generation. The first net was trained on data representative of the verb classes from Old English. However, training was stopped before learning could reach optimal performance. This reflected the causal role of imperfect transmission in language change. The imperfect output of the first net was used as input for a second generation net, for which training was also halted before learning reached asymptote. Output from the second net was then given as input to a third net, and so on, until seven generations were trained. This training regime led to a gradual change in the morphological system. These changes can be explained by verb frequency in the training corpus, and internal phonological consistency (i.e., distance in phonological space between prototypes). The results revealed that membership in small classes, inconsistent phonological characteristics, and low frequency all contributed to rapid morphological change. As the morphological system changed through generations in these simulations, the pattern of results closely resembled the historical change in English verb inflection from a complex past tense system to a dominant "regular" class and small classes of "irregular" verbs.

## Discussion

This article has surveyed the use of neural networks for the modeling of language evolution and change. The results discussed here are encouraging, even though neural network modeling of language evolution is very much in its infancy. However, it is also clear that the current models suffer from obvious shortcomings. Most of them are highly simple and do not fully capture the vast complexity of the issues at hand. For example, the models of the emergence of verb-object syntax and linguistic diversity incorporated very simple relationships between meaning and form. Moreover, although the simulations of the influence of processing constraints on the shape of language involved relatively complex grammars, they did not include any relationship between the language system and the world. Nevertheless, these models demonstrate the potential for exploring the evolution of language from a computational perspective.

Both connectionist and nonconnectionist models (e.g., Nowak and Komarova, 2001) have been used to provide important thought experiments in support of theories of language evolution. Connectionist models have become prominent in such modeling, both for their ability to simulate social interaction in populations and for their demonstrations of how learning constraints imposed on communication systems can engender many of the linguistic properties we observe today. Together, the models point to an important role for cultural transmission in the origin and evolution of language. This perspective receives further support from neuroscientific considerations, suggesting a picture of language and brain that argues for their co-evolution (e.g., Deacon, 1997). The studies discussed here highlight the promise of neural network approaches to these issues. Future studies will likely seek to overcome current shortcomings and move toward more sophisticated simulations of the origin and evolution of language.

# Language Evolution: The Mirror System Hypothesis

*Michael A. Arbib*

## Introduction

What is the evolutionary path leading to language in humans, and what are the relevant data on brain mechanisms? Since the fossil record offers no trace of brain structure beyond clues from ancient skulls on brain size and perhaps some fissures of the brain, the answers to these questions are varied and controversial (Wilkins and Wakefield, 1995). The present article emphasizes the *mirror system hypothesis* (MSH). The "mirror system" for grasping in monkey, which contains *mirror neurons* that are active both when the monkey executes a specific hand action and when it observes a human or other monkey carrying out a similar action, is the homologue of Broca's area, a crucial speech area in humans. MSH asserts that the matching of neural code for execution and observation of hand movements is present in the common ancestor of monkey and human and is the precursor of the crucial language property of *parity*, namely, that an utterance usually carries similar meaning for speaker and hearer (using these terms neutrally for spoken and signed languages). This provides a neurobiological "missing link" for the hypothesis that communication based on manual gesture preceded speech in language evolution (e.g., Stokoe, 2001).

Where the present article focuses on brain mechanisms for vision, action, and language, the article LANGUAGE EVOLUTION AND CHANGE, focuses on the use of connectionist modeling to test hypotheses (usually more psychological than neurological in nature) about specific aspects of language evolution.

## What Does the Biology of the Brain Provide?

Chomsky (e.g., 1975) has argued that since children acquire language rapidly despite the "poverty of the stimulus," the basic structures of language must be innate, forming a universal grammar encoded in the human genome. For example, universal grammar would encode the knowledge that sentences in a human language could be ordered as subject-verb-object, subject-object-verb, or one of a few other options, so that the child simply needs to hear a few sentences of his first language to "set the parameter" for the preferred order of that language. Against this, others have argued that the child has both a rich set of language stimuli linked to action and perception and powerful learning mechanisms, so that a child can indeed learn from its social interactions aspects of syntax which Chomsky would see as genetically prespecified (see LANGUAGE ACQUISITION). There is no argument against the view that human evolution yielded genetic specification of some of the structures which *support* language. Humans have hands, a larynx, and facial mobility suited for generating gestures that can be used in language, and the brain mechanisms needed to produce and perceive rapidly generated sequences of such gestures (Lieberman, 1991). In this sense, the human brain and body is *language ready*. The term *language readiness* was, I believe, my coinage (Arbib, 2002), but of course I was not the first to assert that the biological evolution that took us to ancestors with a language-ready brain (by some other name) had to be followed by a cultural evolution that took us from rudimentary manual-vocal communication to full language capability.

Although it is a matter of ongoing debate to delimit what constitutes language readiness and how it differs from language, we offer here a tentative list of criteria as a basis for future research.

### *Language Readiness*

The first three properties support communication system without necessarily yielding language, while the last four properties are more general:

*Symbolization*: The ability to associate an arbitrary symbol with a class of events, objects, or actions, etc. At first, these symbols may not have been words in the modern sense, nor need they have been vocalized.

*Intentionality*: Communication is *intended* by the utterer to have a particular effect on the recipient.

*Parity (mirror property)*: What counts for the speaker (or producer) must count for the listener (or receiver).

*Hierarchical structuring*: Production and recognition of components with subparts. This relates to basic mechanisms of action-oriented perception with no necessary link to the ability to communicate about these components and their relationships.

*Temporal ordering*: Temporal activity coding these hierarchical structures.

*Beyond the here-and-now*: The ability to recall past events or imagine future ones.

*Paedomorphy and sociality*: The prolonged immaturity of the infant and the prolonged caregiving of adults combine to create conditions for complex social learning.

Deacon (1997) makes symbolization central to his account of the co-evolution of language and the human brain. He stresses the componential homology that allows us to learn from relations between the brains of monkeys and humans. His more recent writings stress the role of self-organization as the child's brain adapts to the cultural environment in which the child develops. Where Deacon places most emphasis on the enlargement of frontal cortex, we place more emphasis on the differential development of specific subsystems that support language readiness. Interestingly, Semendeferi et al. (2002) argue that magnetic resonance imaging shows that human frontal cortices are not disproportionately large in comparison to those of the great apes. They thus suggest that the special cognitive abilities of humans may be due to differences in individual cortical areas and to a richer interconnectivity, rather than to an increase in the overall relative size of the frontal lobe during human evolution.

### *Language*

We now turn to criteria for language, which we here hypothesize as what cultural evolution and learning add to the brain's capabilities for language readiness. Note that nothing in this list rests on the medium of exchange of the language, and that the list applies both to spoken language and to sign language.

*Symbolization*: The symbols become words in the modern sense, interchangeable and composable in the expression of meaning.

*Syntax and semantics*: The matching of syntactic to semantic structures co-evolves with the fractionation of utterances. This includes the ability to build utterances recursively (see CONSTITUENCY AND RECURSION IN LANGUAGE).

*Beyond the here-and-now*: Verb tenses (or alternative syntactic constructs) arise to express recall of past events and imagination of future ones.

*Learnability*: To qualify as a human language, it must contain a *significant subset* of symbolic structures learnable by most human children (but children do not master a language completely by 5 or 7 years of age).

Bickerton (1995) characterizes *protolanguage* as a form of communication whose users can only string together a small handful of words at a time, may leave out words arbitrarily, may often depart from customary word order, cannot form any complex structures, and use only a tiny fraction of the inflections and "grammatical words" that make up 50% of true language utterances. Bickerton then makes two distinct claims: (1) that the productions of apes who have been taught to use signs, early-stage pidgin languages, and the speech of children under 2 share enough properties in common that they can all be characterized as examples of a common entity, "protolanguage"; and (2) that this same entity, protolanguage, characterizes the "prelanguage" of early hominids. The counterhypothesis advanced here is that the prelanguage of early hominids was not a protolanguage in Bickerton's sense, but rather was made up of "one-word utterances" in which the "words" were *holophrastic*, i.e., more like today's complete phrases or sentences, with modern-sense words and syntax later co-evolving culturally.

## Neurobiological Foundations

With this, we turn to the neurobiology of the monkey to ground claims as to the brain of the common ancestor of monkeys and humans of perhaps 20 million years ago, and hypotheses on how such brains changed to become language ready.

### *Brain Mechanisms for Grasping*

Parietal area AIP and ventral premotor area F5 anchor the cortical circuit in monkey that transforms visual information on intrinsic properties of an object into hand movements for grasping it (see GRASPING MOVEMENTS: VISUOMOTOR TRANSFORMATIONS). Discharge in most F5 neurons correlates with an action rather than with the individual movements that form it, so that one may relate F5 neurons to various motor schemas (see SCHEMA THEORY) corresponding to the action associated with their discharge.

The FARS model (Fagg and Arbib, 1998) provides a computational account of the system centered on the AIP → F5 pathway (Figure 1): AIP cells encode "affordances"—visual features of the object relevant to action—for grasping and send (neural codes for) these on to area F5, which selects one of these for action. Inferotemporal cortex (IT) and prefrontal cortex (PFC) modulate F5's selection of an affordance. However, the dorsal stream via AIP does not know "what" the object is, it can only see the object as a set of possible affordances. The ventral stream (from primary visual cortex to IT), by contrast, is able to recognize what the object is (see DISSOCIATIONS BETWEEN VISUAL PROCESSING MODES). This information is passed to PFC, which can then, on the basis of the current goals of the organism and the recognition of the nature of the object, bias F5 to choose the affordance appropriate to the task at hand. (See GRASPING MOVEMENTS: VISUOMOTOR TRANSFORMATIONS for recent neuroanatomical data suggesting that PFC may act on action selection at the level of parietal cortex rather than premotor cortex.)

Figure 1 gives only a partial view of the FARS model, which also provides mechanisms for sequencing actions. It segregates the F5 circuitry that encodes unit actions from the circuitry encoding a sequence, possibly the part of the supplementary motor area called pre-SMA (Rizzolatti, Luppino, and Matelli, 1998). The administration of the sequence (inhibiting extraneous actions, while priming imminent actions) is then carried out by the basal ganglia (see BASAL GANGLIA and SEQUENCE LEARNING).

### *The Mirror System for Grasping*

Further study revealed a class of F5 neurons that discharged not only when the monkey grasped or manipulated objects, but also when the monkey observed the experimenter make a gesture similar to the one that, when actively performed by the monkey, involved activity of the neuron. Neurons with this property are called *mirror neurons* (Gallese et al., 1996). Mirror neurons respond only to an interaction between the agent and the object of an action. The simple presentation of objects, even when held by hand, does not evoke the neuron discharge.

Not all F5 neurons respond to action observation. We thus distinguish mirror neurons from *canonical neurons* in F5, which are active only when the monkey itself performs the relevant actions. Mirror neurons receive input from the PF region of parietal cortex encoding observations of arm and hand movements. This is in contrast to the canonical F5 neurons, which receive object-related input from AIP. It is the canonical neurons, with their input from AIP, that are modeled in the FARS model.

## Bridging from Action to Language

### *A Mirror System for Grasping in Humans*

The notion that a mirror system might exist in humans was tested by PET experiments, which showed that grasp observation significantly activated the superior temporal sulcus (STS), the inferior parietal lobule, and the inferior frontal gyrus (area 45). All activations were in the left hemisphere. The last area is of special interest: areas 44 and 45 in the left hemisphere of the human constitute Broca's area. F5 in monkey is generally considered (see analysis by Matelli in Rizzolatti and Arbib, 1998) to be the homologue of Broca's area in humans; i.e., it can be argued that these areas of monkey and human brain are related to the same region of the common ancestor. Thus, the cortical areas active during action observation in humans and monkeys correspond very well, indicating that there is a fundamental primate mechanism for action recognition: we argue that individuals recognize actions made by others because the neural pattern elicited in their premotor areas during action observation is similar to a part of that internally generated to produce a similar action. Note, however, that "understand-

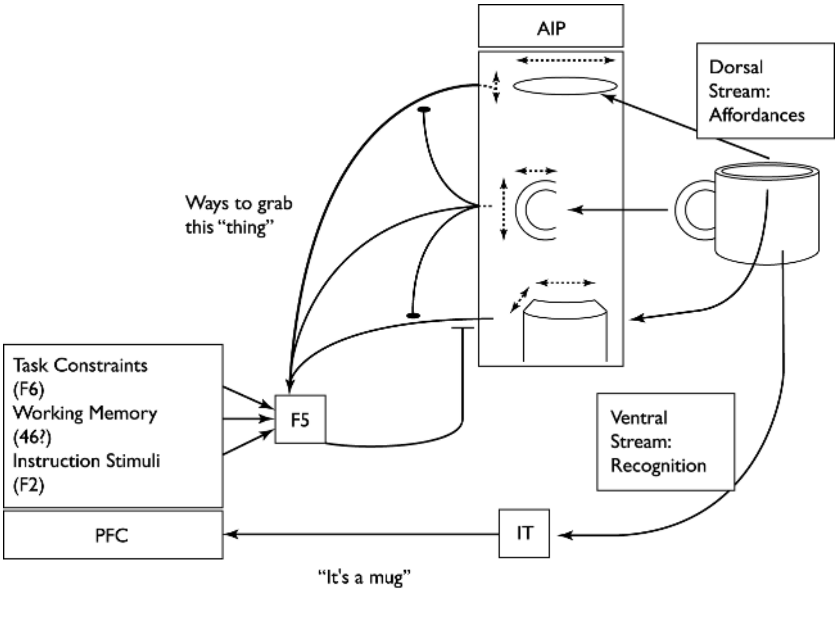

**Figure 1.** The role of IT (inferotemporal cortex) and PFC (prefrontal cortex) in modulating F5's selection of an affordance from the repertoire forwarded by AIP.

ing" involves the cooperation of many brain systems and cannot be reduced to just the activity in a subset of F5 neurons.

### *Primate Vocalization*

Monkeys exhibit a primate call system (a limited set of species-specific calls) and an orofacial (mouth and hand) gesture system (a limited set of gestures expressive of emotion and related social indicators). This communication system is *closed* in the sense that it is restricted to a specific repertoire. This is to be contrasted with the open nature of human languages. (Although each human language is open as to, e.g., nouns and verbs, it is [almost] closed with respect to prepositions and grammatical markers.) Strikingly, the neural substrate for primate calls is in a region of cingulate cortex distinct from F5, which we have seen to be the monkey homologue of Broca's area in the human. One challenge, then, is to understand why it is F5, rather than the cingulate area already involved in monkey vocalization, that is homologous to the human's frontal substrate for language. Note that the claim is not that Broca's area is genetically preprogrammed for language, but rather that the development of a human child in a language community normally adapts this brain region to play a crucial role in language performance.

### *The Mirror System Hypothesis*

What turns a movement into an action is that it is associated with a goal, so that initiation of the movement is accompanied by the creation of an expectation that the goal will be met. We distinguish "pragmatic action," in which the hands are used to interact physically with objects or the bodies of other creatures, and "gestures" (both manual and vocal), whose purpose is communication. Our assumption is that monkeys use hand movements only for pragmatic actions. The mirror system allows other monkeys to understand these actions and act on the basis of this understanding. Similarly, the monkey's orofacial gestures register emotional state, and primate vocalizations can also communicate something of the current situation of the monkey.

Stokoe (2001) provides a recent summary of the argument, rooted in the analysis of sign language, that communication based on manual gesture played a crucial role in human language evolution, preceding communication by speech. In this regard, we stress that the "openness" or "generativity" that some see as the hallmark of language is present in manual behavior, which can thus supply the evolutionary substrate for its appearance in language. With our understanding that the mirror system in monkeys is the homologue of Broca's area in humans, we can now appreciate the mirror system hypothesis.

**The mirror system hypothesis:** Language evolved from a basic mechanism *not* originally related to communication: the *mirror system for grasping*, with its capacity to generate *and* recognize a set of actions. More specifically, Broca's area in the human contains a mirror system for grasping that is homologous to the F5 mirror system of monkey, and this provides the evolutionary basis for *language parity*; i.e., an utterance means roughly the same for both speaker and hearer.

However, having a mirror system is not equivalent to having language. Monkeys have mirror systems but do not have language, and we expect that many species have mirror systems for varied socially relevant behaviors.

### *Simple and Complex Imitation Systems for Grasping*

It is unclear whether the mirror system for grasping is sufficient for the copying of actions. It is one thing to recognize an action using the mirror system and another thing to use that representation as a basis for repeating the action. In any case, the ability to copy *single* actions is just the first step toward imitation, since imitation involves "parsing" a complex movement into more or less familiar pieces and then performing the corresponding composite of (variations on) familiar actions. Myowa-Yamakoshi and Matsuzawa (1999) observed that chimpanzees typically took 12 trials to learn to "imitate" a behavior, and in doing so paid more attention to where the manipulated object was being directed rather than to the actual movements of the demonstrator. This may involve using one or both hands to bring two objects into relationship or to bring an object into relationship with the body. Thus the form of imitation reported for chimpanzees is a long and laborious process compared to the rapidity with which humans can acquire novel sequences. I have called this the contrast between "simple" imitation and "complex" imitation (Arbib, 2002) and assert that monkeys have neither, chimpanzees have simple imitation, and humans have complex imitation (not all primatologists accept this distinction; see IMITATION for further discussion).

If we assume (1) that the common ancestor of monkeys and apes had no greater imitative ability than present-day monkeys and (2) that the ability for simple imitation shared by chimps and humans was also possessed by their common ancestor, but that (3) only humans possess a talent for "complex" imitation, then we have established a case for the claim that brain mechanisms for simple imitation developed in the 15 million-year evolution from the common ancestor of monkeys and apes to the common ancestor of apes and humans, and that a complex imitation system—acquiring (longer) novel sequences of more abstract actions in a single trial—developed in the 5 million-year evolution from the common ancestor of apes and humans along the hominid line that led, in particular, to *Homo sapiens*. The argument, then, is that extension of the mirror system from recognition of single actions to imitation of compound actions was one of the key innovations in the brains of hominids relevant to language readiness.

### *A Manual-Based Communication System*

Given a creature with the ability for complex imitation, how might further hominid evolution have yielded a manual-based communication system that could lead to the further evolution of brain and body mechanisms supporting language readiness? Our hypothetical sequence leading to manual gesture and beyond is the following:

1. Pragmatic action directed toward a goal object
2. Imitation of such actions
3. Pantomime in which similar actions are produced in the absence of any goal object

In terms of observable movements, imitation of an action and pantomime of an action may appear the same. However, imitation is the generic attempt to reproduce movements performed by another, whether to master a skill or simply as part of a social interaction. By contrast, pantomime is essentially communicative, performed with the intention of getting the observer to think of a specific action or event. Thus, even though the movements may be similar, the actions (movement + goal) are very different.

4. Abstract gestures divorced from their pragmatic origins (if such existed). In pantomime it might be hard to distinguish a grasping movement signifying "grasping" from one meaning "a [graspable] raisin," thus providing an "incentive" for coming up with an arbitrary gesture to distinguish the two meanings.

This suggests that *arbitrary* symbols emerged when the communicative capacities of pantomiming were exhausted. This can be illustrated with modern American Sign Language, in which, for example, noun/verb pairs may be differentiated by movement. For example (Stokoe, 2001), the AIRPLANE/FLY pair of signs uses the same handshape, but the noun has short, repeated movements, whereas the verb has a single prolonged movement.

We thus distinguish *complementary roles for imitation* in the posited evolution of manual-based communication: extending imitation to pantomime to provide "natural" gestures that may convey a situation to the observer; and extending the mirror system from the grasping repertoire to mediate imitation of gestures that provide "conventionalized" symbols that can reduce ambiguity and extend the semantic range.

My current hypothesis is that stages (2) and (3) and a rudimentary (presyntactic) form of (stage 4) were present in prehuman hominids, but that the explosive development of linked symbols that we know as language depended on cultural evolution, well after biological evolution had formed modern *Homo sapiens*.

### The Path to Protospeech Is Indirect

Earlier we noted that the neural substrate for primate calls is in a region of cingulate cortex distinct from F5, which latter is the monkey homologue of Broca's area in the human. Rizzolatti and Arbib (1998) suggest two evolutionary stages:

1. A *distinct* manuobrachial (hand-arm) communication system evolved (as just described) to complement the primate calls/orofacial communication system. At this stage, the "speech" area (i.e., the area of the hominid brain presumably homologous to monkey F5) mediated only orofacial and manuobrachial communication.
2. The manual-orofacial symbolic system then "recruited" vocalization. The association of vocalization with manual gestures allowed it to assume a more open referential character, yielding "protospeech" (but not full-blown spoken language). This yields the MSH explanation of why F5, rather than the primate call area, provides the evolutionary substrate for language readiness.

However, language and vocalization systems are nonetheless linked. Lesions centered in the anterior cingulate cortex and supplementary motor areas of the brain can also cause mutism in humans, similar to the effects produced in muting monkey vocalizations. Conversely, a patient with a Broca's area lesion may nonetheless swear when provoked. But note that "emitting an imprecation" is more like a monkey vocalization than like the syntactically structured use of language. Lieberman (1991) suggests that the primate call made by an infant separated from its mother not only survives in the human infant, but in humans develops into the breath group, i.e., the pattern of breathing in and breathing out that is shaped to provide the contour for each continuous sequence of a spoken utterance. This suggests that the evolution of speech yielded the pathways for cooperative computation between cingulate cortex and Broca's area, with cingulate cortex involved in breath groups and emotional shading and Broca's area involved in providing (in concert with, e.g., the basal ganglia) motor control for rapid production and interweaving of elements of an utterance.

### From Protospeech to Language

The cultural evolution of *Homo sapiens* may have involved an increased ability to name actions and objects to create a rapidly growing set of verb-argument structures, and the ability to compound those structures in diverse ways. Earlier I suggested that many grammatical structures would have been "postbiological" in their origin (Arbib, 2002). We might then see as ingenious human discoveries that the one word *ripe* halves the number of fruit names to be learned, or that separating action names from object names requires one to learn only $m + n$ words ($m$ nouns and $n$ verbs) to be able to form $m*n*m$ of the most basic utterances.

The spread of these innovations resided in the ability of other humans not only to imitate the new actions and compounds of actions demonstrated by the innovators, but also to do so in a way that related increasingly general classes of symbolic behavior to the classes, events, behaviors, and relationships they were to represent. Indeed, consideration of the spatial basis for "prepositions" may help show how visuomotor coordination underlies some aspects of language, while variations in the use of corresponding prepositions, even in English and Spanish, show how the basic, functionally grounded semantic-syntactic correspondences have been overlaid by a multitude of later innovations and borrowings.

## Toward a Mirror System–Based Neurolinguistics

The monkey needs many brain regions for the mirror system for grasping. We will need many more brain regions for a full neurolinguistic model that extends the linkages far beyond the F5 ≈ Broca's area homology. To set the stage for the future development of such a model, we briefly link our view of AIP and F5 in monkey to data on human abilities. Studies of the visual system of monkey led to the distinction between IT mechanisms for object recognition ("what") and posterior parietal (PP) mechanisms for localizing objects ("where"). Others extended this to a dichotomy between human "what" (IT) and "how" (PP): a patient with damage to the IT pathway could grasp and orient objects appropriately for manipulating them but could not report, either verbally or by pantomime, how big an object was or what the orientation of a slot was; another patient with damage to the PP pathway could communicate the size of a cylinder but not preshape appropriately (see Dissociations Between Visual Processing Modes).

Let us now try to reconcile these observations with our mirror system–based approach to language. Our evolutionary theory suggests a progression from action to action recognition to language, as follows:

| | |
|---|---|
| 1. Object → AIP → F5$_{\text{canonical}}$ | pragmatics |
| 2. Action → PF → F5$_{\text{mirror}}$ | action recognition |
| 3. Scene → Wernicke's → Broca's | utterance |

The "zero-order" model of the above PP/IT data is:

4. Parietal "affordances" → preshape
5. IT "perception of object" → pantomime or verbally describe size

However, step 5 implies that one cannot directly pantomime or verbalize a parietal affordance; one needs the "unified view of the object" (IT) before one can communicate attributes. The problem with this is that the "language" path as shown in step 3 is independent of the IT system. To resolve this paradox, we note the experiments of Bridgeman and his colleagues (Dissociations Between Visual Processing Modes). When an observer sees a target in one of several possible positions and a frame either centered before the observer or deviated left or right, verbal judgments of the target position are altered by the background frame's position, but "jabbing" at the target never misses. The point is that communication must be based on the size estimate generated by IT, presumably for overall planning of movement, and not on that generated by PP, which provides precise parameters for motor control.

Given these data, we may now recall (Figure 1) that although AIP extracts a set of affordances, it is IT and PFC that are crucial to F5's selection of the affordance to execute, and then offer the scheme shown in Figure 2 (from Arbib in Cangelosi and Parisi,

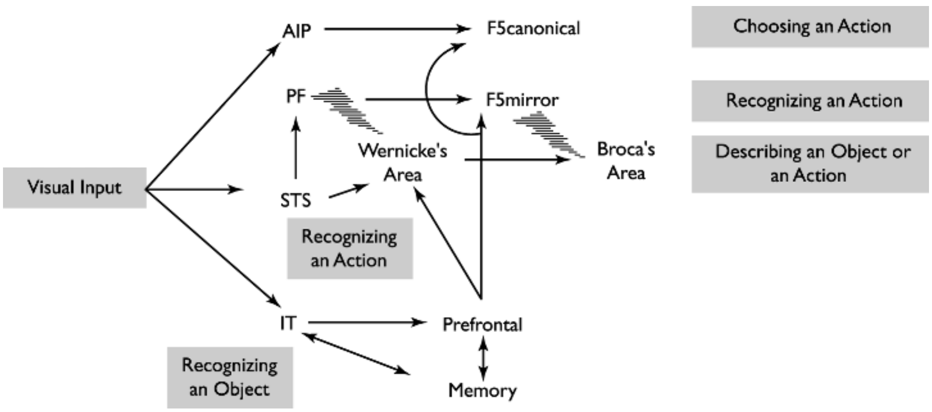

**Figure 2.** An early pass on a mirror system–based neurolinguistics. (From Arbib, 2002.)

2001). Here we emphasize the crucial role of IT-mediated functioning of PFC in the activity of Broca's area. This is the merest of sketches. For example, we do not tease apart the roles of different subdivisions of PFC in modulating $\mathrm{F5}_{\mathrm{canonical}}$, $\mathrm{F5}_{\mathrm{mirror}}$, and Broca's area. However, the crucial suggestion is that, just as $\mathrm{F5}_{\mathrm{mirror}}$ receives its parietal input from PF rather than AIP, so Broca's area receives its size data as well as object identity data from IT via PFC, rather than via a side path from AIP. This is just the beginning.

## Discussion

The approach taken here has rich implications for the study of human evolution and NEUROLINGUISTICS (q.v.).

1. It is a mistake to assume that features common to modern-day languages must be biological in nature. Work on brain mechanisms of language must seek to distinguish the biological givens of language readiness from the cultural extensions that define the world's languages today.
2. We must be open to multiple hypotheses about the nature of hominid "prelanguage," seeking to evaluate the claims of Bickerton's protolanguage hypothesis against the claims for fractionation and imitation-based symbolization advanced here.
3. MSH offers a clear explanation for why Broca's area is homologous to an area for grasping in the human brain rather than to the cingulate area involved in primate vocalizations.
4. MSH also explains why language is multimodal, so that a deaf child can acquire sign language as readily as a hearing child acquires speech.

Even the canonical system (the FARS model) involves multiple regions in the monkey's brain (including AIP, F5, IT, pre-SMA, and basal ganglia), and the mirror system involves many more (including STS and PF). As we seek to understand the extensions of these that mediate complex imitation and undergird language readiness, we see that there is far more to the human brain's unique capability to master language than "F5 becomes Broca's area to provide parity." Building on Figure 2, or on other hypotheses grounded in the comparative study of primate brains, to develop a rich model of language readiness—and developing an integrated view of syntax and semantics to build upon it—will require both analysis of neurological data and subtle modeling that links neurolinguistics to the basic neural mechanisms for the recognition of the interactions of actors and objects, and for the elaboration of suitable motor plans for interacting with the environment so perceived. A further challenge is to explore the extent to which MSH constrains the structure of modern languages, despite the great variations wrought by cultural evolution. One such example (Arbib and Jean-Roger Vergnaud, in prep.) is the assertion that sentences are canonically structured as

$$[_{S}\mathrm{NP}_{s}[_{vP}\mathrm{v}[_{VP}\times \mathrm{NP}_{0}]]]$$

v-V being the analysis of the verb in the sentence, because the canonical system of F5 binding action to object underlies the merging of the V-component with the object $\mathrm{NP}_{o}$, while the mirror system of F5 binding agent to action underlies the merging of the subject $\mathrm{NP}_{s}$ with the complex v-VP.

# Language Processing

*Richard Shillcock*

## Introduction

Language has provided some of the most important opportunities and challenges for connectionist cognitive modeling. There is a wealth of human behavioral data, from cognitive psychology experiments, from observations of children acquiring language, and from studies of developmental or acquired language disorders. There are also comprehensive insights from formal domains, such as phonology and syntax. Since McClelland and Rumelhart's (1981) Interactive Activation Model of visual word recognition, connectionist modeling has been applied to most areas of language processing. For instance, neural network architectures have been employed to discover syllable structure from waveforms, to manage constraint satisfaction with different categories of linguistic information in parsing, and to simulate data from historical linguistics and language typology. Even in formal syntax, the connectionist paradigm shift has provoked notions such as the graded application of rules (see Optimality Theory in Linguistics). In the following paragraphs we review a number of models that capture detailed behavioral data and simulate the brain's discovery and manipulation of structure in spoken and written language.

This modeling was conducted against the backdrop, within psychology and cognitive science, of two related concerns: modularity and top-down feedback. Researchers have asked whether the functional architecture of cognition is modular: Are certain kinds of processing autonomous and encapsulated from other kinds of information, or do different types of information freely interact? The paradigm example has been the claimed autonomy of syntactic processing. Researchers have also asked whether genuine top-down feedback occurs: Is more sophisticated, higher-order, contextual information ever used to enhance the processing of lower-order, more peripheral representations, or is cognition fundamentally "bottom-up"? The paradigm example here has been the relationship between a word and its constituent letters or speech segments (see Speech Processing: Psycholinguistics).

Many classical box-and-arrow cognitive models have become very elaborate in an attempt to accommodate additional human data, and have often been limited in their ability to generate interesting emergent behavior that might be tested against human subjects. Finally, there has been a fierce debate over the nature of representation in the brain, the status of rules, and the extent of any specific genetic endowment underlying human language learning. Despite the insights gained from the formal study of language, the formal approach has allowed researchers to say relatively little about learning and development. Thus, the "connectionist program" for understanding language has concentrated on the process of *change*, exploring topics such as language development (see Language Acquisition; Past Tense Learning); language breakdown (see Lesioned Networks as Models of Neuropsychological Deficits; Neurolinguistics); the dynamics of representation in complex systems, which themselves may be receiving changing input (see Speech Processing: Psycholinguistics); and, more recently, the evolution of language (see Language Evolution and Change). Despite the fact that connectionist models of language have often been built to cover restricted domains, such as learning the past tense, a common goal has been to show the *emergence* of complex linguistic behavior from more basic foundations, which may not themselves be specifically linguistic in nature.

## Lexical Processing

### *Reading Single Words*

Models of single-word reading and pronunciation have perhaps been the most compelling of any connectionist models of cognition. McClelland and Rumelhart's Interactive Activation Model (IAM) is an enduring example of a large-scale model producing illuminating and testable emergent behaviors through the management of very large numbers of interactions. It identifies four-letter words from an input of visual features in the four-letter positions. This input level is connected to a level containing a representation of each letter in each position, which is connected to a level containing a representation of each word. The model was handwired so that excitatory connections between levels cause features to activate the relevant letter representations, which then activate all of the words in which they occur. Each activated word node sends supportive activation to its constituent letters. Inhibitory connections between and within levels suppress inconsistent representations. This localist model accurately simulated human data concerning the perception of letters in briefly presented words, such as the apparent top-down support of "gangs" of similar words for shared letters in particular positions. The model has been incorporated as a proper part of Coltheart and colleagues' (1993) symbolic/connectionist hybrid model of pronunciation.

### *Recognizing Spoken Words*

Top-down feedback similar to the IAM's appeared in McClelland and Elman's TRACE model of spoken word recognition, in which an interactive activation network was replicated across subsequent time slices to capture the flow of activation from phonetic features to segments to words. Interesting behaviors were observed, such as the trading of different cues to segment identity and an emergent segmentation of the continuous speech stream into a single string of words simply by the activation of all possibly implicated words, combined with winner-take-all competitions. Top-down feedback in TRACE is computationally effective, but in the long-running controversy over the existence of such feedback, Norris, McQueen, and Cutler (2000) have argued that it is unwarranted and unnecessary in a model of spoken word recognition. In related models of spoken word recognition and of phoneme recognition in speech (Norris et al., 2000), interactive activation principles have been employed in purely bottom-up architectures.

### *Distributed Lexical Representations*

The modeling of normal and impaired single-word reading is the flagship of the connectionist cognitive modeling enterprise (Seidenberg and McClelland, 1989; Plaut et al., 1996). Seidenberg and McClelland (1989) characterized lexical processing in terms of a triangle of mappings between orthographic, phonological, and semantic representations, using three-layer networks trained by the backpropagation of error. (Only in later developments of this model has semantic processing been implemented.) An identity mapping from orthographic representations to orthographic representations was used to model the capturing of a secure visual representation of the word. The model did not possess a discretely structured lexicon; instead, information about a particular word was distributed across the many weighted connections between the three sets of representational units as the model learned the words in its training set. The goal has been to simulate the reading of regular words, irregular words (e.g., *pint*), and nonwords (e.g., *tenk*) within the same homogeneous architecture, and to explore an emergent division of labor between orthographic and semantic contributions to the pronunciation of different word types (see READING). An important improvement in later versions of this model involved employing local orthographic and phonological representations that respected the formal distinctions of the onset, nucleus, and coda of monosyllabic words (e.g., the *d*, *e*, and *sk* of *desk*). This innovation illustrates a criticism heard on both sides of the debate over connectionist cognitive modeling. Critics have stated that specifying the input and output representations relies on the formal insights of the classical, symbol-processing tradition and takes the crucially hard work out of solving the problem. Quartz and Sejnowski (1997), arguing a "constructivist" case for concentrating on the role of activity and growth in development, make the related point that it is the identification of the problem in the first place that is critical in learning and development. We might add that employing representations developed by formal linguists, such as phonemes, distinctive features, or syntactic categories, brings both advantages and disadvantages; all such categories involve ambiguity at their boundaries, even in the formal domains for which they were developed. All symbolic distinctions made about natural language are graded, in the limit.

Further improvements in the modeling of lexical processing have come from using recurrent architectures trained to settle into steady states, each corresponding to a desired output. Such attractor networks allow a feedforward model to map initially to an approximate output, which is then "cleaned up" appropriately if the initial approximation falls within the "basin of attraction" of the desired output. This innovation has been crucial in mapping between orthographic and semantic representations (Hinton and Shallice, 1991), where the relationship is essentially arbitrary. It has also allowed better generalization in the quasi-regular mapping between orthographic and phonological form, as such attractors have been shown to behave componentially in generating pronunciations.

The modeling of lexical processing has been important because of its psychologically realistic scale. The benchmark has been the pronunciation of a more or less complete slice of the lexicon, such as all the four-letter words or all the monosyllabic words of English. (Modeling with polysyllabic words has been limited.) A further aspect of the models' scale is that they involve the full repertoire of letters and speech segments. In these respects, such modeling is psychologically grounded in a way that cannot be claimed for small models with unrepresentative training sets. The modeling of other language domains, such as morphology, syntax, or semantics, has typically not achieved this rich, realistic scale and coverage.

The folk interpretation of the mental lexicon as a dictionary suggests a discrete lexical entry for each word, and it is surprising that models based on superpositional storage can achieve so much. Models of visual and spoken word recognition employing distributed representations of words have largely superseded the localist, handwired models such as the IAM and TRACE, which cannot capture the phenomena of learning and development and that are also relatively large architectures to build if they are to achieve wide coverage. Nevertheless, both types of connectionist model continue to generate important, experimentally testable predictions, and there has been eloquent advocacy of the merits of localist representation.

Less attention has been given to semantic processing in lexical models, partly because the central ability of connectionist models to generalize is maladaptive, given the arbitrary relationship between form and meaning, and partly because of the inherent difficulties of representing the meanings of words. However, when semantic representations have been studied, they have been based either on hand-crafted (sometimes dictionary-derived) semantic features (e.g., "+edible" or "+living"), or on corpus-derived context vectors, which specify the lexical contexts in which words are found. It is easier to see the latter type of semantic representation as being psychologically grounded: the context vectors are derived from very large corpora of real language, and wide coverage of the lexicon is more feasible than with an approach that uses semantic features.

## *Word Production*

Research on word production has been overwhelmingly concerned with slips of the tongue and with dysphasia resulting from strokes, but there has been a growing interest in the priming of syntactic structure. Connectionist modeling of word production has not been extensive and has centered on Dell's interactive activation model (Dell, 1986). In this model, activation initially flows downward from a lexical node to levels representing linguistic units—syllables, onsets and rimes, phonemes, and phonological features. Activation also feeds back upward, and after a set time the most activated nodes are selected for the onset, vowel, and coda slots. In a later version, semantic units activate word units and, in a second phase, word units activate phoneme units. Dell and colleagues have simulated both slips of the tongue and dysphasic errors within this framework, and have also developed learning models based on recurrent networks to avoid the limitations of hand-coded interactive activation models.

## *Learning Rules*

Researchers have explored the analogy between a connectionist model learning the structure of a linguistic domain and an infant acquiring language. Formal theories of language acquisition had led to the conclusion that a universal grammar had to be genetically specified in some detail. Within this approach, symbol-based rules are explicitly implemented. Connectionist modeling has held out the prospect that language learning could arise from more general-purpose cognitive processing, with rule-like behavior emerging from distributed representations. The learning of morphology has attracted the most research, but attention has recently centered on the abilities of very young infants to learn the regularities present in very simple "artificial grammars" and on the capabilities of connectionist models to simulate these data.

Rumelhart and McClelland began this debate about development with their model of past tense acquisition (see PAST TENSE LEARNING). Their model attracted robust criticism, but later modeling of morphological processing, even involving the apparently problematic case of minority default forms in German, has revealed a more detailed developmental picture that has supported Rumelhart and McClelland's original insight that a quasi-regular mapping can be captured by a model with a single mechanism operating with distributed representations of words. However, the broader debate continues, with one side exploring the capacity of models with a homogeneous architecture to account for the data while the other side argues for "dual-route" models containing explicit rules and stored exceptions to those rules.

## Higher-Level Processing

Higher-level, sentential processing involves syntax and semantics and immediately differs from lexical processing in terms of productivity: a speaker can produce an infinite number of different sentences. Syntactic processing is the paradigm example of symbolic behavior: the usage of the word *John* is determined by the category to which it belongs, proper nouns, rather than by features intrinsic to that particular word, so that being able to process *John sees Kim* necessarily implies being able to process *Kim sees John*. It has been claimed that connectionist models cannot transcend their inherent capacities to associate and to generalize between similar items so as to be able to capture the productivity and systematicity of natural language. Nevertheless, a variety of models have been developed to show that the principles of the connectionist modeling of cognition can be applied to sentence processing.

There is a long history of using the constraint satisfaction abilities of localist connectionist models to parse strings of words when syntactic and semantic categories are given. Such approaches implement insights such as the role of the frequency of particular transitions or the competition between possible parses. However, they take for granted the discreteness of the given formal categories, they can say little about development, and they cannot arbitrate the psychological issue of whether any particular category or type of information (typically syntax) has priority in processing.

An important departure came with Elman's simple recurrent network (SRN) and the demonstration that such models could discover and use syntactically relevant information in sentences (Elman, 1990). The SRN was developed to take account of temporal context in a sequence of inputs with no length restriction. In a three-layer network, the state of the hidden units at a particular point in time is recycled back to the hidden units simultaneously with the new input at the next point in time. Thus, the hidden units are affected by the previous inputs and states of the network. Elman required SRN models to predict the identity of the next word in a novel sentence as a means of testing whether the models had learned syntactic and semantic generalizations from the training corpus. Elman and others have shown, using this approach, that SRNs can capture some of the processing behavior observed in human readers, involving difficulties with particular construction types. Christiansen and Chater have shown that such models are capable of behavior that resembles the human ability to use words in accordance with their constituent nature, such as using *boy* in a novel syntactic position appropriate for a noun.

These approaches to higher-level structure in language have been shown to be capable of at least beginning the process of language learning (see Constituency and Recursion in Language). Further work has been directed to extending the complexity of the input; more construction types have been covered, and the effects of memory constraints on syntactic processing have been revealed, with implications for the observed distribution of different language types.

An influential approach to modeling adult parsing competence has been based on Pollack's Recursive Auto-Associative Memory (RAAM), in which the hidden units of the model are made to develop distributed representations of successive layers of a parse tree. The model is required to autoassociate these patterns, which are provided by the modeler. The hidden unit activations may be stored and read back off a stack, when they may be used to recreate the parse across the output units. In addition, the trained model may generalize its parsing behavior to novel inputs. A recurrent version of this model has been developed that, like the SRN, discovers sequential dependencies in its inputs that correlate with syntactic roles.

In general, parsing models that have been claimed to learn structured syntactic relationships between words also discover a variety of other types of information relevant to parsing. In the real world, potential clues to syntactic structure may include prosody, phonosyntactic regularities, punctuation, semantic attributes of words, argument structure, discourse context, and real-world knowledge; it is a strong claim to say that any potentially useful information is ignored by the brain in assigning a parse. Some brain imaging studies suggest autonomous syntactic processing of unproblematic input and fast interaction with other types of information when ambiguity is encountered. The debate about the autonomy of syntax continues even with the advent of sophisticated imaging techniques (see Imaging the Grammatical Brain).

Overall, the period from the mid-1980s has seen an explosion in the increasingly sophisticated application of connectionist methods to the discovery and/or management of higher-level structure in language, from syntax and morphosyntax through to semantics and discourse structure. Researchers have simulated processing in such subdomains as parsing, variable binding, question answering, sentence generation, topic identification, anaphora resolution, application of world knowledge to language understanding, translation, grammaticality judgment, text compression, information retrieval, and discourse understanding. Some researchers have dealt with the more ambitious combinations of tasks using completely connectionist modular architectures, and others have augmented connectionist architectures with more traditional computational approaches, creating hybrid models. (For coverage of some of this growing field, see Reilly and Sharkey, 1992; Wermter, Riloff, and Scheler, 1996; Dale, Moisl, and Somers, 2000; and Christiansen and Chater, 2001.)

Finally, the last decade has seen growing interest in modeling the evolution of language. Connectionist architectures have been used, along with other statistical models, to simulate the evolution, by iterative learning, of simple "languages" by successive generations of individuals. The goal has been to elicit the emergence of compositional structure and other attributes of natural language.

### *Starting Small*

One set of studies addressing development has attracted wide attention across a range of disciplines. Elman captured in network terms the intuition from language learning research that the cognitive constraints found in the developing infant may actually be advantageous to learning. Elman trained an SRN to learn syntactic dependencies separated by different numbers of intervening words in a sequential input and found that constraints that were intended to mimic the memory and attention limitations of infants acted to structure the training regimen by focusing learning on the shorter dependencies before the longer ones. The model that began with constraints that were subsequently relaxed outperformed the model that began with "adult" abilities. However, even though the notion of "starting small" still has deep implications for understanding development, Rohde and Plaut have shown that this principle may not be so unambiguously demonstrated using SRNs.

### *Anatomical Reality*

Models have not typically incorporated observable anatomical detail beyond the general claims regarding interactivity, distributed representations, and superpositional storage (although some researchers have explored giving priority to short connections in cortical processing). Arguably there is little, if any, discrete brain anatomy exclusively dedicated to language processing, unlike the areas and pathways responsible for vision, for instance. Some neuroimaging research suggests that although some language activities may be closely associated with certain brain areas, it may be truer to say that those areas specialize in particular subtasks (e.g., Broca's area and sequence storage) that are not exclusively linguistic. Furthermore, task difficulty seems to affect the configurations of activation seen (e.g., Broca's area may be only minimally activated by syntactically undemanding language), perhaps reflecting the redundancy present in language. These observations may mean that for a very long time, our best understanding of language processing may still come from relatively high-level connectionist modeling.

However, the largest anatomical distinction, the hemispheric division of the brain, indisputably has an impact on language processing. Reggia, Goodall, and Shkuro have modeled hemispheric lateralization of phonological processing during development, and Shillcock and Monaghan (2001) have modeled single-word reading based on the observation that the fovea in the human retina is vertically split and projects contralaterally to the two hemispheres.

The issue of anatomical reality is closely connected to attempts to model cognitive impairment by lesioning trained connectionist models. Indeed, a critical part of the validation of models of normal processing has been to study their ability to capture impaired processing. The modeling of dyslexia is the most developed part of this field. Some of the lesions applied to the relevant models may be interpreted anatomically, but the range of possible instantiations of such damage is large. Thus, "impairment to the orthographic representations" could refer to anything from ocular problems to hemispheric desynchronization. Finally, a different approach to anatomical specificity comes from Miikkulainen (1997), who shows how the development and subsequent lesioning of a self-organizing feature map of word meanings can result in the category-specific impairment observed in deep dyslexia, in which particular semantic categories (e.g., furniture, tools, fruit) are disproportionately affected.

## Discussion

Perhaps the most important outcome of this expanding field of research is that testable predictions have been made about normal and impaired language processing in human subjects. The resulting experiments tell us more about the phenomena concerned. Some of the models represent the state-of-the-art theory about their domain, vying with nonconnectionist models for best coverage of the data; other models remain principled existence proofs of the application of soft constraint satisfaction or distributed representations, for instance, to language processing problems. However, the major debates—over top-down feedback, over the capacity of connectionist models to capture the productivity and systematicity of human language, and over the degree of modularity in language processing—have not been settled by this combination of modeling and human experimentation. The terms of the debates may well change before any such resolution is manifest. For instance, much still remains to be understood about the nature of the brain's pervasive recurrent connectivity. In addition, we are becoming aware of the speed with which visual input makes contact with sophisticated stored cortical representations.

The most secure results have arguably come from modeling that possesses psychologically realistic dimensions. Some aspect of the model might be full-scale; for instance, the number of words in a lexical model might be large enough to approach the real ambiguities of word recognition. Or the model might contain the full repertoire of representations found in a particular domain, such as the full range of phonemes. Alternatively, the model might contain a comprehensive range of *types* of representation. For instance, lexical models containing implemented semantic representations are more convincing than those that do not. Plaut and Shallice's (1993) model of deep dyslexia captures seemingly disparate data by virtue of the range of representations it contains: it simulates visual, semantic, and mixed visual/semantic errors, together with category-specific errors and a concreteness effect (see LESIONED NETWORKS AS MODELS OF NEUROPSYCHOLOGICAL DEFICITS). A further dimension of psychological reality involves how the model is tested. For example, in modeling the pronunciation of a written word, the error over the representation of the whole word at the output of the model may be an inappropriate measure of the difficulty of naming that word if pronunciation can commence on the strength of the processing of the first part of the word alone. Finally, models of language processing can be psychologically grounded by extending them to other languages. Individual human languages differ substantially as to where their complexity resides, and lexical, morphological, and syntactic categories may not be closely comparable across languages. Thus, it is possible to apply some of the insights present in connectionist models of the pronunciation of English words to the pronunciation of Chinese characters and words (indeed, Perfetti and Tan discuss a nonimplemented interaction activation model), but the orthographies are so different that only the major themes of the modeling of English pronunciation survive. Nonetheless, such a cross-linguistic perspective can provide valuable insights into the nature of language impairments and into the parameter space within which models of normal processing may exist.

When a model comprehensively covers a domain, the connectionist approach may have more in common with the conventional statistical analysis of that domain. Connectionist modeling may allow the researcher to avoid making certain representational decisions, and lesioning the trained model can be a convenient means of producing a picture of impairment. Nonetheless, the behaviors of such models will typically be relatively opaque, and they are usually most convincingly explained in terms of the statistics of the training regimen, once the researcher knows the relevant statistic to look for. Accordingly, connectionist modeling and the conventional statistical exploration of language corpora may often be complementary: the former demonstrates mechanisms but often cannot be full-scale, and the latter confirms that the training regimen was representative of the language in its fullest extent.

Finally, the relationships between production and perception, and between spoken and written language, are critical areas for further research. The continuing uncertainty about just what representations and processes are shared across these major divides speaks to the difficulties of these issues. It is also testament to the flexibility of the brain in incorporating the daunting cognitive task of reading, a recent cultural innovation, into the brain's older mastery of spoken communication.

In summary, there has been important progress in many areas of connectionist-based research into language processing, and this modeling continues to influence psychological and neuropsychological experimentation and observation.

# Layered Computation in Neural Networks

*Hanspeter A. Mallot*

## Introduction

Layering is a common architectural feature of many neural subsystems, both in vertebrate and in invertebrate brains. It is best studied in the mammalian neocortex but can be found in regions as diverse as the optic tectum, the avian visual wulst, or the cephalopod optic lobe. In a broader sense, layered neural areas with strong vertical connectivity and topographic organization of input and output may be called *cortical* in all these different structures.

Neural layers are characterized by various anatomical and physiological parameters, such as relative abundance of cell classes, soma size, pharmacology, and both intrinsic and interarea connectivity (Braitenberg and Schüz, 1991; see also NEUROANATOMY IN A COMPUTATIONAL PERSPECTIVE). These parameters remain constant within a two-dimensional sheet but vary between sheets. In contrast, the "layers" of artificial neural networks are defined by topology only (block structure of the connectivity matrix), leaving no room for geometrical concepts such as two-dimensional extent. Some important properties of cortical layering are as follows:

1. Both intralayer and interlayer connectivity are largely determined by spatial constraints, such as nearness. In particular, the two-dimensional topology of layers is important.
2. Connections between two neurons can be mediated by multiple synapses located in different layers. If detailed timing is considered, this multiplicity of connections can be functionally significant, owing to differences in propagation time.
3. Layers can be void of nerve cell somata, mediating fiber contacts of neurons whose somata are located elsewhere (e.g., the molecular layer of the neocortex).
4. Feedback connections can occur even within each layer.

This article deals with three aspects of layering: quantitative descriptions of layered or cortical organization, the activation dynamics of network models incorporating this organization, and applications to problems of information processing and computation. Although the concepts are general, examples will repeatedly be drawn from (primate) visual cortex.

## Quantitative Anatomy

### Uniformity and Continuous Models

Given the vast numbers of cells found in layered cortical areas, it seems appropriate to build spatially continuous models (neural "fields") where each point in space corresponds to a neuron (Korn and von Seelen, 1972; Amari, 1977; see also the references in Mallot and Giannakopoulos, 1992). Besides being a good approximation of large neuron numbers, the continuous description allows for a natural modeling of position and distance of neurons. In a continuous model, a "neuron" consists of (1) a point on the sheet at the position of its soma, (2) a cloud or density function of postsynaptic (dendritic) sites specifying the input sensitivity for each point on the sheet, (3) a density function of postsynaptic (axonal) sites, and (4) an appropriate activation function (see the discussion that follows). The usefulness of these model features rests on two assumptions:

- The strength (or likelihood) of a connection between two neurons is proportional to the overlap of their dendritic and axonal clouds and the efficiencies of the presynaptic and postsynaptic sites involved. This assumption is discussed at length by Braitenberg and Schüz (1991), who have termed it "Peters's rule" (see also Peters, 1985:64*ff*).
- Intrinsic connectivity is largely uniform; i.e., the fiber clouds of the neurons are shifted versions of each other.

While space variance (nonuniformity) presents a problem to the sketched continuous approach, some common cases can be dealt with rather easily: e.g., by topographic maps between brain areas and modulations of neuron density within single layers. Topographic mapping can be modeled in terms of piecewise, continuous, point-to-point coordinate transforms. Explicit mathematical functions have been derived from known or assumed distributions of areal magnification by integrating the "mapping-magnification equation" in one or two dimensions (Schwartz, 1980, log $z$; Mallot and Giannakopoulos, 1992). Point-to-point models have also been proposed for columnar input patterns, such as ocular dominance stripes (Mallot, von Seelen, and Giannakopoulos, 1990). An important case of intrinsic space variance is the columnar pattern of cell densities such as the one revealed by the cytochrome oxidase stain. In the continuous model, this can be accounted for by a space-variant density factor.

### Populations, Layers, and Areas

In the continuous approach, the unit of modeling is the neural population, i.e., a set of neurons from the same anatomical class with a space-invariant connectivity pattern. Examples of such populations in the visual system (see VISUAL CORTEX: ANATOMICAL STRUCTURE AND MODELS OF FUNCTION) are the spiny stellate cells in layer 4a, the GABAergic cells in layer 3, the pyramidal cells of layer 6 connecting to the lateral geniculate nucleus, and so on. The neural population is characterized by a number of variables that fall into three groups. *Anatomical variables* include the dendritic and axonal fiber clouds, $\delta(\mathbf{x})$, $\alpha(\mathbf{x})$; cell density, $\rho(\mathbf{x})$; and topographic output maps, $\mathcal{R}(\mathbf{x})$. Physiological variables include a nonlinear compression function, $f(u)$; time delays for the propagation of activity, $T$; synaptic integration time, $\tau$; and gain factors. Activity is described by three *state variables*: input, $s(\mathbf{x}, t)$; potential, $u(\mathbf{x}, t)$; and output, $e(\mathbf{x}, t)$, where $\mathbf{x} \in \mathbb{R}^2$.

When connecting neural populations into networks, it is convenient (although slightly redundant) to keep the two separate state variables for input and output, the somatic activity $e(\mathbf{x}, t)$, and the "synaptic" activities $s(\mathbf{x}, t)$. The idea is that the output of one population is not the immediate input to some other population. Rather, several outputs from different populations are accumulated into one distribution of presynaptic activity, which then feeds into all neural populations with an appropriate dendritic port. We call the support of the presynaptic activity *connection planes*; they are indexed by $l \in \{1, \ldots, L\}$ in Equations 1 and 3 in the next section. Connection planes are reminiscent of the *blackboard* structure in multi-agent computer systems (see MULTIAGENT SYSTEMS) in that they collect activity from several populations without keeping track of the original source of the activity. When in turn a neural population "reads" from the connection plane, it cannot know whose activity it is reacting to; this lack of labeling of the activities is a direct consequence of Peters's rule.

Using the idea of connection planes, we can now give a definition of the terms layer and area. A *layer* is a connection plane together with all neuron populations whose somata are located in that plane. (The number of populations in a layer may be zero, as is the case in the molecular layer of the cortex. There may also be just one population allowing for specific circuitry; in this case, the pooling effect of the connection planes is bypassed and the distinction between layers and populations becomes obsolete.) An *area* is a set of layers connected without topographic maps (other than the identity). That is to say, in the case of modeling a visual system, just one retinotopic map, $\mathcal{R}_i$, is assigned to each visual area $A_i$, which is valid for all its layers. For projections between different areas—e.g., from $A_i$ to $A_j$—a mapping of the form $\mathcal{R}_j \circ \mathcal{R}_i^{-1}$ is required to connect points representing the same retinal location.

## Activation Dynamics

### *Network Equations*

Consider a network of $P$ neural populations (index $p$, state variables $e_p(\mathbf{x}, t)$ and $u_p(\mathbf{x}, t)$) connected via $L$ connection planes (index $l$, state variable $s_l(\mathbf{x}, t)$). The activation dynamics of the resulting network can be formulated in three steps (cf. Figure 1 and Mallot and Giannakopoulos, 1992):

1. Dendritic summation ($s_l \rightarrow u_p$): For each population $p$, inputs from different connection planes $s_l, \ldots, s_L$ are accumulated according to dendritic arborizations, $\delta_{pl}$; delays, $T_l^\delta$, and synaptic integration time, $\tau$:

$$\frac{\partial}{\partial t} u_p(\mathbf{x}, t) = -\frac{u_p(\mathbf{x}, t)}{\tau} + \sum_{l=1}^{L} \int s_l(\mathbf{x}', t - T_l^\delta)\delta_{pl}(\mathbf{x} - \mathbf{x}')d\mathbf{x}' \quad (1)$$

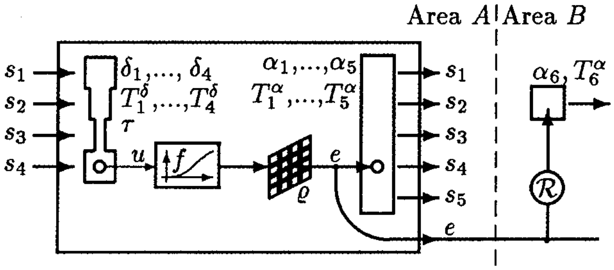

**Figure 1.** Activation transfer function of a neural population modeling dendritic summation, somatic point operations, and axonal spreading of activity. In Equations 1–3 (explained in the text), an additional index $p$ is used to distinguish between different populations.

2. Somatic point operations ($u_p \rightarrow e_p$): The resulting intracellular potential is passed through a nonlinearity $f_p$ and locally weighted with the density of the cell population $\rho_p(\mathbf{x})$. For example, if we consider a cell population in the magnocellular stream, $\rho_p(\mathbf{x})$ reflects the pattern of cytochrome oxidase blobs (see VISUAL CORTEX, ANATOMICAL STRUCTURE AND MODELS OF FUNCTION)

$$e_p(\mathbf{x}, t) = \rho_p(\mathbf{x})f_p(u_p(\mathbf{x}, t)) \quad (2)$$

3. Axonal spread ($e_p \rightarrow s_l$): The resulting excitation is spread over the axonal densities $\alpha_{lp}$ and added to the activity of the connection layer to which the axon projects, again with appropriate delays (propagation times) $T_l^\alpha$. For axons from population $p$ projecting to a connection layer $l$ in another cortical area, a point-to-point mapping $\mathcal{R}_{lp}$ has to be considered.

$$s_l(\mathbf{x}, t) = \sum_{p=1}^{P} \int e_p(\mathbf{x}', t - T_l^\alpha)\alpha_{lp}(\mathbf{x} - \mathcal{R}_{lp}(\mathbf{x}'))d\mathbf{x}' \quad (3)$$

Integro-differential equations of the leaky integrator type, such as the equations just given, have been studied extensively. One important special case is the interaction of two populations—one excitatory and one inhibitory—with all of the space-variant terms in Equations 1–3 omitted (e.g., Amari, 1977; Ermentrout and Cowan, 1979; Chipalkatti and Arbib, 1988; Murray, 1989). The formulation given here allows for space variances, both in the inter-area connections (topographic mapping functions $\mathcal{R}_{lp}$ in Equation 3) and in the cell densities ($\rho_p$ in Equation 2). In addition, cell populations can be multiply connected via different cortical layers so that each path has its own spatiotemporal characteristic (Krone et al., 1986; Mallot et al., 1990; Mallot and Giannakopoulos, 1992).

### *Receptive Fields and Point Images*

When stimulated with an external signal, $s_{\text{ext}}(\mathbf{x}, t)$, the network reacts with a distribution of activity $e(\mathbf{y}, t)$ that corresponds to the neural representation of the stimulus. As an example, let $\mathbf{x}$ denote retinal and $\mathbf{y}$ cortical coordinates. In neurophysiological experiments, the relation between stimulus and excitation is often described by two so-called characteristic functions that can easily be modeled in continuous neural networks:

- The point image, point spread function, or impulse response, $p_{ps}(\mathbf{y}, t)$, is the distribution of activity resulting from stimulation with a spatiotemporal Dirac function, $\delta(\mathbf{x}, t)$, e.g., a briefly flashed spot of light in the visual system. If the system were linear, space invariant, and stationary, responses to arbitrary stimuli could be predicted by superposition of appropriately shifted, delayed, and weighted impulse responses (convolution).

- The receptive field profile $p_{rf}(\mathbf{x}, t)$ of a cortical unit at position $\mathbf{y}$ describes the influence that each input site $\mathbf{x}$ at each instant in time has on the unit in question. In linear, space-invariant, and stationary systems, point spread function and receptive field are identical up to a mirroring in spatial and temporal coordinates (e.g., while $p_{rf}$ "looks backward in time," $p_{ps}$ "looks forward"). In general linear systems, they are the kernels of adjoint operators (Mallot et al., 1990).

Point images and receptive fields are most useful in linear systems, where they completely describe the stimulus-response behavior by way of superposition. In order to interpret neurophysiological measurements of these functions, nonlinear approaches are required. Possible choices are (1) cascades of linear systems with stationary nonlinearities, (2) Wiener-Volterra expansions (usually terminated after order 2), and (3) nonlinear network equations, such as presented earlier in Equations 1–3.

### *Receptive Field Properties*

Figure 2 shows four steps for increasing realism in the modeling of receptive fields. Figure 2*A* illustrates the space- and time-invariant feedforward system, where the spatiotemporal version of linear systems theory can be applied (Korn and von Seelen, 1972). Since the early work on lateral inhibition in the compound eye of the chelicerate *Limulus*, a number of filter functions have been discussed as models of both receptive fields and spatial vision (difference of Gaussians, various derivatives of Gaussians, Gabor functions). Many of these are now used as filters in image processing. In the feedforward case, the spatial and temporal parts of the neural "filter function" are usually considered separable, equivalent to a cascade of two steps, one of which is temporal only and the other of which is spatial only. Simple nonseparability can be introduced by adding several of these cascades (e.g., one for the on-center and another for the off-surround of a retinal ganglion cell; see Dinse, Krüger, and Best, 1990). One important computational application of the resulting spatiotemporal filters is the processing of visual motion (Korn and von Seelen, 1972). Interestingly, many more can be found, if receptive fields specifically responding to other stimulus parameters (orientation, velocity, spectra, etc.) are considered (Adelson and Bergen, 1991; Mallot et al., 1990).

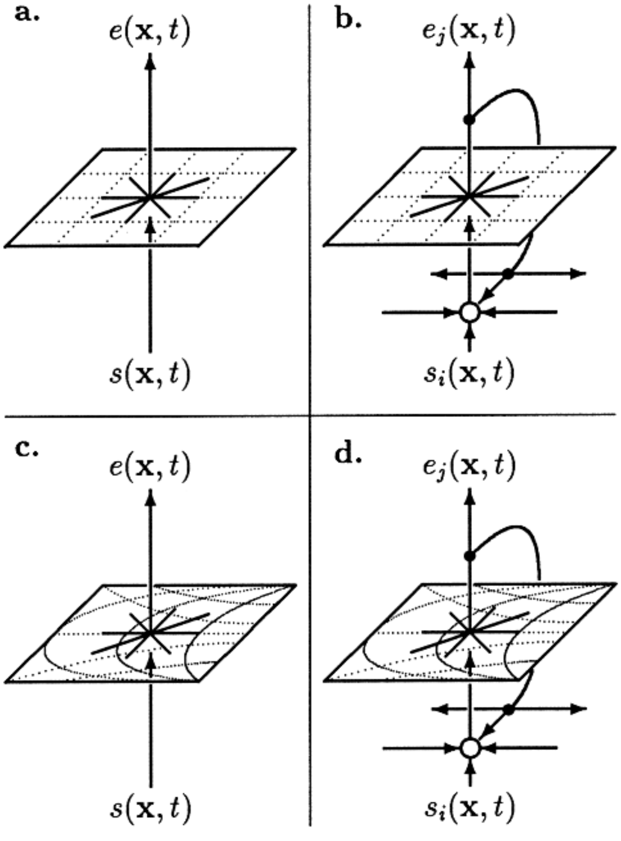

**Figure 2.** Continuous layers as models of receptive fields. *A*, Space-invariant, feedforward (spatiotemporal convolution). *B*, Space-invariant network of continuous layers. *C*, Space-variant, feedforward. *D*, Space-variant network of continuous layers.

Parts *B* and *C* of Figure 2 show simple extensions of the space-invariant feedforward situation. In Figure 2*B*, many layers with feedback connections are considered (Krone et al., 1986). The main effects of this architecture include (1) increased width of receptive fields, since point stimuli can be signaled through the entire network by feedback connections, and (2) full nonseparability of spatial and temporal aspects of the receptive field. The first of these effects has been used by Horn (1974) in the deconvolution step of the "retinex" scheme for recovering lightness from image intensities. This article also introduces the idea of resistive networks for image processing which links the continuous Equations 1–3 to discrete implementations, as well as to diffusion-type equations in which spatial interaction is modeled by partial derivatives rather than by integral kernels.

In Figure 2*C*, the feedforward situation is extended by allowing for space variance by retinotopic mapping (Mallot et al., 1990). The combination of mapping and feedback illustrated in Figure 2*D* has not yet been studied in detail. Its activation dynamics is described by Equations 1–3 cited earlier.

## Information Processing Capabilities of Neural Layers

The filter operations discussed earlier exploit the neighborhood relations in a neural layer. Other features that can be used for computational purposes are nonlinear activation dynamics and neural maps. Some examples include the following:

1. *Lateral cooperativity.* Lateral interactions between neural activities in a layer can have cooperative and/or inhibitory effects, leading to filling-in or related kinds of shaping of the activity pattern (Murray, 1989). One important application of this principle is the solution of the correspondence problem in stereovision by means of cooperative dynamics in a disparity map (for a review, see Blake and Wilson, 1991; see also Chipalkatti and Arbib, 1988, and Stereo Correspondence). Other examples of nonlinear lateral interactions include various winner-take-all or nonmaximum-suppression schemes that are widely used in artificial neural networks.
2. *Topographic mapping.* While the continuity of neural representations is a prerequisite for neighborhood operations, such as filtering, the smooth distortions introduced by topographic mapping can simplify subsequent information processing tasks. Examples include the allocation of cortical neurons to different parts of the visual field (fovea/periphery), and the simplified processing of images with systematic space variances, such as optic flow patterns. The optic flow resulting from translation in a plane can be compensated for by so-called inverse perspective

mapping of the input images. Obstacles in the way of the observer lead to uncompensated changes in the flow field that are easily detected. A review of applications of topographic mapping to image processing problems is given elsewhere (Mallot et al., 1990).

3. *Feature maps and population coding*. While the examples presented so far apply to sensory input, analogous results have been obtained for motor pathways. Here, the distribution of activity on a neural layer has to be interpreted in terms of the "motor fields" of its active neurons. If this is done, the flow of activity in the appropriate motor areas predicts the initiated movements.

## Discussion

The type of cortex model sketched in this article has the advantage of modeling a prominent structural unit of the vertebrate nervous system, the neural layer, on a rather high level. It can easily deal with geometrical features, such as maps, columns, dendritic and axonal arborization patterns, varying cell densities, and the like. This level of modeling is required to understand large-scale activation dynamics of cortical networks as have been made accessible by recently developed imaging techniques. The continuity limit seems appropriate when entire cortical areas are to be represented in a neural network model. On the other hand, it is not very well suited to model properties that differ from one cell to the next. For example, synaptic plasticity is not easily included. It is, therefore, most useful for the modeling of rather short time scales, where plasticity may be excluded, and for systems in steady states.

# Learning and Generalization: Theoretical Bounds

*Ralf Herbrich and Robert C. Williamson*

## Introduction

The fundamental difference between a system that learns and one that merely memorizes is that the learning system *generalizes* to unseen examples. In order to understand the performance of learning machines and to gain insight helpful for designing better ones, it is useful to have theoretical bounds on the generalization ability of the machines. The determination of such bounds is the subject of this article. In order to formulate the bounds it is first necessary to formalize the learning problem and turn the question of how well a machine generalizes into a mathematical question. In the next section we introduce one possible formalization, the one adopted in the field of statistical learning theory.

## Formalization of the Learning Problem

To study the learning problem in a mathematical framework, we assume the existence of an *unknown* distribution $\mathbf{P}_{\mathsf{XY}}$ over an *input space* $\mathcal{X}$ (e.g., $\mathbb{R}^n$) and an *output space* $\mathcal{Y}$ (e.g., $\{0, 1\}$). We are given only a *sample* $\mathbf{z} = ((x_1, y_1), \ldots, (x_m, y_m)) \in (\mathcal{X} \times \mathcal{Y})^m = \mathcal{Z}^m$, which is assumed to be drawn *iid* (independent identically distributed) from $\mathbf{P}_{\mathsf{XY}}$; we define $\mathbf{P}_{\mathsf{Z}} := \mathbf{P}_{\mathsf{XY}}$. (In this article, random variables are always written sans-serif, e.g., $\mathsf{X}$.)

In an attempt to discover the unknown relation $\mathbf{P}_{\mathsf{Y}|\mathsf{X}=x}$ between inputs and outputs, a *learning algorithm* $\mathcal{A}$ chooses a deterministic *hypothesis* $h$*:* $\mathcal{X} \to \mathcal{Y}$ solely on the basis of a given training sample $\mathbf{z} \in \mathcal{Z}^m$. Formally,

$$\mathcal{A} : \bigcup_{i=1}^{\infty} \mathcal{Z}^i \to \mathcal{H},$$

where $\mathcal{H} \subseteq \mathcal{Y}^{\mathcal{X}}$ is the *hypothesis space* used by the algorithm. (Recall that $\mathcal{Y}^{\mathcal{X}}$ denotes the set of maps from $\mathcal{X}$ to $\mathcal{Y}$.) Some of the bounds take account of more information regarding $\mathcal{A}$ than just $\mathcal{H}$.

The performance of the learning algorithm is judged according to a *loss function* $l$: $\mathcal{Y} \times \mathcal{Y} \to \mathbb{R}^+$, which measures the cost of the prediction $\hat{y}$ if $y$ is the correct output. The choice of the loss function is a key part of the formal specification of the learning problem. The *learning problem* is to find an hypothesis, $h : \mathcal{X} \to \mathcal{Y}$, such that the *expected risk,* $R[h] := \mathbf{E}_{\mathsf{XY}}[l(h(\mathsf{X}), \mathsf{Y})]$, is minimized.

*Pattern recognition.* In this case, $|\mathcal{Y}| < \infty$. Typically one is interested in the misclassification error $\mathbf{P}_{\mathsf{XY}}(h(\mathsf{X}) \neq \mathsf{Y})$. This can be modeled by the *zero-one loss,* $l_{0\text{–}1}(\hat{y}, y) := \mathbb{I}_{\hat{y} \neq y}$. (Here $\mathbb{I}$ denotes the indicator function.) More complex loss functions are obtained by using a cost matrix $\mathbf{C} \in \mathbb{R}^{|\mathcal{Y}| \times |\mathcal{Y}|}$.

*Function learning.* Here, $\mathcal{Y} = \mathbb{R}$. The classical regression scenario utilizes squared loss, $l_2(\hat{y}, y) := (\hat{y} - y)^2$. Other loss functions are the $\ell_1$ loss function, $l_1(\hat{y}, y) := |\hat{y} - y|$, and the $\varepsilon$-insensitive loss, $l_\varepsilon(\hat{y}, y) := \max\{|\hat{y} - y|, \varepsilon\} - \varepsilon$.

If we knew $\mathbf{P}_\mathsf{Z}$, the solution of the learning problem would be straightforward:

$$h_{\text{opt}}(x) := \underset{y \in \mathcal{Y}}{\operatorname{argmin}}\ \mathbf{E}_{\mathsf{Y}|\mathsf{X}=x}[l(y, \mathsf{Y})]. \tag{1}$$

The fact that $h_{\text{opt}}$ cannot be identified only on the basis of the training sample $\boldsymbol{z}$ is the motivation for studying *theoretical bounds* on the generalization error of learning algorithms. These bounds are only valid for most random draws of the training sample. Formally, they read as follows:

$$\mathbf{P}_{\mathsf{Z}^m}(R[\mathcal{A}(\mathbf{Z})] \leq \varepsilon_{\mathcal{A}}(\mathbf{Z}, \ldots, \delta)) \geq 1 - \delta. \tag{2}$$

In the analysis of such bounds, it is convenient to think of the loss function induced function class

$$\mathcal{L}_{\mathcal{H}} := \{(x, y) \mapsto l(h(x), y) \mid h \in \mathcal{H}\}.$$

For simplicity, we will mostly consider the pattern recognition case and the zero-one loss; the reasoning in the function learning case is conceptually similar.

## Consistency of Learning Algorithms

Consistency is a property of a learning algorithm that guarantees that in the limit of an infinite amount of data, the learning algorithm will achieve the minimum possible expected risk. The definition is relative to a fixed hypothesis space $\mathcal{H} \subseteq \mathcal{Y}^{\mathcal{X}}$ and requires

$$\forall \varepsilon > 0:\ \lim_{m \to \infty} \mathbf{P}_{\mathsf{Z}^m}(R[\mathcal{A}(\mathbf{Z})] - \inf_{h \in \mathcal{H}} R[h] > \varepsilon) = 0. \tag{3}$$

For the results stated below (Vapnik, 1998), a more complex notion of *nontrivial consistency* is needed. In particular, this notion requires that Equation 3 holds even if $\mathcal{H}$ is replaced by $\mathcal{H}_c := \{h \in \mathcal{H} \mid R[h] \geq c\}$ for all $c \in \mathbb{R}$. Note that in this case, $\inf_{h \in \mathcal{H}_c} R[h] = c$. It is known that for the class of *empirical risk minimization* (*ERM*) *algorithms*

$$\mathcal{A}^{\mathcal{H}}_{\text{ERM}}(\mathbf{z}) := \underset{h \in \mathcal{H}}{\operatorname{argmin}}\ \underbrace{\frac{1}{m} \sum_{i=1}^{m} l(h(x_i), y_i)}_{\hat{R}[h, \boldsymbol{z}] \quad \text{(the empirical risk)}}$$

consistency is equivalent to uniform one-sided convergence of empirical risks to expected risk; that is,

$$\forall \varepsilon > 0:\ \lim_{m \to \infty} \mathbf{P}_{\mathsf{Z}^m}(\sup_{h \in \mathcal{H}} (R[h] - \hat{R}[h, \mathbf{Z}]) > \varepsilon) = 0 \tag{4}$$

A slightly stronger condition than that in Equation 4, namely uniform two-sided convergence, is equivalent to

$$\forall \varepsilon > 0:\ \lim_{m \to \infty} \frac{\ln(\mathbf{E}_{\mathsf{Z}^m}[\mathcal{N}(\varepsilon, \mathcal{L}_{\mathcal{H}}, \mathbf{Z})])}{m} = 0 \tag{5}$$

where $\mathcal{N}(\varepsilon, \mathcal{L}_{\mathcal{H}}, \mathbf{z})$ is the *covering number* of $\mathcal{L}_{\mathcal{H}}$ on the sample $\mathbf{z}$ at scale $\varepsilon$. This is the smallest number of functions $\hat{g}: \mathcal{Z} \to \mathbb{R}$ such that for every induced loss function $g \in \mathcal{L}_{\mathcal{H}}$ there exists a function $\hat{g}$ with

$$\frac{1}{m} \sum_{i=1}^{m} |g(z_i) - \hat{g}(z_i)| \leq \varepsilon.$$

In the case of the zero-one loss, $l_{0\text{–}1}$, the covering number $\mathcal{N}(1/m, \mathcal{L}_{\mathcal{H}}, \mathbf{z})$ equals the number of different error patterns $(g(z_1), \ldots, g(z_m)) \in \{0, 1\}^m$ incurred by induced loss functions $g \in \mathcal{L}_{\mathcal{H}}$.

This *characterization* result (that consistency of $\mathcal{A}^{\mathcal{H}}_{\text{ERM}}$ is "almost" equivalent to Equation 5) is the justification for the central place that covering numbers play in statistical learning theory. It is important to note that the results are only for $\mathcal{A}^{\mathcal{H}}_{\text{ERM}}$. It is still an open problem to characterize consistency for algorithms other than $\mathcal{A}^{\mathcal{H}}_{\text{ERM}}$, and thus it is not known what their "right" technical parameters are.

## Theoretical Bounds for Learning Algorithms

The starting point of all the analysis presented here is the observation that for a *fixed* hypothesis $h: \mathcal{X} \to \mathcal{Y}$ (and induced loss function $g$, $g((x, y)) := l(h(x), y)$), we know that

$$\mathbf{P}_{\mathsf{Z}^m}(R[h] - \hat{R}[h, \mathbf{Z}] > \varepsilon) = \mathbf{P}_{\mathsf{Z}^m}\left(\mathbf{E}_{\mathsf{Z}}[g(\mathsf{Z})] - \frac{1}{m} \sum_{i=1}^{m} g(\mathsf{Z}_i) > \varepsilon\right) < \exp(-c \cdot m\varepsilon^{\beta}) \tag{6}$$

where $c$ is some constant and $\beta \in [1, 2]$, if the loss is bounded or has bounded moments. This is due to well-known results in large deviation theory (see Devroye and Lugosi, 2001, chap. 1).

The second tool is the *union bound,* which states that for events $A$ and $B$,

$$\mathbf{P}(A \cup B) = \mathbf{P}(A) + \mathbf{P}(B) - \mathbf{P}(A \cap B) \leq \mathbf{P}(A) + \mathbf{P}(B)$$

As a consequence, if we consider a hypothesis space of finite size, say $n$, then the chance that for at least one of the hypotheses the expected risk is larger than the empirical risk by more than $\varepsilon$ is of order $n \cdot \exp(-m\varepsilon^{\beta})$. The general application of this simple inequality for learning theory is that given *n high-probability bounds* $\Upsilon_i: \mathcal{Z}^m \times \ldots \times [0, 1] \to \{\text{false}, \text{true}\}$ such that

$$\forall i \in \{1, \ldots, n\}: \forall \delta \in [0, 1]: \quad \mathbf{P}_{\mathsf{Z}^m}(\Upsilon_i(\mathbf{Z}, \ldots, \delta)) \geq 1 - \delta, \tag{7}$$

then

$$\forall \delta \in [0, 1]: \quad \mathbf{P}_{\mathsf{Z}^m}\left(\Upsilon_1\left(\mathbf{Z}, \ldots, \frac{\delta}{n}\right) \wedge \ldots \wedge \Upsilon_n\left(\mathbf{Z}, \ldots, \frac{\delta}{n}\right)\right) \geq 1 - \delta.$$

There are two conceptual simplifications that aid the study of the generalization performance of learning algorithms:

1. *Algorithm independence*: Motivated by Equation 4, consider the uniform convergence and bound this probability. This automatically gives a bound which holds for all hypotheses, including the one learned with a given learning algorithm. Although this is a very crude step, it has largely dominated statistical learning theory for the past 30 years; the whole analysis is independent of the learning algorithm used except via $\mathcal{H}$.
2. *Data independence*: If the training sample is entering the bound only via the empirical risk, we call the analysis *sample independent*, as we are unable to exploit the serendipity of the training sample to obtain a better bound.

### *Algorithm-Independent Bounds*

Algorithm-independent analysis has historically been the most common. Below we examine the Vapnik-Chervonenkis framework, data-dependent structural risk minimization, and the PAC-Bayesian framework.

*The Vapnik-Chervonenkis framework.* The Vapnik-Chervonenkis (VP) framework, established in 1971, studies $\mathcal{A}^{\mathcal{H}}_{\text{ERM}}$ via uniform convergence (see Vapnik, 1998, and Anthony and Bartlett, 1999, for more details). The bounds are sample independent in the sense defined above. The only extra tool required is the *basic lemma.* This result makes precise the idea that whenever it is likely that two empirical risks measured on a training sample and a *ghost sample* (another sample of the same size drawn independently) are close to each other, then it must also be likely that the empirical risk on a training sample is close to the expected risk. A result of this is a generalization bound in terms of $\mathbf{E}_{\mathsf{Z}^{2m}}[\mathcal{N}(1/2m, \mathcal{L}_{\mathcal{H}}, \mathbf{Z})]$, where the $2m$ is a consequence of the basic lemma. However, this is still not really useful, since computing $\mathbf{E}_{\mathsf{Z}^{2m}}[\mathcal{N}(1/2m, \mathcal{L}_{\mathcal{H}}, \mathbf{Z})]$ requires knowledge of the distribution $\mathbf{P}_{\mathsf{Z}}$. For $l_{0\text{–}1}$ loss, use is made of the inequalities

$$\mathbf{E}_{\mathsf{Z}^{2m}}\left[\mathcal{N}\left(\frac{1}{2m}, \mathcal{L}_{\mathcal{H}}, \mathbf{Z}\right)\right] \leq \sup_{z \in \mathcal{X}^{2m}} \mathcal{N}\left(\frac{1}{2m}, \mathcal{L}_{\mathcal{H}}, \mathbf{z}\right) \leq \left(\frac{2em}{d_{\mathcal{H}}}\right)^{d_{\mathcal{H}}},$$

where $d_{\mathcal{H}}$ is known as the *VC-dimension* of $\mathcal{H}$:

$$d_{\mathcal{H}} := \max \left\{ m \in \mathbb{N} \,\middle|\, \sup_{z \in \mathcal{X}^{2m}} \mathcal{N}\left(\frac{1}{2m}, \mathcal{L}_{\mathcal{H}}, \mathbf{z}\right) = 2^m \right\}.$$

The generalization bound for the zero-one loss $l_{0\text{–}1}$ then reads as follows: *With probability at least* $1 - \delta$ *over the random draw of the training sample* $\mathbf{z} \in \mathcal{X}^m$, *for all hypotheses* $h \in \mathcal{H}$, $R[h] \leq \varepsilon_{\mathrm{VC}}(\mathbf{z}, d_{\mathcal{H}}, \delta)$, *where*

$$\varepsilon_{\mathrm{VC}}(\mathbf{z}, d_{\mathcal{H}}, \delta) := \hat{R}[h, \mathbf{z}] + \sqrt{\frac{8}{m}\left(\underbrace{d_{\mathcal{H}} \ln\left(\frac{2em}{d_{\mathcal{H}}}\right)}_{\text{effective complexity}} + \ln\left(\frac{4}{\delta}\right)\right)}. \quad (8)$$

The key term in this bound is labeled the *effective complexity* and in this case is essentially determined by the VC-dimension $d_{\mathcal{H}}$. Note that for general loss functions $l: \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}^+$, similar results are obtained by studying the family $\{(\hat{y}, y) \mapsto \mathbb{I}_{l(\hat{y},y)>\theta} \mid \theta \in \mathbb{R}\}$ of zero-one loss functions.

There are many results bounding the VC-dimension for specific hypothesis spaces (see VAPNIK-CHERVONENKIS DIMENSION OF NEURAL NETWORKS and PAC LEARNING AND NEURAL NETWORKS). Since the result in Equation 8 is uniform, it automatically provides a bound on the generalization error of any algorithm that chooses its hypotheses from some fixed hypothesis space $\mathcal{H}$.

*Data-dependent structural risk minimization.* An application of the union bound allows the combination of several VC bounds for different hypothesis spaces $\mathcal{H}_1 \subseteq \mathcal{H}_2 \subseteq \ldots \subseteq \mathcal{H}_k \subseteq \mathcal{Y}^{\mathcal{X}}$. This is the idea underlying *structural risk minimization* (SRM): using the combination of VC bounds, an SRM algorithm aims to minimize the bound directly. It is thus applicable to regularized risk-minimization learning algorithms. The bound, however, requires that the series of hypothesis spaces be defined *independently* of the training sample. Hence, we cannot directly use the training sample to control the effective complexity (only implicitly via the resulting training error).

We can relax this assumption by introducing an ordering among the hypotheses to be covered for a given sample $\mathbf{z} \in \mathcal{X}^m$. Such a function, $L: \cup_{i=1}^{\infty} \mathcal{X}^i \times \mathcal{H} \to \mathbb{R}$, is called a *luckiness* (see Shawe-Taylor et al., 1998). For each luckiness function it is required that a value measured on the training sample allows one to bound the covering number on the training sample *and* ghost sample of hypotheses that increase the luckiness. This property is called *probable smoothness* with respect to a function $\omega: \mathbb{R} \times \mathbb{N} \times [0, 1] \to \mathbb{N}$.

The main result (which is data dependent in the sense used above) for the zero-one loss $l_{0-1}$ reads as follows: *For all luckiness functions L that are probably smooth with respect to* $\omega$, *with probability at least* $1 - \delta$ *over the random draw of the training sample* $\mathbf{z} \in \mathcal{X}^m$, *for all hypotheses* $h \in \mathcal{H}$ *such that* $\hat{R}[h, \mathbf{z}] = 0$, $R[h] \leq \varepsilon_{\mathrm{DSRM}}(\mathbf{z}, h, \omega, L, \delta)$ *where*

$$\varepsilon_{\mathrm{DSRM}}(\mathbf{z}, h, \omega, L, \delta) := \frac{2}{m} \times \left(\underbrace{\log_2\left(\omega\left(L(h, \mathbf{z}), m, \frac{\delta}{2m}\right)\right)}_{\text{effective complexity}} + \log_2\left(\frac{2m}{\delta}\right)\right). \quad (9)$$

The result can also be stated for non-zero training error and general loss functions shown by Equation 8. Each probably smooth luckiness function defines a data-dependent structuring $\mathcal{H}_1(\mathbf{z}) \subseteq \mathcal{H}_2(\mathbf{z}) \subseteq \ldots \subseteq \mathcal{H}_m(\mathbf{z}) \subseteq \mathcal{H}$ of the hypothesis space $\mathcal{H}$ by

$$\mathcal{H}_i(\mathbf{z}) := \left\{ h \in \mathcal{H} \mid \omega\left(L(h, \mathbf{z}), m, \frac{\delta}{2m}\right) \leq 2^i \right\}.$$

The choice of the luckiness function is not unique; it is best compared to the choice of a prior in a Bayesian analysis (see BAYESIAN METHODS AND NEURAL NETWORKS).

*PAC-Bayesian framework.* The PAC-Bayesian framework (McAllester, 1998) studies only Bayesian learning algorithms. The main ideas are very similar to the luckiness framework. One of the motivations is to capture an important feature of Bayesian confidence intervals—their width depends on the sample itself and not just its size.

A direct application of the union bound with factors different from $1/n$ leads to the following result: *For all measures* $\mathbf{P}_{\mathsf{H}}$ and $\mathbf{P}_{\mathsf{Z}}$, *with probability at least* $1 - \delta$ *over the random draw of the training sample* $\mathbf{z} \in \mathcal{X}^m$, *for all hypotheses* $h \in \mathcal{H}$ *such that* $\mathbf{P}_{\mathsf{H}}(h) > 0$, $R[h] \leq \varepsilon_{\mathrm{PB}}(\mathbf{z}, h, \mathbf{P}_{\mathsf{H}}, \delta)$, *where*

$$\varepsilon_{\mathrm{PB}}(\mathbf{z}, h, \mathbf{P}_{\mathsf{H}}, \delta) := \hat{R}[h, \mathbf{z}] + \sqrt{\frac{1}{2m}\left(\underbrace{\ln\left(\frac{1}{\mathbf{P}_{\mathsf{H}}(h)}\right)}_{\text{effective complexity}} + \ln\left(\frac{1}{\delta}\right)\right)}.$$

If the likelihood function $\mathbf{P}_{\mathsf{Z}|\mathsf{H}=h}((x, y))$ equals $\mathbb{I}_{h(x)=y}$, then the bound maximizer is given by the *maximum a posteriori* estimator $h_{\mathrm{MAP}} := \operatorname{argmax}_{h \in \mathcal{H}} \mathbf{P}_{\mathsf{H}|\mathsf{Z}^m=\mathbf{z}}(h)$.

Using a tool known as the *quantifier reversal lemma,* it is possible to study the *Gibbs classification strategy,* which uses a randomly drawn hypothesis for each new data point to be classified:

$$\mathcal{A}^H_{\mathrm{Gibbs}}(x) := h(x), \quad h \sim \mathbf{P}_{\mathsf{H}|\mathsf{H} \in H}$$

The quantifier reversal lemma is a high-probability equivalent of the union bound: *Given n* high-probability bounds $\Upsilon_i$ (*see Equation 7*) *and any distribution* $\mathbf{P}_{\mathsf{I}}$ *over the numbers* $\{1, \ldots, n\}$,

$$\forall \alpha \in [0, 1]: \forall \delta \in [0, 1]: \\ \mathbf{P}_{\mathsf{Z}^m}(\mathbf{P}_{\mathsf{I}}(\Upsilon_{\mathsf{I}}(\mathbf{Z}, \ldots, \alpha\delta) \geq 1 - \alpha) \geq 1 - \delta.$$

The proof is very simple and makes use of Markov's inequality. Noticing that for all loss functions $l: \mathcal{Y} \times \mathcal{Y} \to [0, 1]$,

$$R[\mathcal{A}^H_{\mathrm{Gibbs}}] = \mathbf{E}_{\mathsf{H}|\mathsf{H} \in H}[R[\mathsf{H}]] \leq c \cdot \mathbf{P}_{\mathsf{H}|\mathsf{H} \in H}(R[\mathsf{H}] \leq c) \\ + 1 \cdot \mathbf{P}_{\mathsf{H}|\mathsf{H} \in H}(R[\mathsf{H}] > c)$$

it is possible to prove the following result: *Given a prior measure* $\mathbf{P}_{\mathsf{H}}$, *with probability at least* $1 - \delta$ *over the random draw of the training sample* $\mathbf{z} \in \mathcal{X}^m$, *for all subsets* $H \subseteq \mathcal{H}$, *the generalization error of the Gibbs classification strategy* $\mathcal{A}^H_{\mathrm{Gibbs}}$ *satisfies*

$$R[\mathcal{A}^H_{\mathrm{Gibbs}}(\mathbf{z})] \leq \mathbf{E}_{\mathsf{H}|\mathsf{H} \in H}[\hat{R}[\mathsf{H}, \mathbf{z}]] \\ + \sqrt{\frac{1}{2m}\left(\underbrace{\ln\left(\frac{1}{\mathbf{P}_{\mathsf{H}}(H)}\right)}_{\text{effective complexity}} + \ln\left(\frac{m^2}{\delta}\right)\right)} + \frac{1}{m}.$$

The effective complexity scales inversely with $\mathbf{P}_{\mathsf{H}}(H)$, which in the case of the likelihood function $\mathbf{P}_{\mathsf{Z}|\mathsf{H}=h}((x, y)) = \mathbb{I}_{h(x)=y}$ and the Bayesian posterior $\mathbf{P}_{\mathsf{H}|\mathsf{Z}^m=\mathbf{z}}$ equals the *evidence* $\mathbf{E}_{\mathsf{H}}[\mathbf{P}_{\mathsf{Z}^m|\mathsf{H}=h}(\mathbf{z})]$ (see Bayesian Methods and Neural Networks). The complexity term is minimized if we choose $H$ such that $\mathbf{P}_{\mathsf{H}}(H) = 1$. However, for a small overall bound value, it is also required that the expected empirical risk $\mathbf{E}_{\mathsf{H}|\mathsf{H}\in H}[\hat{R}[\mathsf{H}, \mathbf{z}]]$ be small. It is worth mentioning that the results are still algorithm independent, since they hold not only for the Bayesian posterior but for all hypotheses $h \in \mathcal{H}$ and all subsets $H \subseteq \mathcal{H}$.

## *Algorithm-Dependent Bounds*

We now summarize three distinct but related approaches to the analysis of learning algorithms that utilize particular properties of the algorithm apart from the space $\mathcal{H}$ it draws its hypotheses from.

*The compression framework.* The compression framework (Floyd and Warmuth, 1995) is based on the idea that a good learning algorithm is able to reconstruct its hypothesis using only a small fraction of the training sample $\mathbf{z}$. It is assumed that the learning algorithm can be written as

$$\mathcal{A}(\mathbf{z}) := \mathcal{R}(\mathbf{z}_{\mathcal{C}(\mathbf{z})}) \tag{10}$$

where $\mathcal{C}\colon \cup_{m=1}^{\infty}\mathcal{Z}^m \to \mathcal{I}$ maps the training sample to indices $\mathbf{i} \in \mathcal{I}$, $\mathcal{I} = \{(i_1, \ldots, i_n) \mid n \in \mathbb{N}, i_1 \neq \ldots \neq i_n\}$, $\mathbf{z}_{\mathbf{i}} := (z_{i_1}, \ldots, z_{i_n})$, and $\mathcal{R}\colon \cup_{m=1}^{\infty}\mathcal{Z}^m \to \mathcal{Y}^{\mathcal{X}}$ computes the final hypothesis using only the subsample indexed by $\mathcal{C}(\mathbf{z})$. A typical example of such an algorithm is the perceptron learning algorithm (see Perceptrons, Adalines, and Backpropagation), which can reconstruct its hypothesis using only the training patterns on which it needed to update the weight vector.

The mathematical tool needed to study this class of learning algorithms is again the union bound:

$$\begin{aligned}
&\mathbf{P}_{\mathsf{Z}^m}(R[\mathcal{A}(\mathbf{Z})] - \hat{R}[\mathcal{A}(\mathbf{Z}), \mathbf{Z}] > \varepsilon) \\
&\quad \leq \mathbf{P}_{\mathsf{Z}^m}(\exists \mathbf{i} \in \mathcal{I}\colon R[\mathcal{R}(\mathbf{Z}_{\mathrm{i}})] - \hat{R}[\mathcal{R}(\mathbf{Z}_{\mathrm{i}}), \mathbf{Z}] > \varepsilon) \\
&\quad\quad \leq \sum_{\mathbf{i}\in\mathcal{I}} \mathbf{P}_{\mathsf{Z}^m}(R[\mathcal{R}(\mathbf{Z}_{\mathrm{i}})] - \hat{R}[\mathcal{R}](\mathbf{Z}_{\mathrm{i}}), \mathbf{Z}] > \varepsilon)
\end{aligned}$$

Interestingly, for any index vector $\mathbf{i}$ the sample $\mathbf{z}\backslash\mathbf{z}_{\mathbf{i}}$ is an iid test sample on which the fixed hypothesis $\mathcal{R}(\mathbf{z}_i)$ is assumed to have a difference in empirical and expected risk of more than $\varepsilon$. Using Equation 6—which holds independent of $\mathbf{i}$—and the fact that there are no more than $\binom{m}{d} \leq (em/d)^d$, $d = |\mathbf{i}|$, many different index sets for a training sample $\mathbf{z}$ of size $m$, leads to the main result of the compression framework: *For the zero-one loss $l_{0-1}$ and any learning algorithm that can be written in the form of Equation 10, with probability at least $1 - \delta$ over the random draw of the training sample $\mathbf{z} \in \mathcal{Z}^m$, $R[\mathcal{A}(\mathbf{z})] \leq \varepsilon_{\mathrm{cr}}(\mathbf{z}, |\mathcal{C}(\mathbf{z})|, \delta)$, where for $d = |\mathcal{C}(\mathbf{z})|$*

$$\begin{aligned}
\varepsilon_{\mathrm{cr}}(\mathbf{z}, d, \delta) := {} & \frac{m}{m-d} \cdot \hat{R}[\mathcal{A}(\mathbf{z}), \mathbf{z}] \\
& + \sqrt{\frac{1}{2m-d}\left(\underbrace{d \ln\left(\frac{em}{d}\right)}_{\text{effective complexity}} + \ln\left(\frac{m^2}{\delta}\right)\right)}.
\end{aligned} \tag{11}$$

A similar result can be stated for general loss functions. Note that this bound is data dependent, since $|\mathcal{C}(\mathbf{z})|$ depends both on the learning algorithm $\mathcal{A}$ and on the training sample $\mathbf{z}$.

The compression framework has its roots in the theory of online learning (Littlestone, 1988). An *on-line learning algorithm* proceeds in trials. In each trial, the algorithm is presented with a training sample $x_i \in \boldsymbol{x}$ and makes a prediction $\hat{y} \in \mathcal{Y}$. It then receives the desired output $y_i \in \boldsymbol{y}$ and incurs a mistake whenever $\hat{y} \neq y_i$. The performance measure of an on-line learning algorithm is the number of mistakes it incurs on a training sample $\mathbf{z}$. If the on-line algorithm is *mistake driven,* that is, if it only updates the hypothesis whenever a mistake is incurred, then any mistake bound is also an upper bound on $|\mathcal{C}(\mathbf{z})|$. This scheme allows the determination of generalization error bounds for on-line learning algorithms applied in batch mode (see, e.g., Cesa-Bianchi et al., 1997).

*The Algorithmic Stability Framework.* In the algorithmic stability framework (Bousquet and Elisseeff, 2001), it is assumed that any additional training example has a limited influence on the function learned insofar as the prediction on any possible test point is concerned. Such algorithms are called *uniformly stable* and have the property that for all $i \in \{1, \ldots, m\}$:

$$\forall \mathbf{z} \in \mathcal{Z}^m : \forall (x, y) \in \mathcal{Z}\colon |l(\mathcal{A}(\mathbf{z})(x), y) - l(\mathcal{A}(\mathbf{z}_{\backslash i})(x), y)| \leq \beta(m),$$

where $\mathbf{z}_{\backslash i} := (z_1, \ldots, z_{i-1}, z_{i+1}, \ldots, z_m)$. The $\beta(\cdot)$-stability of learning algorithms can be determined if the loss function is *Lipschitz continuous* with (Lipschitz) constant $C_l$: the difference $|l(\hat{y}, \cdot) - l(\hat{y}, \cdot)|$ is bounded from above by $C_l \cdot |\hat{y} - \tilde{y}|$. The $\ell_1$ loss $l_1$ and the $\varepsilon$-insensitive loss $l_\varepsilon$ are both Lipschitz continuous with the constant $C_l = 1$.

Given a Lipschitz continuous loss function $l$ and a reproducing kernel Hilbert space $\mathcal{H}$ with kernel $k\colon \mathcal{X} \times \mathcal{X} \to \mathbb{R}$, the class of regularized risk minimization learning algorithms

$$\mathcal{A}_{\mathrm{RRM}}^{\mathcal{H},\lambda} := \operatorname*{argmin}_{h\in\mathcal{H}} (\hat{R}[h, \mathbf{z}] + \lambda\|h\|^2)$$

is $\beta(\cdot)$-stable with $\beta(m) \leq C_l \sup_{x\in\mathcal{X}} k(x, x)/2\lambda m$. Intuitively, the larger $\lambda > 0$, the smaller the influence of the empirical term $\hat{R}[h, \mathbf{z}]$, and hence the more stable the learning algorithm (see also Generalization and Regularization in Nonlinear Learning Systems).

In order to exploit the $\beta(\cdot)$-stability of a learning algorithm, a result from the theory of large deviations of functions of random variables known as *McDiarmid's inequality* is used (Devroye and Lugosi, 2001). This inequality asserts that the probability of a deviation of $\varepsilon$ between the value of a function $f$ of $m$ iid variables and the expected value of that function decays as $\exp(-\varepsilon^2/mc^2)$, where $c$ is the maximal deviation of the function's value when exchanging one variable. In this sense, McDiarmid's inequality is a generalization of Equation 6 for nonpointwise loss functions. Considering the deviation between the expected risk and the empirical risk of the function learned by $\mathcal{A}$ as a function of $m$ iid random variables leads to the following result: *For any $\beta(\cdot)$-stable learning algorithm $\mathcal{A}$ and a bounded loss function $l$: $\mathcal{Y} \times \mathcal{Y} \to [0, 1]$, with probability at least $1 - \delta$ over the random draw of the training sample $\mathbf{z} \in \mathcal{Z}^m$, $R[\mathcal{A}(\mathbf{z})] \leq \varepsilon_{\mathrm{AS}}(\mathbf{z}, \beta, \delta)$, where*

$$\begin{aligned}
\varepsilon_{\mathrm{AS}}(\mathbf{z}, \beta, \delta) := {} & \hat{R}[\mathcal{A}(\mathbf{z}), \mathbf{z}] + 2\beta(m) \\
& + \sqrt{\frac{2(4\beta(m) \cdot m + 1)^2 \ln\left(\frac{1}{\delta}\right)}{m}}.
\end{aligned} \tag{12}$$

There are three interesting observations to make:

1. In order for the result to be nontrivial, it is required that $\beta(m)$ decay faster than $1/m$. This readily tells us the range of $\lambda$ values to consider for $\mathcal{A}_{\mathrm{RRM}}^{\mathcal{H},\lambda}$.
2. The result as stated in Equation 12 is not directly applicable to the zero-one loss $l_{0-1}$, as the difference in the latter cannot decay at a rate of $1/m$ but is fixed to the values $\{0, 1\}$. Noticing that in practice we often use thresholded real-valued functions $h(\cdot) = \operatorname{sign}(f(\cdot))$ for classification, it is possible to overcome this limitation by bounding the zero-one loss function from above. In particular, if $\mathcal{Y} = \{-1, +1\}$ then

$$l_{\text{margin}}(f(x), y) := \min(\max(0, 1 - yf(x)), 1) \geq l_{0-1}(f(x), y) := \mathbb{I}_{yf(x)\leq 0},$$

that is, any upper bound on the expected risk $\mathbf{E}_{\mathsf{XY}}[l_{\text{margin}}(f(\mathsf{X}), \mathsf{Y})]$ is by definition an upper bound on $R[h]$ for the zero-one loss $l_{0-1}$ and the associated binary classification function $h$.

3. The result is data independent, as the stability $\beta(m)$ needs to be known before the training sample arrives. Recent developments in this area aim to overcome this problem by the notion of a stability measured on the given training sample.

*The algorithmic luckiness framework.* Finally, we present a recently developed algorithm-dependent framework (Herbrich and Williamson, 2002) that builds on ideas of the data-dependent structural risk-minimization framework. The key observation is that the basic lemma is true not only when one considers the maximum deviation between the expected and empirical risk, it is also true for the deviation between the expected and empirical risk of the *one* function learned using a fixed learning algorithm $\mathscr{A}$. As a consequence, for any double sample $\mathbf{zz}' \in \mathscr{Z}^{2m}$ (training sample $z$ and ghost sample $\mathbf{z}'$), one need only consider the set $\mathscr{H} \subseteq \mathscr{Y}^{\mathscr{X}}$ of functions that can be learned by a fixed learning algorithm $\mathscr{A}$ from any subsample of size $m$. If the learning algorithm under consideration is permutation-invariant, then this set cannot be larger than $|H| \leq 2^{2m}$, regardless of the loss function considered.

The notion of *luckiness* changes in that it now maps a given learning algorithm $\mathscr{A}$ and a given training sample $\mathbf{z}$ to a real value, which effectively measures the extent to which the given data align with an encoded prior belief. In accordance with the data-dependent structural risk-minimization framework, it is required that the measured value of the luckiness on a random training sample $\mathbf{z}$ can be used to upper bound the number of subsets of a double sample that will lead to an increase in the luckiness value. This rather technical condition is known as $\omega$-smallness and is best compared to the probable smoothness of luckiness functions earlier. Using the union bound together with the refined basic lemma leads to the following generalization error bound for all loss function $l$: $\mathscr{Y} \times \mathscr{Y} \rightarrow [0, 1]$: *For all algorithmic luckiness functions L which are ω-small, with probability at least* $1 - \delta$ *over the random draw of the training sample* $\mathbf{z} \in \mathscr{Z}^m$, $R[\mathscr{A}(\mathbf{z})] \leq \varepsilon_{\text{AL}}(\mathbf{z}, \mathscr{A}, \omega, L, \delta)$

$$\varepsilon_{\text{AL}}(\mathbf{z}, \mathscr{A}, \omega, L, \delta) := \hat{R}[\mathscr{A}(\mathbf{z}), \mathbf{z}] + \sqrt{\frac{8}{m}\left(\underbrace{\log_2\left(\omega\left(L(\mathscr{A}, \mathbf{z}), \frac{\delta}{2m}\right)\right)}_{\text{effective complexity}} + \log_2\left(\frac{2m}{\delta}\right)\right)}.$$

The main difference from Equation 9 is in the definition of the luckiness function. In contrast to Equation 9, we can now exploit properties of the learning algorithm in the definition of the $\omega$-smallness. As an easy example, consider the luckiness function $L_0(\mathscr{A}, \mathbf{z}) := -|\mathscr{C}(\mathbf{z})|$ for algorithms of the form given by Equation 10. Then, given a value $d = -L_0(\mathscr{A}, \mathbf{z})$ of the luckiness function on any training sample, there cannot be more than $\binom{2m}{d}$ distinct subsets of the training sample and ghost sample, which shows that $\omega(L_0, m, \delta) = \binom{2m}{-L_0}$ is a valid $\omega$ function. Note that this example removes the factor $m/(m - d)$ in front of the empirical term in Equation 11 at the cost $2m$ rather than $m$ in the complexity term $d$ ln $(2em/d)$.

## Discussion

Our presentation of the theory of learning and generalization is nonstandard, since we sought to present many, seemingly different approaches. For standard presentations with more details, see Devroye, Györfi, and Lugosi (1996), Vapnik (1998), Anthony and Bartlett (1999), Herbrich (2002), and Schölkopf and Smola (2002). A fairly comprehensive overview is given in Kulkarni, Lugosi, and Venkatesh (1998). In this article, we have assumed that the genuine interest is in bounds on the generalization error (see Equation 2). It is worth mentioning that another way to quantify generalization behavior of learning algorithms is in terms of bounds on the leave-one-out error (for further details, see Devroye et al., 1996).

Although we would like to use theoretical bounds directly for model selection and model validation, it currently seems that the potential value of these results is to provide insight into the design of learning algorithms. For example, the question of consistency says that covering numbers are the "right" quantities to look at for ERM algorithms.

For other algorithms the situation is less clear, although there are now several variants on classical VC analysis methods that use the same formal learning problem setup. The various bounds we presented ($\varepsilon_{\text{VC}}(\mathbf{z}, d_{\mathscr{H}}, \delta)$, $\varepsilon_{\text{DSRM}}(\mathbf{z}, h, \omega\, L, \delta)$, $\varepsilon_{\text{PB}}(\mathbf{z}, h, \mathbf{P}_{\mathsf{H}}, \delta)$, $\varepsilon_{\text{cr}}(\mathbf{z}, |\mathscr{C}(\mathbf{z})|, \delta)$, $\varepsilon_{\text{AS}}(\mathbf{z}, \beta, \delta)$, $\varepsilon_{\text{AL}}(\mathbf{z}, \mathscr{A}, \omega, L, \delta)$) were in terms of a range of parameters; we still do not really know what the "right" ones are. Recent work (Mendelson, 2001) has shown the power of alternative geometric approaches to develop certain classes of generalization bounds. We expect that these and other approaches will lead to deeper understanding of the generalization ability of learning machines.

# Learning and Statistical Inference

*Shun-ichi Amari*

## Introduction

Neural networks, real or artificial, have an ability to learn from examples. Learning takes place under stochastic fluctuations, because learning from examples in neural networks is of a stochastic nature in the sense that examples are randomly generated and a network's behavior is intrinsically fluctuating owing to noise. Statistical estimation identifies the mechanism underlying stochastic phenomena and has a long tradition and history of research. Promising approaches to the study of learning problems from the statistical point of view include such concepts as the Fisher information measure, Bayesian loss, and sequential estimation. Information geometry (Amari and Nagaoka, 2000) affords a more advanced approach connecting statistics and neural networks (see Neuromanifolds and Information Geometry).

Nonlinear neurodynamics, learning, and self-organization, among others, are key concepts leading to new developments in statistical science. Consequently, many statisticians have recently become interested in neural network technology (see, e.g., Bishop, 1995; Ripley, 1996). The present article reviews various aspects of neural learning from the statistical point of view.

## Neural Networks and Statistical Models

We first describe stochastic behaviors of single neurons, and then those of networks. A mathematical neuron receives a number of input signals $\{x_1, \ldots, x_n\}$, summarized in an input vector $\mathbf{x} = (x_0, x_1, \ldots, x_n)$, and emits an output $z$. Here, $x_0 = 1$ is added to set the bias or the threshold term. The neuron calculates the weighted sum of inputs

$$u = \mathbf{w} \cdot \mathbf{x} = \sum w_i x_i \tag{1}$$

where $w_i$ are the synaptic efficacies or connection weights. The output $z$ is determined stochastically, depending on $u$. When $z$ takes analogue values, representing the firing rate of a neuron, it is given by a sigmoidal nonlinear function $f(u)$ of $u$, disturbed by additive noise,

$$z = f(u) + n \tag{2}$$

Since the noise $n$ is random, let $r(n)$ be its probability density function. The expectation of $n$ is assumed to be zero. When input $\mathbf{x}$ is applied, $z$ is determined stochastically, and its conditional probability density is given by

$$p(z|\mathbf{x}) = r\{z - f(\mathbf{w} \cdot \mathbf{x})\}$$

The expectation of $z$ is

$$E[z|\mathbf{x}] = \int zp(z|\mathbf{x})dz = f(\mathbf{w} \cdot \mathbf{x}) \tag{3}$$

where $E[z|\mathbf{x}]$ denotes the coditional expectation of $z$ under the condition that the input is $\mathbf{x}$ (White, 1989). That is, the output $z$ is fluctuating around $f(\mathbf{w} \cdot \mathbf{x})$.

In the binary neuron model, $z$ takes on the binary values 0 and 1, representing nonfiring and firing of a neuron, respectively. A widely used stochastic neuron model is specified by the following probability:

$$p(z|\mathbf{x}) = \frac{\exp\{\beta z \mathbf{w} \cdot \mathbf{x}\}}{1 + \exp\{\beta \mathbf{w} \cdot \mathbf{x}\}}, \quad z = 0, 1 \tag{4}$$

Here, $\beta > 0$ is a constant, and, when $\beta$ is large, the probability of firing ($z = 1$) is very large for $\mathbf{w} \cdot \mathbf{x} > 0$. When $\beta$ is small, the probability of firing is almost fifty-fifty, that is, randomness dominates. For this reason, $\beta$ is called the "inverse temperature," in analogy with statistical physics. In this case,

$$E[z|\mathbf{x}] = f(\mathbf{w} \cdot \mathbf{x})$$

with the sigmoidal function

$$f(u) = \frac{\exp\{\beta u\}}{1 + \exp\{\beta u\}}$$

A multilayer perceptron is a neural network with feedforward connections (see Perceptrons, Adalines, and Backpropagation). It consists of input neurons, hidden neurons, and output neurons. It receives an input $\mathbf{x}$ from the input neurons and emits an output vector signal $\mathbf{z} = (z_1, \ldots, z_m)$ from the $m$ output neurons. Even when the hidden neurons behave deterministically, noise is added to the output neurons. Hence, the behavior of a network is stochastic and represented by the conditional probability distribution $p(\mathbf{z}|\mathbf{x})$. Since the network includes a large number of modifiable parameters (synaptic efficacies and thresholds of component neurons), we summarize all of them in a vector $\mathbf{w} = (w_1, \ldots, w_k)$. The conditional probability is expressed in the form $p(\mathbf{z}|\mathbf{x}; \mathbf{w})$, showing that it depends on the parameters $\mathbf{w}$. The conditional expectation of $\mathbf{z}$ is represented by $\mathbf{f}(\mathbf{x}, \mathbf{w}) = E[\mathbf{z}|\mathbf{x}; \mathbf{w}]$.

Let $(\mathbf{x}_t, \mathbf{z}_t)$, $t = 1, \ldots, T$, be observed examples of input-output pairs. Learning as well as statistical estimation is carried out based on the training set

$$D_T = \{(\mathbf{x}_1, \mathbf{z}_1), \ldots, (x_T, \mathbf{z}_T)\} \tag{5}$$

to identify the true $\mathbf{w}$ from which the data are generated. In many cases, $\mathbf{x}_t$ are generated independently, subject to an unknown probability distribution $q(\mathbf{x})$, and $\mathbf{z}_t$ is the desired output provided from the "teacher," which has the true parameter $\mathbf{w}$. In the case of self-organization or unsupervised learning, the desired outputs $\mathbf{z}_t$ are missing, so that $D_T$ consists of only $\mathbf{x}_t$s. Statistical estimation uses all the data $D_T$ to estimate the true parameter, whereas on-line learning assumes that data come in one by one. The current candidate for $\hat{\mathbf{w}}$ is modified by a new input-output pair when it arrives. The old data are discarded and are not used again. Hence, on-line learning is a procedure to modify the network parameters $\mathbf{w}$ sequentially, based on the series of training data $D_T$, such that the trained network performs sufficiently well to simulate the true network from which the training data are obtained.

Different from on-line learning, batch learning uses all the data $D_T$, modifies the current estimate $\hat{\mathbf{w}}$, and repeats the procedure until it converges. Hence, batch learning is an interactive estimation procedure.

## Information Measures

Data $(\mathbf{x}_t, z_t)$ include information to identify the probability distribution $p(\mathbf{z}|\mathbf{x}; \mathbf{w})$ or its parameters $\mathbf{w}$. How can one measure it? R. A. Fisher argued this problem, and proposed the Fisher information measure, which is defined soon. This is different from the Shannon information measure, which measures uncertainty by using the entropy of random variables. However, there are certain connections between them. We briefly summarize these information measures and their relations.

Let $p(x, \mathbf{w})$ be the probability density function of a random variable $x$ parameterized by $\mathbf{w}$. In the case of neural networks, $x$ represents a pair $(x, \mathbf{z})$. The family $M = \{p(x, \mathbf{w})\}$ is called a statistical model. Let $x_1, \ldots, x_T$ be $T$ independent observations, and let $\hat{\mathbf{w}}$ be an estimator of the true $\mathbf{w}$. How much information is included in the training data concerning $\mathbf{w}$? The Fisher information matrix $G = (g_{ij})$ represents such information. It is defined in component form by

$$g_{ij}(\mathbf{w}) = E\left[\frac{\partial}{\partial w_i}\log p(x, \mathbf{w})\,\frac{\partial}{\partial w_j}\log p(x, \mathbf{w})\right] \tag{6}$$

where $E$ denotes the expectation with respect to $p(x, \mathbf{w})$. In vector matrix notation, this can be rewritten as

$$G(\mathbf{w}) = E[\nabla \log p(x, \mathbf{w})\nabla \log p(x, \mathbf{w})^T] \tag{7}$$

where $\nabla f(\mathbf{w})$ is the gradient (columm) vector of $f$

$$\nabla f = \left[\frac{\partial f}{\partial w_1}, \ldots, \frac{\partial f}{\partial w_n}\right]^T \tag{8}$$

$T$ denoting transposition.

When we measure the accuracy of an estimator $\hat{\mathbf{w}}$ by its error covariance matrix $V = (v_{ij})$,

$$v_{ij} = E[(\hat{w}_i - w_i)(\hat{w}_j - w_j)] \tag{9}$$

the Crámer-Rao theorem shows that

$$V \geq \frac{1}{T}G^{-1} \tag{10}$$

implying that the error covariance matrix is at best as small as the inverse of the Fisher information measure divided by the number $T$ of observations. One of the most popular estimates is the maximum likelihood estimator $\hat{\mathbf{w}}_{mle}$, which maximizes the likelihood $p(x_1, \mathbf{w}) \ldots p(x_T, \mathbf{w})$, that is, the probability of obtaining the observed data $x_1, \ldots, x_T$ when the underlying distribution is $p(x, \mathbf{w})$. This estimate attains the bound asymptotically, that is, $V \approx G^{-1}/T$ for large $T$. When $G$ is large, the error $V = G^{-1}/T$ is small, so it is natural to regard $G$ as the measure of information. This topic is covered in standard textbooks (e.g., Cox and Hinkley, 1974).

Another important quantity is the divergence measure between two probability distributions $p(x)$ and $q(x)$. How different are they? The Kullback-Leibler divergence, or the relative entropy, defined by

$$KL(p\|q) = \int p(x)\log\frac{p(x)}{q(x)}\,dx \tag{11}$$

is a frequently used measure in statistics and information theory (Cover and Thomas, 1991). It is related to both Shannon and Fisher information measures, as follows. Let $p_{XY}(x, y)$ be the joint probability of $X$ and $Y$, and let $p_X(x)$ and $p_Y(y)$ be their marginal distributions. Then the mutual information between $X$ and $Y$, defined by Shannon, is

$$I(X : Y) = KL\{p_{XY}(x, y)\|p_X(x)p_Y(y)\} \tag{12}$$

When $\mathbf{w}$ and $\mathbf{w} + d\mathbf{w}$ are infinitesimally close, the divergence between $p(x, \mathbf{w})$ and $p(x, \mathbf{w} + d\mathbf{w})$ is given by

$$KL(p(x, \mathbf{w})\|p(x, \mathbf{w} + d\mathbf{w})) = \frac{1}{2}\sum g_{ij}(\mathbf{w})dw_i dw_j \tag{13}$$

so that the $KL$ divergence is measured locally by the quadratic form of the Fisher information measure.

The behavior of a parameterized network is given by the conditional probability $p(\mathbf{z}|\mathbf{x};\, \mathbf{w})$. When $\mathbf{x}$ is generated subject to $q(\mathbf{x})$, the input-output joint distribution is $p(\mathbf{x}, \mathbf{z};\, \mathbf{w}) = q(\mathbf{x})p(\mathbf{z}|\mathbf{x};\, \mathbf{w})$. Consider the set $M = \{p(\mathbf{x}, \mathbf{z};\, \mathbf{w})\}$ of all such probability distributions related to neural networks specified by parameter $\mathbf{w}$. This is identified with the space of parameters $\mathbf{w}$.

Given data $D_T$, the maximum likelihood estimator $\hat{\mathbf{w}}_{mle}$ is the one that maximizes the likelihood of the data, $P(D_T;\, \mathbf{w}) = \Pi p(\mathbf{x}_t, \mathbf{z}_t;\, \mathbf{w})$ or its logarithm

$$\log P(D_T;\, \mathbf{w}) = \sum \log q(\mathbf{x}_t) + \sum \log p(\mathbf{z}_t|\mathbf{x}_t;\, \mathbf{w})$$

The $\hat{\mathbf{w}}_{mle}$ is a consistent estimator in the sense that $\hat{\mathbf{w}}_{mle}$ converges to the true parameter $\mathbf{w}_0$ from which the training data are derived, or its optimal approximation in $M$. More precisely, $\hat{\mathbf{w}}_{mle}$ is asymptotically normally distributed with mean $\mathbf{w}_0$ and covariance matrix $G^{-1}/T$ (Cox and Hinkley, 1974), where $G$ is the Fisher information matrix, defined in this case by

$$G = E[\nabla \log p(\mathbf{z}|\mathbf{x}, \mathbf{w})\{\nabla \log p(\mathbf{z}|\mathbf{x}, \mathbf{w})\}^T] \tag{14}$$

As $T$ becomes large, the error term $G^{-1}/T$ converges to 0.

Since the Fisher information matrix plays a fundamental role in the accuracy of estimation and learning, some examples are shown here. In the first case, the output $\mathbf{z}$ is a noise-contaminated version of $\mathbf{f}(\mathbf{x};\, \mathbf{w})$, which is the output of a multilayer perceptron with analogue activation function:

$$\mathbf{z} = \mathbf{f}(\mathbf{x};\, \mathbf{w}) + \mathbf{n}$$

where $\mathbf{n}$ is Gaussian noise with mean 0 and covariance matrix $\sigma^2 I$, $I$ being the identity matrix. From the statistical viewpoint, this is the nonlinear regression problem of observed data $D_T$ to the nonlinear model $f(\mathbf{x}, \mathbf{w})$. By simple calculations, the Fisher information matrix is given by

$$G = \frac{1}{\sigma^2}E[\nabla\mathbf{f}(\mathbf{x};\, \mathbf{w})\{\nabla\mathbf{f}(\mathbf{x};\, \mathbf{w})\}^T] \tag{15}$$

where the expectation is taken over the distribution $q(\mathbf{x})$. This shows that the Fisher information tends to infinity, and the estimation error tends to 0, as the noise term $\sigma^2$ becomes 0.

In the case of binary neurons given by Equation 4, the Fisher information is calculated as

$$G = \frac{2\beta e^{\beta f}}{1 + e^{\beta f}}\nabla\nabla f + \frac{\beta^2 e^{\beta f}}{(1 + e^{\beta f})^2}\nabla f(\nabla f)^T \tag{16}$$

It should also be noted that $G$ tends to $\infty$ as the temperature term $\beta^{-1}$ tends to 0.

## Stochastic Descent On-Line Learning and the Bayesian Standpoint

The aim of learning is not to estimate $\mathbf{w}$ but to obtain a network with good information-processing performance. The Bayesian standpoint (Berger, 1985) assumes that we have prior knowledge concerning the probability of $\mathbf{w}$ to be estimated. After observing data, it is modified to the posterior distribution of $\mathbf{w}$. It also suggests using the notion of a risk or loss function that is to be minimized through learning.

Let $l(\mathbf{x}, \mathbf{z}, \mathbf{w})$ be a loss when an input signal $\mathbf{x}$ is processed by a network of parameter $\mathbf{w}$, where $\mathbf{z}$ is the desired output given by the teacher. A simplest example is the squared error,

$$l(\mathbf{x}, \mathbf{z};\, \mathbf{w}) = \tfrac{1}{2}\,|\mathbf{z} - \mathbf{z}(\mathbf{x}, \mathbf{w})|^2 \tag{17}$$

where $\mathbf{z}(\mathbf{x}, \mathbf{w})$ is the output from the network specified by $\mathbf{w}$. In the case when $\mathbf{z}(\mathbf{x}, \mathbf{w})$ is given by

$$\mathbf{z}(\mathbf{x}, \mathbf{w}) = \mathbf{f}(\mathbf{x}, \mathbf{w}) + \mathbf{n} \tag{18}$$

where $\mathbf{n}$ is a Gausian noise subject to $N(0, I)$, this $l(\mathbf{x}, \mathbf{z}; \mathbf{w})$ coincides with the negative of the log likelihood $l(\mathbf{x}, \mathbf{z}, \mathbf{w}) = -\log p(\mathbf{x}, \mathbf{z}; \mathbf{w})$ except for a constant term $-\log q(\mathbf{x})$ not depending on $\mathbf{w}$. Hence, minimizing the loss is equivalent to maximizing the likelihood in this case.

Sometimes, a function $F(\mathbf{w})$ of $\mathbf{w}$ is added to the loss in order to penalize a complex network. The function $F(\mathbf{w})$, called the regularization term, takes a large value when the network with parameter $\mathbf{w}$ is complex (Poggio, Torre, and Koch, 1985). One typical example is

$$F(\mathbf{w}) = \sum w_i^2$$

which penalizes large $w_i$. Another one is

$$F(\mathbf{w}) = \sum \frac{w_i^2}{1 + w_i^2} \tag{19}$$

which penalizes the number of nonzero $w_i$s when $w_i$ are large.

The risk function $R(\mathbf{w})$ is the expected loss

$$R(\mathbf{w}) = E[l(\mathbf{x}, \mathbf{z}; \mathbf{w})] \tag{20}$$

where expectation is taken with respect to the distribution given by the teacher. When the teacher generates $\mathbf{z}$ by using the network with parameter $\mathbf{w}_0$, the distribution of $(\mathbf{x}, \mathbf{z})$ is $q(\mathbf{x})p(\mathbf{z}|\mathbf{x}; \mathbf{w}_0)$. The function $R(\mathbf{w})$ is called the generalization error, since the behavior of the network specified by $\mathbf{w}$ is evaluated by the expectation with respect to a new example $(\mathbf{x}, \mathbf{z})$ subject to the same distribution. The best network is supposed to be the one that minimizes $R(\mathbf{w})$.

However, we do not know the risk function $R(\mathbf{w})$, since the true $\mathbf{w}_0$ which is used in Equation 20 for taking expectation is unknown. Instead, we have a training set $D_T$ generated from the true distribution. This gives us the empirical risk function

$$R_{\text{train}}(\mathbf{w}) = \frac{1}{T}\sum_{t=1}^{T} l(\mathbf{x}_t, \mathbf{y}_t; \mathbf{w}) \tag{21}$$

which is an estimate of $R(\mathbf{w})$ by using the training data themselves. It is called the training error, and it converges to $R(\mathbf{w})$ as $T$ tends to infinity.

The penalty term may be derived from the Bayesian standpoint. Assume that we have prior knowledge of $\mathbf{w}$ such that $\mathbf{w}$ is subject to a prior distribution $p_{pr}(\mathbf{w})$. Then, the joint probability of $(\mathbf{x}, \mathbf{z}, \mathbf{w})$ is given by

$$p_{pr}(\mathbf{w})q(\mathbf{x})p(\mathbf{z}|\mathbf{x}, \mathbf{w}) \tag{22}$$

Therefore, the joint probability of data $D_T$ and the parameter $\mathbf{w}$ is

$$p_{pr}(\mathbf{w}) \prod p(\mathbf{x}_t, \mathbf{z}_t; \mathbf{w}) \tag{23}$$

When data $D_T$ are obtained, the posterior probability of $\mathbf{w}$ is

$$p_{\text{post}}(\mathbf{w}|D_T) = \frac{p_{pr}(\mathbf{w})P(D_T|\mathbf{w})}{P(D_T)} \tag{24}$$

A good candidate for $\mathbf{w}$ suggested by data $D_T$ is the maximum posterior estimate that maximizes $p_{\text{post}}(\mathbf{w}|D_T)$. This reduces to the maximum likelihood estimator when $p_{pr}(\mathbf{w})$ is uniform. Minimizing $-\log p_{\text{post}}(\mathbf{w}|D_T)$ is equivalent to minimizing

$$R_{\text{train}} = \frac{1}{T}\sum r(\mathbf{x}_t, \mathbf{z}_t; \mathbf{w}) \tag{25}$$

where

$$l(\mathbf{x}, \mathbf{z}; \mathbf{w}) = -\log p(\mathbf{x}, \mathbf{z}, \mathbf{w}) - \frac{1}{T}\log p_{pr}(\mathbf{w}_t) \tag{26}$$

In this case, the penalty term is given by $-(1/T)\log p_{pr}(\mathbf{w})$.

Learning is a procedure to estimate the optimal $\mathbf{w}$ based on a given data set $D_t$. Batch learning uses all the stored data $D_T$ repeatedly. The batch gradient learning method modifies the current estimate $\mathbf{w}_t$ at time $t$ into $\mathbf{w}_{t+1} = \mathbf{w}_t + \Delta\mathbf{w}_t$ by

$$\Delta\mathbf{w}_t = -\eta_t \nabla R_{\text{train}}(\mathbf{w}_t) \tag{27}$$

Here, $\nabla R_{\text{train}}$ is the gradient vector of $R_{\text{train}}$ whose components are $(\partial/\partial w_i)R_{\text{train}}(\mathbf{w})$, and $\eta_t$ is a learning rate. This is called the *gradient descent method*, because $\mathbf{w}_t$ is modified in the direction of the gradient of $R_{\text{train}}$. For an adequate sequence $\eta_t$, $\mathbf{w}_t$ converges to the minimizer of $R_{\text{train}}(\mathbf{w})$. Hence, when $l$ is the negative log likelihood, $\mathbf{w}_t$ converges to the maximum likelihood estimator.

On-line learning, on the other hand, cannot use all the data $D_T$ at once. Instead, one input-output training pair $(\mathbf{x}_t, \mathbf{z}_t)$ becomes available at time $t$. The current estimator $\mathbf{w}_t$ is updated to $\mathbf{w}_{t+1}$ by using this. The data $(\mathbf{x}_t, \mathbf{z}_t)$ are then discarded so that they cannot be used again. On-line learning provides a simple learning rule, and its behavior is flexible even when the behavior of the teacher is changing.

The stochastic descent on-line learning procedure updates $\mathbf{w}_t$ by

$$\Delta\mathbf{w}_t = -\eta_t \nabla l(\mathbf{x}_t, \mathbf{z}_t; \mathbf{w}_t) \tag{28}$$

This simple stochastic descent learning was proposed by Amari (1967) and was later called the *generalized delta rule* (Rumelhart, Hinton, and Williams, 1986). When it is applied to the multilayer perceptron, the calculation of $\nabla l$ is performed through error propagation in the backward direction. This is a nice interpretation (Rumelhart et al., 1986), and the algorithm is called the *error backpropagation method* (see BACKPROPAGATION: GENERAL PRINCIPLES).

For a deterministic neural network without stochastic fluctuations, the squared error (Equation 17) is not related to the negative log probability. This corresponds to the case with $\sigma^2 \to 0$. However, the gradient descent learning algorithm does not directly include $\sigma^2$. This method was proposed in the deterministic case, and its relation to statistics became clear only later (White, 1989).

The backpropagation learning method has been widely used and is one of the standard engineering tools. However, it is not free from a number of flaws. It is not Fisher efficient; that is, the estimation error of $\mathbf{w}_t$ does not satisfy the Cramér-Rao bound, which the maximum likelihood estimator does. There exist a large number of local minima in $R_{\text{train}}$ so that $\mathbf{w}_t$ converges to one of the local minima, which might be different from the global minima. Further, its convergence has been found very slow because of "plateaus."

It is known that the error decreases quickly in the beginning of learning, but its rate of decrease becomes extremely slow. After surprisingly many steps, the error again decreases rapidly. This is understood as showing that $\mathbf{w}_t$ is trapped in a plateau. A *plateau* is a critical point of $R_{\text{train}}(\mathbf{w})$, but it is not a local minimum. However, it takes a long time for learning to escape from it. The statistical physical method makes clear that plateaus exist because of the "symmetry" existing in the hidden units in the multilayer perceptron (Saad and Solla, 1995).

Various acceleration methods for the backpropagation learning rule have been proposed, but they cannot eliminate plateaus. The natural gradient method (Amari, 1998), based on the Riemannian structure of a neuromanifold, not only eliminates plateaus but is Fisher efficient, as will be shown in the next section.

We should mention that this type of learning is applicable to any parameterized family $p(\mathbf{z}|\mathbf{x}, \mathbf{w})$ of stochastic behaviors as well as to deterministic behaviors. The idea is also used in the self-organization scheme, where there are no desired outputs $\mathbf{z}_{\text{true}}$ but the network modifies its structure depending only on the input data $D_T = \{\mathbf{x}_1, \ldots, \mathbf{x}_T\}$. For example, if the loss function is put equal to

$$l(\mathbf{x}, \mathbf{w}) = a|\mathbf{w}|^2 - \tfrac{1}{2}|\mathbf{w} \cdot \mathbf{x}|^2 \tag{29}$$

for a single neuron, the connection weight vector **w** of the neuron converges to the principal eigenvector of the correlation matrix

$$V = \int q(\mathbf{x})\mathbf{x}\mathbf{x}^T d\mathbf{x} \tag{30}$$

of the input signals, if $|\mathbf{w}|$ is normalized. This fact was pointed out in more general perspectives on neural learning by Amari (1977) and studied in detail by Oja (1982) (see PRINCIPAL COMPONENT ANALYSIS).

Another example of self-organization is Kohonen's learning vector quantizer (see LEARNING VECTOR QUANTIZATION). Let us consider a set of $k$ neurons whose connection weights are $\mathbf{w}_1, \ldots, \mathbf{w}_k$. The neurons receive a common input **x** and calculate the distance $|\mathbf{w}_i - \mathbf{x}|$. The neuron whose weight $\mathbf{w}_i$ is closest to **x** is called the winner, and its output is assigned $z_k = 1$, while all the other $z_j = 0$. This is called the *winner-take-all rule*. Let us put

$$l(\mathbf{x}, \mathbf{w}) = \tfrac{1}{2} \min_i |\mathbf{w}_i - \mathbf{x}|^2$$

where $\mathbf{w} = (\mathbf{w}_1, \ldots, \mathbf{w}_k)$. Then the risk is given by

$$R(\mathbf{w}) = \tfrac{1}{2} \int \min_i |\mathbf{w}_i - \mathbf{x}|^2 q(\mathbf{x}) d\mathbf{x} \tag{31}$$

The learning rule (Equation 28) in this cases leads to the Kohonen learning vector quantizer.

## Natural Gradient Learning

The natural (Riemannian) gradient learning method based on the Fisher information matrix was proposed by Amari (1998) to eliminate plateau phenomena and to accelerate convergence. The gradient $-\nabla l(\mathbf{w})$ is usually believed to be the steepest descent direction of a scalar function $l(\mathbf{w})$. However, in a parameter space $M$ of multilayer perceptrons, it is natural to define

$$\tilde{\nabla} r(\mathbf{w}) = G^{-1}(\mathbf{w})\nabla r(\mathbf{w}) \tag{32}$$

Here, $G^{-1}$ is the inverse of the Fisher information matrix $G = (g_{ij})$. This is called the natural gradient.

The natural gradient learning algorithm was proposed as the steepest descent method in a Riemannian space where $G$ is the metric,

$$\Delta\mathbf{w}_t = -\eta_t G^{-1}(\mathbf{w}_t)\nabla l(\mathbf{x}_t, \mathbf{z}_t; \mathbf{w}_t) \tag{33}$$

It has two remarkable properties. First, it avoids plateaus, so that it has an optimal dynamic rate of convergence. Second, the accuracy of estimator $\mathbf{w}_t$ by the natural gradient is Fisher efficient when $\eta_t = 1/t$, that is, it has the same asymptotic property as the best batch estimator. The natural gradient method is also successfully applied to INDEPENDENT COMPONENT ANALYSIS (q.v.). The natural gradient method does not eliminate local minima. There are a number of techniques to overcome this problem (see NEUROMANIFOLDS AND INFORMATION GEOMETRY).

## Learning Curves and Generalization Errors

A learning curve shows how quickly a learning network improves its behavior evaluated by the generalization error. This is related to the dynamical behavior of neural learning and the complexity of neural networks. We analyze this important problem in this section.

The stochastic approximation guarantees that $\hat{\mathbf{w}}_t$ converges to the optimal parameter $\mathbf{w}_0$ with probability 1, when the learning constant $\eta_t$ tends to 0 in an adequate speed. However, when $\eta_t$ is too small, learning becomes ineffective. What learning is for, in many cases, is to adjust the network parameters in a changing environment. In this case, $\eta_t$ should be kept at least to a small constant $\varepsilon$. When $\eta_t$ is put equal to a small constant $\varepsilon$, the dynamical behavior of $\hat{\mathbf{w}}_t$ is studied in an old paper (Amari, 1967), where the stochastic descent learning rule was proposed for the multilayer perceptron from the Bayesian standpoint.

Let us analyze the accuracy of estimator $\mathbf{w}_t$ obtained by Equation 28. We assume the case that the initial value $\mathbf{w}_1$ is in a neighborhood of the (local) optimal value $\mathbf{w}_0$ such that it converges to $\mathbf{w}_0$. Let us define two matrices, the Hessian and the covariance of the gradient of $l$,

$$A = E[\nabla\nabla l(\mathbf{w}_0)] \tag{34}$$

$$B = E[\nabla l(\nabla l)^T] \tag{35}$$

The expected value of $\hat{\mathbf{w}}_t$ converges to $\mathbf{w}_0$ exponentially, and the covariance of the error $\hat{\mathbf{w}}_t - \mathbf{w}_0$ also converges exponentially to $\varepsilon V$, where $V$ is a matrix obtained from $A$ and $B$ (Amari, 1967). The dynamical behavior of $\mathbf{w}_t$ was also studied when the environment, that is, the optimal $\mathbf{w}_0$, is periodically changing over time slowly.

Since the behavior of the net is evaluated by $R(\hat{\mathbf{w}}_t)$, but not directly by $\hat{\mathbf{w}}_t$, it is important to know how fast $R(\hat{\mathbf{w}}_t)$ approaches its optimum value. Here, $R(\hat{\mathbf{w}}_t)$ is the expectation of the loss $l(\mathbf{x}, \mathbf{z}; \hat{\mathbf{w}}_t)$ with respect to a new example pair $(\mathbf{x}, \mathbf{z})$. This is the generalization error, which evaluates the behavior of the net by a new example $(\mathbf{x}, \mathbf{z})$ that is not included in the training set $D_T$. This is different from the training error in Equation 25, which is an evaluation of $\hat{\mathbf{w}}_t$ based on the training data $D_T$. We can calculate the latter, but it is difficult to know the generalization error $R(\hat{\mathbf{w}}_T)$ because we do not know the function $R(\mathbf{w})$ itself. If we know the relation between $R_{\text{train}}$ and $R$, we can then evaluate $R$ through $R_{\text{train}}$.

A standard technique of asymptotic statistical inference (Cox and Hinkley, 1974) can be applied to this problem. Let us fix the training data $D_t$, and let $\hat{\mathbf{w}}_t$ now be the best estimator obtained therefrom, where $t$ is assumed to be a large number. It maximizes $R_{\text{train}}$, so that it satisfies

$$0 = \nabla R_{\text{train}}(\hat{\mathbf{w}}_t)$$

On the other hand, the optimal $\mathbf{w}_0$ satisfies $\nabla R(\mathbf{w}_0) = 0$. From this we have, by mathematical analysis,

$$E[R(\hat{\mathbf{w}}_t)] = R(\mathbf{w}_0) + \frac{1}{2t}\operatorname{tr}(B^{-1}A) \tag{36}$$

Mathematical analysis also gives

$$E[R_{\text{train}}(\hat{\mathbf{w}}_t)] = R(\mathbf{w}_0) - \frac{1}{2t}\operatorname{tr}(B^{-1}A) \tag{37}$$

The relation between the training error and generalization error $E[R(\hat{\mathbf{w}}_t)]$ is given from Equations 36 and 37 by

$$E[R(\hat{\mathbf{w}}_t)] = E[R_{\text{train}}(\hat{\mathbf{w}}_t)] + \frac{1}{t}\operatorname{tr}(B^{-1}A)$$

The term $\operatorname{tr}(B^{-1}A)$ shows the difference between the training error and the generalization error. When this term is large, $R_{\text{train}}$ is much smaller than $R$ because of overfitting. That is, the estimated network fits too much to the observed examples, but it fails to capture the mechanism generating the examples. If a complex network is used, the observed data $D_t$ are easily overfitted. Therefore, this term represents the penalty due to the use of a complex network. This is a generalization of the Akaike information criterion, which is widely used in statistical inference. When the loss is the negative log likelihood and the model includes the true one, both $A$ and $B$ are equal to the Fisher information matrix, so that we have an evaluation of complexity by the number of modifiable parameters, $\mathrm{tr}(B^{-1}A) = \mathrm{tr}(I) =$ the number of modifiable parameters. This is the result first obtained by Akaike for selecting a reasonable model. This is universal in the sense that the complexity (overfitting factor) depends only on the number of parameters, independently of the architecture of the network. Universal properties of this type are more or less known in various situations concerning learning machines (Amari and Murata, 1993). One more remarkable fact is the $t^{-1}$ convergence of the learning error in learning curves. As the number $t$ of training examples increases, the generalization decreases in proportion to $1/t$. This was first remarked on by T. Cover in his doctoral thesis in 1964. This result is proved in Amari and Murata in a general situation. Learning attracts researchers from algorithmic, information-theoretic, and physics points of view because of its general and flexible ability for information processing related to the human ability.

## Discussion

We have focused on neural network learning from the viewpoint of statistical inference. Learning is a sequential estimation from the statistical point of view. The accuracy of learning was shown in terms of the Fisher information measure. We are interested in the dynamical behaviors of a learning network under a general loss criterion. The natural gradient learning algorithm was introduced in this respect. The behavior of learning curves was shown, and the complexity of a neural network was introduced to elucidate the discrepancy between the training and generalization errors.

# Learning Network Topology

*Chuck P. Lam and David G. Stork*

## Introduction

To create a neural network, a designer typically fixes a network topology and uses training data to tune its parameters such as connection weights. The designer, however, often does not have enough knowledge to specify the ideal topology. It is thus desirable to learn the topology from training data as well.

Traditional learning can be viewed as a search in the space of parameters. This article looks at topology learning as a search in the space of topologies. In particular, we define in general terms a measure that quantifies the "goodness" of a topology and some search strategies over the space of topologies to find the best one. This framework is applied to learning the topologies of the two forms of networks that have found use in pattern recognition, feedforward neural networks, and BAYESIAN NETWORKS (q.v.).

## Objectives of Learning

Learning is the automated process of modifying a system to improve its performance on its given task. When learning is restricted to modifying a network's weights, performance is generally measured as just the network's ability to model a set of input samples. However, this performance measure alone is problematic when one can choose arbitrary topologies, since a large enough network can model a given data set arbitratily well, leading to overfitting. Therefore, for topology learning, a bias is added to prefer smaller models. It is often found that this bias produces a network that has better generalization and is more interpretable.

A principled approach to topology selection is to find the most probable topology $T$ given training data $D$ (Cheeseman, 1990). Applying Bayes's rule, one is thus searching for the topology that maximizes $p(T|D) \propto p(T)p(D|T)$. Here $p(T)$ is a *prior* probability that expresses one's belief about the probabilities of various topologies to be a "good" topology. One can express one's *bias* for smaller topologies through $p(T)$. Viewed another way, $p(T)$ allows one to impose a *penalty* on larger topologies. Next, $p(D|T)$ is interpreted as how well a topology models the data, and this measure generally has a higher maximum as $T$ gets bigger and more complex. Most topology learning algorithms follow this framework at least in spirit, somehow incorporating the trade-off between a topology's fit to data, measured as the output error, and the desirability of that topology, measured as some penalty term. This framework expresses a simple, explicit trade-off between how well a model predicts the data and our belief in the goodness of that model. As we shall see subsequently, learning the topology of Bayes nets often follow this framework explicitly (Buntine, 1996).

Using a measure that takes into account a topology's fit to data and one's preference for smaller networks, one can search for the topology with the highest value. Except for certain unique cases, a greedy search is used over this topology space. For feedforward neural networks there are two dominant approaches to this searching, growing, and pruning (Figure 1). In *growing*, a small network is created initially, and nodes are added through learning. The search space is constrained by the particular method and its way of adding nodes. In some cases the search space is limited to the set of neural networks with a single hidden layer. Conversely, *pruning* starts with a sufficiently large network specified by the designer and proceeds to eliminate "unimportant" weights or nodes. The search space is thus limited to pruned versions of the initial network. In Bayesian networks, all the nodes of the network are given and set, and one searches for a topology by adding or deleting links.

## Growing

In network growing, nodes are added and the network is retrained iteratively until it reaches satisfactory performance. Adding nodes to a network can always improve the network's fit to the training data. The penalty/bias to prevent overly large networks can be expressed as a stopping criterion. One stops adding nodes once the network has satisfactory performance or when adding more nodes does not improve performance further.

### *Cascade-Correlation Learning Architecture*

Fahlman and Lebiere (1990) developed a growing algorithm that searches in the topology space of *cascade architectures*. A cascade architecture is a special type of feedforward neural network in which each hidden layer has only one unit and each layer gets input from all the nodes in all the input and hidden layers before it. Thus each output node is connected to all the input nodes and all the hidden nodes of the network (see the top left of Figure 1).

In this algorithm, the network is frozen before the addition of each node. A pool of candidate nodes is trained to predict the current residual error. The best of the candidates is then connected to the network's output nodes, thereby reducing the residual error. The rest of the candidates are discarded. This is repeated until the network's error rate is satisfactory. Conceptually, this is like a Taylor approximation, in which early nodes express lower-order terms while later nodes are like higher-order terms that add to making a finer approximation.

### *Dynamic Node Creation*

Ash (1989) introduced the dynamic node creation (DNC) method for adding hidden nodes to a three-layer feedforward neural network. The algorithm starts with a network with only one hidden node. The given network is then trained normally to reduce its average squared error $E$. A new hidden node is added whenever learning has slowed down. Specifically, the algorithm adds a node when the reduction in error in the previous $T$ epochs is less than some threshold $\Delta$ set by the designer, given that no nodes were added during those $T$ epochs. The algorithm stops when another user-defined criterion (e.g., average or maximum output error) is met.

A major difference between cascade-correlation learning and DNC is that cascade-correlation learning freezes the network before the addition of each node. Ash (1989) argued in favor of DNC, claiming that since all weights are continuously adjusted as each node is added, a more complete search is done in the lower-dimensional weight space. For this reason, DNC can often find smaller acceptable networks than can cascade correlation. On the other hand, Fahlman and Lebiere (1990) believe that a significant amount of time in weight learning is due to the weights trying to adjust to each other. Freezing the network before each node addition enables the weights to learn in a stable context and focuses the learning effort on reducing the output error. Therefore, overall training should be faster.

## Pruning

Pruning entails removing weights or nodes from a trained network. When growing a network, one knows that adding nodes will always decrease a network's training error. Conversely, pruning nearly always increases a network's training error. A good pruning algorithm should thus start with a fairly large network with low training error, and should prune the weights or nodes whose removal will

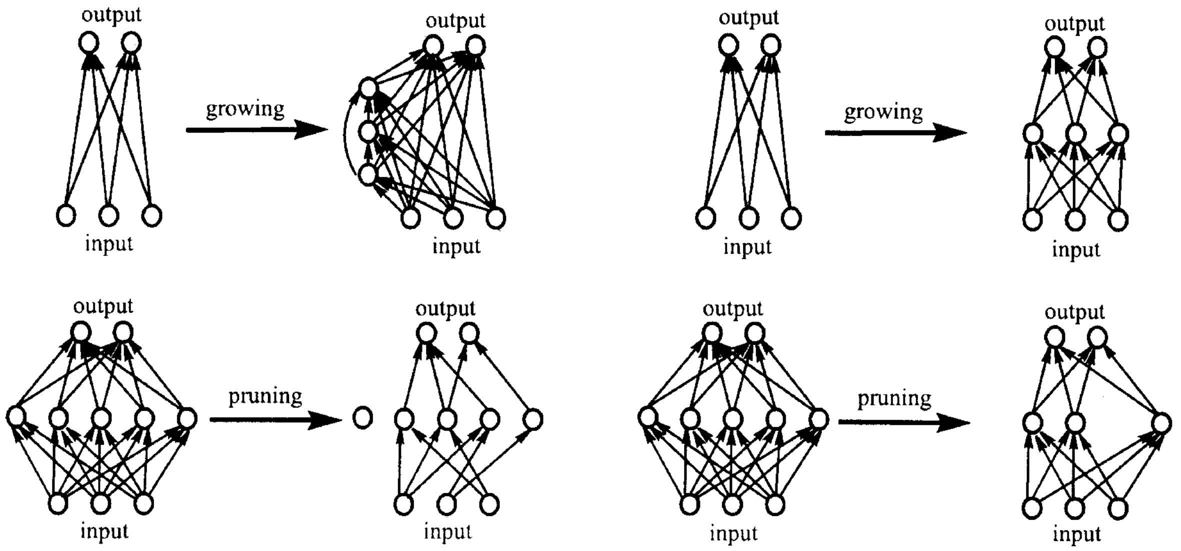

**Figure 1.** The figure shows network growing and pruning. At the top left, hidden nodes are added in a cascade topology. At the top right, hidden nodes are added in a three-layer topology. At the bottom right, nodes are pruned from a network. At the bottom left, individual weights are pruned. Note that if all weights are eliminated from a node, then that node has been effectively pruned from the network.

increase a network's training error the least (Reed, 1993). After such removal one may elect to retrain the network for better performance. Some pruning methods were designed to remove individual weights, while others remove entire nodes. Pruning all of a node's input weights or all of its output weights is equivalent to pruning the node itself.

Various researchers have developed approximations to a weight or a node's *saliency*, which is defined as the increase in training error from that weight/node's removal. Those algorithms then proceed to prune weights/nodes with low saliency. Other researchers have worked under the magnitude-based pruning paradigm. In this approach, weight-learning algorithms (generally backpropagation) are modified such that the magnitude of weights (or some other parameters) are trained to become good indicators of saliency. After such training, low-magnitude weights are then pruned.

### Magnitude-based Pruning

A weight with zero magnitude can be pruned without any effect on the network. This leads to the intuitive notion that weights with small magnitude can be pruned away without affecting training error too much. This simple version of *magnitude-based pruning* often does not work, however. Consider a neuron working in the linear region of its input-output function. The same function can be expressed either as a neuron with small input weights and large output weights, or as a neuron with medium input weights and medium output weights. The magnitude of each individual weight alone does not necessarily tell one about its saliency.

However, many researchers have added bias terms to the network error in weight-learning algorithms to penalize "complex" networks (Chauvin, 1989; Hanson and Pratt, 1989; Ji, Snapp, and Saltis, 1990). These biases are designed to favor networks in which magnitude-based pruning makes sense. The topological bias is thus embedded in the weight-learning algorithm.

Ji et al. (1990) proposed a penalty term to reduce the number of hidden units and the magnitude of weights. Their effect was to impose a smoothness constraint on the network's input-output function. Chauvin (1989) proposed a penalty term to reduce the sum of "energy" from all the hidden nodes, in which "energy" is some positive monotonic function of the square of a node's output. Examples of energy function include $o^2$, $\log(1 + o^2)$, and $o^2/(1 + o^2)$, where $o$ is the output of a node. Hanson and Pratt (1989) proposed a penalty term that is the sum of biases from all units. They specifically examined the hyperbolic bias, $w_i/(1 + \lambda w_i)$, and the exponential bias, $1 - e^{-\lambda w_i}$ (where $\lambda$ is an adjustable parameter and $w_i = \Sigma_j \|w_{ij}\|$). Kruschke and Movellan (1991) proposed a penalty term that eliminates hidden nodes that are functionally redundant, as when the correlation between their input weights is high. Some authors (Hanson and Pratt, 1989; Ji et al., 1990) have noted that the addition of a penalty term significantly slows learning.

### Skeletonization

Mozer and Smolensky (1989) developed skeletonization, a technique that prunes one node at a time. They introduce an *attentional strength* $\alpha_j$ for each node $j$. The output of node $i$ is then

$$o_i = f\left(\sum_j \alpha_j w_{ij} o_j\right)$$

If $\alpha_j = 1$, then node $j$ is just a conventional node. If $\alpha_j = 0$, then node $j$ is considered pruned. The saliency of a node is then just the difference between the network's output error when $\alpha_j$ is 1 and when $\alpha_j$ is 0. They note that this saliency is an approximation to the derivative of the output error function with respect to $\alpha_j$,

$$E_{\alpha_j=0} - E_{\alpha_j=1} \approx -\left.\frac{\partial E}{\partial \alpha_j}\right|_{\alpha_j=1}$$

Conversely, they use the derivative to approximate saliency for pruning. The approximation can be computed with a backpropagation-like algorithm. In practice, $\partial E/\partial \alpha$ fluctuates strongly in time, and the saliency estimate is smoothed by exponentially decay time averaging. Mozer and Smolensky also use a linear error function in assessing saliency while using the traditional squared error for training.

When tested over a set of logic problems, skeletonization showed that it could correctly identify the salient input and hidden nodes. The skeleton network can also learn with comparable or fewer number of training epochs than a standard network (Mozer and Smolensky, 1989).

### Optimal Brain Damage and Optimal Brain Surgeon

The effect of a weight change on output error, which we have defined before as saliency, can be approximated by a Taylor-series expansion,

$$\delta E = \left(\frac{\partial E}{\partial \mathbf{w}}\right)^T \cdot \delta\mathbf{w} + {}^1\!/\!_2\, \delta\mathbf{w}^T \cdot \mathbf{H} \cdot \delta\mathbf{w} + O(\|\delta\mathbf{w}\|^3)$$

where $\mathbf{H} \equiv \partial^2 E/\partial \mathbf{w}^2$ is the Hessian matrix, $\delta\mathbf{w}$ is a small candidate weight change, and the superscript $T$ denotes vector transpose. When the network is trained to a local optimum on the error surface, the first term on the right-hand side becomes zero. In the quadratic approximation, cubic and higher-order terms are ignored. One is left with just the second term and can then solve for $\delta\mathbf{w}$ such that (at least) one of the weights become zero in $\mathbf{w} + \delta\mathbf{w}$ yet the predicted increase in error, ${}^1\!/\!_2\delta\mathbf{w}^T \cdot \mathbf{H} \cdot \delta\mathbf{w}$, is minimum. In addition to finding the weight whose removal increases error the least, this approach also finds an adjustment for the remaining weights to compensate for the weight removal.

The full algorithm follows:

1. Train a "reasonably large" network to minimum error.
2. Compute $\mathbf{H}^{-1}$. Optimal Brain Damage (OBD) (Le Cun, Denker, and Solla, 1990) assumes $\mathbf{H}$ to be diagonal, which has a simple inverse. Optimal Brain Surgeon (OBS) (Hassibi and Stork, 1993) gives an efficient recursive algorithm to calculate the inverse of the full Hessian.
3. Find the candidate weight (indexed by $j$) that gives the smallest saliency

   $$L_j = \frac{w_j^2}{2[\mathbf{H}^{-1}]_{jj}}$$

   If this candidate error increase is greater than a user-specified threshold, go to step 5.
4. Delete the candidate weight. Update the remaining weights by

   $$\delta\mathbf{w} = -\frac{w_j}{[\mathbf{H}^{-1}]_{jj}} \mathbf{H}^{-1} \cdot \mathbf{u}_j$$

   where $\mathbf{u}_j$ is the unit vector corresponding to $j$, the index of the weight that was deleted. Go back to step 2.
5. No more weights can be deleted without a large increase in network error. At this point one may want to retrain the network.

OBS is more effective than OBD at finding the correct weights to prune and is suitable for small and medium-size networks. For large networks, however, the computational and storage requirement for deriving the full $\mathbf{H}^{-1}$ may be infeasible, and OBD should be used instead.

## Topology Learning in Bayes Nets

Topology learning in Bayes nets has become a significant research area (Buntine, 1996). Since the usage of Bayes nets can be quite different from that of feedforward neural networks, topology learning for Bayes nets operates under a different set of assumptions.

Typically, each node in a Bayes net stands for a random variable that has some specific meaning in the real world. Adding or deleting a node in a Bayes net changes the semantics of the underlying domain, and neither growing nor pruning nodes is therefore done in Bayes nets. Furthermore, the direction of the links in a feedforward neural network denotes information flow and is predetermined (i.e., going from input layer to the hidden layers to the output layer), whereas the direction of links in a Bayes net establishes parent-child relationships to imply certain conditional independencies.

As with neural nets, topology learning in Bayes nets relies on a trade-off between network complexity and accuracy in modeling training data. In Bayes net topology learning, this trade-off is often expressed explicitly in a single metric. One of the more popular metrics is minimum description length (MDL) (Lam and Bacchus, 1994). Heckerman, Geiger, and Chickering (1995) derived another metric, BDe, from methods of Bayesian statistics. The MDL metric is simply the sum of a network's complexity and its accuracy in modeling data, while the BDe is a measure of prior belief plus data. These two metrics converge asymptotically as more data are given (under certain technical assumptions).

As expected, searching over the topology space to optimize a metric is computationally expensive. One usually has to resort to greedy searches. Fortunately, both metrics mentioned above are decomposable into a sum of scores for each node. That is, for nodes labeled $X_1, \ldots, X_n$, the metric for the network can be written as $\Sigma_i\ Score(X_i, Parents(X_i))$. When an arc is added or deleted, i.e., when a parent is added or deleted, the action affects only one term in the summation. The overall metric can thus be quickly recalculated for each step of the search.

## Discussion

This article has highlighted two main issues in topology learning. One is the trade-off between network complexity and fit to data, the other is the selection of a search strategy over the topology space. Growing is a search strategy that adds nodes, while pruning deletes parameters or nodes. In learning Bayesian networks, any efficient greedy search strategy can be used. In practice, when a "good" topology is highly problem dependent and the practitioner has little guideline on how to select a "good" topology, it makes sense to learn it from available data.

# Learning Vector Quantization

*Teuvo K. Kohonen*

## Introduction

Neural network models are often applied to statistical pattern recognition problems, in which the class distributions of pattern vectors usually overlap and one must pay attention to the optimal location of the decision borders. The *learning vector quantization* (*LVQ*) algorithms discussed in this article define very good approximations for the optimal decision borders. These algorithms are computationally very light.

In the basic competitive learning neural networks to which the LVQ belongs, all cells may be thought to form an input layer, while there also exist mutual feedbacks or other types of lateral interaction between the cells. All cells receive the same external input, and by means of comparisons made in the lateral direction of the layer, an active response is switched on at the cell with the highest activation (the "winner"), while the responses of all the other cells are suppressed; this is called the *winner-take-all* (*WTA*) *function* (cf. Didday, 1970, 1976; Grossberg, 1976; Amari and Arbib, 1977).

Although many competitive learning neural networks have been based on nonlinear dynamic neural models, the decision or classification functions that ensue from their collective behavior are simply described by a formalism that was originally developed for signal analysis, namely, *vector quantization* (*VQ*). (For a general review of VQ, see Makhoul, Roucos, and Gish, 1985.) Thus, VQ and the neural network models of competitive learning are not alternative methods: the former is an idealized description of the latter on the signal-space level.

## Vector Quantization

As in simple neural network models, we assume a signal vector $x = (\xi_1, \xi_2, \ldots, \xi_n) \in \mathbb{R}^n$ and a set of units or cells, each provided with a parametric vector (called *codebook vector*) $m_i = (\mu_{i1}, \mu_{i2}, \ldots, \mu_{in})^T \in \mathbb{R}^n$. The winner in the category of VQ problems is usually defined as the unit $c$ whose codebook vector has the smallest Euclidean distance from $x$:

$$\|x - m_c\| = \min_i \{\|x - m_i\|\} \tag{1}$$

If $x$ is a natural, stochastic, continuous-valued vectorial variable, we need not consider multiple minima: the probability for $\|x - m_i\| = \|x - m_j\|$ for $i \neq j$ is then zero.

The VQ methods were originally developed to compress information. The $m_i$ had to be placed into the input signal space such that the average expected quantization error $E$ was minimized:

$$E = \int \|x - m_{c(x, m_i, \ldots, m_k)}\|^2 p(x) dx = \text{min!} \tag{2}$$

where $p(x)$ is the probability density function of $x$, and $dx$ is a hypervolume differential in the signal space. Notice that $c$, the index of the winner, depends on $x$ and all the $m_i$. It has been shown by Zador (1982), for example, that the point density of the $m_i$ values that minimize $E$ is proportional to $[p(x)]^{n/(n+2)}$. Since in practical problems usually $n \gg 2$, it can then be said that the distribution of the $m_i$ approximates $p(x)$.

## Optimal Decision

Assume that all samples of $x$ are derived from a finite set of classes $\{S_k\}$, the distributions of which are allowed to overlap. The problem of optimal decision or statistical pattern recognition is usually discussed within the framework of the Bayes theory of probability (for a textbook account, see, e.g., Kohonen, 1989, chap. 7.2). Let $P(S_k)$ be the a priori probability of class $S_k$, and $p(x|x \in S_k)$ be the conditional probability density function of $x$ on $S_k$, respectively. In this method the so-called *discriminant functions* are defined as

$$\delta_k(x) = p(x|x \in S_k)P(S_k) \tag{3}$$

It can be shown that the average rate of misclassifications is minimized if the sample $x$ is determined to belong to class $S_c$ according to

$$\delta_c(x) = \max_k \{\delta_k(x)\} \tag{4}$$

## Learning Vector Quantization Algorithms

### *The LVQ1*

Consider now Figure 1. In the LVQ approaches we assign *a subset of codebook vectors to each class* $S_k$ and then search for the codebook vector $m_i$ that has the smallest Euclidean distance from $x$. This assignment can be made in such a way that codebook vectors belonging to different classes are not intermingled, although the class distributions overlap. The sample $x$ is then thought to belong to the same class as the closest $m_i$. As only codebook vectors closest to the class borders define the decision borders, a good approximation of $p(x|x \in S_k)$ is not necessary everywhere. We must place the $m_i$ into the signal space in such a way that the nearest-neighbor rule (Equation 1) minimizes the average expected misclassification probability. Notice that in considering the average expected classification accuracy, the quantization errors can be large in regions where $p(x)$ has small values.

Let

$$c = \arg\min_i \{\|x - m_i\|\} \tag{5}$$

define the index of the nearest $m_i$ to $x$, denoted by $m_c$; $x$ is then determined to belong to the same class to which the nearest $m_i$ belongs.

Let $x = x(t)$ now be a time-series sample of input, and let the $m_i(t)$ represent sequential values of the $m_i$ in the discrete-time domain, $t = 0, 1, 2, \ldots$, obtained in the following process. Starting with properly defined initial values $m_i(0)$, Equation 6 shall define the basic learning vector quantization process (Kohonen, 1988; Kohonen, Barna, and Chrisley, 1988); this particular algorithm is called LVQ1.

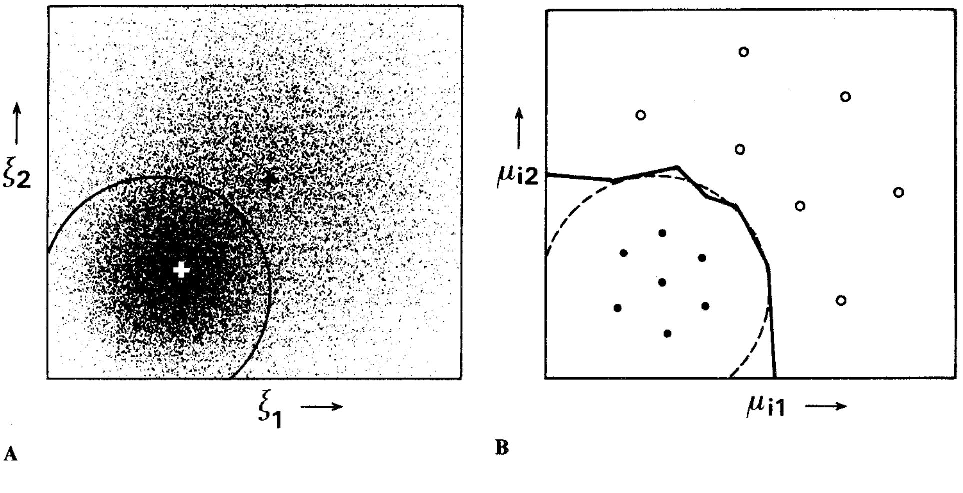

**Figure 1.** *A*, The probability density function of $x = [\xi_1, \xi_2]^T$ is represented here by its samples, the small dots. The superposition of two symmetric Gaussian density functions corresponding to two different classes $S_1$ and $S_2$, with their centroids shown by the white and dark cross, respectively, is shown. Solid curve denotes the theoretical optimal Bayes decision surface. *B*, Large black dots denote codebook vectors of class $S_1$; open circles denote codebook vectors of class $S_2$; the solid curve indicates a decision surface obtained by LVQ1; the broken curve indicates a Bayes decision surface.

$$\begin{aligned} m_c(t+1) &= m_c(t) + \alpha(t)[x(t) - m_c(t)] \\ &\quad \text{if } x \text{ and } m_c \text{ belong to the same class} \\ m_c(t+1) &= m_c(t) - \alpha(t)[x(t) - m_c(t)] \\ &\quad \text{if } x \text{ and } m_c \text{ belong to different classes} \\ m_i(t+1) &= m_i(t) \text{ for } i \neq c \end{aligned} \tag{6}$$

It will be shown that the asymptotic values of $m_i$ obtained in this process define a vector quantization for which the rate of misclassifications is approximately minimized. Here $0 < \alpha(t) < 1$, and $\alpha(t)$ (learning-rate factor) is usually made to decrease monotonically with time. It is recommended that $\alpha$ should initially be rather small, say, smaller than 0.1. If only a restricted time is available for learning, the exact law $\alpha = \alpha(t)$ is not crucial, especially also if only a restricted set of training samples is available; they may be applied cyclically, and $\alpha(t)$ may even be made to decrease linearly to zero.

It is in general difficult to show what the exact convergence limits of Equation 6 are. The following discussion is based on the idea that VQ tends to approximate density functions such as $p(x)$. Instead of $p(x)$, we may also consider any non-negative function $f(x)$ in Equation 2.

The Bayes decision borders defined by Equations 3 and 4 divide the signal space into class regions $B_k$ such that the rate of misclassifications is minimized. All such borders together are defined by the condition $f(x) = 0$, where, for $x \in B_k$ and $h \neq k$,

$$f(x) = p(x|x \in S_k)P(S_k) - \max_k \{p(x|x \in S_h)P(S_h)\} \tag{7}$$

Notice that $f(x)$ is piecewise continuous and non-negative. For each $x \in B_k$, $f(x)$ has a positive hump, and these humps are separated by the Bayes borders at which $f(x) = 0$.

If we approximate $f(x)$ by the point density of codebook vectors defined by classical VQ, this point density must then also tend to zero at all borders.

In order to find the minimum of $E$ in Equation 2 and the optimal values for the $m_i$ in VQ by gradient descent, we need an expression for the gradient of $E$. From Kohonen (1991, Equations A1 through A14) we obtain the result

$$\nabla_{m_i} E = -2 \int \delta_{ci} \cdot (x - m_i)p(x)dx \tag{8}$$

where $\delta_{ic}$ is the Kronecker delta, and $c$ is the index of the $m_i$ that is closest to $x$ (i.e., the winner). The gradient step of vector $m_i$ is

$$m_i(t+1) = m_i(t) - \lambda \cdot \nabla_{m_i(t)} E \tag{9}$$

where $\lambda$ defines the step size, and

$$\nabla_{m_i(t)} E = -2\delta_{ci}[x(t) - m_i(t)] \tag{10}$$

If $p(x)$ in $E$ is now replaced by $f(x)$, we get by substitution:

$$\begin{aligned} \nabla_{m_i} E &= -2 \int \delta_{ci}(x - m_i)f(x)dx \\ &= -2 \int \delta_{ci}(x - m_i)[p(x|x \in S_k)P(S_k) \\ &\quad - \max_k \{p(x|x \in S_h)P(S_h)\}]dx \end{aligned} \tag{11}$$

The gradient steps must be computed separately in the event that the sample $x(t)$ belongs to $S_k$, and in the event that $x(t) \in S_h$. In the event that $x(t) \in S_k$, we obtain

$$\nabla_{m_i(t)} E = -2\delta_{ci}[x(t) - m_i(t)] \tag{12}$$

with the a priori probability $P(S_k)$.

The class with $\max_h\{p(x|x \in S_h)P(S_h)\}$ is the runner-up class signified by index $r$. In the event that $x(t) \in S_r$, the following expression for $\nabla_{m_i} E$ is obtained with the a priori probability $P(S_r)$:

$$\nabla_{m_i(t)} E = +2\delta_{ci}[x(t) - m_i(t)] \tag{13}$$

The different cases are collected into the following set of equations, rewritten with $\alpha(t) = 2\lambda$:

$$\begin{aligned} m_c(t+1) &= m_c(t) + \alpha(t)[x(t) - m_c(t)] \\ &\quad \text{for } x(t) \in B_k \text{ and } x(t) \in S_k \\ m_c(t+1) &= m_c(t) - \alpha(t)[x(t) - m_c(t)] \\ &\quad \text{for } x(t) \in B_k \text{ and } x(t) \in S_r \\ m_c(t+1) &= m_c(t) \text{ for } x(t) \in B_k \text{ and } x(t) \in S_h,\ h \neq r \\ m_i(t+1) &= m_i(t) \text{ for } i \neq c \end{aligned} \tag{14}$$

If the $m_i$ of class $S_k$ are already within $B_k$, the VQ will further attract them to the hump corresponding to $B_k$, at least if the learning steps are small. With a sufficiently large number of codebook vectors in each class region $B_k$, the closest codebook vectors in adjacent regions $B_k$ will be arbitrarily close to the Bayes border. Thus, VQ and Equation 7 have been shown to define the Bayes borders with arbitrarily good accuracy.

Near equilibrium, close to the borders at least, Equations 6 and 14 can be seen to define almost similar corrections; notice that in Equation 6, *the classification of x was approximated by the nearest-neighbor rule*, and this approximation will be improved during learning. However, notice too that in Equation 6 the minus sign corrections were made every time when $x$ was classified incorrectly, whereas Equation 14 only makes the corresponding correction if $x$ is exactly in the runner-up class. The error thereby made is often insignificant. As a matter of fact, the algorithms called LVQ2 and LVQ3 (Kohonen, 1990) are even closer to Equation 14 in this respect.

## *The Optimized-Learning-Rate LVQ1 (OLVQ1)*

If an individual learning rate $\alpha_i(t)$ is assigned to each $m_i$, we obtain the following modified learning process (Kohonen, 1992). Let $c$ be defined by Equation 5. Then

$$\begin{aligned} m_c(t+1) &= m_c(t) + \alpha_c(t)[x(t) - m_c(t)] \\ &\quad \text{if } x \text{ is classified correctly} \\ m_c(t+1) &= m_c(t) - \alpha_c(t)[x(t) - m_c(t)] \\ &\quad \text{if } x \text{ is classified incorrectly} \\ m_i(t+1) &= m_i(t) \text{ for } i \neq c \end{aligned} \tag{15}$$

We may try to determine the $\alpha_i(t)$ for fastest convergence of Equations 15. Let us express Equations 15 in the shorter form

$$m_c(t+1) = [1 - s(t)\alpha_c(t)]m_c(t) + s(t)\alpha_c(t)x(t) \tag{16}$$

where $s(t) = +1$ if the classification is correct, and $s(t) = -1$ if the classification is wrong. It may be obvious that the *statistical accuracy* of the learned codebook vector values is approximately optimal if all samples have been used with equal weight, i.e., if the effects of the corrections made at different times, when referring to the end of the learning period, are of approximately equal magnitude. Notice that $m_c(t+1)$ contains a trace of $x(t)$ through the last term in Equation 16, and traces of the earlier $x(t')$, $t' = 1, 2, \ldots, t-1$, through $m_c(t)$. In a learning step, the magnitude of the last trace of $x(t)$ is scaled down by the factor $\alpha_c(t)$, and, for instance, during the same step the trace of $x(t-1)$ becomes scaled down by $[1 - s(t)\alpha_c(t)] \cdot \alpha_c(t-1)$. Now we first stipulate that these two scalings must be identical:

$$\alpha_c(t) = [1 - s(t)\alpha_c(t)]\alpha_c(t-1) \tag{17}$$

If this condition is made to hold for all $t$, by induction it can be shown that the traces collected up to time $t$ of all the earlier $x(t')$ will be scaled down by an equal amount at the end, and thus the "optimal" values of $\alpha_i(t)$ are determined by the recursion

$$\alpha_c(t) = \frac{\alpha_c(t-1)}{1 + s(t)\alpha_c(t-1)} \tag{18}$$

For fast learning, the OLVQ1 algorithm can be started with the $\alpha_i(0)$ in the range of 0.3 to 0.5.

## General Considerations

### *Initialization of the Codebook Vectors*

A rather good strategy is to start with the same number of codebook vectors in each class. An upper limit to the total number of codebook vectors is set by the restricted recognition time and computing power. An identical number of codebook vectors per class is justifiable, since for optimal approximation of the borders the average distances between the adjacent codebook vectors (which depend on their numbers per class) ought to be the same in each class. Because the final placement of the codebook vectors and thus their distances are not known until the end of the learning process, equalization of the distances in the various classes ought to be made iteratively.

Once the numbers of codebook vectors have been fixed, one may use first samples of the real training data for their initial values. Referring to the derivation of Equation 9, however, the codebook vectors should always remain inside the respective class regions. For the initial values one can then accept only samples that are not misclassified. In other words, a sample is first tentatively classified against all the other samples in the training set, for instance by the traditional *k*-nearest-neighbor (kNN) method, and accepted for a possible initial value only if this tentative classification is the same as the class identifier of the sample. (In the learning algorithm itself, however, no samples must be excluded; they are applied independently of whether they fall on the correct side of the class border or not.)

### *Overall Learning Strategy*

One may start the learning with the OLVQ1 algorithm, which has fast convergence; its final recognition accuracy will approximately be achieved after a number of learning steps that is about 30 to 50 times the total number of codebook vectors. In an attempt to ultimately improve recognition accuracy, one may try to continue with the basic LVQ1, or with the other LVQ versions, using a low initial value of learning rate, which is then the same for all classes.

The neural network algorithms often "overlearn"; i.e., when the learning and test phases are alternated, the recognition accuracy is first improved until an optimum is reached. After that point, the accuracy often starts to decrease slowly. A possible explanation in the present case is that when the codebook vectors become very specifically tuned to the training data, the ability of the algorithm to generalize with respect to new data suffers. It is therefore necessary to stop the additional learning process after some optimal number of steps, say, 50 to 200 times the total number of the codebook vectors. Such a stopping rule can only be found by experience.

## Comparison with Other Methods

### *LVQ and SOM*

Another related algorithm, the *self-organizing map* (*SOM*) (Kohonen, 1989, 1990, 1993; see also SELF-ORGANIZING FEATURE MAPS) should be mentioned in this context. It is an unsupervised learning method, whereas supervised training is used in the LVQ. In LVQ, only one or two winner cells are updated during each adaptation step, whereas in the SOM, a block of neighboring cells around the winner *relating to the physical network* is updated simultaneously. The main application areas of these algorithms are also different: LVQ is used for the classification of stochastic data, whereas the SOM is more useful for the visualization of high-dimensional data on a two-dimensional display.

**Table 1.** Error Percentages in Phonemic Classification

| Parametric Bayes | kNN | LVQ1 |
|---|---|---|
| 12.1 | 12.0 | 10.2 |

### *Relative Performance of LVQ as a Classifier*

The number of different applications of LVQ (and SOM) is for the present at least on the order of many hundreds, and it is very difficult to make any comparative survey. Just to give a feeling of the relative performance, Table 1 (Kohonen, 1990) compares the classification accuracies achievable by a couple of classical methods as well as by LVQ1. The data, 15-channel acoustic spectra representing 19 different phonemic classes, were collected from Finnish speech. A total of 1,550 samples were used for training, and another set of 1,550 independent samples for testing, respectively. There were in total 117 codebook vectors.

The term *parametric Bayes* in Table 1 means a Bayesian classification method in which the discriminant functions are approximated by multivariate normal distributions, and kNN is the classical *k*-nearest-neighbor method, i.e., comparison of each test sample against all the training samples and voting over *k* closest ones (here $k = 5$). It is generally known that the kNN algorithm gives a very good approximation of the theoretical Bayes limit; but LVQ1 is still better, and here more than ten times faster computationally.

# Lesioned Networks as Models of Neuropsychological Deficits

*John A. Bullinaria*

## Introduction

Cognitive neuropsychology uses the patterns of performance observed in brain-damaged patients to constrain our models of normal cognitive function. Historically, this methodology was rooted in simple "box-and-arrow" models, with particular cognitive deficits being taken to indicate selective breakdown of corresponding "boxes" or "arrows." Studying patients with complementary patterns of deficit allows us, in principle, to piece together a complete model of mental structure (Shallice, 1988). Of particular importance in this process has been the concept of *double dissociation*, which has been taken to imply modularity within many systems. If one patient can perform task 1 better than task 2 and another can perform task 2 better than task 1, then a natural explanation is in terms of separate modules for the two tasks.

In recent years, connectionist techniques have been employed to model the operation and interaction of these "modules" in increasing detail (Farah, 1994). Networks of simplified processing units loosely based on real neurons are set up with general architectures based on known physiology, trained to perform appropriately simplified versions of the human tasks, and iteratively refined by checking their performance against humans'. Such network models can clearly be wired together in the manner of the old box-and-arrow models, with all the old explanations of patient data carrying through. The obvious advantage now is that we can look at the details of the degradation of the various components and, by removing neurons or connections in our models, construct natural analogues of real brain damage. Moreover, in addition to elaborating previous models, we can also question the validity of the old assumptions of neuropsychological inference and explore the possibility that processing is actually more distributed and interactive than the older models implied.

This article reviews the general issues involved in lesioning neural network models to simulate neuropsychological deficits. I shall point out potential sources of misleading results, clarify apparent contradictions in the literature, and discuss some representative models.

## Lesioning Simple Feedforward Networks

Many neural network models of human performance are based on simple feedforward networks that map between conveniently simplified input and output representations via a single hidden layer, or that have such systems as identifiable subcomponents. An important feature of these models is that they *learn* to perform the relevant tasks by iteratively adjusting their connection weights (e.g., by some form of gradient descent algorithm) to minimize the output errors for an appropriate training set of input-output pairs. Generally, we simply assume that the quick and convenient learning algorithms we choose will generate results similar to those produced by more biologically plausible procedures. Comparisons between backpropagation and contrastive Hebbian learning by Plaut and Shallice (1993) provide some justification for this assumption. We can then compare the development of the networks' performance during training and their final performance (e.g., their output errors, generalization ability, reaction times, priming effects, speed-accuracy trade-offs, robustness to damage, etc.) with the performance of human subjects to narrow down the correct architecture, representations, and so on, to generate increasingly accurate models.

An obvious feature of network learning is that performance on one pattern will be affected by training on other patterns. It follows straightforwardly from adding up the network weight change contributions resulting from individual training patterns that:

1. Regular items will be learned more quickly than irregular items, because consistent weight changes combine and inconsistent weight changes cancel.
2. High-frequency items will be learned more quickly than low-frequency items, because the appropriate weight changes get applied more often.
3. Ceiling effects will arise as sigmoids saturate and weight changes tend to zero.

These fundamental properties of neural network learning not only result in human-like *age of acquisition* effects but indirectly account for realistic patterns of reaction times, speed-accuracy trade-off effects, and so on (Bullinaria, 1997). After training our networks and confirming that they are performing in a sufficiently human-like manner, we can then set about inflicting simulated brain damage on them. Small (1991) considered the various ways in which connectionist networks might be lesioned, and discussed their neurobiological and clinical neurological relevance. He identified two broad classes of lesion: *diffuse*, such as those created by globally scaling or adding noise to all the weights, and *focal*, such as those created by removing adjacent subsets of connections and/or hidden units. Which class we choose will depend on the type of patient we are modeling. Focal lesions would be appropriate for stroke patients, whereas diffuse lesions would be required for diseases such as Alzheimer's. Generally, for our simplified models, it is appropriate to examine all these possibilities. Finally, we should be aware that relearning after damage may affect the observed pattern of deficits, and so we must check this also (Plaut, 1996).

The relevant issues have been explored in an abstract setting by Bullinaria (1999), who trained a simple feedforward network (with 10 inputs, 100 hidden units, and 10 outputs, with binary inputs and output targets) on two sets of 100 regular items (different permuted identity mappings) and two sets of 10 irregular items (random mappings). One regular set and one irregular set appeared during training 20 times more frequently than the others. Figure 1 shows that both regularity and frequency do indeed affect the speed of learning in the expected manner.

Bullinaria and Chater (1995) explored the effects of damage on fully distributed, homogeneous connectionist systems and investigated the possibility that double dissociation between regular and irregular items could arise without modularity. They found that lesioning trained networks by removing random hidden units, removing random connections, globally scaling the weights, or adding random noise to the weights all led to very similar patterns of deficits. They concluded that, assuming one successfully avoids small-scale artifacts and controls for all other factors, only single dissociations were possible. Moreover, these single dissociations were seen to be a natural consequence of the ease with which the mappings were originally learned. Plotting the patterns of activation feeding into the output units revealed why this should be the case. Each form of damage results in these activations either drifting in a random direction or falling to zero. For every output unit there will be some correct response threshold, and the items that are learned first during training will end up furthest past the thresholds when the training is stopped. They will consequently tend to be the last to cross over again and hence be the last to result in output errors as more damage is incurred. Thus we get clear dissociations, with the regulars more robust than frequency-matched irregulars and high-frequency items more robust than regularity matched low-frequency items. Figure 2 shows this pattern explicitly for the network of Figure 1.

These basic effects extend easily to more realistic models, for example, surface dyslexia in the reading model of Bullinaria (1997). Here we successfully simulate not only the relative error proportions for the various word categories (i.e., regular/irregular, high/low frequency) but also the types of errors that are produced. The closest threshold to an irregularly pronounced letter will be that of regular pronunciation, and hence the errors will be predominantly regularizations of the lowest-frequency irregular items, exactly as is observed in acquired human surface dyslexia.

Figures 1 and 2 also reveal what is behind a potential source of confusion. Bullinaria and Chater (1995) argued that network lesions would always result in single dissociations with the regular items more robust. Marchman (1993), however, studied models of past tense production and seemingly found dissociations, with the irregular items more robust than the regulars. It is easy to see from the figures that sufficiently high-frequency irregulars can be more robust than regulars. The English language has evolved to leave the irregulars with much higher frequencies than the regulars; otherwise, they would have been lost from the language. Marchman built this into her models, with the expected consequences. This illustrates how important it is to control for all confounding factors when describing dissociations and drawing conclusions from them. Lavric et al. (2001) provide a review of the issues involved in understanding the dissociations of verb morphology.

It is also evident from Figure 2 that, if the frequencies and regularities are carefully matched, performance on the high-frequency irregulars can cross performance on the lower-frequency regulars. Initially there is a dissociation with better performance on the irregulars, and later the opposite dissociation. Such a "double dissociation" is a form of *resource artifact* that is well known not to imply underlying modularity (Shallice, 1988, p. 234). Patterns of deficits of this type are actually rather easily obtainable in neural network models. Devlin et al. (1998) present an interesting example involving a connectionist account of category-specific semantic deficits. The finer grain of detail that connectionist modeling affords here allows explicit accounts of human deficits that older box-and-arrow models could accommodate only with difficulty.

The general point one can make about single, fully distributed subsystems is that some items are naturally learned more quickly and more accurately than others, and the effects of subsequent network damage follow automatically from these patterns of learning. There are actually many factors, in addition to regularity and frequency, that can cause differing learning and damage rates. We can explore them all in a similar manner and use them in models of neuropsychological data in the same way. Consistency and neighborhood density are the factors most closely related to regularity and are commonly found in models of language tasks such as reading and spelling (e.g., Plaut et al., 1996; Bullinaria, 1997). Representation sparseness or pattern strength are often used to distinguish between concrete and abstract semantics, as in models of deep dyslexia (e.g., Plaut and Shallice, 1993). Correlation, redundancy, and dimensionality are commonly used in models to distinguish the semantics of natural things versus artifacts, as in models of category-specific semantic deficits (e.g., Devlin et al., 1998). At some level of description, all of these factors act in a similar manner as frequency and regularity, and their effects can easily be confounded. Which we use will depend on exactly what we are attempting to model. If we want to make claims about neuropsychological deficits involving one of them, however, we need to be careful to control for all the others.

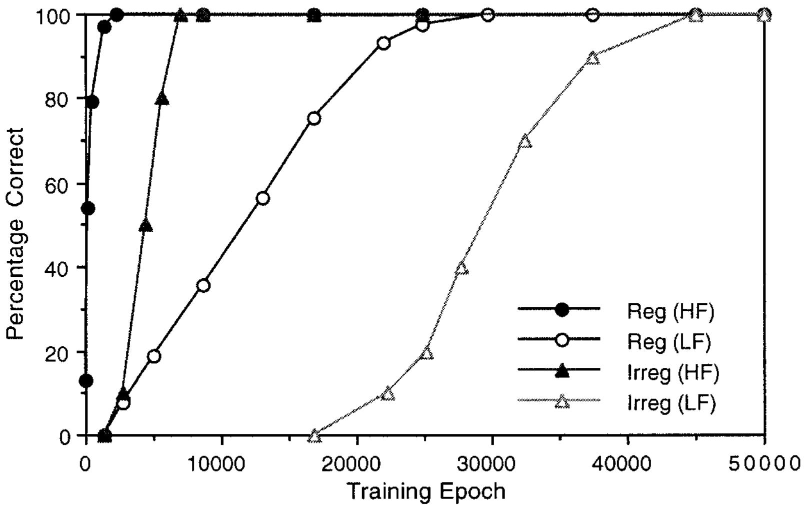

**Figure 1.** Regularity and frequency effects during the course of learning. HF, high frequency; LF, low frequency.

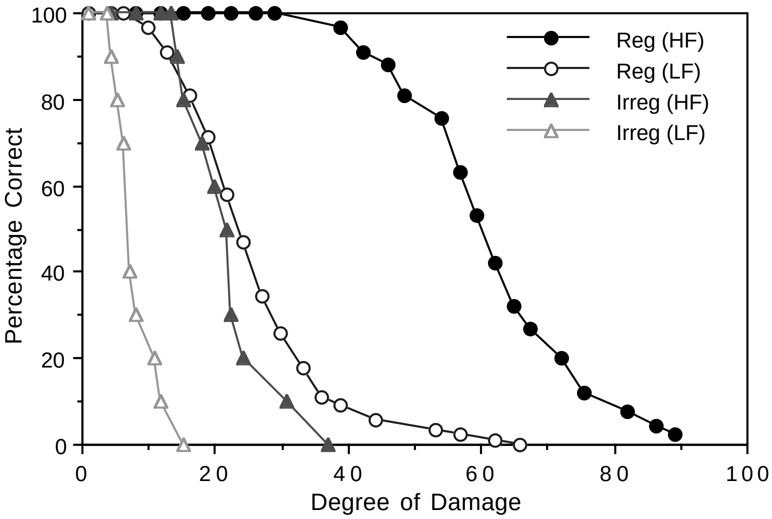
**Figure 2.** Regularity and frequency effects with increasing degrees of network damage. HF, high frequency, LF low frequency.



Following brain damage, patients often show a rapid improvement in performance. This is important to connectionist modelers for two reasons. First, if relearning occurs automatically and quickly in patients, then we need to be sure that the same effects are observed in our models, and that we are comparing patient and model data at equivalent stages of the relearning process. Second, our models may be of assistance in formulating appropriate remedial strategies for brain-damaged patients (Plaut, 1996). Since learning and damage have the same underlying regularity and frequency effects, relearning from the original training data is unlikely to reverse this pattern; indeed, it is likely to enhance it (Bullinaria and Chater, 1995). However, if some rehabilitation regime is employed that involves a very different set of training examples from that of the original learning process, it is possible for different results to arise (Plaut, 1996). Here the models can be used to predict or refine appropriate relearning strategies, and the patients' responses can be used to validate our models.

## Small-Scale Artifacts

One should never forget that modeling massively parallel brain processes by simulating neural networks on serial computers is rendered feasible only by abstracting the essential details and scaling down the size of the networks. It is clearly important not to take the abstraction and scaling process so far that we miss important fundamental properties of the systems we are modeling, or introduce features that are nothing but small-scale artifacts. The damage curves of Figure 2 are relatively smooth because our network has many more hidden units and connections than are actually required to perform the given mappings, and individual connections or hidden units make only small contributions to the network's outputs. For smaller networks, however, the effect of individual damage contributions can be large enough to produce wildly fluctuating performance on individual items, and this can result in dissociations in arbitrary directions. Often these small-scale artifacts are sufficient to produce convincing-looking double dissociations (Shallice, 1988, p. 254). Bullinaria and Chater (1995) showed that as we scale up to larger networks, the processing becomes more distributed, and apparent double dissociations dissolve into single dissociations.

Our modeling endeavors would be much easier if some independent procedure could determine when networks were sufficiently distributed to obtain reliable results. In effect, we need to make sure that individual processing units are not acting as "modules" in their own right, and the obvious way to do this is by checking that all the individual contributions feeding into each output unit are small compared to the total. In this case, many such lost contributions must conspire to result in an output change large enough to be deemed an error. This is the brain-like resilience to damage often known as *graceful degradation*. Fortunately, this distribution of information processing tends to occur automatically if the network is supplied with a sufficiently large number of hidden units. However, in general, it seems that we do need many hidden units to avoid small-scale artifacts—many times the minimal number required to learn the given task (Bullinaria, 1999). So, what can be done if limited computational resources make this impossible? Obviously, after removing a random subset of the hidden units or connections, the number of contributions will be reduced by some factor, but in large, fully distributed networks, the mean contribution will not change much, and so the total contribution after damage is simply reduced by the same factor. We can achieve the same result simply by globally scaling all the weights by the same factor. In smaller networks, this equivalence breaks down because the means tend to suffer relatively large random fluctuations during damage. However, since global weight scaling does not suffer from such random fluctuations, it can be used to simulate a smoothed form of lesioning and give a reasonable approximation in small networks to what will happen in more realistic networks. Alternatively, if one wants to claim that each hidden unit corresponds to a number of real neurons, then the weight scaling can be regarded as removing a fraction of those neurons.

## Lesioning Attractor Networks

Many successful models of human performance and their associated neuropsychological deficits have been based on attractor networks (see COMPUTING WITH ATTRACTORS) rather than simple feedforward networks. These are recurrent networks that develop *attractors* to appropriate patterns of activity; i.e., they have points in the *state space* of output activations to which the network settles. Lesions of this type of network can alter the settling behavior by distorting or shifting the *basins of attraction*. Here the errors correspond to the network settling into the wrong attractor, rather than an output unit activation failing to reach a particular threshold. Nevertheless, the resilience to damage still follows directly from how the particular items were originally learned.

One of the earliest applications of attractor networks to neuropsychology was the Mozer and Behrmann (1990) model of *neglect* *dyslexia*. But perhaps the most successful models of this type are the Plaut and Shallice (1993) models of *deep dyslexia*, which were extensions of earlier work by Hinton and Shallice (1991) showing how both visual and semantic errors could arise from a single lesion. These attractor networks mapped from orthography to semantics via a layer of hidden units, and then from semantics to phonology via another set of hidden units, with layers of *clean-up units* at the semantics and phonology levels. One particular model was trained on 40 words, using backpropagation through time, until it settled into the correct semantics and phonology when presented with each orthography. Lesions at two different locations in the trained network were then found to produce a double dissociation between concrete and abstract word reading, where concreteness was coded as the proportion of activated semantic microfeatures. Specifically, removal of orthographic to hidden layer connections resulted in preferential loss of abstract word reading, whereas removal of connections to the semantic clean-up units primarily impaired performance on the concrete words. Although the two damage locations do not constitute modules in the conventional sense, it is not difficult to understand how they contribute to the processing of the two word types to different degrees, and give opposite dissociations when damaged. It is simply a consequence of the sparser representations of the abstract words making less use of the semantic clean-up mechanism, and depending more on the direct connections, than the richer representations of the concrete words (Plaut and Shallice, 1993). This does not conflict with the claim of Bullinaria and Chater (1995) that only single dissociations are possible. The robustness of each location in the attractor network is fully consistent with the general discussion above, and the only disagreement concerns the appropriateness of using the word "module" to describe the two damage locations. As Plaut himself points out (Plaut, 1995), one of the problems when discussing modularity is that different authors define the term differently. This is fine, but to avoid confusion one should be careful to quote the definitions along with the conclusions.

## Discussion

This article has covered the basic issues and complications involved in lesioning neural network models to provide accounts of neuropsychological deficits, and has provided pointers to a range of representative case studies. It seems clear that, despite all the abstractions and simplifications involved, connectionist modeling has a lot to offer in fleshing out the details of, or even replacing, earlier box-and-arrow models to provide a more complete picture of cognitive processing. The resulting enhanced models and the new field of connectionist neuropsychology not only are producing good accounts of existing empirical data, but are also beginning to suggest more appropriate experimental investigations for further fine-tuning of these models, and an ethical approach for exploring potential remedial actions for neuropsychological patients.

## Introduction

*Sensorimotor transformations.* Motor control involves the problem of transforming sensory inputs into motor outputs. The outputs are the motor commands that act on muscles and the inputs are derived from sensory feedback and efference copy of the motor commands. The simplest solution would be to encode similar parameters at both input and output levels, such as the kinetic parameters of muscle forces and joint torques. The problem of motor control would then simplify to one of specifying patterns of time-varying muscle activity, and causality would dictate the ensuing limb motion. Some sensory inputs reflect kinetics (e.g., Golgi tendon organs), but many others reflect kinematics. For instance, muscle spindles encode changes in muscle length, and retinal or auditory signals encode target motion. Moreover, motor planning requires the ability to predict the limb motion resulting from the application of a given torque. Prediction is straightforward only for a limited class of movements, those restricted to a single joint; in such cases, angular acceleration is simply proportional to joint torque. However, this simple relation does not hold for movements involving multijointed coordination.

*Multijointed control.* Consider the case of arm movements involving shoulder and elbow rotations. The activation of an elbow flexor will always contribute a flexor torque at the elbow, but the resulting elbow movement can be flexion, extension, or no motion at all, depending on the actively produced torque at the shoulder. In general, the relation between joint torque and angular acceleration of each limb segment depends in a complex manner on limb inertia, angular velocity, and limb geometrical configuration (Soechting and Flanders, 2002; see GEOMETRICAL PRINCIPLES IN MOTOR CONTROL). Limb geometry, in turn, affects limb inertia and determines the gravitational loads that need to be opposed. Because limb inertia, geometry, and velocity may all vary during a movement, the central nervous system (CNS) should be able to estimate each of these parameters by means of feedback or feedforward, to predict the motion resulting from the application of a given torque. However, the time delays in position and velocity feedback and the uncertainties in the estimate of the starting position of the limb may prevent accurate estimates.

*Kinematic and kinetic variables.* Although in principle, a coordinated motor action could be planned muscle by muscle, a more parsimonious solution is to plan more global goals at higher levels of organization and let the lower-level controllers specify the implementation details. Global goals often encompass both kinematics and kinetics. Thus, reaching or walking require the specification of the spatial location and contact force of the respective end point (hand or foot). According to hierarchical control, kinematic and kinetic plans could be fed as inputs to limb controllers; the latter would transform these plans into the appropriate motor commands. A kinematic plan could involve the mere specification of target position, and therefore of the limb end point that matches the target. In addition, however, the plan could include a specification of the path and law of motion of the end point from start to target. Kinematic transformations (inverse kinematics) convert the desired end-point trajectory into the angular motion of each limb segment. Dynamic transformations (inverse dynamics) convert limb motion into the appropriate commands to generate muscle forces and torques. A kinetic plan could involve the specification of the force field at the end point (see MOTOR PRIMITIVES), or it could specify directly the arm and muscle dynamics (Nakano et al., 1999).

*Implementation problems.* Despite the apparent simplicity of this cascade of events, their actual implementation can be very demanding from a computational standpoint and can result in substantial errors. In a redundant limb, such as the arm or leg, that involves many more degrees of freedom at the level of muscles and joints than at the end point, inverse transformations generally are ill defined. Unique solutions can be imposed by introducing kinematic and/or kinetic constraints, or by using optimization principles. In the following sections we briefly review some issues related to the kinematic aspects of limb geometry control for arm movements and for posture and gait.

## Arm Movements

### *Sensorimotor Transformations for Reaching to a Target*

*End-point specification.* To reach a visual target requires transforming information about target location into commands that specify the patterns of muscle activity that bring the hand to the target. Psychophysical evidence suggests that the specification of the final position of the hand depends on a cascade of sensorimotor transformations that remaps target location from the initial two-dimensional (2D) retinal frame of reference to a three-dimensional (3D) binocular viewer-centered frame to arm- and hand-centered frames (Flanders, Helms Tillery, and Soechting, 1992; Gordon, Ghilardi, and Ghez, 1994; McIntyre et al., 2000; see also EYE-HAND COORDINATION IN REACHING MOVEMENTS). Remapping depends on the combination of retinal and extraretinal signals with somatic signals to update target and end-point spatial representations as the eyes, head, trunk, or limb move. Exactly how this remapping occurs is a matter of controversy, but an emerging view is that the frame of reference used to specify the end point may be task and context dependent. Moreover, different spatial dimensions of the end point (e.g., direction and distance) are not treated in a unitary manner but are processed in parallel and largely independently of each other, according to principles of modular organization (see Georgopoulos, 1991; Gordon et al., 1994).

*Egocentric frames.* The spatial patterns of hand errors have been studied extensively in pointing to actual or remembered targets that are presented visually or proprioceptively, the movements being performed with or without visual guidance (Baud-Bovy and Viviani, 1997; Flanders et al., 1992; Gordon et al., 1994; McIntyre et al., 2000). Constant and variable errors may reveal the presence of bias and random noise, respectively, in internal representations of the end point, whereas local distortions may reveal transformations between different frames of reference (McIntyre et al., 2000). Thus, in pointing to a continuously visible virtual target, the presence of radial noise and contraction of distance along the sightline indicates the representation of the target and limb end point in a 3D binocular viewer-centered frame, the anisotropy resulting from fusion of eye position signals with retinal disparity signals and from a coupling of uncompensated eye movements. When vision of the hand is prevented, head- and shoulder-centered distortions characterize end-point distribution and denote the transformation of information into the corresponding frames. The increase in head/shoulder-centered local contraction for increasing delays (up to 8 s) for movements performed toward previously visible then memorized targets indicates that memory storage of the intended end point is held within these frames, with separate storage of distance and direction, the distance information decaying faster than the directional information. Additional variability along the movement direction suggests that target information is combined with hand information to form a hand-centered vectorial plan of the intended movement trajectory as an extent and direction relative to the starting hand position (Gordon et al., 1994). Extent and direction also adapt differentially during motor learning (Krakauer et al., 2000). By contrast, when targets are presented kinesthetically instead of visually, subjects underestimate the perceived target distance relative to the shoulder (Baud-Bovy and Viviani, 1997).

*Allocentric frames.* The evidence reviewed so far indicates that, when targets are immersed in an otherwise neutral space, end-point position is specified in egocentric frames of reference, that is, relative to some body parts (eyes, head, or arm). However, when targets are embedded in a geometrically structured space, the visual or cognitive context can shape pointing errors and reveal the use of allocentric reference frames to represent end-point position. Thus, the final position of a pointing movement toward a remembered target is biased by the position of a surrounding frame (Bridgeman, Peery, and Anand, 1997; see DISSOCIATIONS BETWEEN DIFFERENT VISUAL PROCESSING MODES).

### *Limb Kinematics*

*Kinematic regularities.* A different issue is whether kinematic plans also include a specification of the path and law of motion of the limb. Moreover, is limb kinematics planned at the level of the end point or at the level of joint and limb segments? There is no consensus on these issues. A number of lawful relationships have been described for the kinematic trajectories of the hand in external space and of individual limb segments in the angular coordinates of the joints. Thus, the spatial trajectories of both the hand and the joints are essentially unaffected by wide changes in speed and load. In point-to-point movements the velocity profile of the hand tends to be bell-shaped, while the velocity profiles of shoulder and elbow angular motions tend to be temporally correlated. In curved movements (such as those of drawing and handwriting), the instantaneous tangential velocity of the hand is inversely related (by a power law) to the local curvature of the path (Lacquaniti, 1997).

*Optimum principles.* Although these kinematic regularities are compatible with the existence of a kinematic plan, they do not prove it. Nevertheless, kinematic optimization principles are able to predict the time course of reaching and drawing (see OPTIMIZATION PRINCIPLES IN MOTOR CONTROL). Optimization may involve end-point trajectory or joint angular trajectories. The minimum jerk principle, for instance, constrains hand reaching to follow a maximally smooth time course. Superposition of smooth harmonic oscillations of joint angular motion predicts the power law for drawing.

Kinematic regularities could also result from optimizing kinetic criteria instead of kinematic ones. Nakano et al. (1999) have been able to account for a variety of reaching trajectories by assuming that the commanded change in torque is minimized. In a similar vein, Soechting and Flanders (2002) showed that for reaching to a given target starting from different locations, the final posture of the arm minimizes the amount of work that must be done to transport the arm from start to end.

### *Planning Dynamic Interactions*

In interceptive tasks, such as catching, information about the relative motion between limbs and objects must be preprocessed in order to plan the dynamic interaction in advance of its occurrence. Time, location, and momentum of the impact need be accurately estimated, and limb kinematics and kinetics controlled accordingly. A priori knowledge of the most likely path and law of motion of the object is used in conjunction with visual on-line information. Thus, catching movements are time-locked to time-to-contact computed by combining optic flow information with an internal estimate of the acceleration of gravity (Lacquaniti, 1997). Also, the compliant relation between hand and object appears to be internally modeled by the CNS, resulting in prospective tuning of limb geometry and compliance. This control scheme is adaptive: the response to the dynamic interaction predicted by the internal model is compared with the actual response of the limb (as monitored by kinesthetic and cutaneous signals), and the resulting error is used to calibrate the parameters of the neural controller and to update the internal model.

Processes of trajectory formation have also been shown to undergo adaptive changes in response to novel force fields experienced at the hand; adaptation is based on the progressive changes of the internal models of limb dynamics, initially defined in the intrinsic coordinates of the joints and muscles. Proprioceptive information is essential to maintain internal models (Ghez, Gardon, and Ghilardi, 1995). Indeed, deafferented (as a result of large-fiber neuropathies) subjects are unable to compensate for workspace anisotropies in limb inertia and produce pointing errors that are direction dependent.

### *Neural correlates*

*Positional and directional codes.* Electrophysiological recordings from single neurons in frontal and parietal cortical areas have been related to kinematic parameters of reaching in different frames of reference (see MOTOR CORTEX: CODING AND DECODING OF DIRECTIONAL OPERATIONS; REACHING MOVEMENTS: IMPLICATIONS FOR COMPUTATIONAL MODELS). In general, many neurons are broadly tuned to both the target location and the direction of the hand movement (Georgopoulos, 1991). Target location and movement direction can be defined in eye-centered or arm-centered coordinates, depending on the cerebral area and the task (Batista et al., 1999). The combination of retinal, eye-, and hand-related signals occurs at early stages of cortical processing, as revealed by the activity pattern of parieto-occipital neurons (Battaglia-Mayer et al., 2001). Directional signals of many such neurons for hand reaching are spatially congruent with those for eye saccades. These activity patterns are modulated by context (presence or absence of visual feedback of hand movement, memory delay), in agreement with the psychophysical data reported above.

*Velocity codes.* The time-varying changes in length and direction of the population vectors in M1 parallel the corresponding changes in the vector of tangential velocity in reaching and drawing. In drawing, the virtual changes in movement velocity predicted by the population vectors are related to path curvature by the same power law that applies to actual movement velocity.

*Kinematics or kinetics?* Neural codes of limb kinematics can occur independently of limb kinetics, or there may be an interaction. Thus, when the same movement is performed in the presence of different loads pulling the arm in different directions, some neurons are very sensitive to the applied load and appear to encode parameters related to movement kinetics, whereas other neurons are relatively insensitive to loads and appear to encode movement kinematics, and still other neurons fall in between, exhibiting both kinematic and kinetic tuning.

*Limb geometry configuration.* Another possible interaction is between the movement direction and the geometrical configuration of the limb and the participating muscles. Thus, the directional tuning of wrist muscles for flexion/extension and abduction/adduction depends on forearm pronation/supination. Directional tuning of some motor cortical neurons changes in parallel with the changes in directional tuning of the muscles (compatible with a kinetic code), whereas the tuning of other neurons changes in parallel with changes in posture (compatible with a kinematic code of limb geometrical configuration), and the tuning of still other neurons is not affected (compatible with a kinematic code of abstract movement direction independent of limb configuration and muscle activity; Kakei, Hoffman, and Strick, 1999).

## Posture

### *Control of Limb Geometry in Posture*

Postural control is often equated with stabilization of the body against gravity, i.e., a kinetic control problem. In fact there is now ample evidence that limb geometry can be controlled largely independent of the ground contact forces. Thus, when cats standing on a platform are pitched by variable angles, the resulting distribution of ground contact forces and joint torques is idiosyncratic to each animal and condition, whereas the geometry of both forelimbs and hindlimbs is much more stereotyped (Lacquaniti, 1997). The length and the angle of orientation of the limb axis relative to the vertical change little despite wide changes in platform tilt. Limb geometry is also preserved unmodified after the application of external loads, at the expense of marked changes in the distribution of weight and effort between forelimbs and hindlimbs. The CNS controls postural geometry directly rather than balance (distribution of contact forces), presumably because it has learned that the preferred posture is stable under normal operating conditions. On the other hand, not only has posture largely evolved to oppose gravity for the maintenance of balance, it is also organized in a reference frame that is anchored to the direction of gravity. As was noted earlier, limb orientation is controlled relative to the vertical.

### *Modular Organization.*

In contrast to limb orientation, limb length is not significantly affected by tilt of the visual surround or by application of abnormal somesthetic stimuli. This and the differential dynamic behavior of the changes in limb length and orientation in response to dynamic pitch suggest that these two geometrical variables might be controlled independently of each other. This modular organization is reminiscent of that reported above for the control of direction and distance in arm reaching. Note further that limb length and orientation are encoded independently in the responses of dorsal spinocerebellar neurons to applied changes in lower-limb posture in the anesthetized cat spinal cord (Poppele, Bosco, and Rankin, 2002).

### *Coordinate Transformations for the Control of Posture*

Length and orientation specify the position of the foot relative to the hip in a global manner, leaving the detailed geometrical configuration undetermined. There is an additional processing stage that transforms limb length and orientation into the angular coordinates of the joints (Lacquaniti, 1997). The changes of these angles under both static and dynamic conditions are not independent, but covary close to one plane. The orientation of this plane is essentially the same in all animals (despite wide differences in their biomechanical parameters), and is also the same at the forelimbs and at the hindlimbs. The latter invariance is especially remarkable, considering that the forelimbs differ considerably from the hindlimbs in terms of the length and orientation of the individual corresponding segments. A related planar covariation has also been found in the case of whole-body motion in man (postural responses to external perturbations and anticipatory responses prior to voluntary trunk axial bending). Moreover, these kinematic strategies remain unchanged under microgravity, that is, in the absence of equilibrium constraints.

### *Neural Network Implementation of Coordinate Transformation*

How might a nervous system learn to map limb length and orientation into joint angles? A forward model of the controlled system could be learned by monitoring both the input and the output of the system. The forward model would map the expected relationship between the set of joint angles and the resulting end-point position. This forward model would not need to be learned in its most general and exact manner by the postural system. In fact, although the forward mapping from joint angles to limb length and orientation is generally nonlinear, we find that the latter two parameters can be estimated simply and accurately using linear compounds of the joint angles, at least within the range of postures normally adopted. After the forward model has been learned, the desired movement trajectory (sequence of end-point positions) could be fed to the inverse model to derive the feedforward motor command (sequence of joint angles). The resulting error in end-point position is propagated through the forward model to derive the corresponding error in the motor command space (joint angle space). The latter error represents the signal to train the inverse model. Parameterized constraints, such as the planar constraint on the joint angles for the postural control, could be incorporated into the learning procedure, and could thereby bias the choice of a particular inverse function.

## Locomotion

### *Kinematic Coordination*

A law of planar covariation also applies to the changes of elevation angles of lower limb segments during locomotion (Lacquaniti, Grasso, and Zago, 1999). The fact that similar laws of intersegmental coordination apply to the control of posture and locomotion is functionally significant, inasmuch as locomotion must ensure a forward progression compatible with dynamic equilibrium, adapting to potentially destabilizing factors (e.g., changes in body posture or load, uneven terrain, obstacles) in an anticipatory fashion by means of coordinated synergies of the whole body (see LOCOMOTION, VERTEBRATE).

In walking, the patterns of limb segment angular motion are remarkably simple and consistent. Each segment of the lower limbs oscillates forward and backward, with a waveform that mainly differs in timing and amplitude among different segments. The temporal changes of the elevation angles of lower limb segments do not evolve independently of each other, but they are tightly coupled. When the elevation angles are plotted one versus the others, they describe regular loops constrained close to a plane, common to both stance and swing phases. The specific orientation of the plane of angular covariation reflects the phase relationships between the elevation angles of the lower limb segments, and therefore the timing of the intersegmental coordination. Because the degrees of freedom of limb angular motion in the sagittal plane are reduced to two by the planar constraint, they match the corresponding degrees of freedom of linear motion of the center of body mass (CM).

### *Relation to Energy Expenditure*

Saving the mechanical energy of the body during walking depends to a large extent on the exchange between the forward kinetic energy and the gravitational potential energy of CM. The selection of the elevation angles of each limb segment with respect to the direction of gravity and that of forward progression as the controlled variables may help predict the energetic consequences of the desired kinematics. Moreover, the planar covariation of the elevation angles is instrumental in reducing the degrees of freedom of limb motion to those of CM, where most mechanical energy is expended in walking. There is an additional, important mechanism embedded in the law of kinematic coordination that contributes to the control of mechanical energy expenditure. The net mechanical power tends to increase rapidly with speed, because the changes in potential energy are roughly independent of speed, whereas the changes in kinetic energy increase with speed, and therefore less and less energy is conserved by means of the energy exchange. However, there is a compensatory mechanism that reduces the oscillations of CM. The phase coupling between the instantaneous changes of the elevation angles of the limb segments shifts systematically with increasing speed both in humans and in cats. In humans, it has been shown that the phase shift translates into a reduction in the increment of the net mechanical power with increasing speed. This mechanism is not equally developed in all human subjects, however. Trained subjects generally exhibit a more pronounced phase shift with increasing speed than untrained subjects. Accordingly, the mechanical power output at intermediate and high speeds is significantly lower in the former than in the latter subjects.

## *Interaction Between Posture and Locomotion*

Human erect locomotion is unique among living primates. Evolution selected specific biomechanical features that make human locomotion mechanically efficient. These features are matched by the motor patterns generated in the CNS. But what happens when humans walk stooped (as it happens in a low tunnel)? Are normal motor patterns of erect locomotion maintained, or are locomotor patterns completely reorganized? Walking has been compared in bent postures, either knee-flexed or knee- and trunk-flexed. These postures imply large differences in the position of the CM compared with its position in the standard erect posture: the CM is displaced downward and forward (outside the body), and its oscillations are reduced because the legs cannot fully extend. Thus, the exchange of kinetic and potential energy is much more limited than usual.

In bent posture, ground reaction forces differ prominently from those of erect posture, displaying characteristics intermediate between those typical of walking and those of running. Amplitudes and waveforms of the muscle activities also are deeply affected by the adopted posture. By contrast, the waveforms of the elevation angles along the gait cycle remain essentially unchanged, irrespective of the adopted postures. Thigh, shank, and foot angles covary close to a plane in all conditions, but the plane orientation is systematically different in bent versus erect locomotion. This is explained by the changes in the temporal coupling (phase shift) among the three segments.

An integrated control of gait and posture is made possible because these two motor functions share some common principles of spatial organization. Thus, the kinematic reference frame seems to be anchored to the vertical for both postural responses and locomotion. Also, the planar law of intersegmental kinematic coordination applies to both tasks.

## *Adaptation to Changes in Body Load*

Body weight unloading is compatible with accurate control of limb kinematics in human locomotion. Changing the amount of body weight support (BWS) between 0% and 95% while subjects walk results in drastic changes in kinetic parameters but in limited changes in kinematic coordination. In particular, the peak vertical contact forces decrease proportionally to BWS; at 95% BWS they are 20-fold smaller than at 0% and are applied at the forefoot only. Also, there are considerable changes in the amplitude of EMG activity of most lower limb muscles and a complex reorganization of the pattern of activity of limb muscles. By contrast, the corresponding variation in the parameters that describe shape and variability of the foot path is very limited, always less than 30% of the corresponding values at 0% BWS. Moreover, the planar covariation of the elevation angles is obeyed at all speed and BWS values. At 100% BWS, subjects step in the air, their feet oscillating back and forth just above the treadmill but never contacting it. In this case, step-to-step variability of foot path is much greater than at all other BWS levels, but it is restored to lower values when minimal surrogate contact forces are provided during the "stance" phase. Thus, the detection of minimal contact forces is sufficient for accurate limb trajectory control.

## *Reversal of Walking Direction*

Reversal of walking direction from forward to backward is a key test for studying locomotor patterns. According to the influential scheme put forth by Grillner, backward walking could be produced by switching the sign of the phase coupling among unit oscillators (see Motor Pattern Generation). As a result, the controlled output patterns would simply be the time-reversed copy of those of forward gait. If we consider the patterns of muscle activities, there is no way we can superimpose those of backward gait onto those of forward gait, irrespective of whether the waveforms are plotted in normal forward time or reversed in time (Lacquaniti et al., 1999). This is perhaps not so surprising given that the mechanical requirements of backward walking are very different from those of forward walking. Stance is characterized by an inverted plantigrade-digitigrade sequence in the two movement directions. Forward stance begins with heel contact and ends with toe-off. Backward stance begins with toe contact and ends with heel-off. The anatomical and functional asymmetry of foot and leg muscles along the anteroposterior axis also imposes different biomechanical constraints on forward and backward gait. Forward thrust is mainly provided by ankle plantar flexors, whereas the backward thrust is provided by hip and knee extensors.

However, the time-reversed waveforms of backward gait are almost perfectly superimposable onto those of forward gait (Lacquaniti et al., 1999). Accordingly, the planar covariation is the same; the loop is simply traversed in the opposite direction, owing to a switching of the thigh-shank phase. Thus, kinematic patterns follow Grillner's predictions of a phase switch among unit oscillators. It appears as though the same kinematic templates can be output by CPGs in either direct or time-reversed form (like a motor tape), depending on the direction (forward or backward) of gait.

## *Mechanisms for Kinematic Coordination in Locomotion*

The planar law of intersegmental coordination may emerge from the coupling of neural oscillators between each other and with limb mechanical oscillators. Muscle contraction intervenes at variable times to reexcite the intrinsic oscillations of the system when energy is lost. The hypothesis that a law of coordinative control results from a minimal active tuning of the passive inertial and viscoelastic coupling among limb segments is congruent with the idea that movement has evolved according to minimum energy criteria.

It is known that multisegment motion of mammals locomotion is controlled by a network of coupled oscillators (CPGs; see Half-Center Oscillators Underlying Rhythmic Movements). Flexible combinations of unit oscillators give rise to different forms of locomotion. Interoscillator coupling can be modified by changing the synaptic strength (or polarity) of the relative spinal connections. As a result, unit oscillators can be coupled in phase, out of phase, or with a variable phase, giving rise to different behaviors, such as speed increments or reversal of gait direction (from forward to backward). Supraspinal centers may drive or modulate functional sets of coordinating interneurons to generate different walking modes (or gaits).

Although it is often assumed that CPGs control patterns of muscle activity, an equally plausible hypothesis is that they control patterns of limb segment motion instead. According to this kinematic view, each unit oscillator would directly control a limb segment, alternately generating forward and backward oscillations of the segment. Intersegmental coordination would be achieved by coupling unit oscillators with a variable phase. Intersegmental kinematic phase plays the role of global control variable previously postulated for the network of central oscillators. In fact, intersegmental phase shifts systematically with increasing speed both in humans and in cats. Because this phase shift is correlated with the net mechanical power output over a gait cycle, phase control could be used for limiting the overall energy expenditure with increasing speed. Adaptation to different walking conditions, such as changes in body posture, body weight unloading, and backward walking, also involves intersegmental phase tuning, as does the maturation of limb kinematics in toddlers.

## Conclusion

There is ample evidence that movement trajectories are controlled for tasks as diverse as arm reaching, drawing, catching, and walking. Also, limb kinematics can be controlled independently of kinetics. Ill-defined inverse transformations from end point to joint coordinates can be solved by introducing kinematic constraints, such as the law of planar intersegmental coordination, or by means of optimization principles (see OPTIMIZATION PRINCIPLES IN MOTOR CONTROL). To simplify, control, and reduce errors, hybrid feedback/feedforward control schemes are presumably used whenever possible (see MOTOR CONTROL, BIOLOGICAL AND THEORETICAL). In addition internal models that map motor commands onto their sensory consequences and vice versa are used to improve estimates and to learn new tasks (see SENSORIMOTOR LEARNING). However, we still do not know how the kinematic control is obtained, and in particular, we ignore whether it arises from explicit trajectory planning or is derived implicitly from implementation of intrinsic neural dynamics.

# Localized Versus Distributed Representations

*Simon J. Thorpe*

## Introduction

What happens in the brain when you recognize a familiar stimulus such as your grandmother's face? Most researchers accept that recognition involves activating some sort of internal representation, but there is little agreement about how such representations are physically implemented in neuronal hardware. According to the localist coding view, recognizing an object involves activating neurons tuned to that particular object—an idea often described as "grandmother cell" coding. Alternatively, the presence of a particular object might never be made explicit at the single-cell level. Instead, the final representation of one's grandmother might be distributed across large populations of cells, none responding selectively to grandmothers alone.

Suppose we need to represent four different stimuli—green and red bars that can be either horizontal or vertical. Figure 1 illustrates three options: a local coding scheme using separate units to code each stimulus (Figure 1*A*), a semilocal scheme with color and orientation encoded separately (two active units are needed to represent each stimulus; Figure 1*B*), and a distributed coding scheme representing all four stimuli with just three units (Figure 1*C*). In the last case, someone listening to the response of any individual unit would have difficulty making sense of the activity. Such situations arise both in so-called Hopfield networks (see COMPUTING WITH ATTRACTORS) and in the hidden layer of backpropagation-trained networks that have fewer units than the number of stimuli that need to be represented.

So, what does the brain do? It is likely that the brain uses a range of coding strategies; there are several possibilities. Few neuroscientists have gone so far as to suggest that individual neurons might explicitly represent particular objects, Jerzy Konorski and Horace Barlow being two notable exceptions (Konorski, 1967; Barlow, 1985). Most prefer some form of sparse representation in which a relatively low percentage of active cells represents each object but none is tuned to that particular object (see SPARSE CODING IN THE PRIMATE CORTEX), as in the semilocal scheme illustrated earlier. However, many connectionists have used localist representations to model phenomena that include word and letter perception (see CONNECTIONIST AND SYMBOLIC REPRESENTATIONS) (Grainger and Jacobs, 1998; Page, 2000), and although they generally insist that the units in their models are not real neurons, there is no obvious reason why such models might not map directly to the neural level.

How might we determine the nature of the strategy used by the brain to represent objects? In the first section of this article we examine neurophysiological evidence that both distributed coding and local coding are used in high-order visual areas. In the second section we examine some computational reasons for preferring representations that are more distributed or localist. Finally, we ex-

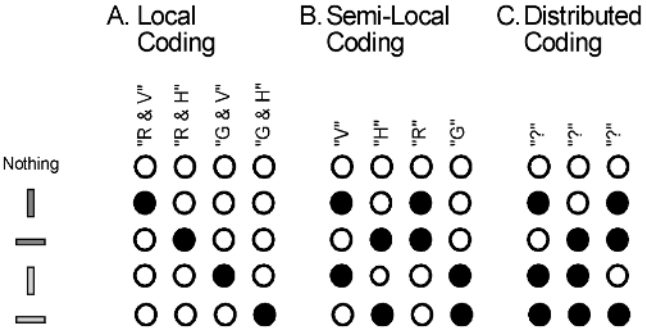

**Figure 1.** Three ways of representing four stimuli. Filled circles correspond to active units. *A*, Local coding. Each stimulus is explicitly coded by dedicated units. *B*, Semilocal coding. The different features—red (R), green (G), vertical (V), and horizontal (H)—are represented by separate units. ***C***, Distributed coding.

amine how work on temporal coding schemes has changed the nature of the local versus distributed debate.

## Neurophysiological Evidence

The best way to analyze how neurons represent objects is to record responses to a wide range of stimuli and determine their selectivity. This should be done at the highest levels of the sensory pathways, in areas such as inferotemporal (IT) cortex (see Object Recognition, Neurophysiology). In the early 1970s, Charles Gross and his colleagues at Princeton described cells in IT with selectivity for complex shapes such as monkey paws. At the time, many scientists read such reports with incredulity, but by the early 1980s, researchers such as Bob Desimone, David Perrett, and Edmund Rolls had started to provide incontrovertible evidence for neurons responding selectively to faces (Perrett, Mistlin, and Chitty, 1987) (see Face Recognition: Neurophysiology and Neural Technology). Although most such cells respond to a range of faces, there have been reports of much higher degrees of selectivity. For example, one study described a cell that responded to only one of a set of 27 photographs of Japanese male faces (Young and Yamane, 1992).

Some researchers feel that the high selectivity for faces constitutes a special case, but highly selective responses to a range of visual stimuli have now been found. Nikos Logothetis and coworkers trained monkeys to respond to arbitrary "paper clip" forms from a range of views. Following training, some cells responded only to particular shapes seen from a limited range of viewing angles (Logothetis, Pauls, and Poggio, 1995). Rufin Vogels (1999) studied neuronal responses to photographs of natural objects in monkeys performing a categorization task and found that 17% responded to less than four out of a set of 60 images. And in a study in which 100 different photographs were presented repeatedly to a large number of IT cells, half of the cells responded to seven or less of the stimulus set (Tamura and Tanaka, 2001). Indeed, the most selective cell responded over five times more to the best stimulus (a photograph of a chair) than to the next best one, and showed significant responses to only three of the 100 photographs.

Some of the most intriguing data have come from single-cell recordings in humans undergoing investigation for intractable epilepsy. Such studies have provided tantalizing hints that in humans, too, neurons are remarkably selective to categories of visual stimuli that include faces, natural scenes and houses, famous people, and animals (Kreiman, Koch, and Fried., 2000).

Clearly, at least some IT neurons show strong selectivity. But there is also plenty of evidence for more broadly tuned cells responding to many different objects, and some authors have argued strongly for distributed coding (Rolls and Deco, 2002). However, the data are also perfectly consistent with a hybrid model using both distributed and local coding. It is important to realize that neuronal selectivity in IT appears strongly experience dependent, the most selective responses being found in monkeys trained with particular sets of stimuli many hours a day for weeks or even months. Furthermore, the response properties of IT cells are plastic: even a few seconds of visual exposure can change selectivity (Tovee, Rolls, and Ramachandran, 1996). It could be that while most cells are relatively broadly tuned, experience might produce small numbers of increasingly specialized cells. Although allowing specialized cells for all possible objects would be impossible, it might not be so unreasonable to devote neural hardware to the relatively small number of objects that are particularly critical. In the next section, we will look at some of the computational reasons why the brain might prefer to opt for more explicit local coding in certain cases.

## Computational Pros and Cons

If it is possible to represent objects with a pattern of activity across a large population of cells, why would the brain ever move to more localist representations? After all, distributed codes have certain clear advantages. They allow large numbers of different stimuli to be represented with a relatively small number of units, as in the case of the ASCII code, where seven binary nodes can encode 128 (or $2^7$) different characters (a localist version would need 128 nodes). By using relatively broad tuning, distributed coding guarantees some sort of activity pattern even for stimuli never experienced before, and it has been claimed that distributed codes have a greater capacity for generalization and graceful degradation in the event of damage to the system (see Rolls and Deco, 2002).

On the other hand, localist representations also have some computational advantages. For example, efficient learning requires organisms to estimate the relative frequencies of events in the outside world, which in turn requires some sort of counting mechanism. It could be considerably easier to estimate the frequency of events represented with a local code than when the representation is distributed across a large number of neurons (Gardner-Medwin and Barlow, 2001). Imagine trying to estimate the frequency of the character E by examining the frequency of activation of the individual bits of the ASCII code. The problem would be trivial with a neuron that responded every time the letter E was presented.

Localist representations are also largely immune to the classic "binding problem" that results when two or more different objects or events need to be represented simultaneously. All three coding schemes in Figure 1 are fine for representing the four different objects as long as only one object is present at a time, but when both a red vertical bar and a green horizontal bar are present, only the local representation can provide reliable information. For the semilocal code, there is no way to decide which color goes with which orientation, and the fully distributed code would be completely unable to generate a meaningful response.

Interestingly, detecting the presence of red vertical bars in a field composed of green vertical and red horizontal distractors is a difficult and time-consuming task. In contrast, even relatively complex visual forms such as animals can be easy to detect in complex natural scenes (see Fast Visual Processing). Why would such high-level objects "pop out" when other, apparently simpler combinations of features pose such problems? One possibility is that only stimuli that are explicitly coded at the single-unit level can be processed in parallel. Our difficulty with certain stimulus conjunctions might stem from the fact that we rarely, if ever, need to use a simple combination of vertical and red to define an object. Perhaps units at the earlier levels of the visual system that would be useful for explicitly coding such combinations are no longer sufficiently plastic in adults to allow such low-level features to be used. In contrast, richer combinations of features of the type that could be encoded in IT cortex might be easier to group together as a result of experience in adults.

## The Impact of Temporal Coding

In this final section, we will examine how the debate over local versus distributed representations has been influenced by the development of ideas concerning temporal coding in neural processing. Many earlier discussions of coding schemes were based on the premise that neurons effectively use a firing rate code. For instance, in Barlow's 1972 formulation, firing rate represents the probability that a particular stimulus configuration is present. But the situation changes radically if we introduce the idea that information can also be contained in the temporal pattern of spikes. There is now considerable evidence that synchronization across populations of cells can help bind features together (see Synchronization, Binding and Expectancy and Dynamic Link Architecture), and this could provide an alternative solution to the binding problem mentioned earlier. With the semilocal coding scheme in Figure 1*B*, the simultaneous presence of a red vertical bar and a green horizontal bar would cause problems. But synchronization could be used to link the different features together by making the "red" neuron fire synchronously with the "vertical" neuron, and the "green" neuron fire with the "horizontal" neuron. This is a clear case of a distributed representation, because analyzing the firing of the four single cells in isolation would fail to disambiguate the stimuli.

Another particularly clear example of a distributed code is rank-order coding that uses the order in which a population of neurons fire to encode information (Thorpe, Delorme, and Van Rullen, 2001). It uses the fact that the time taken for a neuron to reach threshold and fire a spike depends on the strength of the input: the stronger the input, the shorter the latency (Figure 2*A*). Under such conditions, the order of activation across a population of neurons can encode the stimulus (Figure 2*B*). In a sense, this is the ultimate illustration of a distributed code, because listening to each neuron on its own provides no information whatsoever about the stimulus. It is only when the relative ordering across neurons is taken into account that an observer can derive information about the stimulus.

Interestingly, decoding order-related information can be done quite simply using a biologically plausible circuit involving feed-forward excitatory synapses coupled with shunting inhibition. In one step, it is possible to go from a representation of the input pattern that is fully distributed to one in which the information is made explicit in the firing of a single cell. The power of the coding scheme is illustrated by recent results showing that simple feed-forward architectures based on these principles can produce outputs that are effectively grandmother cells, responding to different views of only one particular face (Delorme and Thorpe, 2001). This demonstrates that switching from a fully distributed to a local representation can be done efficiently and with limited hardware.

## Discussion

The suggestion that our brains might contain "grandmother cells" is a very controversial one, but it is a suggestion that should not be rejected without good reason. In recent years, neurophysiological evidence for highly selective neurons has become increasingly difficult to ignore. Furthermore, several computational arguments make local coding attractive in certain situations. But it is also clear that it would be impracticable to use local coding to represent all objects. Common sense would seem to favor hybrid systems with both distributed and local representations, thus allowing the best of both worlds. Indeed, even if neurons at the top end of the visual system do explicitly code the presence of particular objects and stimuli, representations of these objects earlier in the system have to be distributed.

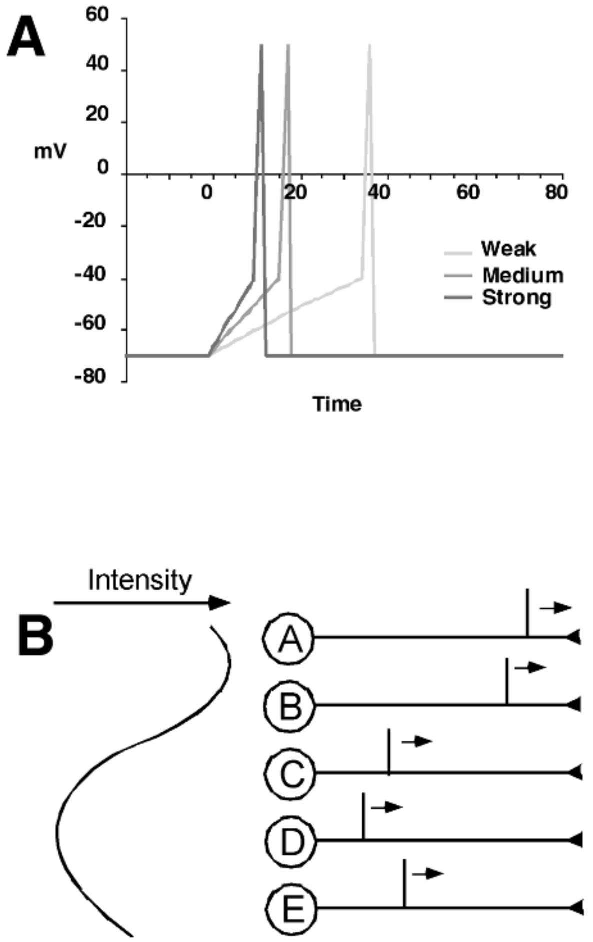

**Figure 2.** *A* distributed representation based on rank-order coding. *A*, Spike latency varies with the intensity of the input. *B*, With several units, the order of firing (in this case A > B > E > C > D) provides information about the input pattern.

The fact that selective neurons are typically found in animals following extensive training suggests that the move toward more explicit, local representations is experience dependent. It might be that high-capacity sparse distributed representations are often sufficient; it may be worth dedicating neurons to the representation of stimuli that are particularly significant. Such local coding could increase reliability and allow such stimuli to be detected in parallel without the need for time-consuming attention-based search.

# Locomotion, Invertebrate

*Randall D. Beer and Hillel J. Chiel*

## Introduction

Locomotion can be defined as an animal's ability to move its body along a desired path, making it fundamental to many other animal behaviors (Dickinson et al., 2000). Given the diversity of ecological niches that animals inhabit, and the variety of body plans that they possess, it is not surprising that their modes of locomotion are equally diverse. Types of locomotion include walking, swimming, flying, crawling, and burrowing.

Despite this diversity, certain common principles can be discerned. All locomotion systems must solve the twin problems of *support* and *progression*. The problem of support arises because in many modes of locomotion (e.g., flight), the gravitational attraction of the earth must be overcome. The problem of progression arises because an animal must generate propulsive forces that overcome not only its body's inertia, but also any drag from the density and viscosity of the medium or the friction of the substrate.

Both support and progression involve the generation of forces. This is accomplished by the contraction of muscles attached to either flexible hydrostatic skeletons or rigid skeletons. In addition, many animals have specialized body structures and appendages that facilitate locomotion, such as fins, wings, and legs. Thus, the detailed design of an animal's body is a crucial component of its locomotion system. As a result of the nature of these specializations, the problems of support and progression are rarely independent. Wings, for example, are used to generate both lift and propulsion in flying animals.

In order to provide support and progression, the movements of these specialized body structures must be coordinated by an animal's nervous system. The diverse modes of locomotion and the variety of body plans lead to equally diverse neural circuitry mediating locomotion. However, once again, certain basic principles can be discerned. Underlying many forms of locomotion are basic oscillatory patterns of movement generated by neural circuits that are referred to as *motor pattern generators* (Motor Pattern Generation). Even when these circuits contain dedicated neurons that autonomously produce rhythmic outputs (so-called *central pattern generators*), this central pattern is often strongly shaped by sensory feedback, fundamentally involving the body and environment in the generation of a locomotor pattern. In fact, sensory feedback can play such a fundamental role that it sometimes makes no sense to speak of a distinct central pattern generator.

Researchers have begun to use computer modeling to understand the neural basis of locomotion. In contrast to most work in computational neuroscience, models of animal bodies are playing an important role in understanding locomotion systems. Increasingly, experimental evidence suggests that motor systems cannot be fully understood without considering the biomechanical properties of the bodies in which they are embedded (Chiel and Beer, 1997). Modeling of both an animal's body and the neural circuitry underlying its behavior has been termed *computational neuroethology* (Neuroethology, Computational). This chapter will focus on invertebrate locomotion systems for which quantitative modeling has been done, reviewing computer models of swimming, flying, crawling, and walking.

## Swimming

In swimming, support is less of a problem than it is in other modes of locomotion. However, unless an animal is neutrally buoyant, it must still make efforts to keep from either sinking or rising. Progression requires much more effort as a result of the drag from water's density and viscosity. Thus, the bodies of swimming animals are streamlined. Swimming invertebrates utilize one of two mechanisms, either hydraulic propulsion or rhythmic undulations of the body.

Although models of swimming in leeches, mollusks, and nematodes have been constructed (Pearce and Friesen, 1988; Niebur and Erdös, 1991), perhaps the most modeled swimming system is not that of an invertebrate but that of a primitive vertebrate known as the lamprey. Lampreys swim using coordinated contractions of muscles on each side of the body. These contractions produce a traveling wave along the body, with a wavelength of approximately one body length across a wide range of swimming speeds. Although the lamprey possesses much of the basic vertebrate neural architecture, the experimental accessibility of its nervous system has allowed a level of neurophysiological analysis that is more typically applied to invertebrate systems. Earlier work used mathematical analysis and simulation of chains of model oscillators to study intersegmental coordination in the lamprey spinal cord (Spinal Cord of Lamprey: Generation of Locomotor Patterns; Chains of Oscillators in Motor and Sensory Systems). Recent work has focused on more realistic models of the underlying neuronal circuit and models of the relevant mechanics of the lamprey body and the water through which it swims.

Ekeberg and Grillner (1999) have reviewed much of the recent work in this area. The rhythm-generation circuit consists of populations of motor neurons, excitatory interneurons, and two distinct types of inhibitory interneurons repeated in each segment. Models of this circuitry have demonstrated that oscillations are relatively easy to generate, but details of the pattern (e.g., burst termination) depend on biophysical details of the nerve cells. The generation and propagation of the traveling wave along the segments has been studied by coupling chains of model segmental oscillators. This work revealed that if the rostral segments receive stronger excitation, they become the source of the traveling wave, and variation of this extra excitation allows the spatial wavelength of the swimming pattern to be controlled separately from its temporal frequency.

Mechanical aspects of swimming have been investigated by coupling pattern-generation circuitry to a segmented body model actuated by linear viscoelastic model muscles and embedded in a model of the static drag force produced by the surrounding water. By varying the level and asymmetry of tonic input, this neuromechanical model could produce swims at a range of speeds, turns, and rolls. In addition, two kinds of sensory feedback have been modeled. Incorporating feedback from intraspinal stretch receptors led to improved robustness of the swim pattern against unpredictable changes in water flow. Feedback from vestibular receptors was incorporated in order to model roll and pitch stabilization.

## Flying

In many ways, flying is similar to swimming. However, because of the much lower density of air, considerably faster motions are required for powered flight than for swimming. While quasi-steady-state aerodynamic analyses of the sort used to understand aircraft have been successfully applied to larger animals, they have not been very successful for small flying insects. According to steady-state theory, many insects should be unable to generate sufficient lift to hold themselves aloft!

A recent model by Dickinson and colleagues has begun to shed considerable light on insect flight (Dickinson, Lehmann, and Sane, 1999). Because of the delicate size and high speed of insect wings, direct measurement of the forces involved is extremely difficult. For this reason, a robotic model was used to explore unsteady flows during hovering by the fruit fly *Drosophila melanogaster*. The model was submerged in mineral oil and scaled both in space and time so as to reproduce the Reynolds number (ratio of inertial to viscous forces) relevant to small insects flying in air. Dickinson and colleagues found that three major mechanisms contributed to lift generation in the model. First, vortices formed at the leading edge of the wing produce lift during much of the power stroke. Second, additional lift is produced by circulation of air around the wings resulting from rapid rotation at the beginning and end of each stroke. Third, further forces are produced at the start of each upstroke and downstroke as a result of collisions of the wings with the swirling wake produced by the previous stroke, a mechanism termed *wake capture*. Because of the sensitivity of the latter two mechanisms to the timing of wing rotation, the model suggests that the control of small details of wing motion can used in steering flight.

## Crawling

In crawling, locomotion occurs along the bottom surface of an aquatic environment or the surface of the earth via rhythmic contact between the body and the substrate. Invertebrates generate propulsive forces for crawling by changing body shape in one of three ways: contract-anchor-extend (as in the leech), pedal locomotion (as in molluscs), or peristaltic locomotion (as in earthworms). Crawling invertebrates typically utilize either hydrostatic skeletons or muscular hydrostatic structures to accomplish these movements.

A detailed neuromechanical model of crawling in the leech has been constructed by Kristan et al. (2000). This model assumes that the cross-sectional geometry of each body segment is elliptical, that the volume of body segments remains constant during movement, and that the animal's shape minimizes total potential energy. Kristan et al.'s simulations incorporate relatively realistic models of the circular and longitudinal muscles found in the leech body wall. Driving the model body with activation patterns deduced from the kinematics of intact animals produces crawling movements that are considerably more realistic than those produced by activation patterns derived from reduced preparations. These results suggest that sensory feedback plays a critical role in providing appropriate timing of activation of longitudinal and circular muscles.

## Walking

In legged animals, the body is raised above the ground and propelled by a sequence of leg movements. During walking, each leg cycles between a *stance phase*, in which the leg is providing support and propulsion, and a *swing phase*, in which the leg is off the ground and swinging forward. Swing phase duration is often nearly constant, while stance phase duration varies considerably with the speed of progression. Because the legs provide both support and propulsion and must be lifted after each stance, their movements must be coordinated so that the center of mass of the body remains within a polygon of support formed by the stancing legs (static stability). Otherwise, the animal must dynamically stabilize its body. Another coordination problem arises because adjacent legs must not interfere with one another. In many-legged animals, avoiding interference between adjacent legs is the crucial coordination problem, whereas the maintenance of stability is more important for animals with fewer legs.

Insect locomotion is remarkably flexible and robust. Insects can walk over a variety of terrains, as well as vertically and upside-down. In addition, they can also adapt their gait to the loss of up to two legs without severe degradation of performance (Delcomyn, Chapter 2 in Beer, Ritzmann, and McKenna, 1993) and sometimes even utilize dynamically stable gaits (Full, Chapter 1 in Beer et al., 1993). Most modeling has focused on statically stable walking across flat, horizontal surfaces. Even under these conditions, insects exhibit different gaits depending on their speed of locomotion.

Slowly walking insects show distinct *metachronal waves* on each side of the body: each leg begins its swing immediately following the termination of the swing of the leg behind it, with a 180° phase relationship between the pair of legs in each segment. Fast-walking insects utilize a *tripod gait*, in which the front and back legs on each side of the body step in unison with the middle leg on the opposite side. In one of the earliest theoretical models of insect walking, Wilson (1966) suggested that the entire range of observed insect gaits could be explained by assuming that fixed, antiphasic metachronal waves on each side of the body increasingly overlap as walking speed increases.

We developed a neural network model based on work by Pearson and colleagues on the neural organization of the American cockroach's walking system (Beer and Chiel, Chapter 12 in Beer et al., 1993). In this model, each leg controller has a pacemaker neuron whose output rhythmically oscillates due to a voltage-dependent intrinsic current. These pacemakers implement the swing burst-generators that Pearson hypothesized. A pacemaker burst initiates a swing by inhibiting the foot and backward swing motor neurons and exciting the forward swing motor neurons, causing the foot to lift and the leg to swing forward. Between bursts, the foot is down and tonic excitation from a command neuron moves the leg backward. Feedback from two sensors that signal when a leg is nearing its extreme forward or backward position fine-tunes pacemaker output. Forward angle sensor inhibition encourages burst termination, whereas backward angle sensor excitation encourages burst initiation. The forward angle sensor also makes direct connections to the motor neurons, modeling leg reflex pathways described by Pearson.

In order to generate statically stable gaits, the swings of the individual legs must be coordinated in some way. Following Pearson, we inserted mutually inhibitory connections between the pacemaker neurons of adjacent legs. We also added an entrainment mechanism for generating metachronal waves: slightly increasing the angle ranges of the rear legs lowers the burst frequency of the rear pacemakers, causing the pattern generators on each side of the body to phase-lock into a stable metachronal relationship.

In simulations of this circuit in a kinematic hexapod body model, a continuous range of statically stable gaits similar to those described by Wilson (1966) were observed. This range of gaits was produced simply by varying the tonic level of excitation of the command neuron. Smooth transitions between gaits could be generated by continuously varying this excitation. We found that the ability of this circuit to generate statically stable gaits was quite robust to lesions. For example, removing any single sensor or interpacemaker connection did not generally disrupt locomotion. These studies also demonstrated that sensory feedback was crucial for the maintenance of the slower metachronal gaits, but was relatively unimportant in the tripod gait.

The stick insect *Carausius morosus* has also been a major focus of legged locomotion research. Cruse (1990) reviewed leg coordination influences in both the stick insect and the crayfish *Astacus leptodactylus*. In the stick insect, there are three major influences: (1) a swinging leg inhibits the swing of a more anterior leg; (2) when a leg begins its stance phase, it excites the swing of a more anterior leg; and (3) as a stancing leg nears the end of its stance, it increasingly excites the swing of a more posterior leg. Some of these influences also operate between pairs of legs in the same segment.

Dean (1991) simulated these and other coordination mechanisms. The pattern generator for each leg was modeled as a relaxation oscillator with two states corresponding to stance and swing. The positions of each of the six legs were the state variables for a kinematic model of walking. The coordination mechanisms modified the position at which an affected leg began its swing, with inhibitory influences producing a posterior shift and excitatory influences producing an anterior shift. Dean's simulations demonstrated that these coordination mechanisms were sufficient to generate a continuous range of gaits, including the wave gait at low stepping frequencies and the tripod gait at high stepping frequencies. The model also exhibited distinct asymmetries in stepping pattern observed in the stick insect, in which the phase relationship between legs in the same segment is consistently lower or higher than 180°. A good review of earlier models of stick insect walking can also be found in Dean (1991).

Dean also explored the robustness of these coordinating mechanisms to various perturbations, including variations in starting configurations, perturbations of individual leg velocities, and obstructions to the swing of individual legs. He found that the gaits generated by these mechanisms were quite robust to such perturbations and that, in most cases, the model's responses were similar to those of the insect. Discrepancies between the model and the insect could be traced to the need for dynamic variables in addition to kinematic ones. Dean varied the strength and form of the coordination mechanisms. He found that influence (3) was the most important to maintaining proper coordination due to its graded nature, though the model was quite robust to substantial variations in the strengths of individual mechanisms.

## Biorobotics

The remarkable flexibility and robustness of animal locomotion has intrigued roboticists. Biologically inspired locomotion controllers offer a number of advantages over more classical approaches, including their distributed nature, their robustness, and their computational efficiency. Likewise, robots can serve as an important new modeling methodology for testing biological hypotheses. Thus, a number of researchers have begun to explore the interface between biology and robotics (Beer et al., 1998; Webb, 2000). Raibert and Hodgins (Chapter 14, in Beer et al., 1993) have argued for the importance of leg and actuator design in locomotion, designing a series of dynamically stable hopping and running robots based on the biomechanical design of animal limbs. For example, we implemented both the locomotion circuit and the stick insect coordination mechanisms described previously in hexapod robots and found that they could generate a range of gaits similar to those observed in simulations and were equally robust to perturbations (Beer et al., 1997), and more recent work has successfully incorporated significantly more biological realism into the latest robot (Quinn and Ritzmann, 1998). Thus, models of animal locomotion may not only yield insights into the neural control of motor behavior, but may also have significant technological applications.

## Discussion

We have touched on several successful examples of quantitative modeling of locomotion. It is notable that the different simulations utilize very different neural models. More fundamentally, it is striking that very different neural architecture can be utilized to generate locomotion. Undoubtedly, this variety is a result of the diverse body plans of animals and the many different ecological niches that they occupy. One consistent theme that does emerge, however, is the complex interplay of sensory input and central circuitry in the generation of locomotion. This complex interplay is responsible for the adaptive flexibility of animal locomotion.

# Locomotion, Vertebrate

*Auke Jan Ijspeert*

## Introduction

Locomotion is a fundamental skill for animals. It is required for a large variety of actions, such as finding food, encountering a mate, and escaping predators. Among the various forms of vertebrate locomotion are swimming, crawling, walking, flying, and the more idiosyncratic movements such as hopping, brachiation, and burrowing.

Animal locomotion is characterized by rhythmic activity and the use of multiple degrees of freedom (i.e., multiple joints and muscles). In vertebrates, motion is generated by the musculoskeletal system, in which torques are created by antagonistic muscles at the joints of articulated systems composed of rigid bones. All types of vertebrate locomotion rely on some kind of rhythmic activity to move forward: undulations or peristaltic contractions of the body, oscillations of fins, legs, or wings. As the animal rhythmically applies forces to the environment (ground, water, or air), reaction forces are generated that move the body forward.

This type of locomotion is in contrast to the motion of most man-made machines, which usually relies on few degrees of freedom (e.g., a limited number of powered wheels, propellers, or jet engines) and continuous rather than rhythmic actuation. From a technological point of view, animal locomotion is significantly more difficult to control than most wheeled or propelled machines. The oscillations of the multiple degrees of freedom need to be well coordinated to generate efficient locomotion. However, as can be observed from the swimming of a dolphin or the running of a goat over irregular terrain, animal locomotion presents many interesting features, such as energy efficiency (for swimming) and agility. The next sections review the neural and mechanical mechanisms underlying vertebrates' fascinating locomotor abilities.

## Neural Control of Locomotion

Despite diversity in types of locomotion, the general organization of the vertebrate locomotor circuit appears to be highly conserved. Locomotion is controlled by the interaction of three components: (1) spinal central pattern generators (CPGs), (2) sensory feedback, and (3) descending supraspinal control. The combination of these three components is sometimes called the motor pattern generator (MPG).

### *Central Pattern Generators*

Central pattern generators are circuits that can generate rhythmic activity without rhythmic input (see Half-Center Oscillators Underlying Rhythmic Movements and Motor Pattern Generation). The rhythms can often be initiated by simple tonic (i.e., nonoscillating) electrical or pharmacological stimulation. In vertebrates, the CPGs are located in the spinal cord and distributed in different oscillatory centers. In the lamprey, for instance, the swimming CPG is a chain of approximately 100 segmental oscillators distributed from head to tail (see Chains of Oscillators in Motor and Sensory Systems and Spinal Cord of Lamprey: Generation of Locomotor Patterns). In tetrapods, the locomotor CPG appears to be composed of different centers, one for each limb, that are themselves decomposed into different oscillatory subcenters for each joint (Grillner, 1981). Recent evidence from intracellular recordings in the mudpuppy suggests that joint subcenters can be decomposed even further into distinct oscillatory centers for flexor and extensor muscles (Cheng et al., 1998).

Experiments in completely isolated spinal cords and in deafferented animals (i.e., animals without sensory feedback) have shown that the patterns generated by the CPG are very similar to those recorded during intact locomotion. This demonstrates that sensory feedback is not necessary for generating and coordinating the oscillations underlying locomotion during stationary conditions.

### *Sensory Feedback*

Although sensory feedback is not necessary for rhythm generation, it is essential for shaping and coordinating neural activity with actual mechanical movements. The main sensory feedback to the CPGs is provided by sensory receptors in joints and muscles (see Motor Control, Biological and Theoretical). Rhythmically moving the tail or a limb of a decerebrate vertebrate is often sufficient to initiate the rhythmic patterns of locomotion. The frequency of oscillations then matches that of the forced movement, illustrating the strong influence of peripheral feedback on pattern generation.

Sensory feedback is especially important in higher vertebrates with upright posture such as mammals (as opposed to vertebrates with sprawling postures, like certain amphibians and reptiles), because the limbs of those vertebrates play an important role in posture control—supporting the body—in addition to locomotion.

A whole set of reflexes exists to coordinate neural activity with mechanical activity. One example is the stretch reflex, which generates the contraction of a muscle when the muscle is lengthened and which therefore helps maintain posture. The reflex pathways often share many of the interneurons that participate in locomotion control, and the action of reflexes is therefore not fixed. During locomotion, the action of reflexes can be modulated by central commands and in some cases even reversed, depending on the timing within the locomotor cycle (see Pearson and Gordon, 2000, and

Sensorimotor Interactions and Central Pattern Generators for reviews).

### *Descending Supraspinal Control*

Locomotion is initiated and modulated by descending pathways from diencephalic and mesencephalic locomotor centers. (For reviews, see Donkelaar, 2001, and Rossignol in Rowell and Shepherd, 1996, chap. 5). Some of these pathways are direct; an example is the pathway from the vestibular nuclei and the cerebellum to the spinal neurons. Other pathways are relayed by centers in the brainstem, in particular the red nucleus and the reticular nuclei. In all vertebrates, the reticulospinal tract plays a crucial role in generating the drive for the basic propulsive body and limb movements. In the lamprey, for instance, reticulospinal neurons control both the speed and direction of locomotion (Grillner et al., 1995). In mammals, additional direct pathways exist between the motor cortex and the spinal cord—the corticospinal tracts. These tracts are unique to mammals and play an important role in visuomotor coordination, such as accurate foot placement in uneven terrain.

Interestingly, the input signals to the brainstem do not need to be complex to generate locomotion. It has been known since the 1960s that simple electrical stimulation of the brainstem initiates the walking gait in a decerebrate cat, and progressively increasing the amplitude of the stimulation leads to an increase in the oscillation frequency, accompanied by a switch from walking to trotting and eventually to galloping (Shik, Severin, and Orlovsky, 1966). This demonstrates that the brainstem and the spinal cord contain most of the circuitry necessary for locomotion, including complex phenomena such as gait transitions (see Gait Transitions).

## The Biomechanics of Locomotion

Locomotion is the result of an intricate coupling between neural dynamics and body dynamics, and many fundamental aspects of locomotion control, including gait transition, control of speed, and control of direction, cannot be fully understood by investigating the locomotor circuit in isolation from the body it controls. A body has its own dynamics and intrinsic frequencies with complex nonlinear properties, to which the neural signals must be adapted for efficient locomotion control. As observed by roboticist Marc Raibert, the central nervous system (CNS) does not control the body, it can only make suggestions.

The body is a redundant system, with many muscles per joint and several muscles acting on more than one joint. Muscles serve as actuators, brakes, stiffness regulators, and stores of elastic energy. During locomotion, the frequencies, amplitudes, and phases of the signals sent to the multiple muscles must be well orchestrated. In most vertebrates, complex coordination is required not only between different joints and limbs but also between antagonist muscles, which combine periods of co-activation for modulating the stiffness of the joint and periods of alternation for actuating the joint.

In legged locomotion, the dynamics of a leg can be approximated by a pendulum model during walking and by a spring-mass model during running. These models allow one to relate several features, such as resonance frequencies, to the length and stiffness of the legs, and are able to describe the mechanics of legged locomotion surprisingly well in many animals.

The importance of the mechanical properties of the body is illustrated by research on passive walkers. Passive walkers are legged machines (some with knees and arms) that transform potential energy from gravity into kinetic energy when walking down a gentle slope. When correctly designed, these machines do not require any actuation or control for generating a walking gait, which in some cases can be strikingly human-like.

## Numerical Simulations of Locomotor Circuits

Although the general organization of the vertebrate locomotor circuit is known, much work remains to be done to elucidate how its different components are implemented and how they interplay to generate the complex patterns underlying locomotion. This is a complex task because (1) these patterns are due to the interaction of the CNS and the body in movement, (2) numerous neurons in the brainstem and the spinal cord are involved, and (3) in most vertebrates, the same circuits appear to be involved in generating very different patterns of activity (e.g., different gaits in tetrapods). For the moment, the best decoded locomotor circuits are probably the swimming circuits in the lamprey and the frog embryo. For other vertebrates, in particular tetrapods, significant parts of the structure and functioning of the locomotion circuitry remain unknown.

Numerical simulations have an important role to play in evaluating whether a potential model of a neural circuit is adequate and sufficient to reproduce the rhythmic patterns observed through intracellular and/or EMG measurements. Several important issues can be investigated in simulation, such as the general stability of the patterns and the effect of modulating the tonic drive on the frequencies and phases of the oscillations. Simulations do not need to be restricted to the CNS. An interesting approach to understanding locomotion control is to couple the simulations of the locomotor circuits to physics-based simulations of the body (or to a robot). Such *neuromechanical* simulations are particularly useful because they embed the neural circuits in a body in interaction with the environment, therefore allowing one to close the sensing-acting loop and to investigate the complete resulting motor patterns (as opposed to only the patterns produced by the isolated CPGs).

## Some Models of Vertebrate Locomotor Systems

This section presents some results of modeling of vertebrate locomotion, with a special focus on neuromechanical simulations.

### *Swimming*

Vertebrate swimming has been most studied in the lamprey (see Spinal Cord of Lamprey: Generation of Locomotor Patterns), an eel-like fish using *anguilliform* swimming, in which a traveling wave is propagated along the whole elongated body. Ekeberg developed a neuromechanical simulation composed of a connectionist neural network representing the lamprey's 100-segment spinal locomotor circuit and a simplified model of the body in interaction with water (Ekeberg, 1993). The neural network produces oscillating activity when tonic input is provided to the neurons, with the frequency of oscillation being proportional to the level of excitation. When extra excitation is provided to the most rostral (i.e., closest to the head) segments, a traveling wave is propagated from head to tail. The extra excitation determines the wavelength, independent of the frequency. With these settings, the model therefore replicates the fact that a swimming lamprey can cover a large range of frequencies while maintaining the wavelength constant at approximately one body length.

The mechanical simulation is a two-dimensional articulated rigid body actuated by muscles simulated as spring and dampers. Although the hydrodynamics of the model is simplified, it produces swimming gaits very similar to those of lamprey swimming (Figure 1). The mechanical simulation allowed Ekeberg to investigate the effect of modulating the locomotor pattern on the speed and direction of locomotion, as well as the effect of sensory feedback from spinal stretch–sensitive cells. The model demonstrated that the speed of swimming can be varied by changing the frequency of oscillation through the level of tonic input, whereas the direction

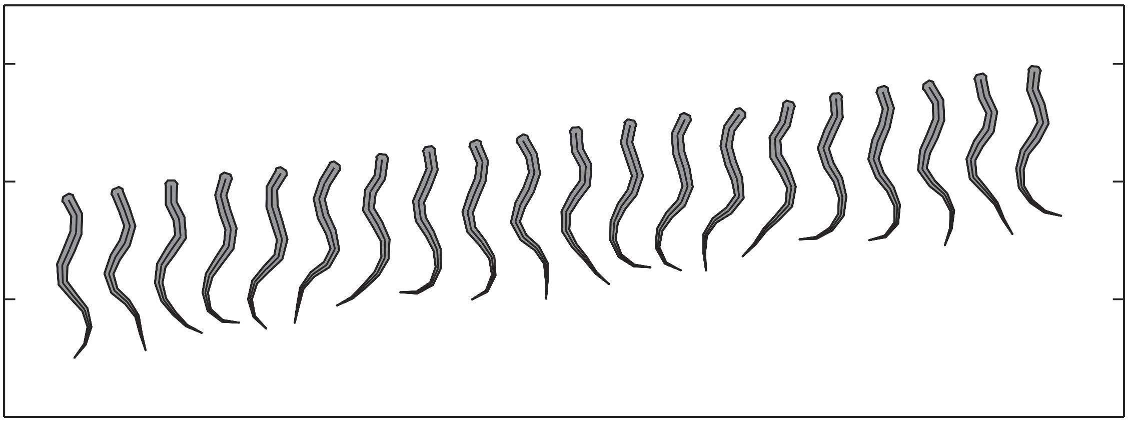

**Figure 1.** Neuromechanical simulation of lamprey swimming. (Reimplementation by the author of the model presented in Ekeberg, Ö, 1993, A combined neuronal and mechanical model of fish swimming, *Biol. Cybern.*, 69:363–374.)

of swimming can be varied by applying asymmetric tonic drive between left and right sides of the locomotor circuit.

Vertebrate swimming has inspired several underwater vehicles, such as eel-like robots that use anguilliform swimming (REEL, at the University of Pennsylvania) and a lamprey-based undulatory robot (at the Marine Science Center of Northeastern University), and caranguiform swimming in the RoboTuna (at the Massachusetts Institute of Technology).

### *From Swimming to Walking*

One of the most important changes during vertebrate evolution has been the transition from aquatic to terrestrial habitats. Our own work investigated the transition from swimming to walking in the salamander, an animal that is believed to be one of the modern animals closest to the first vertebrates that made this transition during evolution.

The salamander swims like a lamprey by propagating an undulation from head to tail. On ground, it switches to a stepping gait, usually with the phase relation of a trot. Although the locomotor circuit of the salamander has not yet been decoded, it has been found to share many similarities with the swimming circuit of the lamprey (Cohen, 1988; Delvolvé, Bem, and Cabelguen, 1997).

Our work sought to demonstrate that a lamprey-like swimming circuit could be extended to produce the swimming and stepping gaits of the salamander, with, in particular, a traveling wave along the body during swimming and a standing wave during stepping. The neural configuration of the model is illustrated in Figure 2. It is composed of a lamprey-like body CPG, extended by forelimb and hindlimb CPGs (Ijspeert, 2001). These limb centers have been identified just rostral to the anterior and posterior girdles, respectively. The mechanical simulation was an extension of Ekeberg's model of the lamprey (see Ijspeert, 2001, for a detailed description).

The model is able to (1) generate stable traveling waves and standing waves, depending on simple tonic input, (2) quickly switch between them, and (3) coordinate body and limb movements so as to produce swimming and walking gaits very similar to those recorded in salamanders. Gait transition is obtained as follows: when only the body CPG receives tonic input, the limb CPGs remain silent (limbs are maintained tonically against the body) and the body CPG produces a traveling wave that propels the salamander forward in water, whereas when tonic input is applied to both the body CPG and the limb CPGs, the body CPG is forced by the limb CPGs to produce a standing wave for stepping. The body then makes a standing S-shaped wave with the nodes at the girdles that is coordinated with the movements of the limbs so as to increase the reach of the limbs during the swing phase (Figure 3, bottom).

Much as in Ekeberg's model of the lamprey, the speed and direction of locomotion can be modulated by respectively varying the level and the asymmetry (between left and right) of tonic input applied to the CPGs. Experiments involving the tracking of a randomly moving target show that locomotion is stable even when the input signals change rapidly and continuously (Ijspeert and Arbib, 2000). In collaboration with Richard Woesler and Gerhard Roth, we are currently extending this work to investigate visuomotor coordination (see VISUOMOTOR COORDINATION IN SALAMANDER).

### *Quadruped Locomotion*

Quadruped locomotion in vertebrates has evolved from the sprawling posture found in salamanders and lizards to the upright posture found in mammals. During that evolution, the limbs gradually moved under the body, and movements in the body evolved from lateral to mainly sagittal (i.e., ventrodorsal) undulations.

The upright posture means that limbs serve both for locomotion and for maintaining balance. Gaits can either be *statically stable*, in which the center of mass is maintained at all times above the polygon formed by the contact points of the limbs with the ground, or *dynamically stable*, when this rule is not maintained at all times and stability is achieved as a limit cycle that balances moments, gravitational forces, and inertial forces over time. Depending on the phase relation between limbs, a large variety of gaits can be distinguished, such as the walk, the trot, the pace, and the gallop. Mammals can usually switch between these gaits very quickly (see GAIT TRANSITIONS).

The neural mechanisms underlying quadruped locomotion have not yet been decoded, but investigations in the cat have shown that the rhythmic patterns for locomotion are generated by spinal CPGs, while control of posture and accurate placement of feet are under control of the cerebellum and motor cortex. Decerebrate cats, for instance, can produce normal-looking gaits on a treadmill, but need to be supported to do so. The mechanisms underlying intra- and interlimb coordination, however, are still far from understood, especially in relation to gait transition.

Kimura, Akiyama, and Sakurama (1999) present a model of quadruped locomotion that emerges from the coupling of a neural controller with a quadruped robot with 12° of freedom. The neural controller is composed of four coupled oscillators, one for each limb, and several types of reflexes. Kimura and colleagues investigated several schemes of how feedback from load sensors, touch

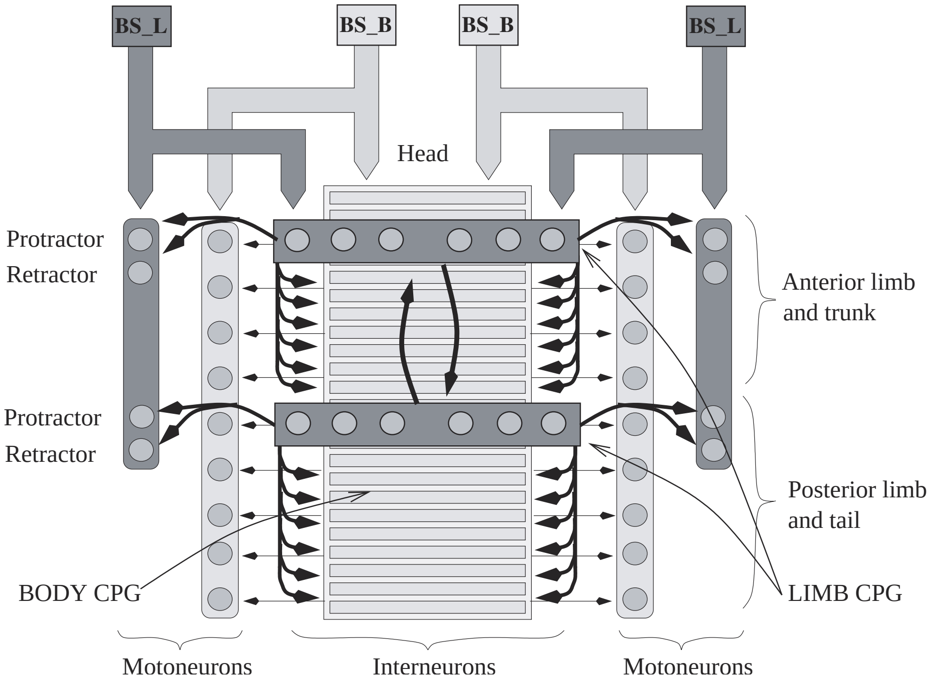

**Figure 2.** Potential model for the central pattern generator responsible for locomotion in the salamander. (From Ijspeert, A., 2001, A connectionist central pattern generator for the aquatic and terrestrial gaits of a simulated salamander, *Biol. Cybern.*, 85:331–348. Reprinted with permission.)

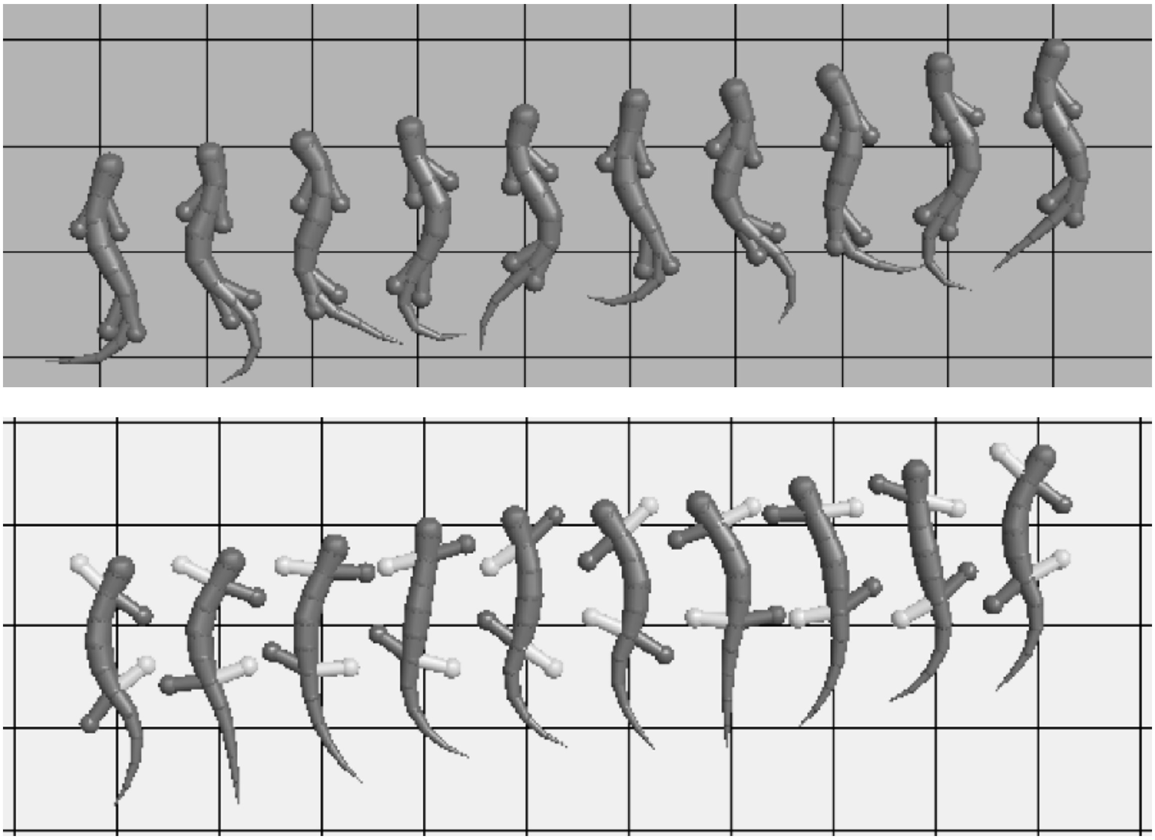

**Figure 3.** Neuromechanical simulation of salamander locomotion. *Top*, swimming; *bottom*, stepping. (From Ijspeert, A., 2001, A connectionist central pattern generator for the aquatic and terrestrial gaits of a simulated salamander, *Biol. Cybern.*, 85:331–348. Reprinted with permission.)

sensors, and a vestibular system (a rate gyro) could be coupled to the CPG. The schemes in which the feedback was fed into and gated by the CPGs (as opposed to being independent of the CPGs) were found to generate significantly more stable gaits on irregular terrain. This strongly resembles the modulation of reflex signals by CPGs found in vertebrates and described earlier under Sensory Feedback. Other examples of impressive running and hopping robots can be found in Raibert and Hodgins (1993), for instance.

### *Biped Locomotion*

Biped locomotion, such as human locomotion, is usually a dynamically stable gait. Humans use mainly two gaits: walking, in which at least one foot is in contact with the ground during the whole locomotor cycle, and running, which has a flight phase without foot contact.

The control of posture is essential in biped locomotion because of the erect posture. In humans, the motor cortex and the cerebellum play a crucial role in locomotion, much more so than in lower vertebrates. As in other vertebrates, there seems to be good evidence that the locomotor pattern can be generated at the spinal level, most likely driven from reticulospinal pathways. Clearly, the postural problem involves an important role of the cerebellum for behaviorally successful locomotion, with the corticospinal pathway playing, in addition, a role in the step-to-step modification (e.g., visually guided) of the locomotor cycle. See Horak and MacPherson in Rowell and Shepherd (1996, chap. 7) for a review.

In a series of papers, Gentaro Taga developed an interesting two-dimensional model of human locomotion (motion in the sagittal plane) in which stable locomotor patterns emerged from the interaction of a set of neural oscillators coupled to a musculoskeletal system composed of eight rigid segments (e.g., Taga, 1998). Taga's work was seminal in showing potential mechanisms of global entrainment between two highly nonlinear systems, the neural oscillators and the body. Balance in the model is maintained by a posture controller that regulates the impedance of the joints in parallel to the oscillators. The patterns are sufficiently stable to generate gaits even in unpredictable environments. In the latest version of the model, the locomotion controller is extended with a discrete movement generator for anticipatory adaptation for stepping over obstacles. The discrete movement generator modifies the stepping by generating a sequence of discrete motor signals, changing the gains of specific muscles. The functional role of the discrete movement generator is therefore comparable to the modulatory effect of the motor cortex observed during obstacle avoidance tasks in cats and humans.

## Discussion

Vertebrate locomotion control is organized such that neural networks in the spinal cord generate the basic rhythmic patterns necessary for locomotion, and higher control centers interact with the spinal circuits for posture control and accurate limb movements. This means that, in general, the control signals sent to the spinal cord do not need to specify all the details of when and how much the muscles must contract, but rather specify higher-level commands such as stop and go signals, speed, and heading of motion. This type of distributed control has provided an interesting inspiration for robotics, as it implies (1) a reduction in the amount of information that has to be communicated back and forth, and (2) a reduction in the time delays between sensing, command generation, and acting.

Locomotor circuits are the result of evolution, which means that there exists a chain of changes from the ancestral vertebrate to all vertebrates. An important question that remains open is to determine which modifications have occurred in the locomotor circuits from the generation of traveling waves for swimming (the most ancestral vertebrates were close to the lamprey) to the generation of standing waves for walking, to the generation of multiple gaits for quadruped locomotion, and finally to the generation of biped locomotion (not to forget all the other forms of vertebrate locomotion mentioned in the Introduction). This is an important issue, since the mechanisms of locomotion in modern vertebrates are strongly shaped by this evolutionary heritage and might not be fully understood without taking evolution into account. In particular, we will need to determine to what extent the three components of locomotion control—CPGs, sensory feedback, and supraspinal descending commands—have changed. It is clear that important morphological changes have significantly modified the patterns of sensory feedback. However, for lower vertebrates, it is likely that most of the changes are due to modifications of the CPGs, since CPGs are able to generate relatively normal gaits without sensory feedback, and comparative studies show that descending pathways are in general strikingly conserved (Donkelaar, 2001). In higher vertebrates such as mammals, changes of the CPGs have been accompanied by important modifications of the descending pathways under the requirements of complex posture control and accurate limb movements, although the extent of the respective changes remains unknown. In addition to neurophysiological experiments and comparative studies, computer models, in particular models that combine neural models with biomechanical models, have an important role to play in answering these fascinating questions.

# Locust Flight: Components and Mechanisms in the Motor

*R. Meldrum Robertson*

## Introduction

The locust flight motor provides an excellent model system for investigations of constraints and mechanisms of Motor Pattern Generation at the neuronal level. In locusts the neural elements involved in generating the patterns of flight motor activity are individually identifiable (see Comer and Robertson, 2001, for a review of identified neurons controlling insect behaviors). It is thus possible to describe the operation of networks of identified neurons, connected by identified synapses, and to determine how these networks contribute to the computational task of producing rhythmical motor patterns capable of keeping the locust aloft in an unpredictable environment.

The flight systems of other insects have attracted research interest in their neural control mechanisms. Indeed, the visuomotor control of dipteran flight has received notable attention (Visual Course Control in Flies). Nevertheless, it is only for the locust that enough is known of the circuitry underlying the form and timing of the wingbeat that it can be useful as a model of central nervous system function.

## The Motor Output

The locust flight system (Figure 1) creates a spatiotemporal pattern of electrical activity in about 80 flight motoneurons that activate muscles controlling the four wings (a pair of forewings and a pair of hindwings) and cause beating of the wings at around 22 cycles/s. Telemetric techniques now exist to monitor the activity of identified flight muscles during free flight under conditions that require the generation of different combinations of rotational and translational flight forces (Kutsch, 1999). Particular features of the motor pattern can be correlated with specific flight parameters that are modified to effect adaptive flight maneuvers (i.e., natural behaviors). It was originally demonstrated that a version of the motor pattern, albeit slower (around 12 cycles/s), could be generated by a central nervous system deafferented from phasic timing information emanating from wing proprioceptors and other sense organs. This discovery was influential in establishing the central pattern generator concept (Motor Pattern Generation). An important question is to what extent the central pattern generator is responsible for controlling the *behavior*, particularly given that afferent input can change the set of active flight interneurons in the locust. There is no doubt that a rhythmic central pattern can be generated, but it is conceivable that this pattern is the output of a network artificially created by the act of deafferentation, i.e., a malformed, degenerate pattern that has no real bearing on the generation of the functional flight motor pattern. There is little evidence for this extreme position, and the extent to which sensory feedback supersedes the role of the central pattern generator in normal intact flight remains unclear. Nevertheless, it is quite clear that proprioceptive feedback is necessary for appropriate timing of the wingbeat phase transitions. The tegulae are external sense organs stimulated by depression of each wing and they can initiate the subsequent elevator phase by excitation of elevator motoneurons and interneurons. The stretch receptors are internal, at the wing base, and activated by wing elevation. They promote the occurrence of the subsequent depression by opposing the hyperpolarization between the bursts of action potentials in depressor moto-

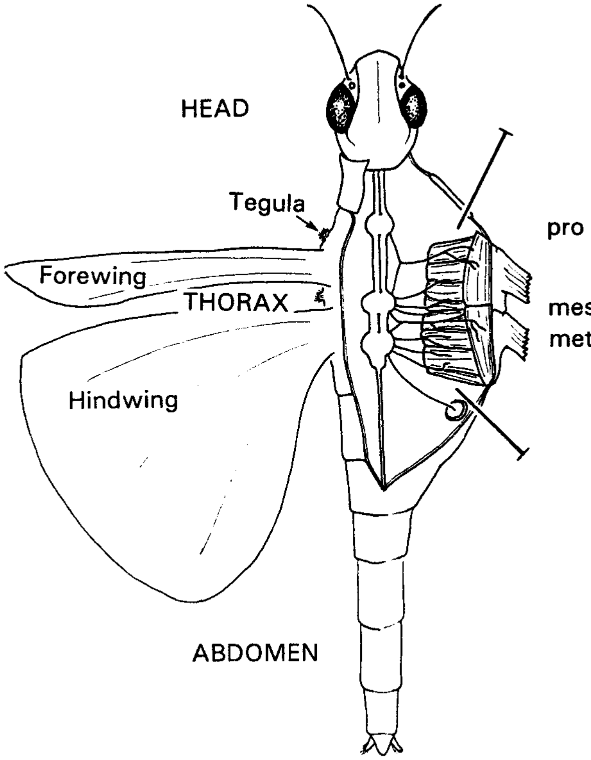

**Figure 1.** The locust flight system. Diagrammatic representation of a locust showing on the left side the form of the forewing and hindwing and the position of the fore and hind tegulae (only the forewing tegula is labeled). On the right side the thorax has been pinned open to reveal the bank of flight muscles that power the wings and the three thoracic ganglia (pro-, meso-, and metathoracic) that contain the motoneurons and interneurons involved in generating flight motor patterns.

neurons. A simple model describing how the stretch receptors regulate wing beat frequency has been described but would benefit from a quantitative implementation (Figure 2) (Pearson and Ramirez, 1990).

## The Neuronal Components and Their Organization

The centrally generated rhythm arises as a result of the cellular properties of interneurons in the three thoracic ganglia (pro-, meso-, and metathoracic) and the interactions between these neurons. Numerous interneurons have been described. They are connected into circuits via standard, short latency, synaptic interactions probably mediated by gamma-aminobutyric acid (inhibitory) and glutamate (excitatory) (Robertson, 1989). This central circuit operates essentially as a unit distributed throughout six serially homologous, segmental neuromeres (Robertson, Pearson, and Reichert, 1982). A simple conceptual model of the circuitry described to date has at its heart a circuit of delayed excitation and feedback inhibition that would result in an elevator-depressor burst sequence (Figure 2*B*) (Robertson and Pearson, 1985).

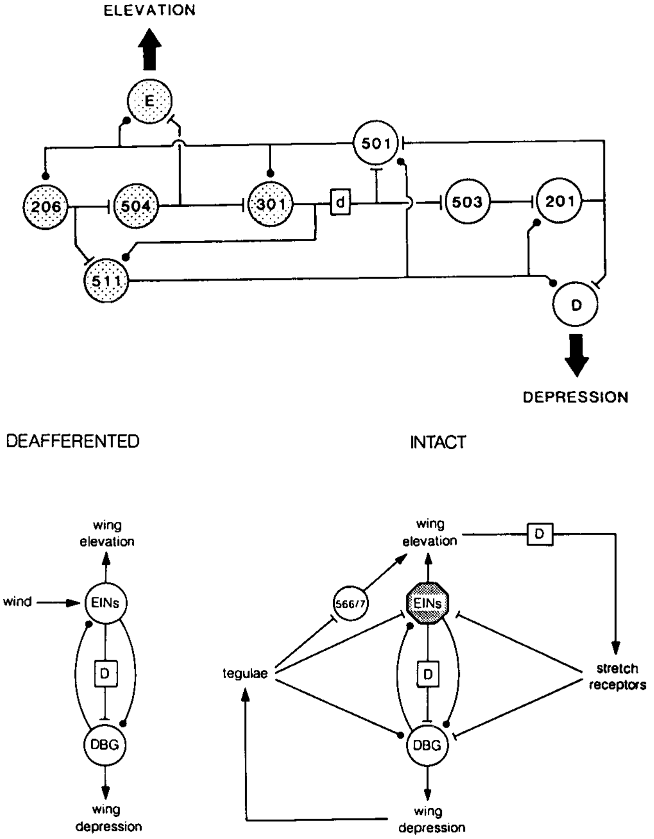

**Figure 2.** Circuit models of the locust flight system. *A*, Model illustrating the role of proprioceptive feedback in generating the flight motor pattern. The deafferented system (left) consists of a depressor burst generator (DBG) with reciprocal inhibitory interactions with elevator interneurons (EINs). These interneurons also pass excitation from wind input to the DBG through a delay (D) pathway. In intact animals (right), feedback from proprioceptors can recruit interneurons (e.g., 566/7) as well as interacting with the elements of the central rhythm generator. Stippling indicates that the activity pattern of the EINs is altered by the feedback. Filled circles, inhibitory connections; 'T'-bars, excitatory connections. Taken from Pearson and Ramirez, 1992. *B*, Model illustrating some of the connections between flight interneurons that may contribute to generating the central flight rhythm. Elevator interneurons are stippled. Interneuron 206 receives excitation from wind input. Note the similarity with the deafferented model in A. The heart of the circuit is delayed excitation (301 to 501) and feedback inhibition (501 to 301). Taken from Robertson, 1986.

Transection and hemisection experiments have demonstrated a multiplicity of patterning elements that may aid in stabilizing the output pattern, an extremely important role for sensory elements in timing and coordination of the four wings during intact flight, and a preeminent role for the metathoracic ganglion, compared with the role of the mesothoracic ganglion, in central pattern generation. There are many oscillator mechanisms contributing to the generation of the rhythm, such that rhythm generation survives much experimental manipulation (see the section, "Modeling in the Locust Flight System," later in this article). However, there is not yet any strong evidence to support the notion that the central rhythm generator is organized as a coupled oscillator system in the sense that each wing, or pair of wings, is controlled by a separate central oscillator with the relative phasing determined by the nature of the coupling between them. This makes the locust flight system apparently unique among locomotor pattern generators, most of which do seem to be organized as coupled central oscillators.

## Circuitry Underlying Steering

An important feature of any motor pattern generator for locomotion is that it must control the direction of movement through space, as well as simple translation (Visual Course Control in Flies and Sensorimotor Interactions and Central Pattern Generators). This entails both maintaining a course in the face of environmental factors tending to displace the animal, and changing the course to enable movement toward or away from biologically relevant stimuli. Most information has accumulated for course correction behaviors—mechanisms of the "autopilot." It is only for the course correction circuitry that there is a model, at the cellular level, explaining how multimodal sensory input signaling deviation from course can be integrated into the operation of the central circuitry to cause the asymmetries in the motor output that would be necessary to compensate for an unintended change in the direction of flight (e.g., Reichert, Rowell, and Griss, 1985). The basis of the model is that continuous signals from exteroceptors, such as the ocelli (simple light detectors) or wind-sensitive head hairs, excite premotor interneurons that are rhythmically activated by the central circuits at the same time. Thus, the course deviation signal is gated through these premotor interneurons and transmitted to the motor neurons at the appropriate phase for an effective change in the motor pattern. Much of the asymmetry in the form of the wingbeat that generates steering torques occurs during the downstroke (the power stroke) of the wings, while the upstroke remains relatively symmetrical. The deviation signal can be gated so that it affects only those motoneurons involved in controlling the form of the downstroke, and it need not interact directly with the central rhythm generator.

## Neuromodulation and Plasticity

The neural networks that control motor patterns are not static entities (Pearson, 2000; also see Neuromodulation in Invertebrate Nervous Systems). The mix of circulating transmitters and neuromodulators controls the particular set of circuit components and characteristics at any one time. Octopamine has a multifaceted role in the control and coordination of locust flight (Orchard, Ramirez, and Lange, 1993). From mobilization of energy resources to the modification of flight muscle properties, octopamine has influences throughout the locust enabling it to fly efficiently and, equally, to respond to the metabolic demands of flight. Indeed octopamine released from specific subgroups of DUM (*d*orsal *u*npaired *m*edian) neurons may orchestrate the peripheral reconfigurations required by different motor programs such as walking or flight (Duch and Pflüger, 1999). Local injection of octopamine at specific sites in the thoracic ganglia is sufficient to release flight-like activity from the nervous system. Similarly, topical application of octopamine to exposed nervous systems can generate flight-like motor patterns, even in immature stages of the locust that normally do not generate such patterns. The basis for these observations is likely the fact that octopamine can induce intrinsic bursting properties (plateau potentials; Oscillatory and Bursting Properties of Neurons) in identified flight interneurons, and there are good reasons for supposing that this experimental manipulation reflects a physiological role for octopamine in the generation of normal flight motor patterns. It also seems likely that, in addition to the described interneuronal circuits, cellular properties and the generation of bistable plateau potentials contribute to the generation of the motor pattern in the absence of octopamine.

A short-term plasticity in the output of the flight system has been described and is ascribed to associations between muscle-specific proprioceptive input and exteroceptive input signaling deviation from course (Möhl, 1993). The interesting concept proposed by this work is that the central circuits provide a motor framework that is subsequently sculpted by the immediately preceding flight experience to provide the output that is most effective in controlling flight (e.g., maintaining a straight and level orientation). Thus, the operating circuit can be tailored to the current condition of the animal and its flight system. The specific synaptic mechanisms underlying this short-term plasticity remain to be determined. In contrast, there is some information on the synaptic mechanisms involved in a longer-term plasticity underlying functional recovery after a specific deafferentation (Wolf and Büschges, 1997). Ablation of the hindwing tegulae impairs the operation of the flight system, and this is reflected in a reduced wingbeat frequency. However, the system recovers during the subsequent two weeks due to the forewing tegulae taking over the function of the ablated hindwing tegulae. The basis for the recovery is the formation of new connections between the afferents and specific flight interneurons, accompanied by sprouting and growth of both the axonal branches of afferent fibers and the dendritic arbors of the interneurons. The synaptic connections are in a dynamic equilibrium that is disrupted by the lesion, and it is particularly interesting that different, though serially homologous, sense organs can replace those ablated.

Finally, locusts do not physiologically regulate body temperature but exist in a harsh ecological niche where ambient temperatures often exceed 45°C. Adaptive mechanisms exist to condition the circuitry by prior exposure to high temperatures and thus to extend the operating range by 5°–7°C. The current model proposes that heat stress-mediated long-term reduction of potassium conductance delays the failure of action potentials as temperature is increased by preventing potassium currents from overwhelming sodium currents at high temperatures (Wu and Robertson, 2001). Given the evolutionary conservation of cellular protective responses (e.g., the heat shock response), the mechanisms underlying thermoprotection of circuit function in this system could have implications for the development of therapeutic strategies to combat thermal failure of mammalian circuits (e.g., the hyperthermic failure of respiratory rhythm generation that has been proposed as an explanation for some cases of SIDS).

## Modeling in the Locust Flight System

Insect flight lends itself to modeling at several different levels. The construction of flapping machines and flying robots is well advanced and our understanding of the aerodynamics of flapping insect flight has been greatly improved by biomechanically modeling the wing kinematics of functionally two-winged fliers (dipteran flies and moths). Extending this approach to functionally four-winged locusts remains a challenge. Robotic and virtual models of the processing and integration of sensory information to control a search strategy (e.g., olfactory stimuli) or avoid collisions (e.g., looming visual stimuli) are well established. However, the modeling of circuit and cellular mechanisms generating flight motor rhythms is unsophisticated compared with that of many other rhythm generating systems.

Initial attempts to model the locust flight circuits used electronic Lewis “neuromimes,” which simulate the behavior of neural membranes and can be connected into networks (Wilson and Waldron, 1968). An arrangement of neuromimes into positively coupled subsets interconnected with reciprocal inhibition successfully mimicked several features of the flight motor pattern. Unfortunately, successive families of detailed models have not followed this early success. What mostly exist in the literature are conceptual circuit models of the common “ball and stick” type (e.g., Figure 2). One notable exception is the computer simulation of the central flight circuit performed with BioSim 3.0 (Grimm and Sauer, 1995). This simulation was rudimentary by current standards and introduced numerous simplifications; nevertheless, it clearly demonstrated the following: that the known circuit could produce acceptable flight-like rhythms; that subloops of the complete circuit could generate comparable rhythms; that circuit operation was relatively resistant to “synaptic strength”; and that the addition of plateau potential generating properties did not greatly affect the output of the circuit or the robustness of the rhythm generating mechanism.

Knowledge of the flight system is currently at a stage at which more detailed models would be beneficial. Could changing the parameters of a model central circuit, according to the known effects of temperature on conduction velocities and synaptic interactions, replicate the known effects of temperature on the motor patterns? Is it possible to generate a model that mimics the coordination of the four wings using a single depressor burst generator located primarily in the metathoracic ganglion? Can the effect of specific ablations and recoveries be accurately modeled? The list here, as for any other nontrivial system, is endless.

## Discussion

Locust flight motor patterns are generated by an interactive mixture of the intrinsic properties of flight neurons, the operation of complex circuits, and phase-specific proprioceptive input. These mechanisms are subject to the concentrations of circulating neuromodulators and are also modulated according to the demands of a constantly changing sensory environment to produce adaptive behaviors. The system is flexible and plastic in the short term and in the long term, able to operate in spite of severe ablations and subsequently to recover from these lesions, and able to cope with extreme environmental conditions.

Without a doubt, the neural processes involved in higher brain functions will not be first described in the locust. However, the basis for these higher functions is likely due both to the generation of patterns of electrical activity in time and space and to the modulation of these patterns by the extracellular environment, by the periphery, and by experience—the control of such spatiotemporal patterning can profitably be investigated in the locust flight system.

# Markov Random Field Models in Image Processing

*Anand Rangarajan and Rama Chellappa*

## Introduction

Markov random field (MRF) models have become useful in several areas of image processing. The success of MRFs can be attributed to the fact that they give rise to good, flexible, stochastic image models. The goal of image modeling is to find an adequate representation of the intensity distribution of a given image. What is adequate often depends on the task at hand, and MRF image models have been versatile enough to be applied in the areas of image and texture synthesis (Zhu, Wu, and Mumford, 1997), image restoration (Geman and Geman, 1984), tomographic reconstruction (Lee, Rangarajan, and Gindi, 1995), image and texture segmentation (Krishnamachari and Chellappa, 1997), flow field segmentation (Konrad and Dubois, 1992), surface reconstruction (Geiger and Girosi, 1991), and object recognition (Gold and Rangarajan, 1996). Our aim in this article is to highlight the central ideas of this field using illustrative examples and to provide pointers to the many applications.

A guiding insight underlying most of the work on MRFs in image processing is that the information contained in the local spatiotemporal structure of images or image sequences is sufficient to obtain a good, global representation. This notion is captured by means of a local, *conditional* probability distribution. Here, the image intensity at a particular location depends only on a *neighborhood* of pixels. The conditional distribution is called an MRF. For example, a typical MRF model assumes that the image is locally smooth except for relatively few intensity gradient discontinuities corresponding to region boundaries or edges. The MRF image models are defined on the image intensities and on a further set of *hidden* attributes (edges, texture, and region labels). The observed quantities are usually noisy, blurred images, feature vectors, or projection data (in the case of emission tomography). The intensity image underlying the observations is needed in applications such as restoration and tomographic reconstruction, whereas region, boundary, and texture labels are sought in applications such as texture segmentation.

Once the local, conditional probability distribution of the MRF is specified, there are five remaining steps involved. First, the joint distribution of the MRF is obtained. In this way, the image is represented in one global, joint probability distribution. Next, the process by which the observations are generated from the image is captured in a *degradation* probability distribution. In image restoration, for example, the degradation corresponds to a (typically uniform) blur. Then, Bayes's theorem is invoked to obtain the posterior probability distribution of the image given the observations. The posterior distribution gives us the probability that an image (with smooth regions and sharp region boundaries, for example) could have been degraded to obtain the particular observed noisy, blurred image. Once the posterior probability distribution is obtained, we can associate a cost with each configuration in the posterior. For example, if only the true underlying image will do, the cost penalizes all other images equally. The cost is formulated, keeping in mind the task at hand. A measure of the cost is minimized with respect to the image intensities (in image recovery tasks) or image attributes (in labeling tasks). Finally, since MRFs are specified with model parameters, these are estimated from a training set (if one exists) or adaptively, along with the cost minimization phase alluded to earlier. The overall MRF framework fits well within a Bayesian estimation/inference paradigm. In the next section, we step through all five phases of MRF modeling.

## A Framework for Estimation and Inference

MRF image models represent knowledge in terms of local probability distributions. Specifically, the kinds of probability distributions generated by MRFs have a local neighborhood structure. Neighborhood systems commonly used by MRFs are depicted in Figure 1*A*.

Let us associate an image with a random process $X$ whose element is $X_s$, where $s \in S$ refers to a site in the image. The local conditional distribution can be written as follows:

$$\Pr(X_s = x_s | X_t = x_t, t \neq s, t \in S) = \Pr(X_s = x_s | X_t = x_t, t \in G_s) \quad (1)$$

where $X$ and $x$ denote the random field and a particular realization, respectively, and $G_s$ is the local neighborhood at site $s$. Note that

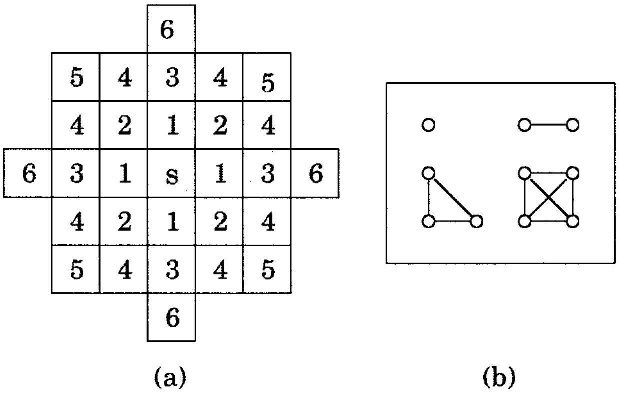

**Figure 1.** *A*, Neighborhood systems for MRFs. *B*, Cliques in MRFs.

in general, $G_s$ can be large or small, but it is usually a local neighborhood, in keeping with the spirit of MRF modeling.

Let $s$ be the site $(i, j)$ and let the local neighborhood be a first-order neighborhood ($G(s)$ is the collection $(i, j + 1)$, $(i, j - 1)$, $(i + 1, j)$, $(i - 1, j)$). Then, let the conditional density take the form

$$p(X_s = x_s|X_t, t \in G_s) = \frac{1}{\sqrt{2\pi}} \times \exp\left[-\frac{1}{2}\left(x_{ij} - \frac{1}{4}[x_{i,j+1} + x_{i,j-1} + x_{i+1,j} + x_{i-1,j}]\right)^2\right] \qquad (2)$$

This is a very simple special case of the first-order Gauss-Markov model (Besag, 1974). The Gauss-Markov model has been widely used in image processing tasks (Dubes and Jain, 1989).

The MRF model consists of a set of *cliques*. A clique is a collection of sites such that any two sites are neighbors. Different orders of cliques are shown in Figure 1*B*. The order of a clique refers to the number of distinct sites that appear multiplicatively. We now calculate the clique energies involving the site $x_{ij}$ by expanding the conditional probability density and collecting the terms. There are cliques of order one and two. They are

$$\frac{x_{ij}^2}{2}, \quad -\frac{x_{ij}x_{i,j+1}}{4}, \quad \text{and} \quad -\frac{x_{ij}x_{i+1,j}}{4} \qquad (3)$$

The first term in Equation 3 is of order one and the latter two terms are of order two.

### MRF-Gibbs equivalence

We now ask the following question: Given the conditional probability structure $\Pr(X_s = x_s|X_t = x_t, t \in G_s)$, what is the joint probability distribution $\Pr(X = x)$? This is of utmost importance, since it is the joint probability distribution and not the conditional distribution that contains the complete image representation.

Before relating the conditional and joint distributions, we introduce the concept of a Gibbs distribution, which will turn out to be crucial in specifying the relationship. A Gibbs distribution is specified by an *energy function* $E(x)$ and can be written as

$$\Pr(X = x) = \frac{1}{Z} \exp\,(-E(x)) \qquad (4)$$

where the *partition function*

$$Z = \sum_x \exp\,(-E(x)) \qquad (5)$$

is a normalizing constant and involves a summation over all possible configurations of $X$. Energy functions have been widely used in spin-glass models of statistical physics. The minimum energy configuration corresponds to an ordered system of spins. $E(x)$ cannot take infinite values.

Our detour into Gibbs distributions is justified for the following reason. The Hammersley-Clifford theorem (Besag, 1974; Geman and Geman, 1984) states that any conditional distribution has a joint distribution, which is Gibbs (Dubes and Jain, 1989) if the following conditions hold.

*Positivity*: $\Pr(X = x) > 0$.
*Locality*: $\Pr(X_s = x_s|X_t = x_t, t \neq s, t \in S) = \Pr(X_s = x_s|X_t = x_t, t \in G_s)$.
*Homogeneity*: $\Pr(X_s = x_s|X_t = x_t, t \in G_s)$ is the same for all sites $s$.

The locality condition is the same as the Markov property described by Equation 1. The Hammersley-Clifford theorem allows us to shuttle between the conditional probability structure in Equation 1 and the joint probability in Equation 4.

The recipe for obtaining the joint density function is as follows: (1) assemble the different clique energies from the conditional probability, and (2) compute the energy function by adding up the clique energies.

We calculate the energy function for the simple first-order Gauss-Markov model:

$$\begin{aligned} E(x) &= \frac{1}{2}\left(\sum_{ij}\left[x_{ij}^2 - \frac{x_{ij}x_{i,j+1}}{2} - \frac{x_{ij}x_{i+1,j}}{2}\right]\right) \\ &= \frac{1}{8}\sum_{ij}\,[(x_{ij} - x_{i,j+1})^2 + (x_{ij} - x_{i+1,j})^2] \qquad (6) \end{aligned}$$

It can be seen from the energy function $E(x)$ and the conditional density that the essence of the Hammersley-Clifford theorem lies in the clique energies. We examined the conditional density and teased apart the different orders of cliques (first and second order) and the associated clique energies. Then, all clique energies were summed (taking care to count each clique only once), yielding the energy function $E(x)$. Our presentation has been quite terse, and further details on cliques and the transition from the conditional to the joint probability distribution can be found in Besag (1974), Geman and Geman (1984), and Dubes and Jain (1989).

## The Prior and Degradation Models

Naturally, we are not content with merely obtaining MRF-Gibbs image models. These models can be used in a variety of image processing and analysis tasks. As mentioned previously, MRF modeling fits perfectly into a Bayesian estimation/inference paradigm. A Bayesian setup consists of two ingredients—the prior and the degradation model. The prior model is defined on the set of image attributes $X$ that are of interest. In edge-preserving image restoration (Geman and Geman, 1984), for example, $X$ includes the set of image intensities and a further set of binary-valued edge labels. In texture segmentation (Lakshmanan and Derin, 1989), $X$ includes the image intensities and a set of texture labels at each location. The degradation model is a model of the physical process by which the observations are generated. Usually, we are faced with noisy and incomplete observations. Denote the set of observations by $Y$, and let the degradation model also be a Gibbs-Markov distribution:

$$\Pr(Y = y|X = x) = \frac{1}{Z_D(x)} \exp\,(-E_D(x, y)) \qquad (7)$$

where

$$Z_D(x) = \sum_y \exp\,(-E_D(x, y)) \qquad (8)$$

In general, the partition function $Z_D(x)$ is a function of the image attributes $x$. $E_D(x, y)$ is the energy function corresponding to the degradation model. For example,

$$E_D(x, y) = \frac{1}{2} \sum_s \left( y_s - \sum_t \mathcal{H}_{st} x_t \right)^2$$

yields a Gaussian degradation model wherein $Y$ is obtained by blurring $X$ with a *blur function* $\mathcal{H}$ and adding additive Gaussian noise at each site $s$. This type of degradation model routinely occurs in image restoration (Geman and Geman, 1984) and (with some modifications) in tomographic reconstruction (Lee et al., 1995).

### A Bayesian Posterior Energy Function

Given the degradation and prior models, Bayesian estimation/inference proceeds as follows. The posterior distribution $\Pr(X = x|Y = y)$ is obtained by using Bayes's theorem:

$$\Pr(X = x|Y = y) = \frac{\Pr(Y = y|X = x)\Pr(X = x)}{\Pr(Y = y)} \tag{9}$$

Once the posterior distribution is obtained, an estimate ($\hat{X}$) of $X$ is found by minimizing the expected cost, which is a measure of the distance between the true and estimated values:

$$C = \sum_x C(x, x^*)\Pr(X = x|Y = y) \tag{10}$$

where $x^*$ is the true value. When the familiar squared-error cost is used, the estimator (MMSE) turns out to be the conditional mean $\mathscr{E}(X|Y = y)$ ($\mathscr{E}$ denotes the expectation operator). If the cost *equally* penalizes all $x$ different from $x^*(C(x, x^*) = \delta_{x,x^*})$, the maximum a posteriori (MAP) estimator results.

When the degradation and prior models are Gibbs, the posterior is Gibbs as well. To see this, assume a prior energy function $E_P(x)$ giving $\Pr(X = x) = (1/Z_p) \exp(-E_P(x))$. The posterior distribution (using Equation 9) is

$$\Pr(X = x|Y = y) = \frac{\exp(-E_D(x, y) - \log(Z_D(x)) - E_P(x))}{\sum_x \exp(-E_D(x, y) - \log(Z_D(x)) - E_P(x))} \tag{11}$$

The posterior energy function $E(x) = E_D(x, y) + \log(Z_D(x)) + E_P(x)$. In the case of the MAP estimate, the entire Bayesian estimation engine reduces to minimizing just this posterior energy function $E(x)$, since the partition function of the posterior is independent of $x$. However, when the MMSE estimate is desired, the expected value of $X$ in the posterior distribution needs to be computed. This computation is usually intractable, since it involves computing the partition function of the posterior distribution.

### MAP Estimation

Restricting our focus to MAP estimation, we observe that MAP estimation reduces to minimizing the posterior energy function $E(x)$. This minimization involves the different kinds of processes that make up $X$. For example, in edge-preserving image restoration (Geman and Geman, 1984), the process $X$ includes both continuous-valued image intensities and binary-valued edge variables. Consequently, the minimization of the posterior objective function is a difficult problem, owing to the presence of nontrivial local minima. A general technique for finding global minima is simulated annealing (Geman and Geman, 1984; Lakshmanan and Derin, 1989) or, more recently, Markov chain Monte Carlo (MCMC) (Zhu et al., 1997), but these methods are usually computationally very intensive. A lot of effort has been expended in obtaining good suboptimal solutions to the MAP estimation problem (Yuille and Kosowsky, 1994; Lee et al., 1995; Gold and Rangarajan 1996). Deterministic annealing (DA) is a general method that has emerged. Deterministic annealing methods begin with a modified posterior:

$$\Pr(X = x|Y = y) = \frac{1}{Z(\beta)} \exp(-\beta E(x)) \tag{12}$$

where $\beta > 0$ is the inverse temperature. Note that the partition function is now a function of the inverse temperature. The terminology is inherited from statistical physics. The idea of cooling a system slowly to reach a minimum energy configuration has a computational parallel in MRFs. The basic idea is to embed the posterior in a $\beta$ exponentiated manner and to track the maximum of this posterior through a gradual increase in $\beta$. In this manner, the posterior energy function is increasingly closely approximated by a sequence of smooth, continuous energy functions.

The main reason for doing this is based on the following statistical mechanics identity:

$$F(\beta) \overset{def}{=} -\frac{1}{\beta} \log Z(\beta) = \mathscr{E}(E(x)) - \frac{1}{\beta} S(\beta) \tag{13}$$

where $S$ is the entropy (defined as $-\Sigma_x \Pr(X = x|Y = y) \log(\Pr(X = x|Y = y))$). The entropy is proportional to the logarithm of the total number of configurations, and as the temperature is reduced (and fewer configurations become likely), it gradually goes to zero. Also, the expected value of the posterior energy goes to the minimum value of the energy. The key idea in deterministic annealing is to minimize the *free energy* $F$ instead of $E(x)$ while reducing the temperature to zero. The free energy (at low $\beta$) is a smooth approximation to the original, nonconvex energy function and approaches $E(x)$ as $\beta$ tends to infinity. However, the free energy involves the logarithm of the partition function, which is intractable! An approximation to the free energy (usually called the naive mean field approximation) is minimized instead. Although the details are beyond the scope of this article (see Geiger and Girosi, 1991; Yuille and Kosowsky, 1994; Lee et al., 1995; and Gold and Rangarajan, 1996), we present an example illustrating the method. Let the energy function contain only binary-valued variables and take the following form:

$$E(x) = \sum_{ij} T_{ij} x_i x_j + \sum_i h_i x_i,\ x_i \in \{0, 1\} \tag{14}$$

The free energy $F$ is given by

$$F(v) = \sum_{ij} T_{ij} v_i v_j + \sum_i h_i v_i + \frac{1}{\beta} \sum_i [v_i \log(v_i) + (1 - v_i) \log(1 - v_i)] \tag{15}$$

where $v_i \in [0, 1]$. The free energy consists of two terms. The first term can be seen as an approximation to the expected value of the energy once the identification $v_i \approx \mathscr{E}(x_i)$ is made. Now,

$$\mathscr{E}(E(x)) = \sum_{ij} T_{ij} \mathscr{E}(x_i x_j) + \sum_i h_i \mathscr{E}(x_i) \tag{16}$$

When the expected value of the product $x_i x_j$ is replaced by the product of the expected values ($v_i v_j$), the naive mean field approximation results. The third term in Equation 15 is an approximation to the entropy. At each setting of $\beta$, Equation 15 is minimized with respect to $v$, after which $\beta$ is increased. In this manner, a deterministic network is obtained. There are questions regarding the choice of annealing schedules and the quality of the minima obtained, and for the most part, except for very specific posterior energy functions, there is a dearth of analytical results in this area. However, the method is quite general and has been applied with varying degrees of success to a variety of image processing and analysis tasks, such as tomographic reconstruction (Lee et al., 1995), flow field segmentation (Konrad and Dubois, 1992), surface reconstruction (Geiger and Girosi, 1991), and object recognition (Gold and Rangarajan, 1996).

### Parameter Estimation

So far we have concentrated on estimating $X$ given the noisy observations $Y$. We have emphasized that Gibbs-Markov models are specified by local clique energies (from which the global distribution can be obtained). Consider a prior distribution

$$\Pr(X = x|\theta) = \frac{1}{Z(\theta)} \exp\left(-\frac{1}{2}\sum_{k}\sum_{\langle s,t\rangle_k} \theta_k(x_s - x_t)^2\right) \quad (17)$$

where $\theta_k$ is a parameter associated with clique $\langle s, t\rangle$. Since pairwise interactions are used, a clique between pixels $s$ and $t$ is denoted by $\langle s, t\rangle$. This is the general form of the Gauss-Markov model. The model is a generalization of our earlier model (Equation 6) since it has the same clique form, although with a more general neighborhood structure. The partition function involves a sum over the configurations of $X$ and is a function of $\theta$. Other than the estimation/inference problem, we are also saddled with the problem of parameter estimation.

The parameters can be estimated by maximizing the joint probability of $X$ with respect to the unknown parameters (Lakshmanan and Derin, 1989). In most cases, this computation is intractable in its pure form, and approximations have to be devised. The typically available approximations are pseudo-likelihood, mean-field, and MCMC. The computational requirements of the different methods range from low for pseudo-likelihood to moderate for mean-field to high for MCMC. The availability of a suitable training set is critical to both likelihood and pseudo-likelihood parameter estimation. When a training set is not available, parameter estimation and cost minimization proceed in lockstep, resulting in the so-called joint MAP procedure wherein the parameters $\theta$ and the states $X$ are bootstrapped (Lakshmanan and Derin, 1989). From a theoretical standpoint, there are important issues of consistency and efficiency of the parameter estimates; for details, see Kashyap and Chellappa (1983).

## Discussion

The MRF framework is well suited to a wide variety of image processing and analysis tasks. Our exposition has been brief, and we have ignored important issues such as validation, choice of the order of MRF models, and sizes of training sets. Validation, for example, takes us into the bias/variance dilemma (Geman, Bienenstock, and Doursat, 1992). MRF models, being parametric, introduce a certain kind of bias into the image representation. This seems to be the right kind of bias (in terms of reducing variance) for tasks like image restoration, tomographic reconstruction, and texture segmentation. However, if the order of the chosen model is incorrect, high bias could result. It is in bias/variance terms that MRF image models should be compared alongside “mechanical” (as opposed to probabilistic) models such as splines, generic representations like radial basis functions (RBFs), and tabula rasa, feedforward neural networks. Also, there are interesting similarities between Gauss-Markov models and thin-plate splines (Lee et al., 1995; Wahba, 1990); see Generalization and Regularization in Nonlinear Learning Systems). For example, the simple case of the first-order Gauss-Markov model with the parameters $\theta_1 = \theta_2 = (1/4)$ is identical to the discrete membrane (first-order thin-plate spline in two dimensions). Correspondences of this sort should be expected, since MRF models, splines, and RBFs impose local smoothness constraints, although in different ways. In recent years there has been increased interest in scale-space and multiresolution image processing and analysis methods. Although there are deep unresolved issues in integrating scale into Markov models, this situation has not deterred researchers from using multiresolution MRFs in specific applications (Lakshmanan and Derin, 1989; Krishnamachari and Chellappa, 1997). Finally, and very recently, interesting interrelationships have been discovered between Bayesian MAP estimation on Gibbs posterior energy functions and Bayesian belief propagation algorithms (Weiss, 2000; see Graphical Models: Probabilistic Inference).

# Memory-Based Reasoning

*David L. Waltz*

## Introduction

Memory-based reasoning (MBR) refers to a family of nearest-neighbor-like methods (Dasarthy, 1991) for making decisions or classifications. MBR differs from other nearest-neighbor methods primarily in its metrics for computing the distance between examples, and in MBR's suitability for use with symbolic-valued features. Nearest-neighbor methods generally use a simple overlap distance metric, which defines distance as the number of mismatched features between two instances. MBR uses metrics related to the value distance metric (VDM), introduced in Stanfill and Waltz (1986). Considerable effort on recoding training cases is generally required in order to use neural nets on symbolic problems. In general, symbolic items need to be mapped to numerical values, feature vectors, or some related form. MBR is specifically designed to handle such cases directly; MBR uses the statistical similarity of outcomes to automatically generate similarity metrics for symbolic inputs, without the need for recoding. MBR has been used for software recommendation agents such as the Firefly (Maes and Kozierok, 1993), classification of news articles (Linoff, Masand, and Waltz, 1992) and U.S. Census Bureau long forms (Creecy et al., 1992), computational biology (Zhang, Mesirov, and Waltz, 1992; Yi and Lander, 1993; Cost and Salzberg, 1993), and a variety of other tasks. See Aha (1997) for a survey of MBR and related systems and applications, and discussions of trade-offs in case-based system design.

## Comparisons of MBR and Neural Nets

Several projects have compared MBR with backpropagation neural nets. In terms of decision accuracy, MBR has often outperformed neural nets, and in some cases all the other learning methods with which it has been compared (Zhang et al., 1992; Cost and Salzberg, 1993; Rachlin et al., 1994); results for MBR are generally comparable with the best other learning methods. MBR has also been applied to cases that are beyond the representational reach of current neural net methods, such as the classification of free-text examples of arbitrary lengths (Creecy et al., 1992). Like neural nets, MBR systems can be built easily and quickly, with very little programming required. Unlike neural nets, no learning phase is necessary. Updating is therefore simple, requiring only additions, deletions, and modifications to MBR's database of examples, and decisions are always based on all known data, even the most recent. Also, unlike neural nets, MBR does not generally require elaborate re-representation schemes. MBR provides "justifications" for decisions, namely the nearest example(s) from the database, whereas considerable analysis effort is generally required to understand why a neural net system behaves as it does. Thus, debugging and tuning tend to be easier with MBR. And finally, MBR methods can provide confidence levels.

MBR does have a major disadvantage: although it does not require a training phase, MBR's decision phase is computationally expensive, and MBR systems have high memory requirements. In general, the entire database of examples is kept, whereas with neural nets, the total storage requirements for a trained net are generally much smaller than the training set used to create it. Because of this, early MBR systems were implemented on massively parallel computers or special-purpose hardware.

### *"Eager" Versus "Lazy" Systems*

Lazy systems (such as MBR) defer classification decisions until a case is presented, while eager systems (like backpropagation and other learning systems) do most of their classification work ahead of time in a training phase (Aha, 1997). Systems intermediate between eager and lazy often have attractive properties (Kasif et al., 1998).

## How Does MBR Work?

Every MBR system requires a similarity metric for judging the distance between an item to be classified and all items in the example database. If the MBR system uses $k$-nearest neighbors, then a scheme for combining the information from $k$ examples is also needed. We can illustrate the idea with a simple metric, the modified value difference metric (MVDM) (Cost and Salzberg, 1993), which is similar to the ones that have been most commonly used in MBR applications. Assume the database is relational, with $n$-tuples consisting of $n - 1$ predictor fields $(p_1, p_2, \ldots, p_{n-1})$ plus a goal field $G$. (This is not the fully general case, but it is the simplest and most common one, and serves well for purposes of illustration.) Each case in the database is a vector of predictor values $(a_1, a_2, \ldots, a_{n-1})$, plus a goal $G$ that can take on any of a finite set of values: $G$ is an element of $(g_1, g_2, \ldots, g_m)$. Then the distance between a novel situation $B = (b_1, b_2, \ldots, b_{n-1})$ and a case $A$ from the database $A = (a_1, a_2, \ldots, a_{n-1})$, is:

$$\sum_j \left[ \sum_i |\text{Prob}(g_j|b_i) - \text{Prob}(g_j|a_i| \right]$$

where $j$ ranges over all possible values for the goal field and $i$ ranges over all predictor fields. To keep computation tractable, the set of goal fields may be limited, for example by only indexing over goals that correspond to database instances with non-zero overlap metrics (which are much cheaper to compute).

The MVDM metric basically compares the distribution of cases for each pair of predictor field values of $A$ and $B$. The distance between $A$ and $B$ is small if these two-predictor field values are associated with similar distributions of goal field values.

The result of applying this metric is a rank-ordered list of cases from the database, with distance values for each. The classification proposed for the novel situation is then the goal field value of the case with the minimum distance (single neighbor case), or the goal field value whose weighted sum of distances over the $k$ closest cases is the smallest ($k$-nearest-neighbor case).

### *NETtalk Task*

MBRtalk, the first MBR system (Stanfill and Waltz, 1986), used as its main example the NETtalk database, and compared its performance with NETtalk (Sejnowski and Rosenberg, 1987). The NETtalk task is to produce pronunciations for all English words, based on a small (700-word) training set. Sejnowski and Rosenberg's NETtalk, a backpropagation system (with some special output processing), achieved a 78% letter-by-letter generalization performance. MBRtalk produced a 78% letter-by-letter generalization performance on the original NETtalk database, the same as that reported by Sejnowski and Rosenberg. MBRtalk demonstrated a 93% correct generalization using a 16,000-word corpus, a task that has not been attempted with a neural net system and one that would probably require very long training times. MBR does not require training, although it is possible to do some precalculation in order make the MBR decision phase run faster.

### Protein Structure Prediction

For several years, the best protein secondary structure prediction systems were based on neural nets (Qian and Sejnowski, 1988). After considerable experimentation and tuning, Zhang et al. (1992) showed that MBR outperforms backpropagation on this task, albeit by a small margin—64.5% correct for MBR, versus 63.5% for a three-layer backpropagation system and 64.0% for a cascaded backpropagation system (Qian and Sejnowski, 1988), all using eight-way cross-validation on the same 19,861-residue database. Interestingly, MBR and neural nets agreed with each other only about 80% of the time, and both methods agreed with a statistical system with 63.5% performance about as often. A hybrid system was constructed that used a backpropagation net to combine the outputs of the three methods, yielding a performance of 66.4%, an improvement that is better than any of the others alone, with high statistical significance (Zhang et al., 1992). Current methods, often combining recurrent neural nets with MBR-like methods, perform significantly better, in the range of 76% (Baldi et al., 1999), although a considerable portion of this improvement may be the result of more complete and accurate protein databases.

### Tests on UCI Repository of Machine Learning Databases

Several papers have reported results on data sets from the University of California–Irvine (UCI) repository that allow us to compare MBR, specifically the widely used PEBLS system (Cost and Salzberg, 1993), with backpropagation neural nets.

As reported in Kasif et al. (1998), PEBLS outperformed or equaled both a Bayes classifier and a Hamming distance nearest-neighbor system on six of eight tasks, and was within 1.1% on the other two tasks. This paper also showed that MBR always outperforms a Bayes classifier in domains with nonplanar decision boundaries. Neural nets outperformed MBR on small databases (soybean disease with 289 examples, iris database with 150 examples).

## Discussion

### MBR as a Neural Model?

It has been suggested that the cerebellum stores many examples of motor movements that can then be interpolated to provide smooth motor movements (Atkeson, Moore, and Schaal, 1997). MBR, as a variant of case-based reasoning (CBR), has been proposed as an associative memory implementation.

### Why Do These Methods Perform Differently?

Generally stated, MBR and neural nets form decision surfaces differently, and so will perform differently. MBR can become arbitrarily accurate if large numbers of cases are available, and if these cases are well-behaved and properly categorized. Neural nets cannot respond well to isolated cases but tend to be good at smooth extrapolation. To give an example, consider training a NETtalk system to pronounce the letter *p*, and assume that all *p*s are either pronounced *P* (as in *pig*) or *F* (as in *photo*) except for one example, where *p* is silent (*psychology*). Given that there are many *P* and *F* examples, these will statistically dominate the hidden units for a backpropagation net, and it is very unlikely that words beginning with *ps* will be correctly pronounced. But MBR is able to pronounce a *ps* word correctly, even with only a single near example.

For other examples, different MBR metrics can be used for systems for tasks that cannot be currently handled by neural nets. In Creecy et al. (1992), for example, a text similarity metric (“vector similarity”—basically normalized weighted word overlap) allowed an MBR system to assign keywords to Census Bureau data with free-text fields. Such a task is beyond current neural net training methods.

# Minimum Description Length Analysis

*Richard S. Zemel*

## Introduction

In this article, we review a variety of ways in which ideas relating to minimum description length (MDL) have been applied to neural networks. We begin with a brief introduction to the historical roots of MDL, and then describe the direct relationship between MDL and Bayesian model selection methods. We divide the applications of MDL to neural networks into two categories corresponding to the two main classes of learning in networks: supervised and unsupervised.

## Historical Background

The underlying approach in MDL—applying coding theory to determine simplicity—grew out of work from the mid-1960s, when Kolmogorov, Solomonoff, and Chaitin introduced theories concerning the information content of an object. Instead of relating information to probabilities, as Shannon had (e.g., Shannon, 1948), they adopted a computational approach. They defined the information in a binary string to be the length of the shortest program with which a general-purpose computer can generate the string. The resulting algorithmic theory of information has significant implications in many areas, but it has not had much impact on the practical construction of programs, because the proposed form of information is not computable in its pure form. However, a number of learning techniques (including MDL) have been derived by making approximations to this information measure. The interested reader should consult Li and Vitanyi (1993) for a detailed mathematical review of the history of MDL and its relationship to many other current inductive inferencing techniques.

## Defining the Minimum Description Length Principle

MDL can be seen as a principled version of Occam's razor, where the goal is to find the simplest accurate description of a set of data. An informal definition of the MDL principle (Rissanen, 1989) is that the best model to explain a set of data is the one that minimizes the summed length, in bits, of (1) the description of the model and (2) the description of the data, when encoded with respect to the model.

In algorithmic information theory, the model is a general computational model, i.e., a Turing machine. The MDL approach makes the problem tractable by considering particular classes of models. For example, if the goal is to infer decision trees, then the model is a decision tree, while if the goal is to learn the weights of a neural network, the model may be a network with a particular architecture. In this article, a model refers to various aspects of a network, such as its weights and activities.

It is useful to formulate MDL based on a communication protocol in which these terms are unified into a single encoded message that must be decoded in order to reproduce the data. The sender transmits a message, encoded in the description language $\mathscr{L}$, that conveys both the model $M$ and the data $D$ with respect to the model; this second term can be seen as the residuals, i.e., aspects of the data not predicted by the model. The standard goal of inferring an optimal $M$ from the data is then equivalent to minimizing the length of this encoded message:

$$|\mathscr{L}(M, D)| = |\mathscr{L}(M)| + |\mathscr{L}(D \text{ using } M)| \tag{1}$$

The notion of comparing models based on simplicity can equivalently be expressed from a Bayesian perspective. The goal is to infer a model $M$ from a set of observations $D$. Bayes's theorem states that the posterior probability of a model is:

$$p(M|D) = \frac{p(M)p(D|M)}{p(D)} \tag{2}$$

The most plausible model is then inferred by comparing these posterior probabilities:

$$\arg\max_M [p(M)p(D|M)] = \arg\max_M [\log p(M) + \log p(D|M)] \tag{3}$$

The trade-off inherent in both these approaches between simpler, more constrained networks and more complex, general networks echoes the *bias-variance dilemma* in statistics: introducing many parameters incurs high variance, while restricting the number of parameters incurs high bias in the set of possible solutions (Geman, Bienenstock, and Doursat, 1992). MDL and Bayesian analysis (see BAYESIAN METHODS AND NEURAL NETWORKS) offer an approach to this dilemma by formalizing the Occam's razor idea—a complex network is preferred only when its predictions are sufficiently more accurate—as an inference rule.

The link between the two objectives (Equations 1 and 3) is provided by the *optimal coding theorem* (Shannon, 1948), which states that $x$ can be communicated at a cost that is bounded below by $-\log_2 p(x)$ bits.

Applying this theorem produces the general MDL equation:

$$-\log p(M, D) = -\log p(M) - \log p(D|M) \tag{4}$$

Shannon's theorem describes the optimal code if the true probability distribution for a set of discrete alternatives is known. In general, however, one does not know the true distribution; so, because coding from a description language based on the wrong probability distribution will always take more bits on average, selecting an appropriate probability distribution for the codes is a key aspect of MDL applications. MDL provides a method of comparing these choices based on the resulting code lengths.

The distribution must be chosen to suit the nature of the task. For example, in a classification task, the data (given the model) consist of a number of discrete alternatives, each with some probability of occurrence. Here we can save bits by simply communicating the fact that the model output is correct on the correctly classified examples. When the information to be encoded takes on real values, a continuous distribution is required. A coding distribution that is often (implicitly) selected is a Gaussian. In this case, if we assume that the residuals (the second term in Equation 1) are independent and have a zero-mean, fixed-variance Gaussian distribution, then, if the values are encoded to some fixed accuracy, the code length is the familiar summed-squared-error cost function.

## An Example of Applying MDL to Neural Networks

One of the standard approaches to improving generalization in neural networks can be formulated as an MDL technique. This approach adds an extra term to the error function that penalizes the complexity of the network, so that the objective function used to train the network involves a trade-off between the data misfit and the network complexity:

$$\text{Cost} = \alpha \text{ Complexity} + \text{Error} \tag{5}$$

If we regard each possible weight vector of the network as a potential model, then this complexity term is simply the cost of specifying the model in the definition of MDL above.

Applying Shannon's theorem then equates the complexity of a network to the negative log probability of its weights. Thus the critical question becomes the choice of encoding scheme, or prior distribution on the weights. A simple prior is a radially symmetric, mean-zero Gaussian. Setting the variance of this Gaussian to $1/\alpha$ yields an often used complexity term—the sum of the squares of the weights, $\Sigma_j w_j^2$. Differentiating this measure produces simple weight decay in the learning rule, which forces weights with small gradients from the error term to decay away, leaving only the required weights for the task. This example points out the key role of probability distributions in MDL; now we consider other encoding distributions and see how this choice affects the models that MDL favors.

## Applications of MDL to Neural Networks

The MDL principle has been applied in a wide variety of areas over the past couple of decades. With respect to neural networks, the duality between Bayesian analysis and MDL means that a range of applications of Bayesian techniques to neural networks may also be expressed in MDL terms. Few neural network methods have referred directly to minimal length encoding, but this relationship to Bayesian techniques makes many network methods relevant to this article.

We separate MDL applications into two classes involving fundamentally different formulations in terms of the communication protocol. In supervised learning, each data item consists of an input-output pair. The sender and receiver both have access to the inputs. The task of the sender is to succinctly communicate the desired outputs for each input. The network is a generative model of the output given the input; this model includes the network architecture and weights, while the data are the residuals.

In unsupervised learning, the receiver does not have access to the input, and the sender must provide enough information to allow an accurate input reconstruction. For example, in a clustering task, the sender first communicates the cluster centers (i.e., the weights of a competitive learning network). Then she only needs to say which cluster each input belongs to, and the residual error, or the distance to the cluster center. Given this information, the receiver can recover the actual input. Thus, here the network is a generative model of the input itself.

Note that this communication protocol formulation is only a device to derive an MDL objective function that can be used to train a neural network. The algorithms described below are not actually interested in sending the message, but rather in developing good models of a data set.

## *Supervised Learning*

In supervised learning, the primary application of MDL techniques has been to improve the generalization performance of networks. Good generalization requires that the amount of information required to specify the output vectors of the training cases must be considerably larger than the number of independent parameters of the network. When only a small amount of labeled training data is available, a large network will not readily produce a good solution.

A range of techniques have been proposed to address this problem. These include weight sharing, weight/unit pruning (see Learning Network Topology), and cross-validation training. MDL techniques offer an alternative approach to this problem. In this section, we highlight two types of techniques. The first class assumes that the network architecture is given, and uses MDL to limit the complexity of the network weights. The second class uses MDL to select between potential network architectures.

*Using MDL to determine network weights.* The standard neural network training problem of finding the appropriate set of weights can usefully be formulated in MDL terms. We showed above that a radially symmetric Gaussian prior on the weights produces a weight decay term in the learning rule. Many different types of priors have been discussed in the literature. MacKay (1992) compared several priors for a single learning problem. He showed that for this problem, using the simple weight-decay prior with a different $\alpha$ for separate weight classes—weights into hidden units, hidden unit biases, and weights into output units—achieves better generalization than using a single $\alpha$ for all the weights.

More complicated priors on the weights can produce better generalization. For example, the prior could be a mixture of two zero-mean Gaussian distributions, a very wide one and a narrow one. The narrow Gaussian encourages small weight values to approach zero; the broader distribution takes responsibility for larger weights, and provides little pressure to change these values. The combined effect is to simplify the network by eliminating small weights.

The prior may also be adapted to the data. For many problems, such as translation-invariant recognition, improved network performance can be achieved by constraining particular subsets of the weights to share the same value. Nowlan and Hinton (1992) accomplished this by fitting a mixture of Gaussians to the weights, allowing the network to decide which weights should be tied together.

Finally, Hinton and van Camp (1993) extended this work to consider the general MDL objective where the cost function is the sum of two encoding costs: the weights of the network and the output error residuals. On a sample problem, coding the weights using an adaptive mixture-of-Gaussians prior allowed the network to find three sharp clusters for the weights. Discovering this structure avoided overfitting the data, as the network was able to generalize even though the number of training cases was less than the dimensionality of the input vector.

Note that the MDL objectives described above involve several hyperparameters, such as the regularization constant $\alpha$ controlling the trade-off between the error and the complexity terms. Several methods have been proposed for determining hyperparameters (MacKay, 1992; Neal, 1996).

Recent work has extended MDL to include hyperparameters, which allows the application of MDL principles to a different class of learning methods. MDL formalizes the Occam's razor idea of finding the simplest model for a given data set. Yet the simplest model is not always one with few parameters. Neal (1996) showed that a particular neural network in the limit of an infinite number of parameters is a Gaussian process, which is actually a simple model that can be handled tractably. Other function approximation methods use a very large set of basis functions to model the data. Rasmussen and Ghahramani (2001) show that learning using these large models can also be expressed in MDL terms, where the model description applies not to parameters but instead to the functions included in the model.

*Using MDL methods to determine a network architecture.* MDL methods have also been applied to evaluate network architectures (see Bayesian Methods and Neural Networks). The weights for various network architectures are learned using an MDL objective, and then these networks are compared based on the same data fit/complexity trade-off. MacKay (1992) demonstrated how this MDL/Bayesian procedure accurately predicts the appropriate number of hidden units on a small interpolation problem, where the target is determined by examining how well the various architectures generalize to an unseen test set.

Kendall and Hall (1993) proposed an MDL approach to network construction in which the model and data misfit are encoded over a discrete space. They computed the code length of the network parameters from a histogram of the weight values; since the task is assumed to be classification, the data code length is simply the cost of specifying which training cases are incorrectly predicted by the model. The authors found that using a genetic optimization algorithm to minimize the total description length succeeded in finding optimal network architectures on some simple problems.

MDL methods have been applied to architecture selection in other areas relevant to neural networks. Stolcke and Omohundro (1993) described an algorithm for inferring the structure of a hidden Markov model that involves a Bayesian/MDL approach. The algorithm begins with a model that directly encodes the training data, and then successively merges states based on a description length criterion that penalizes models according to the number of transitions and output values at each state. In addition, the MDL principle has been applied to learn the structure and parameters of Bayesian Networks (q.v.), (e.g., Suzuki, 1999). Roughly speaking, a Bayesian network can be viewed as a form of neural network in which the nodes correspond to random variables and the weights encode conditional distributions. Encoding a Bayesian network with $n$ nodes entails encoding the parents of each node and its set of conditional probabilities. The MDL approach formalizes the trade-off between the simplicity of the Bayesian network structure and its ability to model the data.

### *Unsupervised Learning*

For unsupervised learning networks, in which the goal of learning can be viewed as a form of probability density estimation, MDL techniques have been applied in several ways. The most popular approach is to use MDL to learn the number of distributions in the estimate, as well as the parameters of those distributions. A second approach involves applying MDL methods not only to the weights of the network, but also to the activities of the hidden units.

*MDL and finite mixture models.* A standard statistical technique for unsupervised classification can be formulated in an MDL framework. In finite mixture models, each datum in a training set is assumed to be drawn from one of $J$ different classes. While learning the class parameters, we can also determine the optimal $J$ by maximizing the posterior distribution of this number given the data set. This search for $J$ resembles the architecture selection approach described above.

AutoClass (Cheeseman et al., 1988) is an unsupervised classification system based on this approach. It determines $J$ by starting with more classes than are believed to be present and iteratively eliminating them. A prior that makes classes accounting for little data improbable can be seen as a description length prior on the model complexity. Similar approaches have been used in clustering algorithms, where a complexity term penalizing complex clusterings (based on measures such as their summed entropy) is added to create an MDL-style objective trading of data fit for model simplicity (see DATA CLUSTERING AND LEARNING).

*MDL and autoencoders.* In the unsupervised schemes described above, the model cost was some function of the number of underlying components in the clustering or mixture model algorithm, while the data cost was simply the summed-squared error. This represents one type of MDL objective function. If we adopt a more general viewpoint, we see that a wide range of other objective functions is possible.

In particular, we can view unsupervised learning in terms of an autoencoder (i.e., a network that attempts to reproduce its inputs on its outputs) where the MDL objective is to minimize the total cost of communicating the input vectors to a receiver. There are three terms in the description length:

- The *representation cost* is the number of bits required to communicate the representation (the hidden unit activities) that the algorithm assigns to each input vector.
- The *model cost* is the number of bits required to specify the hidden-to-output weights of the network, which provide an estimate of the input from its representation.
- The *reconstruction cost* is the number of bits required to fix up errors in the estimate of the input.

The sum of these three terms provides an objective function for training the autoencoder.

We can view many unsupervised algorithms in terms of this framework by understanding how they encode each of these three terms. For example, in competitive learning, the representation is the identity of the winning hidden unit, so the average representation cost is at most the logarithm of the number of units, while the reconstruction cost is proportional to the squared difference of the winner's weight vector and the input. Standard competitive learning algorithms minimize this latter cost, while algorithms that attempt to limit the number of clusters can be seen as trading off representation cost for reconstruction cost. Principal Component Analysis (PCA) can be viewed as a version of MDL in which we ignore the model cost and the representation cost and minimize the reconstruction cost. Factor analysis can be viewed as a version of MDL in which we ignore the model cost but minimize the representation cost and reconstruction cost.

Many new algorithms can be derived by adopting new assumptions about the structure of the data and using them to formulate different methods of encoding the three terms in this MDL cost function. Any method that communicates each hidden activity independently will tend to lead to factorial representations, because any mutual information between hidden units will cause redundancy in the communicated message, so the pressure to keep the message short will squeeze out the redundancy. Zemel (1994) and Hinton and Zemel (1994) describe algorithms derived from this MDL approach for learning factorial representations; Zemel and Hinton (1995) describe how this MDL approach can also be used to develop population codes in which the activities of hidden units are locally correlated so as to form a topographical map. See UNSUPERVISED LEARNING WITH GLOBAL OBJECTIVE FUNCTIONS for a discussion of other algorithms that can be expressed within the MDL framework.

## Discussion

MDL methods have been applied in a variety of neural network training paradigms, both for learning the weights and for assembling the architecture. These methods involve selecting a class of models and an encoding scheme for the two terms in the description: the model and the data. Given these elements, an appropriate objective function can be constructed for either an unsupervised or a supervised learning problem. Because of a common underlying framework, many Bayesian inferencing methods can also be viewed in MDL terms.

Many important issues remain to be explored in this area. One key issue concerns when it is better to use other methods of improving generalization, such as stopping training based on performance on a validation set, versus using an MDL-based regularization. In the unsupervised learning area, an open problem concerns formulating appropriate priors for learning hierarchical representations. Finally, an area that is ripe for MDL applications is temporal learning, in which MDL can be used to develop concise models that can accurately predict sequential events.

## Introduction

Mathematical models of interacting neuronal assemblies occur in brain theory and neural networks research in various ways. In *computational neuroscience*, highly sophisticated and detailed computer models of neurobiological phenomena are developed to gain insight into the complex nonlinear behavior of interacting neuronal populations and synaptic circuitry. The key question—how well does a selected neural network model describe the neurobiology of a neuronal population studied in vivo, i.e., the interactions and the dynamics of living neurons?—should be answered in the tradition of the biological sciences and of scientific investigations into neurobiological phenomena (see PERSPECTIVE ON NEURON MODEL COMPLEXITY). In artificial neural networks, assemblies of neuronal units are combined to represent statistical estimators for supervised learning tasks, i.e., classification and regression, or they model the data source under investigation in an unsupervised fashion by self-organizing maps (see SELF-ORGANIZING FEATURE MAPS), recurrent networks (see RECURRENT NETWORKS), or even more complicated structures.

In both situations the data analyst tries to infer functional dependencies from empirical data (Vapnik, 1982). The usefulness of a model is determined by its ability to capture those properties of the real world that are of interest to the data analyst. Mathematically, we have to measure or estimate the difference between the neurobiological system under investigation and our model simulation. A good model fit should reproduce the behavior of the studied system in the relevant parameter range that is supposed to be explained by the model study. Outside of this parameter range we tolerate large deviations between the model system and the real system. In computational neuroscience as well as in artificial neural networks (ANNs), the model complexity has to be controlled to avoid the following two modeling errors: too simplistic models usually miss essential features of the considered process or system (underfitting), whereas too complicated models adapt to stochastic fluctuations in the data without revealing reliable and useful knowledge (overfitting).

The trade-off between too simple and too complex models is systematically studied in statistics. The statistical literature on simulation (see Deaton, 1988) distinguishes the following five steps in the design of a well-planned simulation study: (1) system identification, (2) model development, (3) model verification, (4) model validation, and (5) model analysis. The first three items in the list summarize the necessary design steps to build a qualitatively correct model. After identifying the essential functional dependencies of a system and their parametric description, the modeler is in a position to develop a conceptual abstraction of these relations. It is important for the success of a simulation study, in particular for model development, to explicitly state the scientific questions that should be answered by the conceptual model. The complexity of reality is never fully captured by the model world, and the modeler should ensure that the conceptual abstraction is appropriate to understand the relevant scientific issues under discussion. In step 3, an implementation of this abstraction has to be verified to guarantee that the computer simulation reflects the behavior and properties of the model. After ensuring the correctness of the implementation, we validate the model in the fourth step by comparing the simulated behavior with observations of the real system. The last step describes the indirect study of real-world phenomena by studying the behavior of the simulation model. The crucial step (step 4) between the model synthesis part (steps 1–3) and the analysis part (step 5) assesses how appropriate the model is to gain insight in the real-world system. In the most likely case of an imperfect model with deviations between model and reality, the *model quality* must be measured by an appropriate weighting according to the relevance of these deviations for answering the scientific questions under investigation. Models might even be developed for one scientific question but be found, on validation, to be more appropriate for another phenomenon than originally intended. For example, the Ising model was supposed to capture the essential collective features of magnetism, but it seems to work even better in studies of surface adhesion, while the wide use of Ising models in neural network theory was never anticipated by his designer.

## Model Quality

How should we compare the model's behavior with the real-world system? We will look into this question first for simulation models in general and then for the more restricted class of probabilistic models for classification and regression.

The deviation of a simulation model from its counterpart in the real world is difficult to quantify, since it strongly depends on the purpose of the model. For the sake of concreteness, let us assume that we have implemented a network of locally coupled neurons of the FitzHugh-Nagumo type (Koch, 1999), a simplified version of the Hodgkin-Huxley equations for neuronal dynamics. This level of detail—two coupled nonlinear ordinary differential equations per neuron—is likely too crude for an experimental physiologist who studies depolarization effects in the cell membrane of neurons at the level of ion channel dynamics, but the same model might be more than adequate to analyze collective synchronization phenomena, even at a quantitative level. It is important to emphasize that the fine details of neural dynamics should be taken into consideration in the case of a physiological study, and therefore deviations between simulations and experiments should be weighted more strongly than in a simulation study of the collective behavior of many coupled BvP oscillators.

The underlying scientific issue of the sufficient explanatory power of a model and its necessary simplicity is traditionally studied in the philosophy of science. The limits—how scientific theories should be designed and compared with reality—are investigated in the *theory of knowledge*, also known as epistemology. Different concepts and ideas have been proposed to explain how general laws can be inducted from a finite number of empirical observations. Since a logically conclusive inductive principle is considered to be impossible, philosophers of empiricism, in particular Karl Popper (1968), have focused on the concept of falsifiability of theories. Models and theories should be designed in such a way that they can be tested, and the degree of empirical testability should allow us to measure how well a theory has been confirmed by experimental observations. In the case of very complex models, the *Turing test* provides a crude experimental procedure to quantify the appropriateness of a model. A panel of experts is asked to distinguish between the real system and its model on the basis of the respective outputs or measurements of system parameters. Statistical tests can then be used to quantify the significance of the experts' answers and their deviations from chance events. A perfect simulation is reached if the experts are unable to distinguish between the real system and its simulation model in a statistically significant way.

A much simpler situation exists in *supervised learning* of classifiers and regression functions. The model quality of regression is defined by the expected deviation between the regression function $f(x;\theta)$ and the random variable $y$, which characterizes the noise-perturbed functional dependency under consideration. The regression function $f(x;\theta) \in \mathcal{H}$ is an element of an application-dependent hypothesis (function) class $\mathcal{H}$, which is indexed by $\theta$. The true model $\theta_0$ is often assumed to be perturbed by additive noise $y(x) = f(x;\theta_0) + \eta(x)$ with $\mathbf{E}[\eta(x)] = 0$, $\mathbf{E}[\eta(x)^2] = \sigma^2$ in regression, or by classification noise $y(x) = f(x;\theta_0)$ with probability $1 - p$ and $y(x) = 1 - f(x;\theta_0)$ with probability $p$. The joint probability $\Pr(x, y)$ of the data point $x$ and the random variable $y$ weights the influence of data on the model quality and determines the expected risk:

$$R(\theta) = \int \ell(y, f(x;\theta))\Pr(x, y)dxdy \qquad (1)$$

The most popular choices of loss functions for regression and classification are the quadratic loss $\ell(x,f) = (y - f(x;\theta))^2$ and the classification error $\ell(x,f) = \mathbf{1}(y \neq f(x;\theta))$ (0–1 loss), respectively. The goal of regression validation is to estimate the minimum $\theta^* = \arg\min_\theta \mathbf{E}[R(\theta)]$ on the basis of a training sample set $\mathcal{X} := \{(x_1, y_1), \ldots, (x_n, y_n)\}$ without explicit knowledge of the joint distribution $\Pr(x, y)$. The true model $f(x;\theta_0)$ does not necessarily have to be an element of $\mathcal{H}$. The induction principle *empirical risk minimization* (ERM) advocates calculating the minimum of the empirical risk:

$$\hat{R}(\theta;\mathcal{X}) = \frac{1}{n}\sum_{i=1}^{n} \ell(y_i, f(x_i;\theta)) \qquad (2)$$

i.e., the empirical risk minimizer $\hat{\theta} := \arg\min_\theta \hat{R}(\theta;\mathcal{X})$ is used as an estimate of the expected risk minimizer $\theta^*$.

## Model Complexity and Model Selection

The validation of models in statistical learning of classifiers and regression curves is inspired by Popper's philosophy of science and the requirement that scientific theories be falsifiable. Vapnik and Chervonenkis (see Vapnik, 2000) have analyzed the nature of statistical learning and have identified necessary and sufficient conditions for learning classifiers by empirical risk minimization. They analyzed the probability $\Pr(R(\hat{\theta}) - R(\theta^*) > \varepsilon)$ that the expected risk of the classifier with minimal empirical risk $\hat{\theta}$ exceeds the best classifier in the hypothesis class $\theta^*$ by more than a constant $\varepsilon$ in costs or risk. In the case of a finite hypothesis class, the probability of this large deviation is bounded by the cardinality of $\mathcal{H}$ times a fit factor that decays exponentially fast with the size $n$ of the sample set (see Devroye, Györfi, and Lugosi, 1996), i.e.,

$$\Pr(R(\hat{\theta}) - R(\theta^*) > \varepsilon) \leq |\mathcal{H}| \sup_{f(.;\theta)\in\mathcal{H}} \Pr(|\hat{R}(\theta) - R(\theta)| > \varepsilon/2) \equiv \delta \qquad (3)$$

where the probability on the right-hand side scales as $\mathcal{O}(\exp(-\lambda n))$. The trade-off between the complexity term $|\mathcal{H}|$ and the model-fitting factor $\sup_{f(.;\theta)\in\mathcal{H}}\Pr(|\hat{R}(\theta) - R(\theta)| > \varepsilon/2)$ allows us to determine a necessary sample size $n_0(\varepsilon, \delta)$ of the training set given the hypothesis class $\mathcal{H}$. Too complex hypothesis classes yield very loose bounds on the large deviations, despite the fact that we have used the best-performing classifier on the training data. Too simple hypothesis classes, on the other hand, introduce a significant model mismatch or bias, and they constrain the parameter space so severely that the signal in the data might not be captured by the learning algorithm.

How can we measure the complexity of a model when the cardinality is infinite, e.g., the space of polynomial discriminant functions of degree $p$ or smaller? Obviously, the complexity depends on the degrees of freedom that are available to adapt to signal properties of the data set. To measure the complexity of a model, statisticians have developed sophisticated mathematical techniques from combinatorics and functional analysis. A very crude but for many practical applications sufficient rule of thumb counts the number of parameters in the model and requires that we provide at least ten data points per parameter to estimate the model. This rule implicitly assumes that all parameters increase the complexity of the model by an approximately constant amount. Consequently, applied statisticians have advocated adding a complexity penalty to the quality measure, which is linear in the number of parameters, like the AIC or the BIC criterion (see Hastie, Tibshirani, and Friedman, 2001). From estimating regression curves, however, we know that the slope of a linear regression function and the frequency of a trigonometric function add a vastly different amount of complexity to the model class. That is, oscillatory functions with a sufficiently high frequency allow us to approximate all data points in a bounded range with arbitrarily high precision, whereas linear functions cannot in general interpolate more than two points. The concept of covering numbers of function spaces measures this effect and relates the fitting power of functions to general properties of the underlying hypothesis (function) class. The *Vapnik-Chervonenkis dimension* and the *fat-shattering dimension* (Anthony and Bartlett, 1999) (see VAPNIK-CHERVONENKIS DIMENSION OF NEURAL NETWORKS) are derived parameters that measure the complexity of a hypothesis class for classification and regression independent of the probability distribution of the data.

## Cross-Validation and Bootstrap

### *Cross-Validation*

Apart from analytical techniques to derive bounds on the validity of models, a large number of numerical techniques have been developed to validate statistical models. Numerical methods for model validation split the data into three different subsets, the training set for parameter estimation, the validation set for selection of the model class, and the test set for estimation of the prediction error. The validation set is used for training if the model class has been selected a priori. One of the most widely used techniques in classification and regression is the *k-fold cross-validation* method, which gains statistical precision at the expense of computation. The data set is split into $k$ subsets of approximately equal size. The learning algorithm uses $k - 1$ of these subsets to estimate the model parameters, e.g., to find the empirical risk minimizer based on the data of these $k - 1$ subsets. The data of the $k$th subset, which have been set aside for model testing, are then used to estimate the model quality on future data. This procedure can be repeated $k$ times, resulting in $k$ different estimators. There exists a rich literature on how these different estimators can be combined, ranging from averages with different weighting schemes in regression (model averaging) to majority votes in classification. Popular versions of cross-validation are fivefold or tenfold cross-validation.

The validation set is required in cases where we not only have to estimate model parameters but also have to select an appropriate model order, e.g., to decide whether we should use a model with four parameters or one with five or more parameters. In such a data analysis scenario, we first train the model on the basis of the training data, then we validate our choice of the model order based on the estimated prediction error for the validation data. The model order with the best performance on the validation data is then selected. At the end of the data analysis process, the test data set is used to estimate the prediction error of the selected model, e.g., how well the selected model performs on future data. Using the test data rather than the validation data for model order selection—an unfortunately common practice among applied data analysts—usually leads to an overly optimistic estimate of the model error, since a selection bias in favor of low errors obscures the true error of the model.

### *Bootstrap*

One of the drawbacks of cross-validation is the loss of training data for validation and testing. In the small-sample-size scenario, which occurs quite often in practical data analysis problems, we have too few data compared to the desired model complexity, and therefore we cannot afford to set aside some data exclusively for testing. Efron (see Efron and Tibshirani, 1993; Davison and Hinkley, 1997) has proposed a *resampling scheme with replacements*, called *bootstrap*, which is schematically summarized in Figure 1. Conceptually, we replace the unknown true probability distribution of the data with the available empirical distribution. Sampling from this empirical distribution generates $B$ bootstrap sample sets $Z^{*b} = \{(x_1^{*b}, y_1^{*b}), \ldots, (x_n^{*b}, y_n^{*b})\}$, $1 \leq b \leq B$. A reasonable number $B$ of bootstrap samples is between 25 and 200. Note that the bootstrap samples are not just permutations of each other, since we sample with replacements. Each of these bootstrap sample sets allows us to fit a model by estimating the model parameters with statistics $S$, e.g., the sample means, variances, or medians for mixture models. Finally, we combine these $B$ bootstrap models by an appropriate averaging or merging procedure to derive an averaged model with supposedly more robust behavior than any single model.

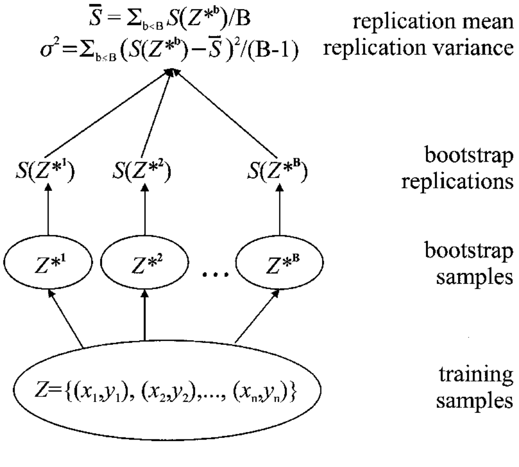

**Figure 1.** Processing pipeline of bootstrap estimation via bootstrap samples $Z^{*b}$ and their associated statistics $S(Z^{*b})$.

To estimate the quality of the models fitted by bootstrapping, we choose those data in the training samples for testing that have not been selected for the bootstrap sample. Using the complete training sample set $Z$ for testing would result in an overly optimistic model quality, since a fraction of approximately $(1 - 1/e)n \approx 0.632n$ of the data have been used in the bootstrap sample for model fitting. Improved and more robust estimators of model quality have been suggested by Efron and others, which are known as the $S^{(.632)}$ estimator and variants of it (Hastie et al., 2001).

## Discussion

Model validation in inference defines the core problem in learning and statistical estimation. When we induce a general model from a finite number of samples, we have to consider the complexity of the model in relation to the amount of data available for inference. Too complex models feign a high quality on small sample sets that is not confirmed on (future) test data. Analytical and numerical methods have been proposed over the last 40 years of neural network research to bound the deviations between empirical and expected risk of a statistical model. Bounds of the VC type usually contain a complexity term that accounts for the richness and flexibility of the hypothesis class, and a fitting term that measures the contraction of measure due to the large number of samples. Both influences have to be controlled, either by numerical methods like cross-validation and bootstrap or by analytical techniques from computational learning theory. The trade-off between model complexity and goodness of fit and its relation to the computational complexity of learning remains one of the deep challenges for future research on learning.

# Modular and Hierarchical Learning Systems

*Michael I. Jordan and Robert A. Jacobs*

## Introduction

In this article we discuss the problem of learning in modular and hierarchical systems. Modular and hierarchical systems allow complex learning problems to be solved by dividing the problem into a set of subproblems, each of which may be simpler to solve than the original problem. Within the context of supervised learning—our focus in this article—modular architectures arise when we assume that the data can be well described by a collection of functions, each of which is defined over a relatively local region of the input space. A modular architecture can model such data by allocating different modules to different regions of the space. Hierarchical architectures arise when we assume that the data are well described by a multiresolution model—a model in which regions are divided recursively into subregions.

Modular and hierarchical systems present an interesting credit assignment problem—it is generally the case that the learner is not provided with prior knowledge of the partitioning of the input space. Knowledge of the partition would correspond to being given "labels" specifying how to allocate modules to data points. The assumption we make is that such labels are absent. The situation is reminiscent of the unsupervised clustering problem in which a classification rule must be inferred from a data set in which the class labels are absent, and indeed, the connection to clustering has played an important role in the development of the supervised learning algorithms that we present here.

The learning algorithms that we describe solve the credit assignment problem by computing a set of values—posterior probabilities—that can be thought of as estimates of the missing "labels." These posterior probabilities are based on a probabilistic model associated with each of the network modules. This approach to learning in modular systems was developed by Jacobs et al. (1991). Jordan and Jacobs (1994) extended the modular system to a hierarchical system, made links to the statistical literature on classification and regression trees (Breiman et al., 1984), and developed an Expectation-Maximization (EM) algorithm for the architecture. We describe these developments in the remainder of the article, emphasizing the probabilistic framework.

## The Mixture-of-Experts (ME) Architecture

The modular architecture that we consider is shown in Figure 1. The architecture is composed of $N$ modules referred to as *expert networks*, each of which implements a parameterized function $\boldsymbol{\mu}_i = f(\mathbf{x}, \boldsymbol{\theta}_i)$ from inputs $\mathbf{x}$ to outputs $\boldsymbol{\mu}_i$, where $\boldsymbol{\theta}_i$ is a parameter vector. We attach a probabilistic interpretation to each of the expert networks by assuming that the experts generate outputs $\mathbf{y}$ with probability $P(\mathbf{y}|\mathbf{x}, \boldsymbol{\theta}_i)$, where $\boldsymbol{\mu}_i$ is the mean of the conditional density $P$.

Because we assume that different expert networks are appropriate in different regions of the input space, the architecture requires a mechanism that identifies, for any given input $\mathbf{x}$, that expert or blend of experts that is most likely to produce the correct output. This is accomplished via an auxiliary network, known as a *gating network,* that produces as output a set of scalar coefficients $g_i$ that serve to weight the contributions of the various experts. These coefficients are not fixed constants but vary as a function of the input $\mathbf{x}$.

The probabilistic interpretation of the gating network is as a *classifier,* a system that maps an input $\mathbf{x}$ into the probabilities that the various experts will be able to generate the desired output (based on knowledge of $\mathbf{x}$ alone). These probabilities (the $g_i$) are constrained to be nonnegative and sum to one (for each $\mathbf{x}$).

There are many ways to enforce the probabilistic constraints on $g_i$. One approach is to utilize the *softmax* function, defined as follows. Let $\xi_i$ denote an intermediate set of variables that are parameterized functions of the input $\mathbf{x}$:

$$\xi_i = \xi_i(\mathbf{x}, \boldsymbol{\eta}) \tag{1}$$

where $\boldsymbol{\eta}$ is a parameter vector, and define the outputs $g_i$ in terms of $\xi_i$ as follows:

$$g_i = \frac{e^{\xi_i}}{\sum_j e^{\xi_j}} \tag{2}$$

It is readily verified that the $g_i$ are nonnegative and sum to one for each $\mathbf{x}$. This approach has the virtue of having a simple probabilistic interpretation: the $\xi_i$ can be viewed as discriminant surfaces for a classification problem in which the class-conditional densities are members of the exponential family of probability distributions (Jordan and Jacobs, 1994).

### *The Mixture Model*

Let us now specify the probabilistic model underlying the mixture-of-experts architecture more precisely. We assume that the training set $\mathscr{X} = \{(\mathbf{x}^{(l)}, \mathbf{y}^{(l)})\}_{l=1}^{L}$ is generated in the following way. Given the choice of an input $\mathbf{x}$, a label $i$ is chosen with probability $P(i|\mathbf{x}, \boldsymbol{\eta}^0)$ (where the superscript 0 denotes the putative true values of the parameters). Given the choice of the label and given the input, the target output $\mathbf{y}$ is assumed to be generated with probability $P(\mathbf{y}|\mathbf{x}, \boldsymbol{\theta}_i^0)$. Each such data point is assumed to be generated independently in this manner.

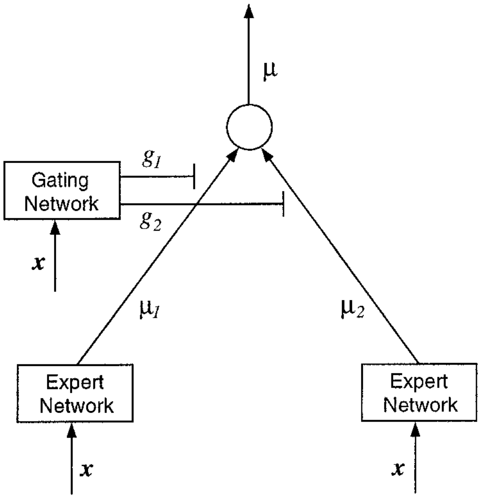

**Figure 1.** A mixture-of-experts architecture. The output $\boldsymbol{\mu}$ is the conditional mean of $\mathbf{y}$ given $\mathbf{x}$ (see text).

Note that a given output $\mathbf{y}$ can be generated in $N$ different ways, corresponding to the $N$ different choices of the label $i$. Thus, the total probability of generating $\mathbf{y}$ from $\mathbf{x}$ is given by the sum over $i$:

$$P(\mathbf{y}|\mathbf{x}, \boldsymbol{\Theta}^0) = \sum_i P(i|\mathbf{x}, \boldsymbol{\eta}^0)P(\mathbf{y}|\mathbf{x}, \boldsymbol{\theta}_i^0) \tag{3}$$

where $\boldsymbol{\Theta}^0$ denotes the vector of all of the parameters ($\boldsymbol{\Theta}^0 = [\boldsymbol{\theta}_1^0, \boldsymbol{\theta}_2^0, \ldots, \boldsymbol{\theta}_N^0, \boldsymbol{\eta}^0]^T$). The density in Equation 3 is known as a *mixture density*. It is a mixture density in which the mixing proportions, $P(i|\mathbf{x}, \boldsymbol{\eta}^0)$, are conditional on the input $\mathbf{x}$.

It is the task of the gating network to model the probabilities $P(i|\mathbf{x}, \boldsymbol{\eta}^0)$, which can be construed as class probabilities in a multiway classification problem of the input $\mathbf{x}$. We parameterize these probabilities via Equations 1 and 2, identifying the gating network outputs $g_{\mathrm{i}}$ with $P(i|\mathbf{x}, \boldsymbol{\eta})$.

It is straightforward to compute moments of the mixture density. For example, the conditional mean $\boldsymbol{\mu} = E(\mathbf{y}|\mathbf{x}, \boldsymbol{\Theta})$ is readily obtained by taking the expected value of Equation 3:

$$\boldsymbol{\mu} = \sum_i g_i \boldsymbol{\mu}_i$$

where $\boldsymbol{\mu}_i$ is the conditional mean associated with the probability distribution $P(\mathbf{y}|\mathbf{x}, \boldsymbol{\theta}_i^0)$. The conditional mean is quite commonly used as the output of supervised learning systems, and this is reasonable in the mixture-of-experts setting as well, but only when no more than one value $g_i$ is significantly different from zero for a given input $\mathbf{x}$. When more than one expert has a large value of $\mathbf{g}_i$, however, the conditional distribution of $\mathbf{y}$ given $\mathbf{x}$ is multimodal, and it is important to make fuller use of the entire mixture density in such cases.

### *A Gradient-Based Learning Algorithm*

To develop an algorithm for estimating the parameters of a mixture-of-experts architecture, we make use of the maximum likelihood (ML) principle. That is, we choose parameters for which the probability of the training set given the parameters (a function known as the *likelihood*) is largest. Taking the logarithm of the product of $N$ densities of the form of Equation 3 yields the following log likelihood:

$$l(\mathscr{X}, \boldsymbol{\Theta}) = \sum_l \log \sum_i P(i|\mathbf{x}^{(l)}, \boldsymbol{\eta})P(\mathbf{y}^{(l)}|\mathbf{x}^{(l)}, \boldsymbol{\theta}_i) \tag{4}$$

a function that we wish to maximize with respect to $\boldsymbol{\Theta}$. One approach to maximizing the log likelihood is to use gradient ascent (a better approach is to use the EM algorithm, as discussed in a later section). Computing the gradient of $l$ with respect to $\boldsymbol{\mu}_i$ and $\xi_i$ yields:

$$\frac{\partial l}{\partial \boldsymbol{\mu}_i} = \sum_l h_i^{(l)} \frac{\partial}{\partial \boldsymbol{\mu}_i} \log P(\mathbf{y}^{(l)}|\mathbf{x}^{(l)}, \boldsymbol{\theta}_i) \tag{5}$$

and

$$\frac{\partial l}{\partial \xi_i} = \sum_l (h_i^{(l)} - g_i^{(l)}) \tag{6}$$

where $h_i^{(l)}$ is defined as $P(i|\mathbf{x}^{(l)}, \mathbf{y}^{(l)})$. In deriving this result, we have used Bayes' rule:

$$P(i|\mathbf{x}^{(l)}, \mathbf{y}^{(l)}) = \frac{P(i|\mathbf{x}^{(l)})P(\mathbf{y}^{(l)}|\mathbf{x}^{(l)}, i)}{\sum_j P(j|\mathbf{x}^{(l)})P(\mathbf{y}^{(l)}|\mathbf{x}^{(l)}, j)}$$

where we have omitted the parameters to simplify the notation. This suggests that we define $h_i^{(l)}$ as the *posterior probability* of the $i$th label, conditional on the input $\mathbf{x}^{(l)}$ and the output $\mathbf{y}^{(l)}$. Similarly, the probability $g_i^{(l)}$ can be interpreted as the *prior probability* $P(i|\mathbf{x}^{(l)})$, the probability of the $i$th label, given only the input $\mathbf{x}^{(l)}$. Given these definitions, Equation 6 has the natural interpretation of moving the prior probabilities toward the posterior probabilities.

An interesting special case is an architecture in which the expert networks and the gating network are linear and the probability density associated with the experts is a Gaussian with identity covariance matrix. In this case, Equations 5 and 6 yield the following on-line learning algorithm (on-line meaning that we have dropped the summation across $l$):

$$\Delta\boldsymbol{\theta}_i = \rho h_i^{(l)}(\mathbf{y}^{(l)} - \boldsymbol{\mu}_i^{(l)})\mathbf{x}^{(l)^T} \tag{7}$$

and

$$\Delta\boldsymbol{\eta}_i = \rho(h_i^{(l)} - g_i^{(l)})\mathbf{x}^{(l)^T} \tag{8}$$

where $\rho$ is a learning rate. Note that both of these equations have the form of the classical LMS rule, with the updates for the experts in Equation 7 being modulated by their posterior probabilities.

It is also of interest to examine the expression for the posterior probability in the Gaussian case:

$$h_i^{(l)} = \frac{g_i^{(l)} e^{-1/2(\mathbf{y}^{(l)} - \boldsymbol{\mu}_i^{(l)})^T(\mathbf{y}^{(l)} - \boldsymbol{\mu}_i^{(l)})}}{\sum_j g_j^{(l)} e^{-1/2(\mathbf{y}^{(l)} - \boldsymbol{\mu}_j^{(l)})^T(\mathbf{y}^{(l)} - \boldsymbol{\mu}_j^{(l)})}} \tag{9}$$

This is a normalized distance measure that reflects the relative magnitudes of the residuals $\mathbf{y}^{(l)} - \boldsymbol{\mu}_i^{(l)}$. If the residuals for expert $i$ are small relative to those of the other experts, then $h_i^{(l)}$ is large, otherwise, $h_i^{(l)}$ is small. Note, moreover, that the $h_i^{(l)}$ are positive and sum to one for each $\mathbf{x}^{(l)}$; this implies that credit is distributed to the experts in a competitive manner.

It is straightforward to utilize other members of the exponential family of densities as component densities for the experts, to allow dispersion (e.g., covariance) parameters to be incorporated in the model and to estimate the dispersion parameters via the learning algorithm (Jordan and Jacobs, 1994; Jordan and Xu, 1995).

## The Hierarchical Mixture-of-Experts (HME) Architecture

The ME architecture solves complex function approximation problems by allocating different modules to different regions of the input space. This approach can have advantages for problems in which the modules are simpler than the large network that would be required to solve the problem as a whole. If we now inquire about the internal structure of a module, however, we see that the same argument can be repeated. Perhaps it is better to split a module into simpler submodules rather than to use a single module to fit the data in a region. This suggests a thoroughgoing divide-and-conquer approach to supervised learning in which a tree-structured architecture is used to perform multiple nested splits of the input space (Figure 2). The splitting process terminates in a set of expert networks at the leaves of the tree, which, because they are defined over relatively small regions of the input space, can fit simple (e.g., linear) functions to the data. This hierarchical architecture, suggested by Jordan and Jacobs (1994), has close ties to the classification and regression tree models in statistics and machine learning (e.g., Breiman et al., 1984). Indeed, the architecture can be viewed as a probabilistic variant of such models.

The mathematical framework underlying the HME architecture is essentially the same as that underlying the ME architecture. We simply extend the probability model to allow nested sequences of labels to be chosen, corresponding to the nested sequence of re-

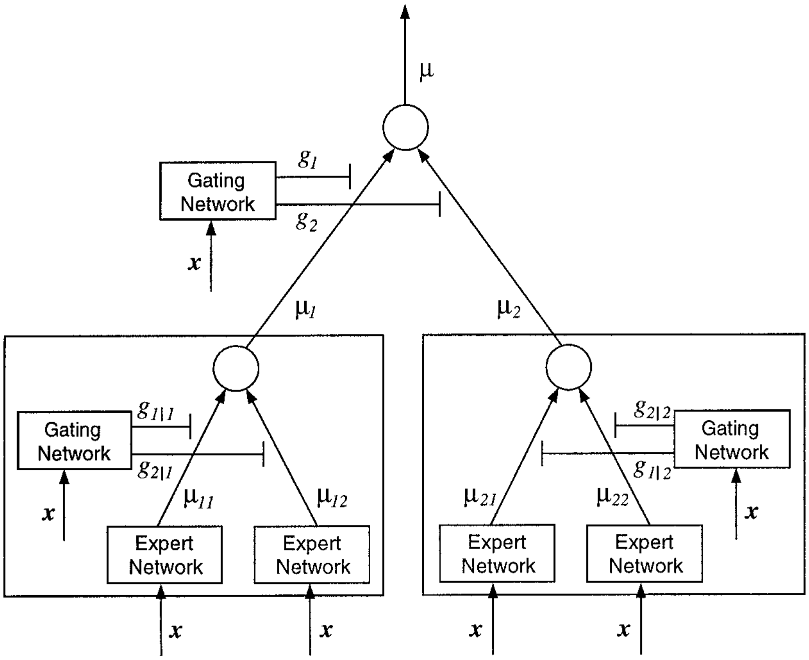

**Figure 2.** A two-level binary hierarchical architecture. The top-level gating network produces coefficients $g_i$ that effectively split the input space into regions, and the lower-level gating networks produce coefficients $g_{j|i}$ that effectively split these regions into subregions. The expert networks fit surfaces within these nested regions. Deeper trees are formed by expanding the expert networks recursively into additional gating networks and subexperts.

gions needed to specify a leaf of the tree. The probability model for a two-level tree is as follows:

$$P(\mathbf{y}|\mathbf{x}, \mathbf{\Theta}) = \sum_i P(i|\mathbf{x}, \boldsymbol{\eta}) \sum_j P(j|i, \mathbf{x}, \mathbf{v}_i) P(\mathbf{y}|\mathbf{x}, \boldsymbol{\theta}_{ji}) \tag{10}$$

which corresponds to a choice of label $i$ with probability $P(i|\mathbf{x}, \boldsymbol{\eta})$, followed by a conditional choice of label $j$ with probability $P(j|i, \mathbf{x}, \mathbf{v}_i)$. This probability model yields the following log likelihood function:

$$l(\mathcal{X}, \mathbf{\Theta}) = \sum_l \log \sum_i P(i|\mathbf{x}^{(l)}, \boldsymbol{\eta}) \sum_j P(j|i, \mathbf{x}^{(l)}, \mathbf{v}_i) P(\mathbf{y}^{(l)}|\mathbf{x}^{(l)}, \boldsymbol{\theta}_{ji}) \tag{11}$$

where, as in the one-level case, the prior probabilities $g_i^{(l)} = P(i|\mathbf{x}^{(l)}, \boldsymbol{\eta})$ and $g_{j|i}^{(l)} = P(j|i, \mathbf{x}^{(l)}, \mathbf{v}_i)$ are defined in terms of underlying variables $\xi_i$ and $\xi_{ij}$ using the softmax function (cf. Equation 2). We also use Bayes' rule to define posterior probabilities in the obvious way:

$$h_i^{(l)} = \frac{g_i^{(l)} \sum_j g_{j|i}^{(l)} P(\mathbf{y}^{(l)}|\mathbf{x}^{(l)}, \boldsymbol{\theta}_{ij})}{\sum_j g_j^{(l)} \sum_k g_{k|j}^{(l)} P(\mathbf{y}^{(l)}|\mathbf{x}^{(l)}, \boldsymbol{\theta}_{jk})} \tag{12}$$

and

$$h_{j|i}^{(l)} = \frac{g_{j|i}^{(l)} P(\mathbf{y}^{(l)}|\mathbf{x}^{(l)}, \boldsymbol{\theta}_{ij})}{\sum_j g_{j|i}^{(l)} P(\mathbf{y}^{(l)}|\mathbf{x}^{(l)}, \boldsymbol{\theta}_{ij})} \tag{13}$$

The posterior probability $h_i^{(l)}$ can be viewed as the credit assigned to the $i$th nonterminal in the tree, and the posterior probability $h_{j|i}^{(l)}$ is the credit assigned to the branches below the nonterminals. The product $h_i^{(l)} h_{j|i}^{(l)}$ is therefore the credit assigned to expert $(i, j)$.

A recursive relationship is available to compute the posterior probabilities efficiently in deep trees. The recursion proceeds upward in the tree, passing the denominator of the conditional posterior upward, multiplying by the priors, and normalizing (cf. the computation of $h_i$ from $h_{j|i}$ in Equations 12 and 13).

We obtain a gradient ascent learning algorithm by computing the partial derivatives of $l$. If, as in the previous section, we assume linear experts and a linear gating network, as well as Gaussian probabilities for the experts, we obtain the following LMS-like learning algorithm:

$$\Delta\boldsymbol{\theta}_{ji} = \rho h_i^{(l)} h_{j|i}^{(l)} (\mathbf{y}^{(l)} - \boldsymbol{\mu}_{ij}^{(l)}) \mathbf{x}^{(l)T} \tag{14}$$

$$\Delta\boldsymbol{\eta}_i = \rho (h_i^{(l)} - g_i^{(l)}) \mathbf{x}^{(l)T} \tag{15}$$

and

$$\Delta\mathbf{v}_{ji} = \rho h_i^{(l)} (h_{j|i}^{(l)} - g_{j|i}^{(l)}) \mathbf{x}^{(l)T} \tag{16}$$

Each of these partial derivatives have a natural interpretation in terms of credit assignment. Credit is assigned to an expert by taking the product of the posterior probabilities along the path from the root of the tree to the expert (cf. Equation 14). The updates for the gating networks move the prior probabilities at a nonterminal toward the corresponding posterior probabilities, weighting these updates by the product of the posterior probabilities along the path from the root of the tree to the nonterminal in question (cf. Equation 16).

## An EM Algorithm

Jordan and Jacobs (1994) have derived an Expectation-Maximization (EM) algorithm for estimating the parameters of the ME and HME architectures. (See McLachlan and Krishnan, 1997, for a general treatment of the EM algorithm.) This algorithm, an alternative to gradient methods, is particularly useful for models in which the expert networks and gating networks have simple parametric forms. Each iteration of the algorithm consists of two phases: (1) a recursive propagation upward and downward in the tree to compute posterior probabilities (the *E-step*), and (2) solution of a set of local weighted maximum likelihood problems at the nonterminals and terminals of the tree (the *M-step*). Jordan and Jacobs (1994) tested this algorithm on a nonlinear system identification problem (the forward dynamics of a four-degrees-of-freedom robot arm) and reported that it converges rapidly, converging nearly two orders of magnitude faster than backpropagation in a comparable multilayer perceptron network.

## Discussion

Mixtures of experts should be compared to ensemble methods such as bagging and boosting (see Ensemble Learning), which provide another general approach to building a supervised learning architecture out of collections of simple learners. In bagging and boosting, the overall input-output mapping is a convex combination of the members of the ensemble, much as in the case of mixtures of experts (in which the conditional mean is a convex combination of the outputs of the experts). However, the weights in this convex combination are constants in the case of bagging and boosting, whereas they are functions of the input for mixtures of experts. Moreover, in the mixture of experts, the weights have an interpretation as prior probabilities under a probabilistic mixture model and are explicitly parameterized as such. In particular, under this model, a single expert is assumed to be associated with each data point, an assumption that is not made for the ensemble methods. In essence, the mixture of experts approaches the supervised learning problem via a divide-and-conquer methodology reminiscent of unsupervised clustering, whereas ensemble methods approach the problem via superposition and averaging.

We conclude with a brief list of pointers to additional papers. The problem of model selection for HME architectures has been addressed by a number of authors. Several papers propose the use of greedy search procedures combined with some form of penalization for model complexity (Ramamurti and Ghosh, 1996; Saito and Nakano, 1996; Fritsch, Finke, and Waibel, 1997). Bayesian approaches for model selection or model averaging have also been presented, including methods based on Gibbs sampling (Jacobs, Peng, and Tanner, 1997) and variational approximation (Waterhouse, MacKay, and Robinson, 1994).

Theoretical analyses of the approximation and estimation rates for the ME (Zeevi, Meir, and Maiorov, 1998) and the HME (Jiang and Tanner, 1998) are available. A basic result is that the HME achieves an approximation rate of $O(m^{-2/s})$, where $m$ is the number of experts and $s$ is the dimensionality of the input vector. Jordan and Xu (1995) present an analysis of the convergence rate for the EM algorithm for the HME. Kang and Oh (1997) provide an analysis of the HME using tools from statistical physics; in particular, they show that successive partitions in the HME can be analyzed as phase transitions.

There is a broad literature on engineering applications of the HME architecture, including applications to state-space filtering, optimization, control, vision, speech recognition, speaker identification, and time series analysis. Recent biological applications of the ME architecture have been presented by Haruno, Wolpert, and Kawato (2001), who describe an architecture for human motor control based on a mixture of experts in which each expert is a paired forward-inverse model, and by Erickson and Kruschke (1998), who used the mixture of experts to build a model of human category learning that combines rule-based and exemplar-based representations.

# Motion Perception, Elementary Mechanisms

*David C. Burr*

## Introduction

Visual motion is essential for many aspects of biological function, including rapidly detecting predators and prey, navigating through the visual environment, and constructing a three-dimensional visual representation from two-dimensional retinal input. However, motion information is not provided by the instantaneous retinal signal, but has to be computed from temporal variations in luminance over the image. Although the neural mechanisms that achieve this vary considerably throughout the animal kingdom, the underlying principles of the algorithms seem to be very similar.

## Models of Motion Perception

In biological visual systems, motion is initially analyzed in parallel by arrays of local motion detectors that exhibit certain basic properties: they require at least two spatially separate sampling units, one delayed with respect to the other, that are combined (usually nonlinearly) to create directional selectivity. Werner Reichardt (1961) was the first to provide a formal model of a motion detector based on these principles, in what has become know as a “correlator-type” model, or more simply, the *Reichardt detector*. The detector, at its simplest, is illustrated in Figure 1. The response of two spatially separated units ($\Delta\varphi$ apart) are multiplied together (at M), after one has been delayed by $\epsilon$. The figure illustrates two such units arranged as mirror images, symmetrically, using the same input. The unit on the left will respond best to rightward motion, maximally for speeds of $\Delta\varphi/\epsilon$; that on the right will respond best to leftward velocities of $\Delta\varphi/\epsilon$. Each unit M can be considered to be an elementary motion detector, in that it shows a direction preference. However, by combining the output of two such mirror-symmetrical units (subtractively in this case), the direction selectivity is further enhanced, to produce what is referred to as the *full Reichardt detector*.

The essential components of the Reichardt detector—spatial and temporal asymmetries and cross-correlation—can be implemented in many different ways. The initial model was inspired by the fly visual system, in which the two sampling points are adjacent ommatidia, and the temporal delay $\epsilon$ is introduced by some form of delay line, typically a low-pass filter. Models of human motion have been heavily influenced by the application of Fourier analysis to vision research, showing spatial and temporal filtering of the visual input at early stages. For moving stimuli, detectors are tuned in both space and time, leading to spatiotemporally oriented filters, or receptive fields. This concept has proven invaluable, not only in constructing physiologically plausible models of motion perception, but also in explaining how the form of moving objects is encoded (Burr and Ross, 1986).

One specific example of a model based on this concept is shown in Figure 2. The model starts with spatiotemporally oriented receptive fields tuned to a finite band of spatial and temporal frequencies, and hence to motion in a given direction (corresponding to a preferred orientation in the spatiotemporal plane). The orientation in space-time is readily achieved by linear combination of filters with appropriate spatial and temporal phase-shifts. In the particular model shown in Figure 2, the output of two such filters in quasi-quadrature phase in space and time, is squared then summed, to produce what has been termed “unidirectional motion energy.” This model responds to a drifting sinusoidal grating with a constant response, strongest when the velocity of the sinusoid corresponds to the orientation of the spatiotemporal receptive field, and weakest when in the orthogonal orientation (opposite direction). However, like the simple Reichardt detector, such a motion unit is not in itself a true motion detector, in that it will respond to many stationary transient stimuli, such as to a briefly flashed pattern of appropriate spatial frequency. Further specificity is achieved by inhibition between opponent motion energies, either by subtraction, as shown here, or by division. Interestingly, the full version of the motion energy model is formally equivalent to the full Reichardt motion detector, elaborated to include a spatial and temporal filtering stage, even though no part of the Reichardt detector corresponds to the unidirectional motion energy extractors (Adelson and Bergen, 1985).

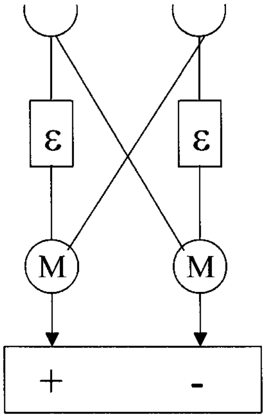

**Figure 1.** Simplified “full Reichardt detector.” (Adapted from Reichardt, 1961.)

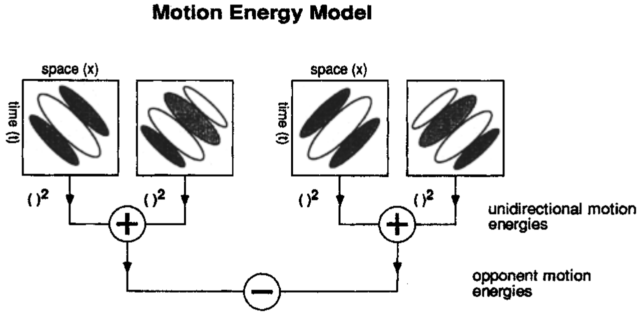

**Figure 2.** An example of a motion detector based on filters oriented in space-time. (Reproduced with permission from Adelson and Bergen, 1985.)

Physiological measurements of neurons in macaque monkey visual cortex have identified plausible neural substrates for the two stages of the motion energy model (Qian and Andersen, 1994). Cells in the primary visual cortex V1 show directional selectivity, but also respond well to bidirectional motion; this is consistent with the expected performance of the first stage. However, cells in the middle temporal area (MT) show a strong inhibition by motion in the nonpreferred direction, consistent with opponent motion stage of the model. FMRI studies in humans provide support for this suggestion: V1 responds more strongly to counterphased sinusoidal gratings (that can be considered as the sum of two opposing drifting gratings) than to a single component drifting grating; whereas in MT complex, the result is reversed, with a much stronger response to the single component (Heeger et al., 1999).

## Velocity Tuning

The selectivity to speed of the two motion detectors of Figures 1 and 2 can be varied by changing either the temporal or the spatial characteristics. For the Reichardt detector, the preferred speed can be increased either by increasing the spacing $\Delta\varphi$ between the two sampling points, or by decreasing the delay $\epsilon$. Similarly, for the energy model, where the spatial and temporal offsets are given by phase shifts, preferred speed will depend on both spatial and temporal frequency preference. In humans, it is possible to measure spatial and temporal selectivity, using a variety of techniques, including “masking,” in which one measures contrast sensitivity to a “test” stimulus in the presence of a high-contrast “mask.” The assumption is that the mask will cause maximum desensitization when its spatiotemporal characteristics match that of the detector responding to the test. To study motion perception, the test stimuli were drifting sinusoidal gratings of variable spatial and temporal frequency, displayed together with mask gratings, also varying in spatial and temporal frequency (Anderson and Burr, 1985). Over a wide range of spatial frequencies (0.025 c/deg to 15 c/deg), maximal masking occurs when the frequency of the mask matches that of the test. This suggests that there exist a battery of detectors with preferred spatial frequency varying over this entire range, so that for any given test frequency the most sensitive detector will be tuned to that frequency; the most effective mask will therefore also be of that spatial frequency. For test frequencies lower than 0.025 c/deg or higher than 15 c/deg, maximum masking occurs not at the frequency of the test, but at 0.025 and 15 c/deg, respectively, suggesting that there do not exist motion detectors tuned to frequencies outside these bounds; a test of 0.01 c/deg will be detected by a mechanism tuned to 0.025 c/deg, so the most effective mask will be tuned to 0.025 c/deg, not 0.1 c/deg. In the temporal domain, the results are quite different. Maximal masking always occurs for masks near 10 Hz, irrespective of the temporal frequency of the test, implying that there is not a range of temporal tuning, but all detectors have similar temporal properties. Taken together, the results imply that in human vision, the variation in speed tuning is achieved not by varying temporal characteristics of the motion detector, but by varying spatial frequency preference, over a 600-fold range.

What is the range of speeds to which humans are sensitive? The lowest speed at which direction can accurately be discriminated is about 1 min/s for small stimuli moving over the fovea. This threshold increases steadily with eccentricity, reaching 8–10 min/s at 90° eccentricity (largely explained by the optical degradation in the periphery). However, the upper limit of motion detection is not a fixed speed but, as may be expected from the previous paragraph, varies considerably with the spatial frequency content of the stimuli (Burr and Ross, 1982). This is brought out clearly in Figure 3, showing contrast sensitivity (inverse of contrast thresholds) for biphasic bars (signal cycles of sinusoid) of various sizes, as a function of drift speed (abscissa). The small bars were seen best (required least contrast to discriminate their direction) when moving slowly, and could not be resolved at all at speeds above 100 deg/s. The largest bars, however, were best seen when moving at 500 deg/s, and could still be reliably resolved at 10,000 deg/s. Thus, the upper limit of motion perception is not so much a speed limit as a temporal frequency limit. The large variation in receptive field size ensures that human motion perception can operate over an extremely wide range of speeds, spanning nearly six orders of magnitude (0.015 to 10,000 deg/s).

## Apparent Motion

Much of the motion we view daily at the cinema and on television is not real motion but an illusion created by displaying a series of still pictures in rapid succession (24 Hz for cinema, 60 Hz for NSTC television). This type of motion is referred to as "apparent motion," "stroboscopic motion," or, most accurately, "sampled motion." For some time it was thought that apparent motion may be detected by different processes from those detecting real motion, but recent studies find little justification for this view. Most motion detectors that incorporate spatiotemporal filtering will respond well to sampled motion, provided the sampling rate is sufficiently high. The spatiotemporal trajectory for apparent motion is a row of dots in space-time. If the spatiotemporal receptive fields (Figure 2) are oriented parallel to this trajectory, they will integrate the discrete samples, effectively causing the motion to become continuous (Burr and Ross, 1986).

The minimum theoretical sampling rate is given by the Nyquist limit, which requires that the image be sampled at at least twice the temporal frequency of image motion. Sampling below this frequency will cause *aliasing*, well-illustrated by the so-called "wagon-wheel" effect: periodic moving stimuli, such as wagon wheels in Westerns, are seen to stop and reverse direction as the wagon accelerates. When the repetition frequency of spokes exceeds half the sampling frequency (12 Hz for cinema), it will be undersampled, creating strong aliasing in the form of erroneous motion. The conditions under which sampled motion is indistinguishable from smooth motion can be predicted quantitatively from measurements of contrast sensitivity and linear systems analysis (Burr, Ross, and Morrone, 1986). Sampling a motion signal introduces spurious artifacts, whose frequency and amplitude depend on the sampling rate. Psychophysical measurements show that subjects are able to distinguish sampled from smooth motion if and only if the spurious frequencies produced by the sampling regime are not resolvable, as determined by measuring their thresholds for isolated sinusoids.

The spatiotemporally oriented receptive fields not only allow for the perception of discontinuous motion, but can also cause the image to be interpolated between the positions where it is displayed on each sample. The extrapolation is extremely accurate, and works over long ranges. Indeed, this property can be used to generate complex spatial forms from temporal information alone (Burr and Ross, 1986). When moving forms pass behind a "virtual slatted fence" (allowing information to be displayed only at discrete points), the visual system interpolates between the display points to give the impression of complete spatial forms. Thus, motion detectors not only encode velocity information about moving objects, but also participate in their spatial analysis.

## Chromatic and Second-Order Motion

The examples discussed so far refer to motion of objects or images defined by luminance, typically bright or dark lines, sinusoidal grat-

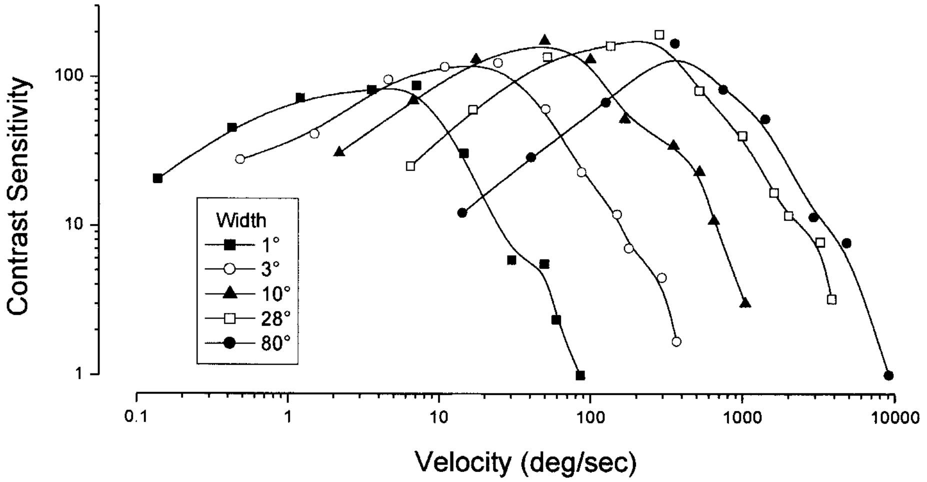

**Figure 3.** Contrast sensitivity for detecting the direction of motion biphasic bars of various sizes, as a function of speed. (Reproduced from Burr and Ross, 1982).

ings, or random dot patterns. However, luminance is not the only way to delineate objects: others include color, texture, and depth, and all these attributes can support motion. A well-studied example is the equiluminant class of stimuli, defined only by chromatic contrast. Movement of these stimuli yields a sensation of motion, albeit slower and jerkier than that for luminance patterns (Cavanagh, 1991).

Another very common stimulus in recent years is the class defined by variations in contrast, rather than luminance, giving rise to what is now called "second-order" motion (Chubb and Sperling, 1988). A typical example of second-order motion is a field of random dots multiplied (or amplitude-modulated) by a broad moving stimulus, typically a sinusoid. The interesting aspect of this stimulus is that although it gives rise to a strong and compelling sense of motion, neither the Reichardt detector of Figure 1 nor the motion-energy detector of Figure 2 would respond to it. However, a fairly simple extension can render both models sensitive to second-order motion: all that is needed is a "texture detector," a filter responding to contrast instead of luminance, at the front stage, and the model will respond to amplitude-modulated motion. The "texture detector" need not be complicated: a simple half- or full-wave rectifier would suffice. It is still a debated point whether first- and second-order motions are detected by different neural structures, or by essentially the same mechanism with an add-on front-end texture detector. Evidence exists for both possibilities, such as mutual induction of aftereffects between the different types of motion, and differential selective activation during fMRI.

## Two-Dimensional Motion

The models shown previously are essentially one-dimensional, discriminating leftward from rightward motion. There are various ways of extending these models to cover the two spatial dimensions, such as constructing many such units with spatial subfields oriented in various directions. Further spatial selectivity can be achieved by extending the spatial filters, or receptive fields, orthogonally to their direction of motion selectivity, emulating the physiological characteristics of receptive fields of mammalian vision. However, these two-dimensional motion units will demonstrate an inherent ambiguity about stimulus direction, usually referred to as the "aperture problem." This stems from the fact that motion along a given trajectory can be decomposed into vectors spanning a range of 180°, so a vast range of detectors will be stimulated by any given trajectory (Figure 4). Various schemes have been proposed for disambiguating the problem, usually involving the combination of signals from more than one detector, either in the form of a "vector sum" of motion units, or "intersection of constraints." There is physiological evidence that the primate visual system adopts one of these schemes (Movshon et al., 1985). When stimulated with "plaids" (two orthogonal sinusoidal gratings) drifting in various directions, neurons in primary visual cortex V1 respond best when the direction of drift is such as to orient one or other of the components appropriately for that neuron, irrespective of the pattern drift. However, in the motion-specialized area MT, neurons respond best when the global motion of the plaid is in the appropriate direction, even though each component is then 45° off-axis. This suggests that as well as being responsible for the opponent stage of the motion detector, MT may help to disambiguate the two-dimensional direction of motion signals.

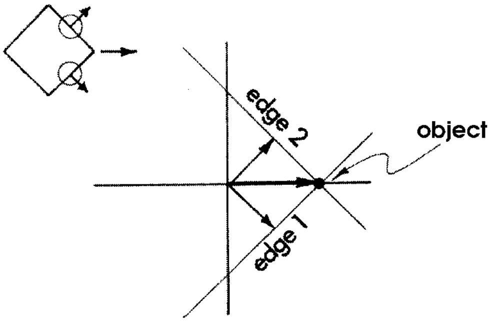

**Figure 4.** Illustration of the inherent ambiguity of two-dimensional motion. As the diamond moves rightward, the motion of the edges, within the receptive fields indicated by the circles, is diagonally upward or downward. In primate cortex, cells in V1 respond to the "component motion" of the edges, while some (but not all) cells in motion area MT respond to the direction of global motion (rightward).

Other solutions have been proposed for the aperture problem, including the novel suggestion of Bill Geisler (1999; see also Burr, 2000). Geisler points out that given the temporal integration of the visual system, a small, localized target will leave a motion streak, much like the "speed lines" used by cartoonist to caricaturize motion. These static streaks provide potential information to disambiguate direction. A series of masking and motion aftereffect studies suggests that this spatial information is in fact integrated with motion information, and may help disambiguation. Another quite different class of experiment has shown that spatial structure of a certain type of moiré pattern can bias otherwise truly apparent motion, showing the influence of static structure on motion direction. Interestingly, however, although the moving streaks may be used to help sense motion, they are not perceived as streaks by the visual system. Although we integrate over time for 120 ms or so, the smear left by moving objects is far less, quite unlike what a camera with that shutter speed would record (Burr and Ross, 1986). Our motion detectors are based on receptive fields that are oriented in space-time, aligning themselves with the motion trajectory, and this should reduce the perceived blur.

This article has concentrated on basic motion mechanisms, the early mechanisms that analyze motion locally. Local-motion signals are combined in various ways, depending on the task. Analysis of optic flow requires integration of local-motion signals over large areas and complex trajectories. On the other hand, the ability to see transparent motion, and to localize accurately the position of small moving objects, requires that the local signals are kept distinct. How these conflicting goals are achieved is the subject of much modern research into motion perception.

# Motion Perception: Navigation

*Constance S. Royden and Ellen C. Hildreth*

## Introduction

When an observer moves through the world, the resulting image motion on the retina, known as *optical flow*, can inform the observer about his own motion through space and about the three-dimensional (3D) structure and motion of objects in the scene. This information is essential for tasks such as the visual guidance of locomotion through the environment and the manipulation and recognition of objects.

This article focuses on the recovery of observer motion from optical flow. We include strategies for detecting moving objects and avoiding collisions, discuss how this information may be used to control actions, and describe the neural mechanisms underlying heading perception.

## The Image Flow Field

This section describes the relationship between two-dimensional (2D) image motion and the 3D translation and rotation of the observer relative to the scene. The mechanisms for deriving the 2D image velocities that result when the observer or objects move are described elsewhere (Hildreth and Koch, 1987; Mitiche and Bouthemy, 1996; see also MOTION PERCEPTION: ELEMENTARY MECHANISMS).

Consider an observer moving relative to a stationary scene, with a coordinate system fixed to the observer and the *z*-axis directed along the optical axis. The instantaneous translation of the observer can be expressed in terms of translation along three orthogonal directions, given by the vector $\mathbf{T} = (\mathrm{T_x}, \mathrm{T_y}, \mathrm{T_z})^{\mathrm{T}}$. Observer rotation can be expressed in terms of rotation around each of these axes, given by $\mathbf{R} = (\mathrm{R_x}, \mathrm{R_y}, \mathrm{R_z})^{\mathrm{T}}$. Let $\mathbf{P} = (\mathrm{X}, \mathrm{Y}, \mathrm{Z})^{\mathrm{T}}$ be the position of a point in space, as shown in Figure 1. The 3D velocity of **P** in the observer's coordinate frame is given by

$$\mathbf{V} = (\dot{\mathrm{X}}, \dot{\mathrm{Y}}, \dot{\mathrm{Z}})^{\mathrm{T}} = -\mathbf{T} - \mathbf{R} \times \mathbf{P}$$

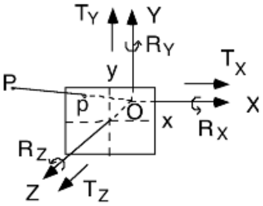

**Figure 1.** Coordinate system for a moving observer who is located at the origin.

where

$$\begin{aligned}\dot{\mathrm{X}} &= -\mathrm{T_x} - \mathrm{R_y Z} + \mathrm{R_z Y}\\ \dot{\mathrm{Y}} &= -\mathrm{T_y} - \mathrm{R_z X} + \mathrm{R_x Z}\\ \dot{\mathrm{Z}} &= -\mathrm{T_z} - \mathrm{R_x Y} + \mathrm{R_y X}\end{aligned}$$

If we assume perspective projection onto the image plane, using a focal length of 1, the projection of **P** onto the image $(x, y)$ is given by

$$x = \mathrm{X/Z}, \quad y = \mathrm{Y/Z}$$

The projected velocities in the image plane $(v_x, v_y)$ are therefore

$$\begin{aligned}v_x &= (-\mathrm{T_x} + x\mathrm{T_z})/\mathrm{Z} + \mathrm{R_x}xy - \mathrm{R_y}(x^2 + 1) + \mathrm{R_z}y\\ v_y &= (-\mathrm{T_y} + y\mathrm{T_z})/\mathrm{Z} + \mathrm{R_x}(y^2 + 1) - \mathrm{R_y}xy - \mathrm{R_z}x\end{aligned}$$

The first term represents the component of image velocity due to observer translation and depends on the depth Z of each point in the scene. The remaining terms represent the component of image velocity due to the observer's rotation and do not depend on depth. The translational component yields a radial pattern of velocity (Figure 2*A*) that emanates from a single location in the image, called the *focus of expansion* (FOE). The FOE corresponds to the observer's heading and occurs at the location $(\mathrm{T_x/T_z}, \mathrm{T_y/T_z})$ in the image. In contrast, the image flow field that results from a pure rotation of the observer is nearly constant over this region of the image. The image flow field for combined translation and rotation of the observer (Figure 2*B*) is the vector sum of the two flow fields from translation and rotation.

For observer translation, one can locate the FOE by finding the point of intersection of lines through the velocity vectors in the image. This simple strategy fails for combined translation and rotation, which occurs when the observer moves along a curved path or rotates his eyes or head, because the additional rotation components of velocity eliminate the FOE. This strategy also fails for nonrigid scenes that contain moving objects whose paths of motion deviate from the radial translational flow lines.

## The Perception of Heading

Perceptual studies show that people judge 3D motion accurately under many conditions (Hildreth and Royden, 1998; Warren, 1998a; van den Berg, in Lappe, 2000). When translating toward a stationary scene, people exhibit discrimination thresholds as low as 0.2° when the heading is near the line of sight. Thresholds rise with more peripheral headings. Heading judgments are performed successfully with sparse, discontinuous flow fields, and require a relatively small field of view if the rotational flow is small. For pure translation, people recover heading with moderate accuracy

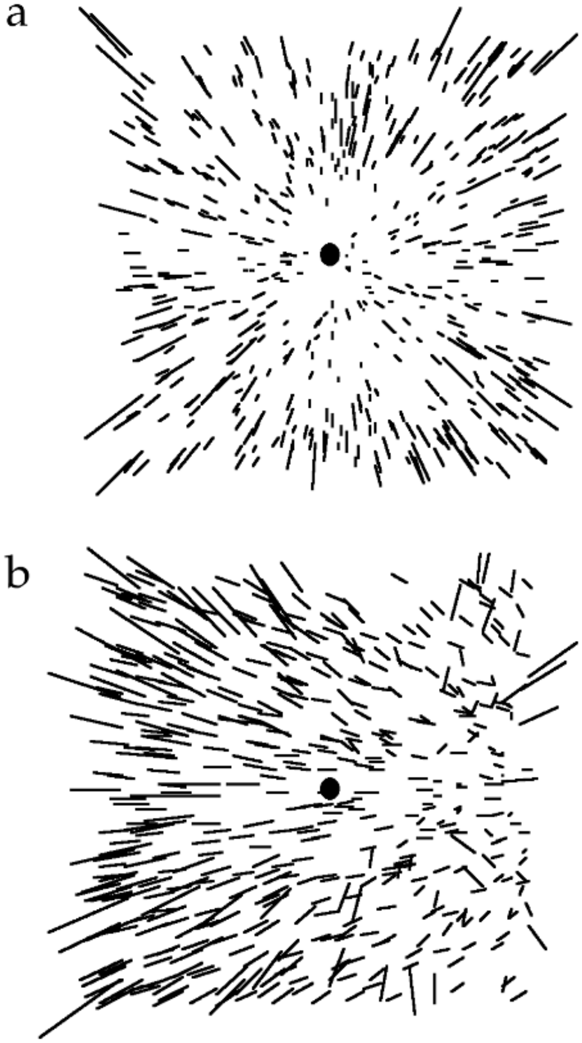

**Figure 2.** *A*, Radial flow field resulting from an observer moving in a straight line through a 3D cloud of dots. *B*, Flow field resulting from an observer translating and rotating (about a vertical axis) through a 3D cloud of dots. The solid circles indicate the direction of observer translation.

from only a 90 ms presentation, but improve up to about 300 ms of viewing time. Heading judgments remain accurate in the presence of moderate amounts of noise in the image flow field. The addition of other static and stereoscopic depth cues can enhance the accuracy of heading judgments in the presence of added noise or observer rotations.

People judge their translational heading accurately in the presence of small rotational rates generated by slow eye movements. Faster eye movements require extraretinal information about the speed of eye movement for accurate heading recovery (Hildreth and Royden, 1998; Warren, 1998a). In contrast, people accurately judge their motion along curved paths at low and high rotation rates (Warren, 1998a; van den Berg, in Lappe, 2000).

Under many conditions, a moving object has no effect on heading judgments. However, when the object crosses the observer's path, small biases in observer heading judgments result (Royden and Hildreth, 1996; Warren, 1998a). The ability to judge heading does not deteriorate when observers attend a second, object-related task (Hildreth and Royden, 1998).

These observations suggest that the human mechanism for judging heading from visual stimuli is remarkably robust and performs well under a variety of nonoptimal conditions.

## Models of Observer Motion Recovery

Computational approaches for recovering heading can be divided into several categories, as described in this section. Many models fit more than one category; we present individual models within a category that best represents the particular approach.

### *Discrete Models*

In discrete models, image features are tracked over time. Their sequence of positions forms the input to a system of equations whose solution yields the parameters of 3D structure and motion, assuming that the features move in a rigid configuration relative to the observer. Computer experiments indicate that such algorithms are vulnerable to error in the image motion measurements, although the use of motion measurements over an extended time can yield better performance (Martin and Aggarwal, 1988).

### *Differential Models*

These models recover 3D motion and structure parameters from first and second spatial derivatives of the image flow field. One approach uses the *differential invariants* of the flow field, divergence (expansion/contraction), curl (rotation), and two components of deformation, dilation and shear (for references see Hildreth and Royden, 1998). Divergence and deformation depend only on the observer's translation and surface slant, and are invariant under observer rotations. In principle, these measures can be used to recover the observer's translation and the 3D shape of object surfaces. Most models that use differential invariants require a continuous, smooth optical flow field. In contrast, the human system can recover heading reliably from a few, sparse features that are sampled from a discontinuous flow field.

### *Motion Parallax Models*

Motion parallax models use the fact that the translational components of the image velocities depend on the depth of the points in the scene, while the rotational components are independent of depth (Longuet-Higgins and Prazdny, 1980). Consequently, subtracting the image velocities from two points located at a depth discontinuity eliminates the rotational components. One can locate the translational heading using the resulting "difference vectors" by calculating the best point of intersection of lines through these vectors.

These models provide a method for quickly assessing heading, independent of the recovery of observer rotation and 3D scene structure. Because they combine information from multiple velocity vectors, they work fairly well in the presence of noisy velocity inputs. Simulations with a motion parallax model developed by Hildreth (1992) show behavior consistent with that observed in earlier perceptual studies. Motion differences computed by neurons in the middle temporal (MT) area of the primate visual system may be used to compute observer translation in the presence of rotations (Royden, 1997).

### *Error Minimization Models*

Error minimization models compute observer motion and 3D structure parameters that yield a flow field that best fits the measured optical flow. For example, Bruss and Horn use this approach to derive observer motion parameters and surface structure that best account for the measured flow field in a least-squares sense (see Hildreth and Royden, 1998). The error minimization strategy, together with spatial pooling of motion measurements over an extended image region, allows the algorithm to tolerate substantial error in the individual image motion measurements. Many models proposed for recovery of observer motion incorporate some form of error minimization. Notably, Heeger and Jepson (1992) presented an error minimization model that has been implemented in a neural network form by Lappe and Rauschecker (in Lappe, 2000).

### *Template Models*

Template models use special-purpose computational mechanisms, such as a family of templates, tailored to detect patterns of optical flow corresponding to specific observer motion parameters. For example, a template for detecting forward motion along the line of sight would respond optimally to a radially expanding pattern of image velocities whose FOE is located at the center of the visual field. Template models deal effectively with noise in the input velocity measurements by integrating over a large area. Perrone and Stone (1994) proposed a template model that computes heading using components that respond to motion similarly to neurons in the primate visual area MT.

### *Eye Movement Models*

In addition to retinal information, the human visual system can use the oculomotor signal to obtain information about eye rotation, either from an efference copy of the signal or from proprioceptive feedback from the extraocular muscles. Royden, Crowell, and Banks suggest that this information is essential for recovering heading accurately in the presence of fast eye rotations. The flow field corresponding to a known eye rotation could be subtracted from the overall flow field before the observer's heading is calculated (Hildreth and Royden, 1998). Lappe (in Lappe, 2000) and van den Berg and Beintema (see Lappe, in Lappe, 2000) have developed neural models that explicitly incorporate eye movement signals.

Cutting (1986) noted that when an observer fixates a point in space, the most rapidly moving objects in the vicinity of the fixation point can be used to judge heading relative to the fixation direction. One can locate the heading with successive fixations on objects in the scene. This model requires little computation from the flow field itself; however, it fails for certain configurations of scenes and eye fixations. It also requires multiple saccades to locate heading, something that is not essential for human heading judgments.

### *Neural Network Models*

Several neural network models use training algorithms to learn to compute heading from optic flow input (Lappe, in Lappe, 2000). Hatsopoulos and Warren created a two-layer neural network that is trained using the Widrow-Hoff learning rule to recognize the correct translational heading for an observer moving along a straight line. The input layer consists of units tuned to direction and speed of motion. After training, the weights connecting the input and output layers adapt so that the output neurons detect radial patterns of motion corresponding to particular headings. The network only interprets flows derived from pure observer translation. Zemel and Sejnowski developed a learning network that segments the scene according to the motion of objects relative to the observer. Heading can be estimated from the resulting encoding.

### *Motion on a Curvilinear Path*

When an observer moves along a curvilinear path, his instantaneous translation and rotation are the same as those for an observer pursuing straight-line motion with eye movement, resulting in an ambiguity. Distinguishing these situations requires an analysis of the flow field over an extended time. Alternatively, eye movement information may be used to disambiguate these conditions. Human observers distinguish curved from straight paths with high accuracy and judge the path curvature well. This finding suggests that the visual system computes both translation and rotation components of observer motion (Warren, 1998a; van den Berg, in Lappe, 2000).

### *Coping with Moving Objects*

For most models, the presence of moving objects in the scene can adversely affect the derivation of observer motion. Image points associated with moving objects may move in a direction inconsistent with the observer's motion, causing errors in the heading estimate. Some models first detect moving objects and then compute heading from the remaining stationary components of the scene. Another approach computes an initial estimate of observer motion by combining all available data or by performing separate computations within limited image regions. One can then identify moving objects by finding areas of the scene for which the image motion differs significantly from that expected from these initial motion parameters (e.g., Hildreth, 1992). See Hildreth and Royden (1998) for a review of models of moving object detection.

## Visuomotor Transformations for Navigation

Successful navigation requires that visual information be used to control motor actions to move through the world. This requires a transformation between the retinocentric heading coordinates computed by the models described in the previous section to a body-centered coordinate system, taking into account eye and head movements. It seems likely that the visual system uses extraretinal information, such as eye movement and vestibular signals, to account for rotations of the head and eyes. Neurons in the medial superior temporal (MST) area of visual cortex may combine these extraretinal signals with visual information to compute the body-centric heading (see Andersen et al., in Lappe, 2000).

The mechanisms for transformation of the visual information into motor control commands are not yet understood, but several approaches have been described. In one approach, motor planning takes place based on the computed heading of the observer. For example, to reach a desired goal, the motor system could initiate turning commands that minimize the error between the computed heading and the direction to the goal. Visual feedback allows constant refinement of the motor strategy to keep errors in heading from accumulating (Warren, 1998b).

Another approach is based on specific tasks the observer must perform to navigate through the environment. Such tasks include steering toward a goal, pursuing prey, braking, avoiding obstacles, or computing time to contact with an approaching surface. It has been suggested that each of these tasks may be accomplished through a task-specific subsystem that uses only the information in the flow field necessary to complete the task (Aloimonos, 1997; Warren, 1998b). For example, time to contact can be computed from the ratio, $\tau$, given as the ratio of size/(rate of size change). The coupling between the task-specific information and the resulting action can be modeled as a nonlinear dynamical system. For example, when steering toward a goal, visual information provides the angle, $\beta$, between the FOE and the direction of the goal. This angle can be used to control the observer's rate of turning. The result is a system with a stable fixed point at $\beta = 0$, corresponding to the observer heading toward the goal. Complex motor behavior may emerge through interactions between loosely coupled subsystems underlying different tasks (Warren, 1998b).

## Neural Mechanisms of Heading Computation

In primates, visual area MST is probably involved in computing heading (Duffy, in Lappe, 2000). Neurons in MST respond well to large motion patterns and receive direct input from cells in area MT, which is known to process motion (see also MOTION PERCEPTION: ELEMENTARY MECHANISMS). Some MST neurons prefer expanding or contracting radial patterns of motion, as would be generated by an observer moving in a straight line forward or backward. These cells have different preferred centers of expansion, so they could be involved in finding the FOE in an optical flow field. Other cells respond well to uniform motion in a single direction, and yet others respond to rotating patterns of motion. Many cells respond to some combination of these.

It is unclear how these cell responses contribute to the computation of heading in the presence of rotations; however, several models have been developed that could explain this. Hatsopoulos and Warren (Warren, 1998a) and Perrone and Stone (1994) proposed template models that use components that behave similarly to neurons in area MT in their response to motion. In both models, these components connect to another layer of cells with properties similar to the cells in MST. The connection patterns are such that the cells in the second layer respond to spatial patterns that mimic the flow fields that result from particular observer motion parameters. The Hatsopoulos and Warren model deals only with pure observer translation. Perrone and Stone used templates that deal with combinations of translations and the rotations that result when the observer makes eye movements to track an object in the scene. This model also recovers the relative depths of surfaces in the scene.

Royden (1997) developed a model that makes use of the motion-opponent properties of MT neurons to deal with observer rotations. Many neurons in MT have both excitatory and inhibitory regions within their receptive fields. The Royden model uses operators with this receptive-field layout to eliminate the observer rotation at the initial processing stage. These cells project to a second layer of cells, similar to those in MST, that are tuned to radial patterns of input. As with the motion parallax models described earlier, the centers of these radial patterns correspond to observer headings.

Finally, Lappe (in Lappe, 2000) and van den Berg and Beintema (cited by Lappe, in Lappe, 2000) developed neural models that explicitly incorporate eye movement signals to deal with rotations generated by eye movements. In Lappe's model, extraretinal input compensates for the image motion induced by eye movements. In van den Berg and Beintema's model, the responses of template cells tuned to retinal flow are multiplied by a "rate-coded" measure of eye velocity, producing a layer of cells that have a preferred flow field that changes dynamically to compensate for eye movements.

Currently, there is insufficient physiological or psychophysical data to distinguish among these models of neural computation of heading. It seems likely that some compensation for eye movements occurs in area MST (see Andersen et al., in Lappe, 2000); however, this compensation could be incorporated into the models that do not currently use it. The models are all reasonably consistent with the known behavior of MT and MST cells. Determination of which, if any, most accurately describes the neural computation awaits further experimentation.

## Discussion

People judge heading well under many conditions; however, it is still uncertain how the visual system accomplishes this task. Superficially, most of the models cited here exhibit general biological plausibility, in that they can be implemented by a network of simple, local processing mechanisms operating in parallel. Physiological observations reveal the general properties of the representation of optic flow information and provide some indication that heading computations take place in areas MT and MST of the primate visual system. It remains a challenge to incorporate all of the important aspects of recovery of 3D observer motion into a neuronal model that exhibits a broad range of human behavior and incorporates the details of physiological observations.

# Motivation

*Alan G. Watts*

## Introduction

Motivated or goal-directed behaviors are sets of motor actions that direct an animal toward a particular goal object, an interaction that promotes the survival of an individual or maintains the species. Goal-directed behaviors consist of sleep/wake, ingestive, reproductive, thermoregulatory, and aggressive/defensive behaviors. At the simplest level, motivated behaviors can be considered the behavioral adjuncts of those physiological (i.e., homeostatic) processes concerned with maintaining the composition of the internal environment. They are often accompanied by emotion or affect.

Despite their apparent utility, defining the terms *drive, instinct*, and *motivation* with respect to the neural substrates of behavior has always been controversial (Grossman, 1979; Pfaff, 1982). Although the most rigorous use of the terms drive and motivation has been as intervening variables between stimulus and behavioral response, there is an attraction to trying to assign particular brain regions responsibility for putting the motivation into behavior. However, "neuralizing" drive, and particularly motivation, has often been criticized because it has been thought impossible to identify and measure their specific neural properties (e.g., Hinde, 1970).

With this in mind, a neural systems approach will be adopted here that downplays the notion of associating motivation with specific neural mechanisms. To this end, this article will concentrate more on discussing what and how particular parts of the brain contribute to the expression of behaviors that have a motivated character. The framework adopted here is based to a large extent on Hullerian incentive models of motivation (see Bindra, 1978, and Toates, 1986, for further discussion), where the probability of a particular behavior being expressed at any one time is dependent on the integration of sets of afferent information: information from systems that control circadian timing and regulate arousal state, inputs derived from interosensory information that encode internal state (e.g., hydration state, plasma glucose, leptin), modulatory hormonal inputs such as gonadal steroids that mediate sexual behavior, and inputs derived from classic sensory modalities (i.e., exterosensory information). The advantage of this approach for identifying neural substrates is that it allows us to utilize the common experimental paradigm of tracing how information derived from sensory inputs known to generate specific behaviors is distributed within the brain (e.g., Swanson and Mogenson, 1981). With the advent of sophisticated functional neuroanatomical methods, this approach is proving quite useful (Watts, 2001; Watts and Swanson, 2002).

## Temporal Organization of Motivated Behavior

A scheme describing the temporal organization of motivated behavior was first outlined by Wallace Craig in 1918, and later elaborated by Mogenson and colleagues (Swanson and Mogenson, 1981). Here, behavior is initiated following interactions among sensory information, the neural systems that control arousal state, and those systems that control sensory object representation. These interactions determine the value of the "drive" associated with a particular behavior. In turn, the integral of competing drives then determines which series of actions will generate the most appropriate procurement (or appetitive) phase, where the goal object is actively sought. The motor events expressed during the procurement phase involve foraging behavior, are individualized for the particular situation, and can be quite complex.

When the goal object has been located, the subsequent consummatory phase involves more stereotypic rhythmic movements—licking, chewing, copulating, etc.—that allow the animal to interact directly with the goal object. During the consummatory phase, how the animal structures the interaction (e.g., determines the duration and the amount consumed during a feeding episode, or the duration of the intermeal interval) is an important function that arises from the dynamic interaction of sensory inputs and the central neural networks that control motor function. Furthermore, reward/aversion functions, together with learning and memory, are also critical processes, particularly during the procurement phase; a previously rewarded or an aversive experience of a particular goal object, remembering where it is located, and remembering how to get there are important considerations that contribute to the integrative process. Finally, as the consummatory phase continues, interosensory feedback signals are generated that increase the probability of its termination, most likely using inhibitory networks. Termination may also occur at any time following new exterosensory signals (e.g., the presence of a predator) that override an ongoing behavior and allow the animal to switch immediately to another, more appropriate behavior (McFarland and Sibly, 1975).

## Neural Substrates

At the simplest level, four broad-ranging neural systems are concerned with generating motivated behaviors: those involved with the transduction and processing of sensory signals, those that control arousal state and circadian timing, those involved with motor control, and those that process the types of information concerned with sensory object representation. These systems are represented at the simplest level in Figure 1 without reference to anatomical locus.

The notion of drive and the idea that particular behaviors are selected to reduce the level of specific drive states have together been very influential if somewhat controversial concepts in neuroscience. From the perspective of delineating neural systems, it is useful to think of drives as being dynamic properties within different sets of neural networks, each of which is concerned with regulating a specific motivated behavior. In this way, drives are properties of behaviorally specific networks within the motor control module of Figure 1. Drive states are determined by the inputs from sensory processing, arousal state control, and object representation systems. The values of drive states within these networks are altered by these inputs in a way that increases or decreases the probability of a particular behavior being expressed at any one time.

Figure 2 expands the scheme shown in Figure 1 to illustrate specific components within the object representational and motor control networks. It shows that there are four principal inputs that can activate motor systems. The most complex motor control processes are those that generate anticipatory behaviors. In some instances, information from systems controlling arousal state—for example, circadian timing—provide the predominant signals (input 1, Figure 2). But this type of anticipatory control often derives from interactions between processed sensory information and those forebrain systems concerned with encoding object representation, particularly learning and memory, reward, and spatial orientation and navigation. The integrated output of these regions then regulates motor control systems (input 2, Figure 2). However, increased drives for motivated behaviors can also be produced by hormones or internally generated deficit signals (e.g., the thirst arising from dehydration, or the hunger from starvation) that access motor control networks more directly (input 3, Figure 2).

SENSORY OBJECT REPRESENTATION
MOTOR CONTROL
MOTOR EVENTS

**Figure 1.** A schematic representation of the neural systems and their interactions involved with controlling motivated behaviors. Sensory inputs are shown in gray, central neural connections in black, and hormonal and feedback signals as dashed lines.

Collectively, inputs 1, 2, and 3 to the motor control networks can be thought of as "drive-determining" interactions. Mechanisms then integrate outputs from different drive networks to select the behavioral action most appropriate for reducing the drive state with the highest value, so initiating the appropriate procurement phase.

Finally, simple reflex actions are generated by direct sensory inputs to the premotor and motor networks with little higher-order processing (input 4, Figure 2). However, although these reflex actions lack any motivated character, they make important contributions to the consummatory phase of motivated behaviors.

## *Sensory Information*

Neural systems that control motivated behaviors are regulated by a host of sensory inputs, which are defined either as interosensory signals encoding internal state or as exterosensory inputs that encode features of the goal object such as smell, taste, temperature, tactile properties, and appearance. Each of these sensory modalities has specific receptors, transduction mechanisms, and "labeled line" access to central processing networks located throughout the brain. Although important sensory processing occurs within the telencephalon, particularly sensory cortex, the initial sensory processing that occurs subcortically has important implications for controlling motivated behaviors; for example, altered sensitivity to the taste of sodium occurs in the hindbrain of hyponatremic animals and is an important adjunct to increased sodium appetite.

Some sensory signals directly access drive networks, as typified by the drinking initiated by increasing plasma osmolality or angiotensin II (A-II), or the deficit-induced feeding activated by adiposity signals (primarily leptin and insulin), which have direct hypothalamic actions (Elmquist, Elias, and Saper, 1999). In both of these cases, however, it is not clear whether the outcome of processing the deficit signal in the hypothalamus requires close interaction with the object representation networks. The fact that hypothalamic regions involved with this type of sensory transduction project directly to regions concerned with ingestive motor control (Elmquist et al., 1999) suggests that they may not.

## *Circadian Timing and Arousal State Control*

Parts of the brain provide critical circadian timing information and control arousal state that enable motor command networks to generate anticipatory behaviors. The circadian timing system originates in the hypothalamic suprachiasmatic nucleus, which generates the signal that entrains virtually all neural activity within limits determined by the prevailing photoperiod. Catecholamine cell groups in the hindbrain (e.g., the locus coeruleus), histaminergic neurons in the tuberomammillary nucleus, the ventrolateral preoptic nucleus, and the recently identified hypocretin/orexin neurons in the lateral hypothalamic area (LHA) supply information that is of critical importance for controlling arousal state.

## *Object Representation*

Those systems that generate neural representations of sensory objects are important for controlling motivational behaviors. These include learning and memory mechanisms in the telencephalon and cerebellum; reward/aversion systems in the midbrain ventral tegmentum, parts of the basal forebrain (particularly the nucleus accumbens), amygdala, and parts of the cortex, particularly prefrontal regions; and systems in the hippocampus and parts of the parietal cortex responsible for allocentric and egocentric spatial representation. A great deal of exterosensory information is processed

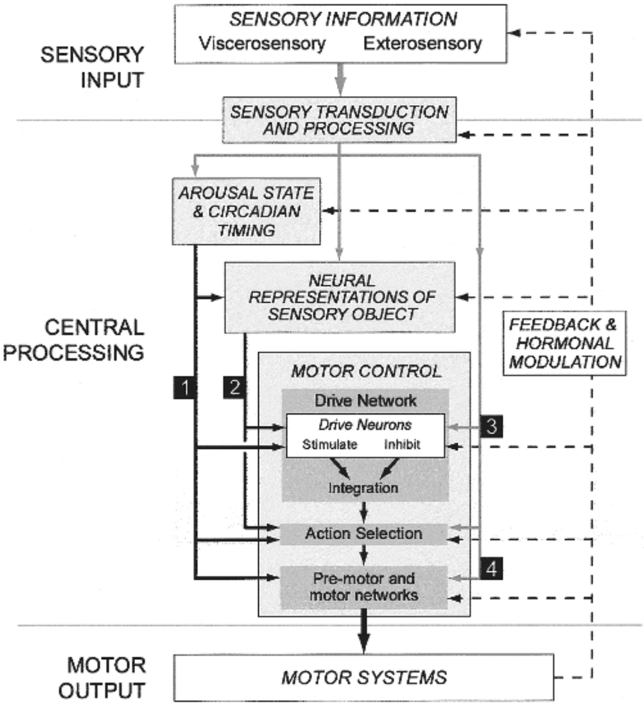

**Figure 2.** Motor control networks are organized at three levels: drive networks, which can either stimulate or inhibit behaviors; action selection networks, which integrate the outputs of drive networks with those of other systems; and executive premotor and motor neuron networks. The generation of motivated behavioral actions by motor control networks can be initiated by four different sets of inputs: (1) from systems controlling arousal state and circadian timing; (2) from systems that generate representations of sensory objects; (3) directly from modulatory hormone and the sensory signals that encode physiological deficits; and (4) from sensory signals that generate reflex actions by interacting directly with premotor and motor neuron networks. Sensory inputs are shown in gray, central neural connections in black, and hormonal and feedback signals as dashed lines.

through these networks, parts of which collectively assign what has been called "incentive value" to a particular goal object. Neural pathways mediating the interactions between the object representation and motor networks are not fully understood, but sets of bidirectional connections between the hypothalamus and cortical structures such as the prefrontal cortex and hippocampus, together with subcortical regions such as the amygdala, septal nuclei, bed nuclei of the stria terminalis, and basal ganglia, are all likely to be critical for the integrative operations that designate and coordinate these aspects of motivated behaviors (Saper, 1985; Risold, Thompson, and Swanson, 1997; Swanson and Petrovich, 1998).

## *Motor Control*

Figure 2 shows that motor control systems operate at three levels: a series of drive networks that set up and coordinate the motor events associated with specific behaviors; regions that are concerned with action selection; and the premotor/motor neuron networks that execute the actions. Figure 2 also shows a clear distinction between drive networks and object representation systems. This derives from the fact that object representation systems appear, at least at the systems level, to be behaviorally nonspecific, whereas drive networks are explicitly concerned with specific behaviors. For example, an animal uses the same parts of the telencephalon for spatial navigation whether it is looking for food, a mate, or shelter, whereas parts of the hypothalamus are concerned specifically with feeding or sexual behavior. However, with regard to other neural structures (for example, cell groups in the basal ganglia), this distinction may not be so clear-cut, and here it may prove difficult to determine to which system particular sets of neurons belong.

The concept of drive networks as defined here evolved from the idea of discretely localized hypothalamic satiety and hunger centers that was popular during the 1950s and 1960s. With elaboration of these pioneering studies over the ensuing 30 years, the idea of isolated centers has been replaced with a scheme whereby sets of more widely distributed but highly interconnected motor control networks direct the motor responses for particular behaviors. Each drive network contain sets of command circuits that stimulate, inhibit, or disinhibit a particular motor event (Figure 2). The exact nature of the expressed behavior, or whether it is expressed at all, is determined by the integrated output of these circuits.

Determining how the neural substrates of specific drive networks are distributed throughout the brain has proved quite difficult. Lesion and electrical stimulation experiments identified some time ago that the hypothalamus was a key structure for the expression of motivated behaviors. More recently, a wealth of neurochemical data has revealed that many neuropeptides have either stimulatory or inhibitory effects on particular motor functions. In turn, the fact that many of these neuropeptides are synthesized in hypothalamic neurons, which in some cases project quite widely throughout the brain, has focused attention on this forebrain region as a key locus of specific drive network components. Furthermore, a synthesis of results from lesion, microinjection, and neuroanatomical tracing studies has identified specific regions of the hypothalamus—particularly cell groups in the medial zone of the hypothalamus (Risold et al., 1997; Watts and Swanson, 2002)—as being principal components of individual drive networks.

One critical point that has emerged from these studies is that it is often difficult to place individual hypothalamic cell groups within specific command circuits (Figure 2). This is because traditionally defined cell groups such as the LHA, arcuate (ARH), or paraventricular (PVH) nuclei appear to contain elements that, in terms of function, belong to more than one type of command circuit; it seems unlikely that there is a tight "one cell group–one command circuit" relationship in the hypothalamus.

A well-documented example of a stimulatory circuit is the one activated by circulating A-II to stimulate drinking. A-II is detected by a central sensory transducer, the subfornical organ (SFO), which then directly and specifically stimulates water intake. The SFO provides efferents, most of which also contain A-II (Swanson, 1987), to a relatively limited set of structures, including parts of the prefrontal cortex, substantia innominata, medial preoptic area, bed nuclei of the stria terminalis, zona incerta, PVH, supraoptic nucleus, and LHA (Swanson, 1987), and presumably it is these regions that constitute part of the stimulatory circuit that initiates the motor aspects of drinking. Neuropeptide Y (NPY) neurons in the ARH contribute to a well-known example of a stimulatory eating mechanism; results from many studies show that NPY contributes to a circuit that directly stimulates food intake. In terms of inhibitory circuits, feeding again provides good examples of hypothalamic components. For example, $\alpha$-MSH, a peptide synthesized in ARH neurons, provides an inhibitory signal to feeding by way of melanocortin 4 receptors expressed by LHA and PVH neurons (Elmquist et al., 1999).

Finally, interactions between different drive networks, particularly in the hypothalamus, are of paramount importance. For example, the effects of starvation are not limited just to increasing the drive to eat, they also reduce reproductive capacity. Similarly, dehydration leads to severe anorexia, as well as increasing the drive to drink (Watts, 2001). This cross-behavioral coordination is part of the mechanism that selects the drive with the highest priority, and most likely involves hormonal modulation acting together with the divergent neuroanatomic outputs from individual drive networks.

Those parts of the brain concerned with the planning, selection, and the moment-to-moment execution of particular motor actions include parts of the motor cortex, basal ganglia, midbrain, and hindbrain. Like the object representational systems, these regions at a systems level are generally behaviorally nonspecific. Although they express topography with regard to the mapping of particular motor actions, they do not seem to be organized in the behaviorally specific manner of the drive networks. To organize the appropriate behavior, regions controlling action selection must receive the integrated outputs of the drive networks. Although not well understood, complex sets of projections from the hypothalamus are most likely involved with this function.

Alpha-motor neurons in the ventral horn of the spinal cord control the striate musculature and hence the expression of all behavior. In turn, sets of premotor networks directly control oscillatory and the more complex patterns of motor neuron firing. Simple rhythmic movement patterns develop from an interaction between oscillatory rhythm generators, which directly involve the motor neurons, and networks of premotor CPGs located somewhat more distally in the spinal cord and hindbrain. A critical feature of these pattern generators is that they are capable of producing rhythmic output without sensory input. In turn, pattern generator output is modulated further by afferents from those parts of the appropriate command networks in the diencephalon and telencephalon. These often highly varied inputs provide the critical drive and contextual information that select the most appropriate motor program at any particular time.

## *Hormonal Modulation*

Hormones have been known for many years to be critical modulators of motivated behaviors that influence a variety of neural structures at all brain levels (Figure 2). In this manner, because they are not encoding aspects of internal state, they are not feedback signals, but act more as permissive factors. Steroid hormones, particularly gonadal steroids, are important signals of this type.

### *Feedback*

Finally, feedback is a critical feature of behavioral motor control, and sensory signals encoding the magnitude and consequences of generated motor actions can control the length of a motivated behavioral episode. For example, postabsorptive humoral feedback (e.g., increasing CCK or decreasing plasma osmolality) and interosensory signals (e.g., gastric distension, oropharyngeal metering) lead to the termination of ingestive behaviors and subsequent behavioral refractoriness.

## Discussion

Sophisticated neuroanatomical and molecular techniques are beginning to clarify the organization of those neural circuits that are responsible for controlling motivated behaviors. They emphasize that understanding how motivated behaviors are controlled requires the interaction of neural systems distributed throughout the brain that are both behaviorally specific and nonspecific. Although the structure of the different hypothalamic drive networks is reasonably well established, future work will need to clarify how each drive network interacts with others, with other forebrain systems concerned with complex sensory object representation, and with those hindbrain circuits concerned more directly with reflex actions and motor execution.

# Motoneuron Recruitment

*Daniel Bullock*

## Introduction

Motoneurons are neurons that directly innervate muscle fibers. When motoneuron discharges cause muscle fibers to contract, the resultant forces oppose static loads, and produce active accelerations and decelerations of limb segments. Moreover, co-contractions of opposing muscles allow us to stiffen joints and thereby maintain desired postures despite perturbations of unexpected magnitude and direction. Because of the direct anatomical link between motoneurons and contractile fibers, there is a close relationship between motoneuron activity and force production.

A motoneuron together with the contractile fibers that it innervates constitutes a *motor unit*. The range of forces producible by one motor unit is small. To make it possible to generate large forces, motor units must be combined into larger aggregates, and the results of such aggregation are the muscles. Immediately associated with each muscle is a population or pool of motoneurons. Muscles are therefore composite structures, and their force-generating components, the motor units, are typically heterogeneous. For example, muscle fibers differ systematically in fatiguability and the associated motoneurons differ systematically in their size. How are these heterogeneous aggregates of force-generating elements recruited in the service of reflexes, voluntary movement, and posture? Such task-dependent recruitment is achieved by a combination of motor unit and neural network specializations.

Consider the simple question of control of force magnitude. If any excitatory input were sufficient to cause simultaneous excitation of all motor units, then the minimum force produced by the aggregate would be much too large for most purposes. To produce accurate movements, forces must be finely graded in response to the input to the motoneuron pool. The fine grading of forces required for accuracy favors a design that allows both partial activation of the motoneuron/fiber pool and finely graded changes, up or down, from preexisting states of activation.

Such force grading by a cells/fibers aggregate provides a functional context for understanding the *size principle* of motoneuron recruitment proposed in 1965 by Henneman, Somjen, and Carpenter (see Burke, 1998, for a review). The size principle encompasses many aspects of the design of motoneuron pools and their embedding within the sensorimotor system. In this design, an excitatory input often reaches all elements of the motoneuron pool at the same time. However, elements of the motoneuron pool differ in their activation thresholds. Because there is a distribution of threshold values from small to large, the larger the excitatory input to the pool, the more elements become active. This enables a continuously varying input signal to produce a graded force response from the muscle. As the excitatory input to the pool grows, motoneurons are recruited in order by size from smallest to largest, because motoneurons with larger somatic volumes also have higher thresholds. As excitatory input declines, or inhibitory input increases, motoneurons are derecruited in order by size, from largest to smallest.

The grading of force by recruitment, which is necessarily quantal, is supplemented by finer grading through firing rate modulation of individual cells, because each cell's firing rate is sensitive to input fluctuations in its suprathreshold range. This design affords finely graded increments and decrements in force over the entire range of muscle force capability.

It might appear that the size principle serves to make each spinomuscular force generator a fixed-gain, near-linear, amplifier of excitatory inputs. However, many factors complicate the situation. First, the gain is not fixed because muscle force can become decoupled from motoneuron pool activation if a contraction-opposing load causes muscle yielding, or if the muscle fatigues. Second, the amplification function is often faster-than-linear because motoneurons with larger cell bodies, and thus higher recruitment thresholds, typically project by larger, faster-conducting axons to more muscle fibers, each of which exhibits shorter twitch contraction times. Third, twitch contractions of muscle fibers are slow relative to rapid fluctuations of excitatory inputs to motoneurons. Fourth, muscle obeys a *force-velocity law*: force output from a muscle decreases as its shortening velocity increases. Fifth, the conventional delimitation of a motor unit, although minimal, is somewhat arbitrary. Several other closely linked neural and sensory constituents appear in most mammalian muscle control systems as part of the apparatus for force generation (cf. Burke, 1998). For example, before exiting the spinal cord, the axons of most alpha-motoneurons give off collaterals that excite Renshaw cells (RCs), which inhibit those same alpha-motoneurons. Sixth, the net torque developed at a joint depends on both mechanical advantage and the balance of forces created by groups of muscles arranged into synergistically antagonistic sets. Each of these considerations reveals a need for network control of recruitment, to ensure that opponent muscle sets generate the right force balances through time.

## Compensations for Fatigue and Yielding

Muscle fatigue and yielding make the functional relation between pool activation and force inherently variable, and network interactions provide compensations that reduce the variability in this linkage. Nichols and Houk (1973) argued that two feedbacks from muscle receptors to spinal motoneuron pools cooperate to reduce variability in *muscle stiffness*, the ratio of muscle force changes to muscle length changes. Muscle yielding events reduce stiffness while also increasing the activity of stretch-sensitive receptors, the spindles, and decreasing the activity of tension-sensitive receptors, the Golgi tendon organs (GTOs). Because spindle feedback directly excites alpha-motoneurons via type Ia sensory fibers, whereas GTOs can inhibit motoneurons via Ib interneurons, both feedbacks are compensatory. It is often noted that GTO feedback also has appropriate characteristics to compensate for muscle fatigue. Bullock and Grossberg (1989) argued that the covariation of motor unit sizes and contraction rates is also compensatory for yielding.

## Linearization or Equalization of Pool Responses

By itself, the covariation of recruitment threshold, number of fibers contacted, and fiber contraction rates with motoneuron size can produce a faster-than-linear relationship between excitatory input to the motoneuron pool and the force output of the muscle, at least under isometric conditions when the system is not approaching saturation. Akazawa and Kato (1990) and Bullock and Grossberg (1989) independently proposed that Renshaw feedback improves this transduction. The Akazawa and Kato analysis (1990) treated a single motor unit pool, and showed that inhibitory Renshaw feedback may be able to linearize the relationship between excitatory inputs and force outputs. Bullock and Grossberg (1989) sought to explain how spinal circuitry enabled the higher brain to achieve independent control of joint angle and joint stiffness. Accordingly, these authors analyzed the "FLETE" circuit (Figure 1), which encompassed a lumped pair of motor unit pools associated with biomechanically opposed muscles. By Factoring the LEngth and TEnsion properties of muscle, the FLETE network allows a descending co-contraction signal to stiffen and thereby stabilize the joint at any desired angle. Available data (Humphrey and Reed, 1983) indicate that voluntary stiffness adjustments are achieved by varying an excitatory signal relayed to both opponent motoneuron pools. Bullock and Grossberg (1989) showed that in the absence of Renshaw feedback, a descending co-contractive signal would generally be unequally amplified by recruitment events within opposing motoneuron pools. Such unequal amplification would lead to an undesired joint rotation as well as to a change in joint stiffness. They then showed that Renshaw-mediated feedback could help guarantee independent control of joint stiffness and joint angle by equalizing the two pools' amplifications of the co-contractive signal. This equalization, which need not involve global linearization of recruitment, is achieved by a local circuit that incorporates mutual inhibition between opponent Renshaw pools and between Ia reciprocal inhibitory interneurons, which, like alpha-motoneurons, are inhibited by Renshaw cells (RCs).

This view of the role of RCs is consistent with data that contradict alternative views. Pratt and Jordan (1987) showed that RCs fired in phase with alpha-motoneurons during fictive locomotion, but that they were not needed for generation of the locomotor cycle. This disconfirmed the hypothesis that they were an integral part of the spinal locomotor generator. Lindsay and Binder (1991) observed that although steady-state Renshaw inhibition caused similar synaptic currents in alpha-motoneurons of different sizes, IPSP amplitudes did correlate with cell size. They concluded that "the

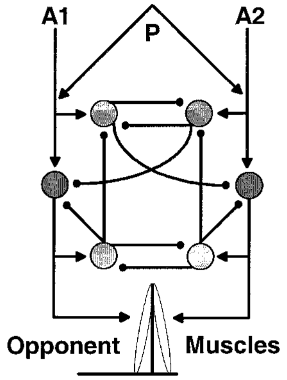

**Figure 1.** Partial connectivity of the FLETE model for independent control of joint angle and joint stiffness. To set desired joint angle, the higher brain reciprocally adjusts descending signals A1 and A2 directed to two opposing alpha motoneuron (MN) pools that project to opposing muscles. Descending signal P to both motoneuron pools adjusts joint stiffness without modifying joint angle if increments in P lead to equal increments in the force outputs of the two opposing muscles. Renshaw (R) cell feedbacks, among others, compensate for nonlinearities in the motoneuron response function and thereby help assure equal force increments in the two muscles affected by P. Renshaw feedback disinhibits opponent MNs via the Ia interneurons (IaIN). Arrow and dot line-endings, respectively, indicate excitatory and inhibitory synapses.

biggest impact of [RC] inhibition will be on the force output of motoneurons firing on the steep part of their force-frequency curve" (p. 176).

A subsequent extension of the FLETE model showed that the *triphasic* EMG bursts characteristic of rapid self-terminated joint rotations *emerge* within an arm-controlling network activated by *monophasic* descending control signals, if the network incorporates velocity-sensitive muscle spindles. Contreras-Vidal, Grossberg, and Bullock (1997) showed that the FLETE model is applicable to multi-joint arm movement control using both mono- and bi-articular muscles, and that the independent control property is enhanced by the incorporation of sensory feedbacks from spindle (Ia), GTO, and joint receptors. Moreover, van Heijst, Vos, and Bullock (1998) showed that connection weights consistent with the independent-control property will self-organize in the circuit of Figure 1 if local synapses are adjusted by a Hebbian learning process while the circuit is stimulated by a rhythmic input. Their developmental simulation modeled how such spinal circuits self-tune during prenatal episodes of rhythmic activity in avian and mammalian embryos.

## Adaptive Central Control of Motoneuron Gain

Renshaw cells also mediate descending modulation of the motoneuron recruitment process. Stimulation in nucleus interpositus (NIP) of the cerebellum, or in its target, the Red Nucleus (RN), which projects to spinal pools via the rubrospinal pathway, enhances the gain of the monosynaptic stretch reflex by inhibiting RCs, thereby releasing alpha-motoneurons from recurrent inhibition. The NIP or RN stimulation also excites motoneurons. Bullock and Grossberg (1989) proposed that the implied bivalent rubral projection to RCs and alpha-motoneurons afforded adaptive, i.e., learning-based, control of the "gain" of movement commands directed to motoneuron pools. Contreras-Vidal et al. (1997) introduced a neural network comprising a central trajectory generator, an extended FLETE model, and a model cerebellar network capable of learning to modulate motoneuron recruitment via a bivalent output to RCs and alpha-motoneurons. Simulations of the circuit (Figure 2) showed that if the cerebellum received both a desired velocity signal and an error feedback routed from spindles to cerebellum via the inferior olive, then a learning-adjusted cerebellar output substantially enhanced the dynamic tracking characteristics of the limb by transiently exciting, and removing inhibition from, the agonist motoneuron pool (Figure 1). This model is consistent with recent biophysics-based models of cerebellar adaptive timing (e.g., Fiala, Grossberg, and Bullock, 1996), and with common observations of phasic RN and interpositus activity during learned movements. A closely related modeling treatment, encompassing cerebellar modulation of the Figure X circuit in the context of realistic sensory lags, has recently appeared (Spoelstra, Schweighofer, and Arbib, 2000).

## Roles of Motor Cortex in Motoneuron Recruitment

Many cells in the primary motor cortex (M1) of primates excite motoneurons via mono- or short polysynaptic pathways, and the pathway for the long-loop stretch reflex traverses M1. Moreover, cooling of the dentate nucleus of the cerebellum, which affects M1 via the thalamus, eliminates anticipatory, force-related, components of normal M1 activity. Many studies have strongly implicated M1 in load compensation achieved by direct recruitment of motoneurons, although a subset of M1 cells are relatively load insensitive (Kalaska et al., 1989). Yet other studies have appeared to implicate M1 in a high-level representation of the direction of movement in Cartesian space. Recently, two models have begun to address the dilemma posed by these observations. The extended Vector Integration To Endpoint (VITE) model of Bullock, Cisek, and Grossberg (1998) proposed a circuit involving 6 electrophysiologically identified cell types in M1 and parietal area 5 to explain the distinct computational roles of load-sensitive and load-insensitive cells in both arm trajectory generation *and* load compensation. This model's relatively load-insensitive cells have polysynaptic links to alpha-motoneurons, whereas the most load-sensitive cells have monosynaptic links. Todorov (2000) proposed a model (pertinent primarily to load-sensitive cells) based on the assumption that M1 recruitment compensates for the negative effects of the force-velocity law on the ability of muscle to sustain force when shortening at a significant velocity.

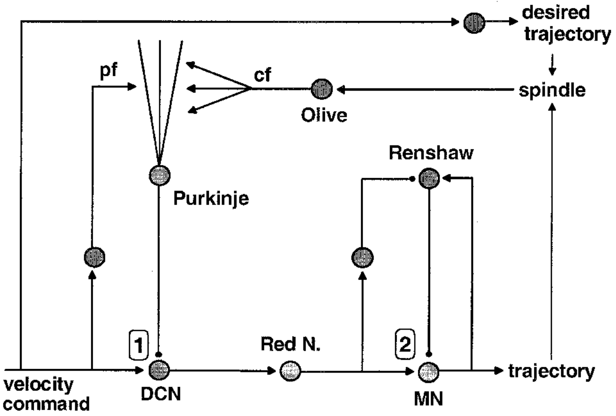

**Figure 2.** Network model incorporating two sites for controlling motorneuron excitation by release from inhibition. Prior to learning, a velocity control signal directed toward a muscle via the deep cerebellar nuclear (DCN) pathway will have a negligible effect due to Purkinje (P) cell inhibition of DCN sites and Renshaw cell inhibition of alpha-motoneurons (MN). However, trajectory errors detected by muscle spindles activate the inferior olive, whose climbing fibers (cf) reach the dendrites of Purkinje cells. Climbing fiber activity causes long term depression of coactive parallel fiber (pf) synapses that excite Purkinje cells. Depression of Purkinje excitation causes disinhibition of DCN sites. This "opens the gate" for the velocity control signal to activate the Red Nucleus. The Red Nucleus both excites alpha-motoneurons and inhibits Renshaw cells.

If some M1 cells directly control motoneuron recruitment, and thus force generation, then theories of sensorimotor transformations (e.g., Barreca and Guenther, 2001) predict that the preferred spatial directions of such M1 cells must be strongly posture dependent—and they are. Several recent simulations based on this premise have succeeded in predicting posture- and trajectory-dependent tuning properties of M1 cells and the muscles to which they project (Ajemian, Bullock, and Grossberg, 2001; Scott and Kalaska, 1997).

## Discussion

Neural network analyses have begun to clarify how local spinal circuits cooperate with central adaptive circuits for task-dependent control of motoneuron recruitment, but many basic questions remain to be addressed. Too little is known about the pathways for descending control of gamma- versus alpha-motoneurons. Also, the behavioral functions of many known aspects of the recruitment system, such as motoneuronal plateau potentials, remain to be elucidated by computational analyses. Models must also be elaborated to accommodate the unique connectivities that govern recruitment in different species, which differ dramatically in biomechanical, behavioral, and neuronal specializations.

# Motor Control, Biological and Theoretical

*R. Christopher Miall*

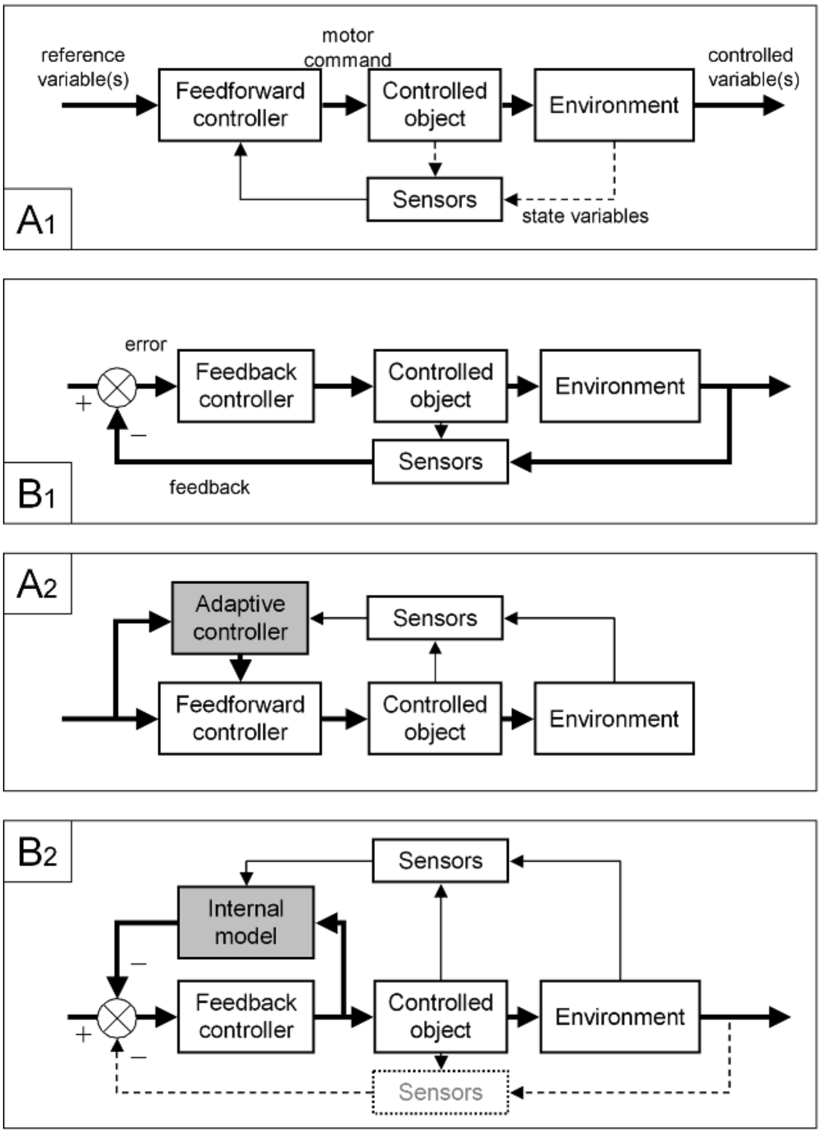
## Introduction

Biological motor control can be characterized as a problem of controlling nonlinear, unreliable systems whose states are monitored with slow and sometimes low-quality sensors. In response to changing sensory inputs, internal goals, or motor errors, the motor system must solve several basic problems: selection of an appropriate action and transformation of control signals from sensory to motor coordinate frameworks; coordination of the selected movement with other ongoing behaviors and with postural reflexes; and monitoring the movement to ensure its accuracy. These stages may be interlinked, so that separation of any one particular problem into these individual stages may not be possible. This article describes some of the ways we think that biological motor systems solve these tasks, based on principles (and terminology) whose origins are in engineering and cybernetics. The field of cybernetics has developed from Norbert Wiener's initial ideas on communication and control theory in complex mechanical and biological systems, which focused on feedback mechanisms.

A motor control system acts by sending motor commands to a controlled object, often called the "plant," which in turn acts on its local environment (Figure 1). The plant or the environment has one or more variables that the motor system attempts to regulate, either to maintain them at a steady reference level in the face of disturbances (a "regulator") or to follow some changing reference value (a "controller"). The motor control system may make use of sensory signals from the environment, from its reference inputs, and from the plant to determine what actions are required. Sensory inputs from the plant can provide information about the *state* of the controlled object. Here, the state can be considered as all relevant variables that adequately describe the controlled object. But note that the sensory inputs to the controller do not necessarily provide direct measures of the true state of the system: they may be inaccurate or delayed, as discussed later. If controller output is based on signals that are unaffected by the plant output, it is said to be a *feedforward controller*: the feedforward control path is the thick line from left to right in Figure $1A_1$, which requires no return signals. If the controller output is instead based on a comparison between the reference and the controlled variables, it is a *feedback controller* (Figure $1B_1$): the control pathway is a closed loop. One can add more complex control strategies to these simple systems (Figure $1A_2$, $1B_2$), as described in more detail below.

The advantage of feedforward control is that it can, in the ideal case, give perfect performance with no error between the reference and the controlled variable. The main disadvantages for biological systems include the potential difficulty in generating an accurate controller for a complex system and the lack of error corrections. If the controller is not accurate, if the plant is unreliable, or if unexpected external disturbances occur, output errors go unchecked. Since no biological system can be both perfectly accurate and perfectly free of external disturbances, error correction is usually necessary. In contrast, the major advantage of negative feedback control lies in its very simple, robust strategy. The controller drives the plant so as to cancel the feedback error signaled by the comparator. Because it constantly seeks to cancel the error, it operates well, even without exact knowledge of the controlled object and despite internal or external disturbances. But feedback control strategies also have disadvantages: errors cannot be avoided but

**Figure 1.** *Feedforward control*: $A_1$, The black arrows represent the on-line control signals; the dotted lines are off-line signals used to update controller. $A_2$, Adaptive controllers using off-line information can adjust parameters of the feedforward controller to reflect changes in the plant properties. *Negative feedback control*: $B_1$, The black circle represents a comparison between the reference and feedback signals. The black arrows now form a closed control loop; the crossed circle is a comparator. $B_2$, An internal model of the controlled object can replace the external feedback loop with a rapid feedback estimate.



must occur and be corrected, and feedback control—especially in biological systems—tends to be slow.

## Feedback Control

The design criteria for negative feedback control are dominated by the closed-loop gain. Gain is defined as the ratio of a system's output to its input. For a linear servo controller, the gain should be close to unity, so that a given input (the reference value) evokes an output of almost equal magnitude. In a feedback circuit (Figure 1$B_1$), one can define both open-loop and closed-loop gains. The open-loop gain $K_o$ is given by the ratio of the response to the error; it gives the response expected if the feedback path shown in Figure 1$B_1$ is cut, thus opening the loop. The closed-loop gain $K_c$ is given by the ratio of response to reference amplitudes. The closed-loop gain $K_c$ is determined by the open-loop gain where $K_c = K_o/(1 + K_o)$. For ideal control, $K_c$ should be unity under all conditions; thus the open-loop gain $K_o$ should be as high as possible, ensuring that $K_c$ approaches unity. In practice, $K_o$ is usually frequency dependent and can never reach infinity; hence $K_c$ is also frequency dependent and less than unity.

The design of nonlinear and multidimensional feedback systems is beyond the scope of this article, except to note that, in many instances, complex control problems can be simplified and linearized around the current state of the system. This may be particularly true of biological systems, in which control is often only approximate.

Notice that the comparison of the reference value with the controlled variable to give an error signal (Figure 1$B_1$) is affected by the dynamics of the motor control and sensory systems. When a command is issued by the controller, its effects are not immediately apparent to the comparator, but are delayed by the plant and sensor dynamics and by transport delays on both the forward and feedback paths. In biological systems, where sensor delays are inevitable, the comparison is always out of date. Hence in any feedback system there will be a frequency at which these delays combine to impart a 180° phase lag. The open-loop gain $K_o$ at that frequency now only needs to be unity (instead of very large) to make $K_c > 1.0$, forcing the system into instability. Any small error or disturbance will be overcorrected and result in even bigger errors, leading to yet bigger corrections. Human examples of instability are indeed seen when control delays are artificially increased in man-machine interfaces

(Miall and Wolpert, 1996) or as a result of increased neural transport delays in neuropathies such as multiple sclerosis.

### *Physiological Feedback Circuits*

Although feedback control circuits are found throughout physiology, let us consider just two examples from vertebrate motor systems. The major tension-producing fibers of the vertebrate muscle, known as extrafusal fibers, contract following excitation by alpha motor neurons. However, the amount of tension produced by the muscle in response to a motor command varies with the length of the muscle, its speed of contraction, level of fatigue, and so on. The muscles are therefore provided with numerous sensory structures, muscle spindles, that signal back to the CNS the length and rate of stretch of the muscle. Spindles are complex sensorimotor structures combining contractile elements (intrafusal fibers, excited by specialized gamma motor neurons) with a central stretch-sensitive region. Their axons project onto alpha motor neurons in the spinal cord that serve the same muscle and synergistic muscles. This circuit (the stretch reflex) is a feedback controller for muscle length. If the muscle is stretched, the spindles respond, exciting the alpha motor neurons, and the resulting reflex contraction of the extrafusal fibers restores the muscle to its original length, silencing the spindles again. Thus the spindles signal a deviation from their regulated length, and the controller (the alpha motor neuron) acts to cancel the error. The muscles also contain Golgi tendon organs (GTOs), which are attached to the tendons of muscle and respond to increased tension in the tendon. They excite interneurons that inhibit motor neurons of that muscle and other muscles acting around the same joint, and also act in a feedback manner. If muscle tension increases due to an external load, for example, the GTOs are activated and, via the inhibitory interneuron, inhibit the motor neurons, causing the muscle to relax. This reduces tension, and thus the negative feedback loop serves to maintain a controlled level of tension. This description of the spindle and GTO is oversimplified, ignoring aspects such as control of muscle stretch velocity, but emphasizes their basic control properties. Together, they act to maintain a muscle in its current state: changes in length or in tension will be automatically opposed.

## Feedforward Control

Feedforward control schemes may be grouped as those based on direct control and those based on indirect control using internal models. Here, direct control means control without *explicit* knowledge of the behavior of the plant (see REINFORCEMENT LEARNING IN MOTOR CONTROL). In practice, a controller that can store and issue appropriate motor programs must have implicitly, if not explicitly, captured knowledge of the plant. Hence feedforward controllers must be matched to the properties of the plant they control. As a physiological example, the equilibrium point hypothesis (see EQUILIBRIUM POINT HYPOTHESIS) makes use of the spring-like properties of muscles. For any set of springs pulling across the multiple joints of a limb, there will be a stable position into which the limb passively settle. Thus, the CNS could define the “end-point” muscle tensions and the limb would move to the desired position without the controller’s knowing either its starting position or its behavior during the movement. An alternative direct scheme is to generate the appropriate commands—a temporal sequence of required changes in muscle force, acquired and stored as a motor program—but again without any explicit knowledge of the plant. In the limit one could use a memorized lookup table to store appropriate motor commands for each input-output pair. However, the memory demands grow explosively if a motor command is stored for every possible pairing. Some form of generalization is assumed to avoid this problem (see SENSORIMOTOR LEARNING) such that a coarse-grained representation is achieved, with interpolation.

### *Physiological Feedforward Control*

Muscle spindles and GTOs are used to ensure that actions occur as planned. By sending motor commands both to the alpha and to the gamma motor neurons, both the force-producing extrafusal fibers of the muscle and the much weaker intrafusal fibers of the spindle co-contract. If the joint fails to move fast enough owing to an unexpected load, the spindle contractile elements shorten within the main muscle, the stretch-sensitive sensory region is stimulated, and additional excitatory drive is reflexively added to the spinal alpha motor neurons to overcome the load. The original position control theory proposed by Merton has had to be supplemented by tension and velocity control; but this simple description, while incomplete, highlights the main principles. Note that by co-activating alpha and gamma motor neurons, the reference values of the feedback circuit described earlier are predictively modified. Thus for the supraspinal centers driving the movement, the spinal circuits can be treated as a feedforward controller, autonomously regulating the muscles without the need for feedback to these higher centers. Of course, if errors become large, cortical control can be invoked. This demonstrates an important principle: biological motor circuits are often hierarchical, with lower levels regularizing the behavior of the controlled object and higher systems providing increasingly indirect control (Loeb, Brown, and Cheng, 1999).

Another example of feedforward control is found in the oculomotor system (see COLLICULAR VISUOMOTOR TRANSFORMATIONS FOR GAZE CONTROL). Human eye muscles have muscle spindles, but they do not seem to have a functional stretch reflex: passive movements of the eyes are not reflexively adjusted, and even seem to be ignored. As Helmholtz noted, if one pushes on the side of one’s own eye, the resulting retinal movement is reported by the visual system as movement of the external world. The reason the oculomotor system may be able to operate in feedforward mode is that the mechanical load (the spherical eyeball) is relatively constant, unaffected by external weights or gravity, and is therefore more easily controlled than a multi-jointed limb. Functionally, of course, there is powerful *visual* feedback: if the eyes drift from the target of gaze, the error is reported as slip of the visual image over the retina. Retinal slip drives “on-line” corrective velocity adjustment during smooth eye movement. Because saccades are of short duration, errors are corrected “off-line” with a secondary saccade. Consistent saccadic under- or overshooting errors lead to long-term changes in the feedforward controller, an example of adaptive control.

## Adaptive Control and Internal Models

### *Adaptive Control*

Adaptive control relies on monitoring performance over a longer time scale than that used by negative feedback control to generate a measure of average performance rather than of moment-to-moment error. The adaptive controller is then used to adjust the motor responses, for example, by modulating the feedforward controller as indicated in Figure $1A_2$ or by modulating the open-loop gain of a feedback controller. The advantage of adaptive control is that it can compensate for gradual changes in the motor performance of the controlled object. Controllers can also be designed to track predictable changes in the reference value. Because the performance of physiological systems (as well as the goals of behavior) changes over time, all biological control systems are to some extent adaptive through mechanisms as diverse as evolutionary change, growth, or learning and memory. In control of eye movements, there is good evidence that the cerebellum is involved in adaptation (Robinson and Fuchs, 2001).

### Internal Models

Two forms of internal model can be distinguished. An ideal feedforward controller will ensure that the plant output (the controlled variable) is always identical to the reference value. Thus it inputs the reference value (and often also the state signals, Figure 1$A_1$) and outputs a motor command; the motor command shifts the plant into a new state, which should equal the reference value. Thus one can describe the ideal feedforward controller as an *inverse* of the plant: the plant translates commands into states whereas the inverse controller translates desired states into commands. If the transfer function of the plant is represented as $P$, its inverse is $P^{-1}$, and the transfer function of the complete system (from reference value to controlled variable) is $P \cdot P^{-1} = 1$. Again, this implies that the perfect system has a gain of unity. Inverse modeling is covered in more detail in Jordan (1994).

The alternative type of internal model is known as a forward model of the plant (Figure 1$B_2$). Its inputs are a copy of the motor command being sent to the plant and also the current feedback of the plant state, and its output is an estimate of the next state of the plant or of the controlled variables. This estimate is available to the feedback controller more rapidly than actual feedback. Thus, the external feedback loop can be replaced by an internal loop, which avoids the feedback delays mentioned above. A negative feedback loop with negligible delay and a high open-loop gain will rapidly and accurately drive its plant in a direction to minimize the comparator error. Thus, a fast internal loop including a forward model is functionally equivalent to an inverse dynamic model. Of course, viewed from outside the loop, it functions as a feedforward controller: it disregards the actual feedback and hence is no longer error correcting. The oculomotor feedforward controller may be an inverse model like that shown in Figure 1$A_2$ (Krauzlis and Lisberger, 1989); an alternative proposal suggests an internal forward model as in Figure 1$B_2$ (Robinson, 1975).

Schemes that combine feedback with feedforward control (Hoff and Arbib, 1992; Miall et al., 1993) depend on estimation of the expected feedback signal, including its delay. Recent theories have proposed combined forward and inverse models, working in pairs for system identification, control, and adaptation (Wolpert, Miall, and Kawato, 1998).

### Physiological Internal Models

Visual guidance of the human arm is based on sensory information from the visual system with processing delays of up to 100 ms. Motor commands issued by the CNS may take 50 ms to initiate muscle contraction, and these changes are signaled by vision and by proprioceptors with delays of perhaps 50 to 100 ms. So feedback signals from the environment will lag significantly behind the issue of each motor command. Despite this, we control our limbs skillfully and accurately with movement durations of well under half a second. Thus, our motor control cannot be based entirely on feedback signals; we also employ feedforward control. It is likely (although not yet certain) that control is based on internal representations of the motor system—internal models (Miall and Wolpert, 1996).

Can we identify these internal models in the brain? The cerebellum is a strong contender for internal model representations (Ito, 1984; Wolpert et al., 1998). The model should receive as inputs either the motor goal or an efferent copy of the motor command, and also receive proprioceptive information about the current state of the body. There must be a mechanism to allow the model to adapt to predict accurately the behavior of the limb, i.e., a neural learning mechanism. And the output of the model must form either the motor command or a sensory prediction of the action outcome. The cerebellum can satisfy all these constraints, but this alone is not proof. Other possible sites are the motor cortex, parietal cortex, and the spinal cord, although a spinal representation would probably be more closely related to individual muscles than a model of the whole arm.

There are strong connections from the motor cortical areas and posterior parietal cortex to the lateral hemispheres of the cerebellum, and from there, ascending paths back to premotor and motor cortices or descending to brainstem nuclei. Spinocerebellar tracts provide a large array of proprioceptive signals, updating the cerebellum on the current state of the limb. For adaptation, we know that coincident activity in climbing fiber and parallel fiber inputs to Purkinje cells results in a sustained change in the strength of the parallel fiber:Purkinje cell synapse (see CEREBELLUM: NEURAL PLASTICITY). Some researchers therefore suspect that the cerebellum acts as an adaptive inverse model on the feedforward control pathway (Figure 1$A_2$; Ito, 1984; Kawato and Gomi, 1992). Ito viewed the cerebellum as an adaptive side path to the descending systems, modulating the feedforward commands issued by cerebral control centers. Kawato views it as an alternative to these cerebral systems, replacing their control function. The alternative forward model-based scheme (Figure 1$B_2$) is also valid; hence the cerebellum may represent an adaptive forward model on a feedback pathway (Miall et al., 1993). This Smith predictor theory places the forward model within the closed cerebrocerebellar loop as the controller and incorporates feedback via an adaptive delay module. Each module is learned independently, with different time courses. It is difficult to distinguish between inverse dynamics models (Figure 1$A_2$) and internal feedback loops containing forward models (Figure 1$B_2$) unless one can get access to their internal structure. One might block the internal feedback loop needed for a forward model or decoding the input and output signals. However, many recent psychophysical, electrophysiological, and functional imaging experiments have generated strong evidence of the use of internal models for motor control, for state estimation, and for planning and interpretation of actions.

## Introduction

Two fundamental issues—how does the brain work, and how can we build intelligent machines?—are the leitmotifs of this *Handbook*. There are many strategies for attacking these questions, depending on what particular aspects of these broad issues we are interested in. One approach lies in the behavioral-neurophysiological domain. The recording of the activity of single cells in the brain of behaving animals provides a tool for directly studying how a particular behavioral pattern is represented and generated. Studies along this line intend to answer the first question: How does the brain work?

In the framework of this approach, the firing of a single neuron or a population of neurons can be correlated with one or several behavioral variables changing in time. The main challenge is to solve a pair of complementary problems: the coding/specification problem and the decoding/implementation problem. The former addresses the question of how the information about a particular behavioral variable is encoded in the neuronal activity being produced (see POPULATION CODES). The latter concerns the neural mechanisms by which encoded variables generate a behavioral pattern unfolding in time.

In the behavioral-neurophysiological domain, the constructive framework for attacking the issue of building "intelligent" machines could be formulated in the context of the decoding problem, namely: How can we design adaptive systems that would transform neuronal signals recorded in the brain of behaving animals into the physiologically appropriate behavioral pattern generated by an artificial machine? (see BRAIN-COMPUTER INTERFACES).

The work reported here summarizes a series of studies based on experimental work and abstract modeling. It exemplifies the successful application of the above-mentioned paradigms to the study of the arm motor system of the monkey and to the design of adaptive systems that transform chronically recorded brain signals into the motor output of artificial actuators. For that purpose, relatively simple but behaviorally meaningful motor actions such as a reaching movement and an exertion of force were chosen. We address the question of how movement variables are encoded in the motor cortex and how this information could be used to drive a simulated actuator that mimics the primate arm.

## Cortical Representation of Movement

### *Coding by Single Cells*

A common and behaviorally meaningful movement is reaching to targets in space. Reaching involves well-coordinated motion about the shoulder and elbow joints for transporting the hand in space and bringing it to a desired location. A reaching movement can be regarded as a vector, pointing from its origin to its target, with direction and amplitude.

A relation between the direction of reaching, **M**, and the cell discharge rate, *d*, has been established for several brain areas, including the motor cortex, the premotor cortex, area 5, the cerebellar cortex, and the deep cerebellar nuclei (Georgopoulos, 1996). This relation is characterized by a broad tuning function, $d(\mathbf{M})$, the peak of which denotes the "preferred" direction of the cell, **C**, that is, the direction of movement for which the cell's activity would be highest (Figure 1). Typically, cell activity (discharge rate) varies as a linear function of the cosine of the angle, $\theta_{MC}$, between the preferred direction of the cell **C** and the direction of reaching **M**:

$$d(\mathbf{M}) = b + k \cos\theta_{MC} \tag{1}$$

where *b* and *k* are cell-specific regression coefficients. (Although other functions could fit the data [Amirikian and Georgopoulos, 2000], the cosine function is a simple one that explains a good percentage of variation in cell activity.) Equation 1 holds both for reaching movements in a two-dimensional (2D) plane and for free reaching movements performed in three-dimensional (3D) space (Georgopoulos, 1996). Preferred directions of single cells range over the directional continuum and are multiply represented in the motor cortex.

Broad directional tuning of motor cortical cells was also observed with respect to the force pulses exerted by the monkey arm against an immovable object (Georgopoulos et al., 1992). A monkey was trained to exert forces in a 2D plane on an isometric handle in the presence of a constant force bias. First, the monkey was required to exert a postural (static) force **P**, which compensated a given bias force **B** ($\mathbf{P} + \mathbf{B} = 0$). After a holding period, a cue instructed the monkey to exert a force **S** such that the net force **N** acting on the handle (i.e., the force exerted by the monkey **S** *plus* the bias force applied to the handle **B**) would be in a visually specified (instructed) direction. Note that the net force **N** is congruent to the incremental (dynamic) component **I** of the force **S** exerted by the animal: $\mathbf{I} = \mathbf{S} - \mathbf{P} = \mathbf{S} + \mathbf{B} = \mathbf{N}$. Eight instructed directions and eight bias force directions evenly distributed in the 2D plane were employed. Recordings of neuronal activity in the motor cortex revealed that when the arm exerted a force without moving, the activity of single cells showed approximately the same broad directional tuning properties as when the arm moved through space. Cells were tuned not to the direction of force **S** exerted by the animal but to the direction of the dynamic component **I** of the force **S**.

Fu, Suarez, and Ebner (1993) investigated the relations between neuronal activity at the single-cell level and the amplitude of motor action. In these studies monkeys moved a handle over a planar working surface in eight directions (0–360°, in 45° intervals) and six amplitudes (1.4–5.4 cm, in 0.8-cm increments) in a pseudorandom order. The activity of cells in the motor and premotor cortex was directionally tuned in a cosine fashion, as described previously; the preferred direction was very similar for movements of different amplitudes. Cell activity generally increased with movement amplitude. Two aspects of this latter finding are noteworthy: first, the highest increase in neuronal activity with movement amplitude was not always along the cell's preferred direction; and second, the strongest relations with movement amplitude were observed for cell activity during but not before the movement (in the latter case, the direction of movement is the most important factor). These findings indicate that the motor cortex is involved primarily in the *specification* of movement direction, as the movement is planned during the reaction time, and in *monitoring* movement amplitude, as the movement evolves during the movement time.

The relationship of ongoing cell activity to evolving movement variables such as position, speed, and acceleration was also studied (Ashe and Georgopoulos, 1994; Schwartz and Moran, 2000). It was found that cell activity was related to all these parameters, although movement velocity and target direction provided the main contribution. Therefore, the activity of motor cortical cells can be tuned to several movement parameters.

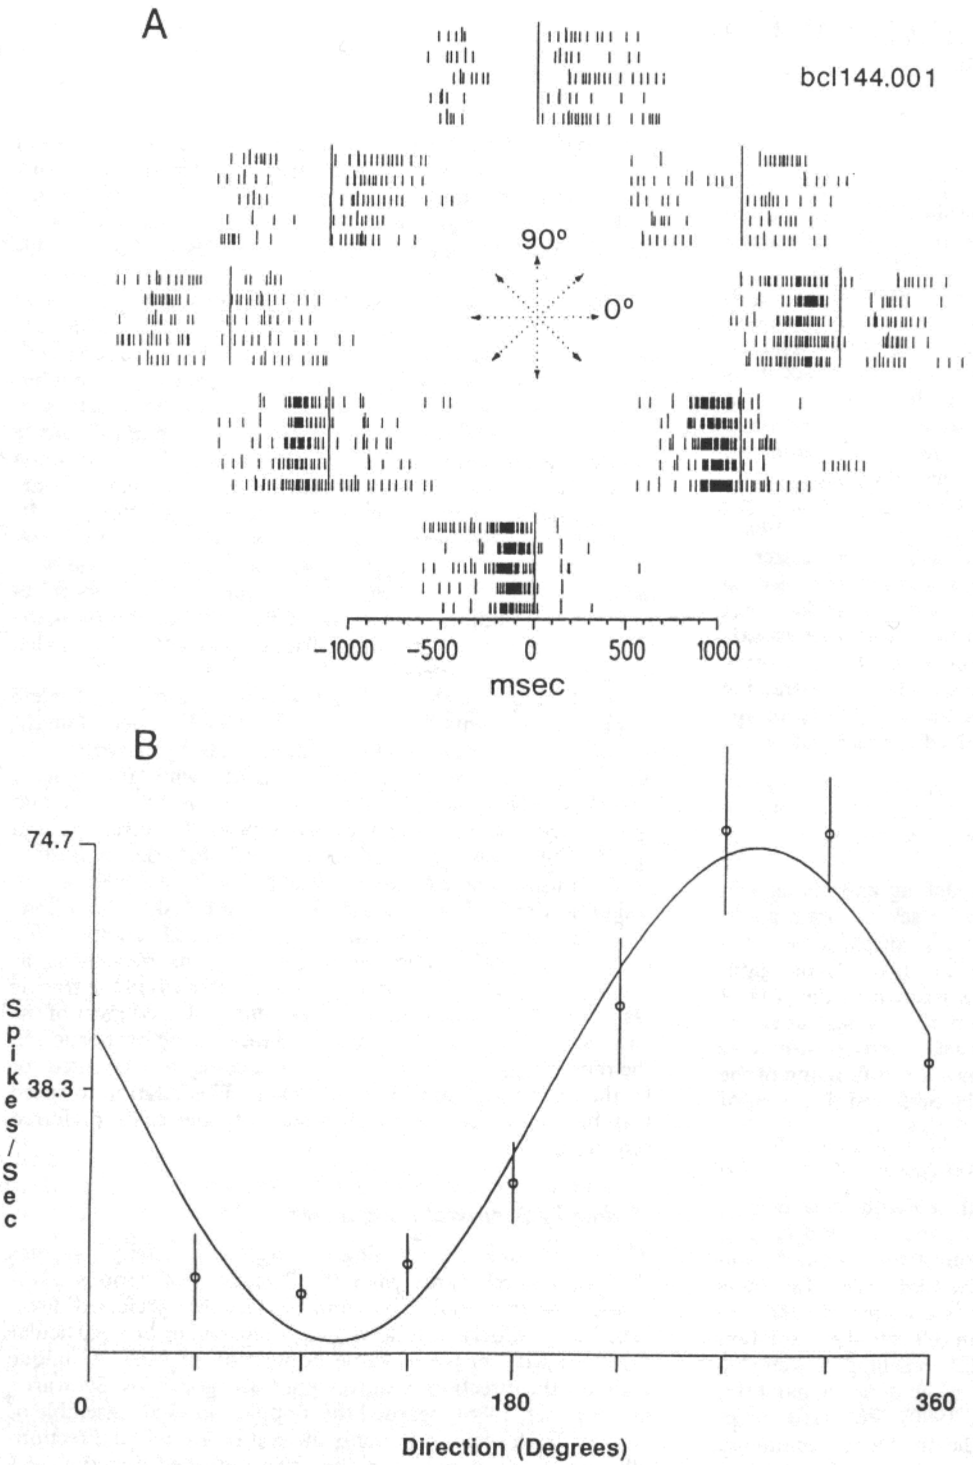

**Figure 1.** Discharge patterns during the center-out task. *A*, Rasters are arranged schematically at each target location around the center start position. Each raster is aligned to the time of exit from the center start position (zero time). The first long tickmark of each trial is the target onset time, the second is the time of movement onset, and the third is the time of target acquisition. *B*, The cosine tuning function was derived from the average rate of discharge (circles) between target onset and target acquisition for each movement. The error bars show the standard deviation of the discharge rate. The regression coefficients (see Equation 1 in the text) were as follows: $b = 37.9$ spikes/s, $k = 36.1$ spikes/s. The proportion of variance in discharge rate explained by the regression was $R^2 = 0.95$. (From Schwartz, A. B., 1992, Motor cortical activity during drawing movements: Single-unit activity during sinusoid tracing, *J. Neurophysiol.,* 68:528–541. Reprinted with permission.)

The findings of the studies reviewed above regard discrete reaching movements. Schwartz (1992) studied the neural mechanisms of continuous, drawing movements by recording the activity of single cells in the motor cortex while the monkey traced on a touch screen sinusoids of various amplitudes and spatial frequencies. Under these conditions, the direction and speed of movement changed continuously in time. In another task, monkeys made equal-amplitude movements from a central point to peripheral targets (center-out task). The following were found: (1) in the center-out task, cell activity varied in a cosine fashion with the direction of the movement, as found previously; (2) in the tracing task, the ongoing direction of movement explained most of the variance in ongoing cell activity; and (3) a good proportion of the remaining, nondirectional variance could be accounted for by the ongoing speed of the movement. This relation to speed was best observed for movements near the cell's preferred direction.

Recently, a thorough assessment of single-cell recording studies in primates (Johnson, Mason, and Ebner, 2001) emphasized the idea of a multiparametric control of movement. Particularly, it was pointed out that the activity of single cells in central motor structures relates to several motor parameters (e.g., end-point force, acceleration, velocity, position), the relative contribution of which may vary in time and is influenced by the motor behavioral context.

### *Coding by Neuronal Populations*

The broad directional tuning of single-cell activity indicates that a given cell participates in movements of various directions; from this result, and from the fact that preferred directions range widely, it follows that a movement in a particular direction will engage a whole population of cells. A unique code for the direction of movement (Georgopoulos, 1996) regards this population of directionally tuned cells as an ensemble of vectors in which each vector stands for the contribution of an individual cell. Specifically, the *i*th cell is represented by a vector that points in the cell's preferred direction $\mathbf{C}_i$ and has a length $w_i(\mathbf{M})$ proportional to the change in cell activity associated with a particular movement direction **M**. The vector sum of these neuronal contributions is the "population vector":

$$\mathbf{P}(\mathbf{M}) = \sum_{i=1}^{N} w_i(\mathbf{M})\mathbf{C}_i \tag{2}$$

where $N$ is the number of cells in the population. The population vector points in the direction of the movement for discrete movements in 2D and 3D space.

The length of the population vector is proportional to the instantaneous speed of the movement (Schwartz and Moran, 2000). The time series of population vectors calculated during the movement were added successively tip-to-tail, resulting in a "neural" trajectory that predicted well the ensuing trajectory of the actual movement by an average time lead of approximately 120 ms. Therefore, the population vector carries information concerning the unfolding movement trajectory.

The population vector algorithm was also used to retrieve information encoded in the ensemble of directionally tuned cells recorded while the monkey executed the isometric force task (Georgopoulos et al., 1992) described above. It turned out that the time-varying population vector reflected neither the force **S** exerted by the animal, which changed appreciably in direction and magnitude during individual trials, nor the static component **P** of the force **S**, which compensated for the constant force bias **B**. Instead, the direction of the population vector remained invariant during the trial and pointed in the direction of the dynamic component **I** of the force **S** exerted by the monkey. Based on this analysis, it was hypothesized (Georgopoulos et al., 1992) that the motor cortex provides the dynamic component of the force signal during force development, while other, possibly subcortical structures provide the static compensatory signal. These signals could converge in the spinal cord and provide an ongoing integrated signal to the motor neuronal pools.

It is important to realize that the population vector is a simple algorithm that retrieves an encoded variable from the activity of cells tuned to that variable, without making any assumptions about how the tuning itself emerges. There is controversy, however, as to what kind of variables these cells are coding: low-level variables such as muscle forces, or high-level variables such as end-point velocity (Flash and Sejnowski, 2001; Johnson et al., 2001). The matter has been recently sharpened by Todorov (2000), who proposed a simple model that (under certain assumptions) explicitly related cell activity to end-point force, acceleration, velocity, and position during small-amplitude movements. Interestingly, the model is consistent with experimental observations of multiparametric tuning of motor cortical cells (Johnson et al., 2001), and directly states that a *required* directional cell tuning is defined by a linear combination of end-point force, acceleration, velocity, and position terms. The relative contribution of each of these terms to the tuning depends on model parameters as well as experimental conditions (e.g., external loads). The main emphasis of Todorov's paper, however, is the "reinterpretation of the population vector." Since model cells were not explicitly related to high-level parameters but directly controlled low-level parameters (muscle forces), it was claimed that the view that motor cortex codes low-level variables "is in principle correct." Conversely, experimentally observed correlations with high-level motor variables (Johnson et al., 2001) is an epiphenomenon rather than a true neural code (Scott, 2000).

Todorov's model, however, does not allow one to make such far-reaching claims. The point is that the model is not "closed": the directional tuning is not an emergent property of the model but rather is built into it. Therefore, the derived expression for cell activity (Equation 2, Todorov, 2000), which is a starting point for all of Todorov's results, specifies a *required* activity of directionally tuned cells in order to generate a particular movement. The model, however, does not concern itself with *how* this required time-varying activity is produced in the course of movement. Note that cortical cell activity is a response to dynamic inputs received from cells in a local environment as well as inputs received from remote cortical areas. None of these factors is present in the model. Therefore, whether the information conveyed to individual cells via these inputs is related to low- or high-level motor variables cannot be answered in the framework of the model. The question of a *true* code is simply beyond the scope of this model. In a sense, the situation is similar to experimental studies in which cell activity, but not the cause of this activity, is recorded.

## Decoding Motor Cortical Signals

The population vector code, by combining activities of broadly tuned cells, provides an unambiguous and reliable estimation (see Population Codes) of the upcoming motor output (movement or force). However, the population vector allows only reading out as a single vector the cortical representation of distributed motor commands. It does not answer the question of how the motor commands, encoded in the cell activities, are translated into coordinated contraction of limb muscles to generate a desired motor action. This problem is closely related to the design of adaptive systems that transform neuronal signals chronically recorded from the motor cortex into physiologically appropriate motor output of artificial actuators such as multijoint prosthetic limbs (Schwartz, Taylor, and Helms Tillery, 2001; see Brain-Computer Interfaces).

Despite apparent similarities between these two problems, the approaches suitable for attacking each one pursue different goals.

The methods used to solve the first problem are heavily based on anatomical, neurophysiological, and biomechanical properties of the actual biological structures involved. The ultimate goal of this data-driven approach is to understand how real biological systems implement motor control. In contrast, the methods used to solve the second problem are usually based on theoretical analysis, the ultimate goal of which is to develop a computational algorithm that utilizes the raw biological signals to drive an artificial actuator. Here, the computational scheme does not try to be biologically realistic. Any control algorithm that successfully solves the problem is acceptable. Despite the difference in goals, the importance of interplay between the data- and theory-driven approaches should not be underestimated. The ideas and concepts developed in one field drive the other, and vice versa.

This was illustrated by Lukashin, Amirikian, and Georgopoulos (1996a, 1996b), who addressed the question of how neuronal signals might be used to drive an artificial actuator so that its motor output would correspond to the performance of a real limb. They suggested a computational scheme that transformed impulse activity recorded from the monkey motor cortex during performance of the isometric force task to the force produced by a simulated actuator. Although this computational model is not an accurate realization of biological motor control, it is biologically plausible. The model was inspired by, and based on, experimental findings obtained in anatomical, neurophysiological, and psychophysical studies conducted on three different organisms: (1) experiments on microstimulation of the frog's spinal cord (see MOTOR PRIMITIVES); (2) studies of human arm stiffness characteristics (Mussa-Ivaldi, Hogan, and Bizzi, 1985; see also references in EQUILIBRIUM POINT HYPOTHESIS); and (3) single-cell recordings in the motor cortex of monkey (Georgopoulos, 1996).

### *Transformation of Spiking Activity into Isometric Force Exerted by an Actuator*

The motor cortical activity used in Lukashin et al., (1996b) as command signals came from single-cell recording experiments (Georgopoulos et al., 1992), discussed above, when there was no force bias applied ($\mathbf{B} = 0$). In this case, the force $\mathbf{S}$ exerted by the monkey had only the dynamic component $\mathbf{I}$ and was the only force acting on the isometric handle. Therefore, the force $\mathbf{S}$ developed over time had to be in the instructed direction and had to increase in magnitude in order to exceed a required threshold. The bottom left part of Figure 2 shows an example of impulse activity of $N = 15$ different cells. These spike trains were recorded in different trials but for the same instructed direction of force (180° in the 2D workspace, Figure 2, top left). The key idea is that these cortical signals must now drive a simulated actuator (Figure 2, top right) in such a way that it would exert an isometric force in the same direction as the monkey did.

The actuator is a planar two-joint, six-muscle model of the arm. The transformation of cortical signals into motor output of the actuator is performed by an artificial neural network (Figure 2, bottom right) connected to the actuator. The network receives experimentally measured impulse activity as a time-varying input to the input layer and transforms it into a time-varying pattern of activity at the output layer. This results in contraction of actuator "muscles" by means of changing the muscle rest lengths. Finally, a set of the muscle rest lengths unambiguously defines the direction and magnitude of the end-point force exerted by the actuator against an immovable object. Thus the motor control algorithm realized in this model transformed a neural field, i.e., cortical activity, to a force field, i.e., end-point force (see GEOMETRICAL PRINCIPLES IN MOTOR CONTROL).

In the framework of this computational scheme, the performance of the model (i.e., the relation between the input cortical signals and the force exerted) depends mainly on the network connectivity, which must provide a synergistic activation of all muscles to generate a required motor action. To ensure physiologically normal motor output of the actuator, the network was trained (Lukashin et al., 1996a) on experimental data obtained from studies of human arm stiffness (Mussa-Ivaldi et al., 1985). As a result, the stiffness properties of the model arm were similar to those measured for the human arm. Moreover, the biological relevance of this model was further independently tested (Lukashin et al., 1996a) by simulating experiments on microstimulation of frog spinal cord (see MOTOR PRIMITIVES). The model was fully consistent with experimentally observed vector summation of active force fields, realizing the idea of a linear combination of a small number of force field primitives to produce a large repertoire of motor behaviors (see MOTOR PRIMITIVES).

After training, the underlying set of synaptic weights was fixed and the performance of the model was tested against the whole neurophysiological data set (Georgopoulos et al., 1992), which included both experimentally measured motor cortical commands and resulting motor actions. An important issue of the performance is the robustness of the decoding scheme with respect to (1) the size of the population of cells generating neuronal signals, (2) variations in the composition of cells included in the population of a given size, and, finally, (3) changes in the cell activity from trial to trial.

The uniformity of the distribution of the cells' preferred directions throughout space is of particular importance in reconstructing the directional signal encoded in the population activity (see POPULATION CODES). Therefore, all other factors being equal, the best performance for a fixed-size population is expected for such a composition of cells whose preferred directions form a nearly uniform distribution. Lukashin et al., (1996b) found that when the uniformity requirement is fulfilled, the performance and robustness of the model improve gradually as the size of the population ($N$) increases, revealing a tendency for saturation as $N$ approaches 15–20 cells.

Typical results for $N = 15$ demonstrating the time-evolving performance of the model are displayed in Figure 3. The forces exerted by the monkey and by the actuator are shown for four instructed directions, together with the corresponding motor cortical activity. It can be seen (Figure 3, templates $A1$, $B1$, $C1$, $D1$) that directional tuning of cortical impulse activity is barely perceptible, owing to the large variability in cell discharge. However, the computation scheme successfully decodes these signals, and the time-varying forces developed by the actuator (Figure 3, templates $A3$, $B3$, $C3$, $D3$) are very similar to those developed by the monkey arm (Figure 3, templates $A2$, $B2$, $C2$, $D2$). Following an initial period of time, which lasts 100–200 ms, the direction of force exerted by the actuator stabilizes and the magnitude of force increases. The stabilized direction of force is close to the instructed direction for which the cortical activity was recorded. This was also observed for the remaining four instructed directions for this particular ensemble of cells and for other ensembles of cells ($N \geq 15$) and trials, thus suggesting a high degree of robustness of the decoding algorithm.

## Discussion

One of the major challenges of brain theory is to elucidate the neural basis of behavior. Significant progress has been made over the past decade in determining functional properties of single motor cortical cells with respect to relatively simple yet behaviorally meaningful motor actions. The finding that neurons are broadly tuned to behavioral variables led to the key idea of distributive coding. The population vector algorithm allows a read-out of this code by transforming aggregates of purely temporal spike trains into a spatiotemporal vector. The neuronal population vector has

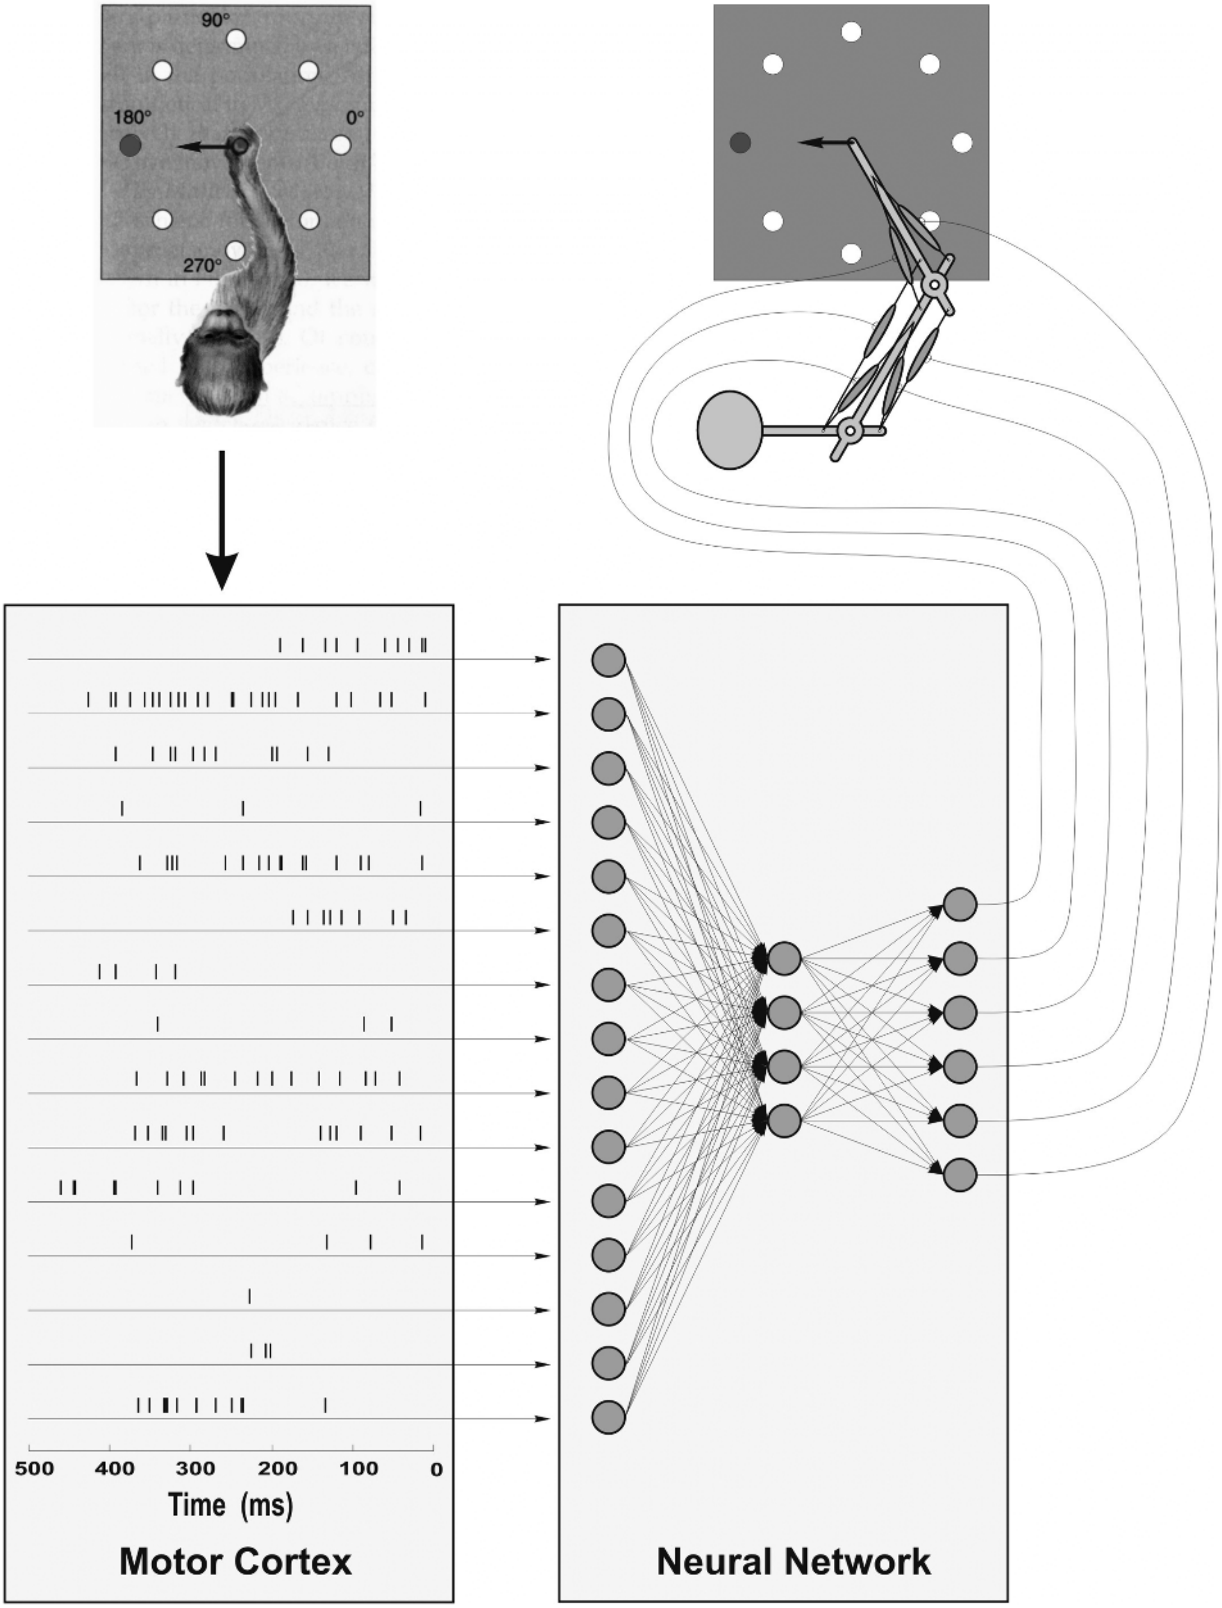

**Figure 2.** The decoding computation scheme used to transform neuronal commands encoded in a series of action potentials into a force exerted by the simulated actuator. The top left part of the figure illustrates a monkey exerting a force against the immovable handle in one (180°) of eight instructed directions. An example of the motor cortical activity recorded while the animal performed this task is represented in the bottom left panel. These neuronal signals drive the simulated actuator sketched in the top right part of the figure. A three-layered feedforward neural network (the directed connections are shown by thin arrows) transforms cortical signals into coordinated activation of actuator muscles.

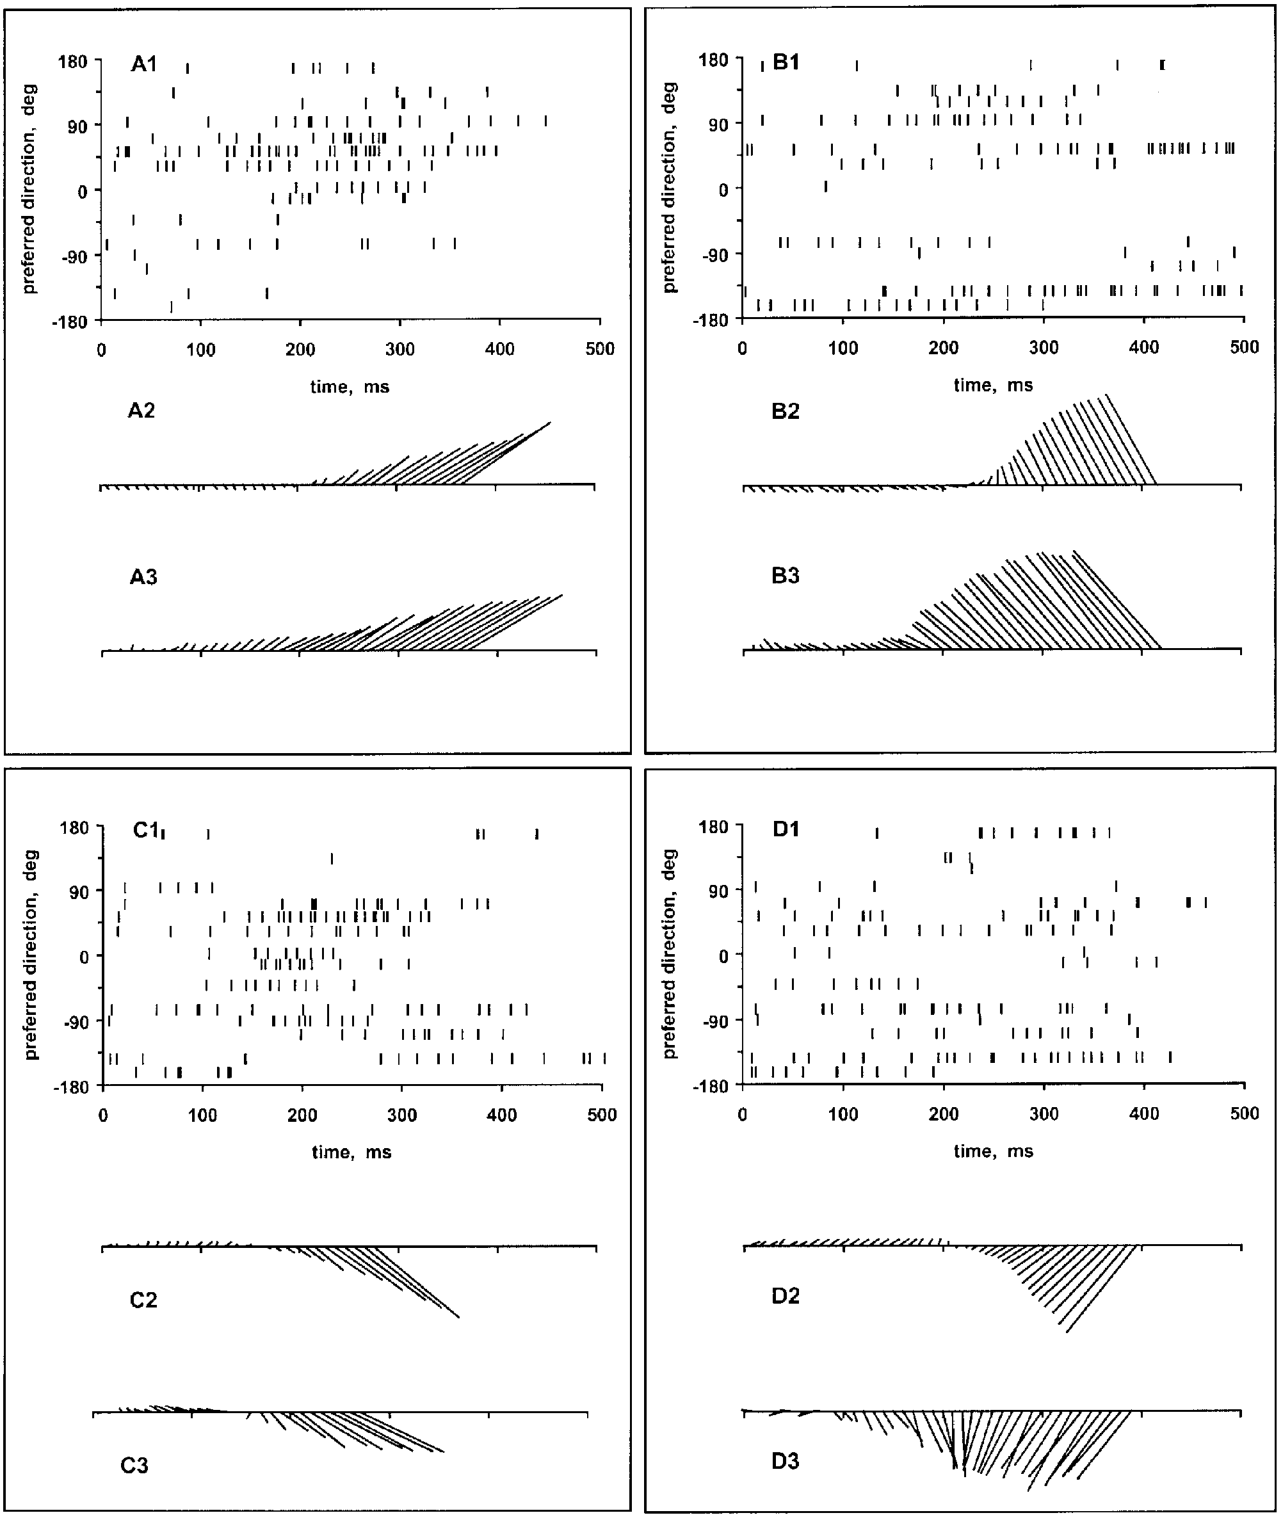

**Figure 3.** The motor cortical activity and the forces exerted by a monkey and by a simulated actuator. Four rasters, *A*1, *B*1, *C*1, and *D*1, show spiking activity recorded while the monkey developed isometric forces in four different instructed directions (45°, 135°, −45°, and −135°, respectively). The spike trains are aligned to the time of visual stimulus (zero time) instructing the monkey to begin the motor action. Each raster includes spike trains for the same 15 cells ordered along the vertical axis in accordance with their preferred directions. The time-varying forces developed by the monkey are depicted in *A*2, *B*2, *C*2, and *D*2. The force vectors measured every 10 ms are displayed as line segments; the tails of force vectors are aligned along the time axis (the horizontal line). The time scale is the same as shown in the rasters above. Finally, *A*3, *B*3, *C*3, and *D*3 show forces exerted by the actuator in response to the neuronal activity presented in the rasters. The forces were calculated using the decoding algorithm described (see text and Figure 2) with a 10-ms time step and were arranged along the time axis in the same way as experimentally measured forces. The measured and calculated forces are normalized to the same magnitude, assigned arbitrarily.

proved to be a robust and accurate measure of the directional tendency of a neuronal ensemble in different brain structures and under a variety of conditions. The discovery of cortical representation of motor commands, combined with the elucidation of neural mechanisms by which these commands generate a particular behavioral pattern unfolding in time, should further advance our understanding of neural basis of motor behavior.

The research in this direction also provides an impetus to the field of neuroprosthetics (see PROSTHETICS, NEURAL) and the design of adaptive systems that transform neuronal signals recorded from the brain into physiologically accurate motor output of multijoint prosthetic limbs (see BRAIN-COMPUTER INTERFACES). The feasibility of this idea was demonstrated by Lukashin et al. (1996b) in a particular case when the required motor output was an exertion of isometric force. The simulated actuator, which mimicked the primate arm, responded to the experimentally recorded motor cortical commands with surprising fidelity, generating forces in quantitative agreement with those exerted by a trained monkey in both the temporal and spatial domains. An important finding was that even a small ensemble of cortical cells can reliably control relatively complex motor output. Recent studies (Schwartz et al., 2001, and references therein) have made further progress toward the cortical control of arm prosthetics.

# Motor Pattern Generation

*Jeffrey Dean and Holk Cruse*

## Introduction

Movement is central to the survival of animals and the performance of machines. The elegance of animals moving in complex environments has long aroused curiosity and the desire to emulate this ability. Animals move using muscles that produce force, sensory systems that signal the state of the organism and its surroundings, and a nervous system that links the two and contributes its own intrinsic activity. All possess some characteristics unattractive to engineers. Muscles are relatively slow and their force varies with muscle length, its rate of change, and the pattern of activation (see MUSCLE MODELS). Most sense organs conflate information about a parameter's value and its rate of change (see ADAPTIVE SPIKE CODING). Most neurons transmit information slowly using a pulse code of limited bandwidth. Response variability necessitates feedback supervision (see MOTOR CONTROL, BIOLOGICAL AND THEORETICAL), but inherent transmission delays, component variability, and limited coding precision force feedback gains to be low to avoid instability and unwanted oscillations.

The contrast between component quality and exquisite motor performance raises major unsolved puzzles. One is whether component characteristics actually simplify control. For example, the spring-like properties of muscles might reduce movement planning to end-point specification (see EQUILIBRIUM POINT HYPOTHESIS). Others lie in the distributed, highly parallel organization of biological control systems.

## Metaphors and Tools

Since Descartes reduced animals to machines, biologists have applied metaphors from contemporary technology to the brain and motor control. As technology advanced, metaphors progressed from clock mechanisms and pneumatic actuators through card readers and magnetic tape to current computer-based concepts. For example, the orchestration of complex muscle activity was attributed to a central motor score that could be stored and replayed like magnetic tape: Graham Hoyle envisioned both a motor tape for motor neuron activation (*motor output* in Figure 1) and a sensory tape for the sensory signals expected during unperturbed execution (*efference copy* in Figure 1).

Currently dominant is *motor program*, analogous to the instructions for a computer (Keele, Cohen, and Ivry, 1990). Varying usage led to alternative suggestions (e.g., *coordinated control program*: see SCHEMA THEORY; *motor control structure*: Cruse et al., 1990). *Motor program* is still apt if program is understood very generally as code that can generate complex output in the absence of input, vary its output depending on inputs, and modify itself. The important caveat is that the term not imply classical von Neumann ar-

coordinative structure
neural Motor Pattern Generator (nMPG)
Motor Pattern Generator (MPG): task oriented

**Figure 1.** A hierarchical description of motor pattern generation showing potential interactions between efferent (motor), afferent (sensory), and central elements. nMPG is the set of neural elements, together with their states and interactions, that produces patterned motor output for a particular behavior; MPG includes the properties of effectors, body, and substrate. Sensory information can modify activity at all levels, but may itself be modified by central activity (efference copy, corollary discharge). Particularly in vertebrates, recurrent connections or corollary pathways may equal or exceed forward connections. For simplicity, the gray pathway (left) combines ascending (recurrent, internal loop) and descending interactions. Not shown are multi-element recurrent loops that implicitly or explicitly implement internal representations, models, and model-reference control. In complex behavioral sequences, planning instances participate in nMPGs. Even in simple nervous systems, functional hierarchies need not correspond to separate anatomical levels: individual neurons may participate in several functions (three leftmost brackets) and transmit signals forward and backward across several levels. NMT, neuromuscular transform.

chitectures with one processor working through sequences of instructions stored in separate memory. Instead, motor programs represent states established in the nervous system that produce coherent, task-related patterns of intrinsic activity and responses to stimuli. Like schemas, they are high-level shorthand for the function of parallel, distributed physiological systems (e.g., Figure 1).

This article focuses on the biological implementation of motor programs. Biomechanics and neurophysiology, supported by neuroanatomy, modeling, and molecular techniques, provide data. Cybernetics, the formal analysis of a system's input-output characteristics whereby systems can range from single neurons to whole animals (see Motor control, Biological and Theoretical), provides systems-level analytical tools. So does the theory of dynamic systems (see Cooperative Phenomena), which seeks collective variables summarizing emergent properties of complex systems and control parameters influencing their behavior.

## Motor Pattern Generation

Like any physical system, animals move subject to the forces acting within and upon them. Animals actively control muscle forces, so generating movement is equivalent to generating appropriate patterns of muscle activity. As Sherrington noted, regardless of the complexity of the central nervous system (CNS), all motor influences must converge on or before the motor neurons, the final common path. *Motor output*—activity in this final common path recorded as muscle electrical activity (EMG), efferent activity in peripheral nerves, or activity in identified motor neurons—is often a convenient measure when experimental conditions preclude movement.

Although typical hierarchical descriptions of motor control (Figure 1) depict effectors, usually muscles, transforming into action a plan represented in motor output, the relationship between motor output and muscle force or movement is not simple (Hooper and Weaver, 2000; see Muscle Models). Nonmuscular forces like gravity or tendon and substrate elasticity strongly influence many movements. The characteristics of the body as a physical plant and the body–environment interaction may already be incorporated into motor output (Chiel and Beer, 1997), further obscuring the relationship between movement and neural activity.

Movement itself and motor output are called motor patterns, but we will focus on active control and use *neural motor pattern generator* (*nMPG*) for the system producing (neural) motor output that in appropriate contexts causes natural behavior. nMPGs can include simple and complex reflexes as well as intrinsic CNS activity. Many scientists would combine the nMPG, the body realizing its output, and the environment into a single dynamical system, arguing that each can contribute equally to molding the movement (Chiel and Beer, 1997); we will use *motor pattern generator* (*MPG*) for this dynamical system.

MPGs are conventionally linked to particular behaviors or actions, but defining units of behavior and thus MPGs is a matter of taste and inherently recursive (see Schema Theory). Investigators adopting whole-animal, functional perspectives might choose walking and a walking MPG as convenient initial units, so that refining the analysis to consider single legs or joints leads to models with many subunits in a walking MPG (e.g., Figure 1). Other investigators might begin with joint flexion and a flexion MPG, so that expanding the scope leads to models with many MPGs interacting to produce walking.

Regardless of the choice, similar questions arise. First, how is a particular motor pattern generated? Which system properties are necessary? Which are sufficient? Is the output stable with respect to external disturbances? Next, how is the pattern switched on and off? How are movement speed, form, and amplitude specified and adapted to task demands? How are external and internal state variables reflected within the nMPG? Finally, in ontogeny and evolution, do genes encode precise circuits—specifying each element and its connections—or crude circuits plus general measures of activity that engage plasticity mechanisms to achieve appropriate behavior (see Activity-Dependent Regulation of Neuronal Conductances), and how do MPGs for similar behaviors compare in different species?

### *A Brief History of Theories of Motor Pattern Generation*

When physiological study of the nervous system began in earnest, the easily accessible parts—peripheral sensory and motor elements and their combination in elementary reflexes—were investigated first. Because theories are built on what is known, reflexes assumed central roles, making animals into reactive, reflex-driven machines. In biology, motor patterns were explained as chains of reflexes in which each movement creates appropriate sensory stimuli to elicit the next movement, leading to complex behavioral sequences or, if the chain is closed, rhythmic behaviors. Timing and continuation of leg movements in walking were attributed to reflexes based on changes in leg position, loading, and equilibrium signals during the step, but such conceptual models were never simulated quantitatively. In psychology, the analogous theory was *response chaining*. Such reaction-based formulations were extended in ethology to interactions between individuals and in psychology to behaviorism.

The rigidity of reflex or response chain theories caused their downfall (e.g., Lashley, 1951; Keele et al., 1990). Both had to postulate subtle stimulus differences to account for different behaviors under seemingly identical conditions and were unable to explain rule-based behavior in novel situations. Response chains based on reflex loops cannot explain rapid sequences when event intervals are shorter than minimum response latencies. Chains based on internal loops have difficulty explaining concurrency of preparatory movements and their dependence on preceding *and* succeeding actions.

A new theory was needed, one incorporating generalized representations of behaviors—plans or schemas (Lashley, 1951; see Schema Theory) or motor programs—which are modifiable by external and internal influences. In psychology, neurological findings implicate specific brain structures in planning (see Basal Ganglia; Cerebellum and Motor Control), but the details are unclear. In biology, motor programs acquired physiological foundations, beginning with the realization that the CNS alone can produce patterned motor output. T. Graham Brown showed that cats deprived of sensory inputs could still produce coordinated stepping; he envisioned a neural oscillator producing alternating activity in flexor and extensor muscles. His experimental approach—deafferentation—and his conceptual model both remain current (see Half-Center Oscillators Underlying Rhythmic Movements). Later, von Holst's (see Delcomyn, 1980) quantitative analyses of rhythmic behaviors were best explained by interactions among multiple intrinsic rhythm generators.

As physiological techniques improved, intrinsic motor patterns were traced within the CNS. Individual neurons or networks able, in the absence of patterned sensory inputs, to produce patterned motor output related to natural behaviors are generally called *central pattern generators* (*CPGs*). *Neural oscillator* or *central oscillator* are terms also used, particularly for rhythmic patterns, but CPG includes discrete movements. (Naming CPGs again raises questions of system boundaries. CPGs in the lobster stomatogastric system originally distinguished according to anatomical segment and function were later found to interact in complex ways within what in a broader view is an ingestion CPG; see Crustacean Stomatogastric System.)

For a time, the importance of CPGs was overemphasized at the expense of peripheral elements. Wilson's demonstration of basic flight rhythms in the efferent motor fibers of deafferented locusts was particularly influential (see Locust Flight: Components and Mechanisms in the Motor). Sensory influences were relegated to providing tonic excitation rather than cycle-by-cycle patterning. Initial physiological descriptions of neural oscillators reinforced this emphasis, especially when evidence for CPGs was found in virtually all rhythmic behaviors (Delcomyn, 1980). Besides the physiological data, however, a willingness to overlook differences between natural motor patterns and those in deafferented preparations contributed to the emphasis on CPGs (Pearson, 1993).

The necessary correction occurred when it was shown that sensory inputs, besides influencing frequency, timing, and form of rhythmic activity, often fulfill both criteria for CPG inclusion (Pearson, 1993): (1) rhythmic activity correlated with the behavior and (2) the ability to shift or "reset" the phase of ongoing rhythms when appropriately stimulated. For example, actual wing movement and loading, visual stimuli, and changes in air flow past the head modulate and stabilize locust wing movement on a cycle-by-cycle basis (see Locust Flight: Components and Mechanisms in the Motor). Similar entrainment by sensory inputs occurs in many systems with well-developed neural oscillators, as does modulation of transitions in sequences of nonrhythmic movements.

Peripheral influences are easily incorporated into motor programs and similar high-level concepts; MPG and nMPG inherently include both central and peripheral elements. Many researchers also expand the CPG concept to incorporate sensory influences when available, but this disrupts the natural congruity of functional and anatomical boundaries.

In summary, most MPGs incorporate both intrinsic CNS activity (CPGs) and peripheral influences reflecting biomechanical characteristics, reflexes, and proprioceptive and exteroceptive afferent activity (Pearson, 1993). As strategies for adaptive behavior, these two elements are analogous to network adaptation via genetic algorithms and via learning or developmental plasticity, respectively. The balance is subject to evolutionary selection, depending on the cost of errors and the predictability of motor command outcomes; it remains a subject of debate and research.

## *Central Pattern Generators*

Understanding of CPGs progressed most rapidly for rhythmic behaviors. Initial conceptual models addressed simple two-phase rhythms, such as alternation between stance and swing. Half-center oscillator models contain two functional units connected by reciprocal inhibition and subject to a common excitatory drive, whereby functional units can be either single neurons or groups of neurons synchronized by reciprocal excitatory synapses. This bistable circuit oscillates if the inhibition decays or if other functionally equivalent changes occur (see Camhi, 1984). George Szekely demonstrated that multiphase rhythms can be generated by neurons or functional groups in a ring with recurrent inhibition (e.g., Camhi, 1984).

Early physiological findings distinguished two kinds of neural oscillators. In *cellular oscillators* (*pacemakers*; see Oscillatory and Bursting Properties of Neurons), rhythms depend on complex, nonlinear membrane properties and continue when the cell is isolated from the nervous system, whereas in *network oscillators* they depend on the connectivity of cells incapable of rhythmic activity on their own. Connectivity was emphasized initially because it was easier to characterize and because several vertebrate and invertebrate networks contained reciprocal or recurrent inhibition, providing a satisfying agreement with theoretical simulations using simple model neurons.

Subsequent results blurred the distinction and emphasized the contribution of cellular properties (Selverston et al., 1997). First, time delays necessary for half-center models require nonlinear properties. Second, some neurons within putative network oscillators, and even some motor neurons, possess nonlinear membrane properties, allowing them to oscillate or exhibit *plateau potentials*, switching between inactivity and prolonged high activity (see Oscillatory and Bursting Properties of Neurons; Neuromodulation in Invertebrate Nervous Systems). Unexpected pacemakers turned up within putative network oscillators. Third, synaptic interactions show similar complexity, changing in strength or even sign, depending on time or on the relative potentials of sender and recipient (see Temporal Dynamics of Biological Synapses). Fourth, besides simple recurrent inhibition, real networks include positive feedback or mixtures of circuits. Even the five-neuron recurrent ring initially identified as the swim CPG of the leech contains reciprocal inhibitory connections within and diagonally across the ring (see Camhi, 1984). Finally, real CPGs incorporate both cellular and network properties, with redundancy contributing to robust rhythmicity.

Complexity and redundancy impede attribution of function to particular elements even in simple invertebrate networks with few neurons. CPG simulations using realistic synaptic interactions and membrane characteristics are absolutely necessary. The practical difficulty is the ever-increasing list of properties of possible significance. Consideration of neuronal morphology adds further complexity (see Dendritic Processing). Morphology influences responses according to both the timing and the location of inputs. Thus, simulation of even a single real neuron, let alone a network, is a formidable problem (see Single-Cell Models). Even some well-studied CPGs lack definitive models. Although the optimism following early successful simulations using simplistic neurons dissipated, newer, more realistic models provide grounds for renewed optimism (e.g., Selverston et al., 2000).

Network simulations and physiological data do show that systems can perform appropriately even when some connections appear nonfunctional or even dysfunctional (e.g., excitatory connections to neurons normally silent when the sender is active). Such "rogue" elements (Robinson, 1992) occur even in simple resistance and withdrawal reflexes. Because natural selection works most directly on behavior, eliminating all rogue elements may not be possible or necessary: motor output is an emergent property of the whole CPG.

CPGs may drive normal movements or merely facilitate particular modes of motor output. They avoid peripheral delays at the expense of adaptability to bodily and environmental changes. They represent predictions for suitable motor output, or a kind of *internal model* for adaptive behavior in a given context. Given the incomplete understanding of simple CPGs and their somewhat stereotyped outputs, moving beyond these to understand flexible motor control presents major challenges. Recurrent connections prominent in higher vertebrates presumably contribute to more elaborate internal models supporting flexible nMPGs (see Action Monitoring and Forward Control of Movements; Reaching Movements: Implications for Computational Models).

### Switching Patterns On and Off

Functionally, pattern generators are controlled by a switch. Neural elements implementing the switch were labeled *command neurons* (see Figure 1) (Kupfermann and Weiss, 2001). Activity in command neurons should be both necessary and sufficient for producing behavior. If action potentials are required, the neuron's threshold determines the behavioral threshold. In practice, few neurons fulfill both criteria (Camhi, 1984). More often, control is distributed among many neurons, reflecting the redundancy common in biological systems. As a result, the concept has been extended to "command systems" containing multiple "command elements" (see Command Neurons and Command Systems).

Two kinds of switches have been identified. Some behaviors continue only as long as an appropriate stimulus is present; others continue after it ends. A similar distinction applies to command neurons: activity in *trigger neurons* initiates a longer-lasting behavior, while activity in *gating neurons* determines the duration of the behavior. Command neurons turning on one behavior may also turn off or inhibit command neurons for interfering behaviors and excite those for functionally linked behaviors—an architecture replicated in P. Maes's ANN. If not actively turned off, gating neuron activity may simply decay below threshold, terminating the behavior.

Real nervous systems often mix command, coordination, and pattern generation, and behavioral choice involves multiple functional levels. Activity in some gating neurons oscillates with the output rhythm. Some can reset the rhythm and fulfill criteria for CPG inclusion. Some leech gating neurons are functionally outside the CPG, but the recurrent, excitatory pathways modulating their activity help prolong this activity. In *Tritonia*'s escape system, the command signal reflects membrane properties of CPG neurons: depending on stimulus strength the network produces either a single longitudinal contraction or multicycle dorsoventral flexions. Thus, one anatomical network may be a *polymorphic network* producing qualitatively different motor patterns; in other words, individual neurons participate in multiple behaviors, and command is a population code (Kristan and Shaw, 1997).

Command signals often work via nonlinear effects of neural activity (see Activity-Dependent Regulation of Neuronal Conductances) or modulatory transmitters and hormones (see Neuromodulation in Invertebrate Nervous Systems) that modify membrane properties, producing qualitative changes in outputs or even functional reconfigurations of nMPGs. Thus, biological nMPGs show a protean variability compared to artificial neural networks, where unit properties are usually static and output changes reflect input changes or connectivity changes through learning.

### Sensory Influences

nMPGs usually incorporate feedforward and feedback using sensory information about the surroundings and motor performance. Formally, feedback depends on the consequences of motor activity. Negative feedback acts to reduce deviations ("errors") from a reference value, as in resistance reflexes, whereas positive feedback (with suitable limiting nonlinearities) maintains or accentuates ongoing movements. Feedforward pathways help select actions or set parameters in advance, such as specifying the size of a saccade or an escape turn. However, in natural, continuous streams of behavior, distinguishing error-correcting feedback from parameter-setting feedforward mechanisms is not always clear (Cruse et al., 1990). For example, learning can be described as delayed negative feedback that adjusts future parameter setting.

Sensory signals can be modified at various levels (see Figure 1). Sensory activity can be modulated peripherally through efferent control or centrally at the output synapses of the primary afferent fibers. Reflexes occurring in one situation can be reversed or replaced by wholly new responses (Pearson, 1993). In invertebrates, resistance reflexes—negative feedback opposing leg displacement during posture—are replaced as stance begins by assistance reflexes to boost propulsion. At other times they remain active, opposing deviations from normal trajectories. Phase-dependent reflex modulation may be a natural consequence of spike thresholds in neurons (see Locust Flight: Components and Mechanisms in the Motor).

The relative importance of central and peripheral components varies considerably. For example, central elements appear weaker in walking than in flying and swimming, where the substrate is more forgiving. In flying, variability in wing movements affecting lift and steering can be corrected over several subsequent cycles, whereas in walking, not finding a foothold or tripping over an obstruction must be corrected immediately. When stick insects walk, movement of the leg itself, as signaled by sensory inputs, determines the state of the step CPG (Bässler, 1986; Dean et al., 1999); isolated CPGs produce slow, fragmentary, irregular motor output. Our work shows that a simple step rhythm can arise from a four-unit, recurrent nMPG in which two units represent the state and two units represent position criteria for changing state. Recurrent connections provide positive feedback to reinforce the current state, causing each movement to continue to its endpoint.

### Other Peripheral Influences on Motor Patterns

Physical characteristics of muscles, tendons, skeletal elements, and the environment modify or even create movement. Motor behaviors are often studied using motor output, but the transformation between this activity and movement is not trivial. Different neural rhythms in the lobster CPG controlling chewing were characterized long before their functional significance was determined (see CRUSTACEAN STOMATOGASTRIC SYSTEM). Modeling the transformation from neural activity to muscle force is difficult but improving (Hooper and Weaver, 2000). Motor neuron activity is difficult to relate to movement, partly owing to the sophistication with which animals use passive and elastic properties of their muscles and skeletons. According to one hypothesis for limb movements to a target (see EQUILIBRIUM POINT HYPOTHESIS, but also ARM AND HAND MOVEMENT CONTROL), muscle activity is not related to movement as such but to the target, the allowable deviation, and an estimate of possible and allowable errors.

Including the periphery in MPG models is particularly important when it strongly affects movement. Algorithms for step coordination simulated using a simplified representation of leg position will be unable to control a machine with real legs if they try to place legs in unreachable positions. Behavioral data on limb interactions, the basis of many coordination models, actually represent the total effect of internal activity, reflexes, and the physics of animal and environment. Dynamical systems theory, using collective variables like phase, can sometimes provide a succinct encapsulation of this system behavior.

In extreme cases, significant aspects of movements are determined by the physical system. Treating bipedal walkers simply as a system of passive, damped pendulums explains many characteristics, suggesting that muscle activity is only occasionally necessary to maintain the pendular motion or correct disturbances (McGeer, 1990). In some insects, flight muscles require general activation, but individual wing beats result from mechanical oscillations involving the muscles' intrinsic response to stretch.

In summary, biological movement is not always driven rigidly by nMPG output (see CEREBELLUM AND MOTOR CONTROL). Taking advantage of physical properties may enable adequate control using neural approximations of exact algorithms and internal models (e.g., Dean et al., 1999), especially when animals are small or compliances are high, so that impacts or stresses arising from inaccuracies can be absorbed without injury. This may not be true of large, powerful robots in an environment where safety is an essential concern.

### *Coordinating Multiple Motor Patterns*

Many behaviors contain distinct elements that occur concurrently or sequentially, requiring spatial and temporal coordination of body parts (e.g., EYE-HAND COORDINATION IN REACHING MOVEMENTS; LOCOMOTION, INVERTEBRATE) or the completion of one action before another begins. For this purpose, several MPGs or subunits within one MPG can be structured hierarchically or in parallel, depending on task requirements (see Figure 1). For speaking and typing, the kinds of errors and time delays, the concurrence of preparatory and execution phases, and the modulation of elements depending on earlier and later elements indicate a hierarchical arrangement, whereas relative coordination of concurrent rhythms indicates a parallel arrangement.

In these cases, interactions among and within MPGs can occur at many levels, ranging from overall planning through parameter setting and CPG activity to peripheral loops involving mechanical coupling and reafference. Network models offer natural simulations of these interactions. Rhythm coordination has been studied extensively (see CRUSTACEAN STOMATOGASTRIC SYSTEM; CHAINS OF OSCILLATORS IN MOTOR AND SENSORY SYSTEMS). Coordination mechanisms within MPGs are often highly redundant and thus robust. In insect walking, multiple centrally mediated mechanisms are augmented by multiple locally mediated (intraleg) mechanisms sensitive to leg position, state, and load (Dean et al., 1999).

## Discussion

In the near future, interactions between theoreticians and experimentalists should be fruitful in many but not all respects. Neuroscience clearly needs computational neuroscientists using simulations of biological nMPGs to represent acquired knowledge and test its completeness. Artificial neural networks provide new tools and, more important, reemphasize several concepts that have important implications for interpreting physiological experiments (e.g., Robinson, 1992): (1) the common currency in neural networks is neuronal activity; (2) this activity need not be simply related to physical parameters; (3) processing is distributed and parallel; (4) redundancy contributes robustness; and (5) approximations may suffice.

Neural engineers naturally look to animals for inspiration in improving technical systems, expecting concise lists of biological solutions for different computational problems. Because animals are so diverse, neuroscience provides only rudimentary guidelines. Each species has its own answer to a very complex and specialized problem, an important part of which is reproduction. Genes and development constrain animals to evolve in small steps that are themselves adaptive, or at least not seriously detrimental. In contrast, technological innovation can create radically new machines; prototypes hopelessly outperformed by existing technologies are not doomed to extinction.

Nevertheless, the very diversity of biological solutions enhances what biology has to offer. Better understanding of biological MPGs should help algorithm selection for technical applications, especially as artificial networks approach the complexity of biological networks in size, connectivity, unit properties, and plasticity. Optimization techniques based on biological learning or evolution already help adapt control systems (see LOCOMOTION, INVERTEBRATE). *Animat research*, by studying real robots, shows that implementing MPGs in real robots sometimes simplifies control and representation issues. Purely reactive robots, with integration at the effectors and no explicit world models, can generate astonishingly complex behavior. Optimally balancing reactive control with implicit and explicit representations is a current challenge for animat research; understanding biological implementations is a challenge for neuroscience.

# Motor Primitives

*Simon F. Giszter*

## Introduction

The concept of a modular organization of spinal motor systems dates back to Sherrington (1910) or earlier (see citation in Giszter et al., 2001a). Recently, a new perspective on motor system modularity (and especially spinal cord) has developed as a result of a series of experiments on the spinal cords of frog, rat, and cat. It has been proposed that a set of motor elements termed "motor primitives" are implemented in the spinal cord. These are recruited by central pattern generators to construct spinal motor acts. Data from the frog have been especially significant in this framework (see SCRATCH REFLEX). The frog wiping behaviors have been utilized in the study of motor control since the nineteenth century. The advantages of these behaviors are the clear adjustments documented, the simplicity of aspects of frog motor organization, and the robustness of the behaviors. The frog's wiping responses are largely organized in the spinal cord: they persist unaltered following spinal transection (i.e., in the isolated spinal cord). Examination of wiping movements and microstimulation of frog spinal cord (and more recently an examination of descending controls) has generated a framework for describing the basis of spinal construction of motor behavior. Movements are constructed as a sequencing and combination of a collection of force-field motor primitives or fundamental elements. Although controversial, because the biological circuit underpinnings are not yet well established, this framework is proving promising, and to date, it is holding up under careful experimental scrutiny and implementation in robots (see Schaal, 1999).

## Properties of Force-Field Motor Primitives

Microstimulation of frog spinal cord in intermediate gray regions using low currents (1–10 $\mu$A, 0.5-ms pulses at 40 Hz for 300 ms) activates a few hundred or thousand cells and elicits specific groups of muscle responses. With the spinal frog held immobile in an isometric apparatus, these muscle responses could be characterized as an endpoint (ankle) force vector and a vector of associated joint torques (see Giszter, Mussa-Ivaldi, and Bizzi, 1993). This measurement was repeated at multiple limb configurations and stimulus strengths. At a single configuration, over time, and at increasing stimulation strength up to 15 $\mu$A, the orientation of force elicited from a single site remained fixed, while the amplitude was modulated. By moving the limb to new positions, the effects of muscle-length-dependent viscoelastic properties, moment arms, and the effects of linkage kinematics on endpoint force and joint torques could be assessed. These effects were summarized by expressing the endpoint force as a function of endpoint position, or the joint torque vectors as a function of limb configuration (see, e.g., force fields measured in this way for a behavioral response in Figures 1*F* through 1*H*). When data were expressed in this way, it was discovered that the magnitude ratios and relative orientations of vectors across the range of positions remained fixed for a single site (Figure 1*H*). Force measured in isometric conditions could be expressed as a function of stimulus amplitude (*s*), configuration (*r*), and time (*t*) as

$$F(r,\ s,\ t)\ =\ A(s)\cdot a(t)\cdot \phi(r) \qquad (1)$$

where $A(s)$ was a scalar function of stimulus strength and $a(t)$ was a scalar function of time; $\phi(r)$ was a fixed field structure that was simply scaled, was conservative, and was often convergent in both limb joint and limb endpoint coordinates. The function $a(t)$ varied with site of stimulation. There were phasic, tonic, and phasic/tonic sites (Giszter et al., 1993).

When the electrode was moved a small distance in spinal cord a similar field $\phi(r)$ was obtained. However, for larger changes in position of the electrode in spinal cord, the force pattern could alter significantly. Over a sampling of the lumbar spinal cord intermediate gray using microstimulation (see Bizzi et al., 2000; Giszter et al., 2001b), chemical stimulation (Saltiel, cited in Bizzi et al., 2000), or combined skin and microstimulation, a small set of force-field types was found. About six force-field patterns were found in all, separated in middle and deep intermediate zones by relatively silent areas (Giszter et al., 2001b).

Combination of stimuli applied to ipsilateral areas producing different force-field types resulted in one of two effects for costimulation: (1) In 85% of combinations, linear superposition or vector summation occurred (see Equation 2); (2) in 15% of combinations, winner-take-all occurred with one site dominating response (see Equation 3). Graded motion of a limb could be obtained by controlled costimulation. The combinations observed are consistent with modular construction of reflex responses; and see Mussa-Ivaldi (cited in Bizzi et al., 2000) and the section below entitled "Wiping Motor Pattern Construction and Control Using Force-Field Primitives." In summary, for ipsilateral costimulation, either linear or winner-take-all combinations occur:

$$\begin{aligned} F(r,\ S_1,\ S_2)\ &=\ B\cdot[\Phi_1(r,\ S_1)\ +\ \Phi_2(r,\ S_2)] \\ &=\ B\cdot[A(S_1)\phi_1(r)\ +\ a(S_2)\phi_2(r)] \qquad (2)\end{aligned}$$

or

$$F(r, S_1, S_2) = B \cdot [\Phi_1(r, S_1)] \tag{3}$$

where $B$ is a scalar scaling parameter and $A$ and $a$ are scalar functions of stimulus strength.

More recently, costimulation between contralateral sites has also been tested (Giszter et al., 2000a). For bilateral costimulation, some spinal cord regions do show nonlinear responses to costimulation while the remainder obey the combination rules above (Giszter et al., 2000a). Taken in total, these effects are consistent with microstimulation providing access to primitives and parts of the CPGs that can be combined in various ways.

## Localization and Circuit Underpinnings of Motor Primitives

It is worth considering how microstimulation recruits cells and what the underpinnings of the functional relations observed above might be. The next sections demonstrate the functional uses of primitives in theory and real behavior, but the circuit underpinnings of these primitives are poorly understood, and the initial microstimulation that was used remains extremely controversial. Microstimulation as a technique of mapping has often been used. However, the laminar, nucleated, and segmentally organized spinal cord, such maps are harder to interpret and understand than, for example, in cortical columns. Spinal cord's recursive or looped projections, as opposed to simple output cascades, are confounding factors. Thus, although mappings with microstimulation or chemical stimuli reveal topographies, they may not reveal the localization (if any) that can be ascribed to primitives (Bizzi et al., 2000, and Giszter et al., 2001b). Rather, they are hot spots for more or less pure access to (and control of) primitives, which is entirely different. The circuit underpinning of the primitive may be discretely localized, broadly distributed, or an emergent pattern or mode of the spinal circuitry. Nonetheless, the fact that the circuitry supports these computational and functional primitives and that they may be accessed and combined in different ways through different localized sites is an important contribution. It may affect understanding of both motor control and neuroprostheses. Important future tasks are discovering how the circuitry supports primitives and how to link this meta-organization of primitives to the enormous body of exquisite physiology and anatomy of the spinal cord elaborated in the last 50 years by groups in Sweden, Denmark, Russia, Britain, Canada, and the United States. Some of the recent findings provide a series of strong hypotheses for this future work.

## Capabilities of a System of Primitives: Theory

Important theoretical issues for motor primitives are (1) how to build time-varying field structures from motor primitives to support movement, (2) discovering the motor primitive basis sets that best provide general approximations and stability guarantees, and (3) discovering how appropriate basis sets might be constructed and modified by developmental or learning mechanisms.

Initially, Mussa-Ivaldi (1992, cited in Giszter et al., 2000b) showed that arbitrary fields were readily approximated by using a linear combination of conservative and circulating (or rotational) radial vector field primitives. In biological testing, circulating fields accounted for less than 5% of the variance of field structures observed. This concept has now been applied in the frog and in human biomechanics (see Equilibrium Point Hypothesis). The coefficients of these basis-field elements could be found by standard methods.

Mathematically, the force field $F(x)$ relating force to position $x$ can be approximated by using $k$ basis fields $q_i(x)$ and control parameters $c_i$:

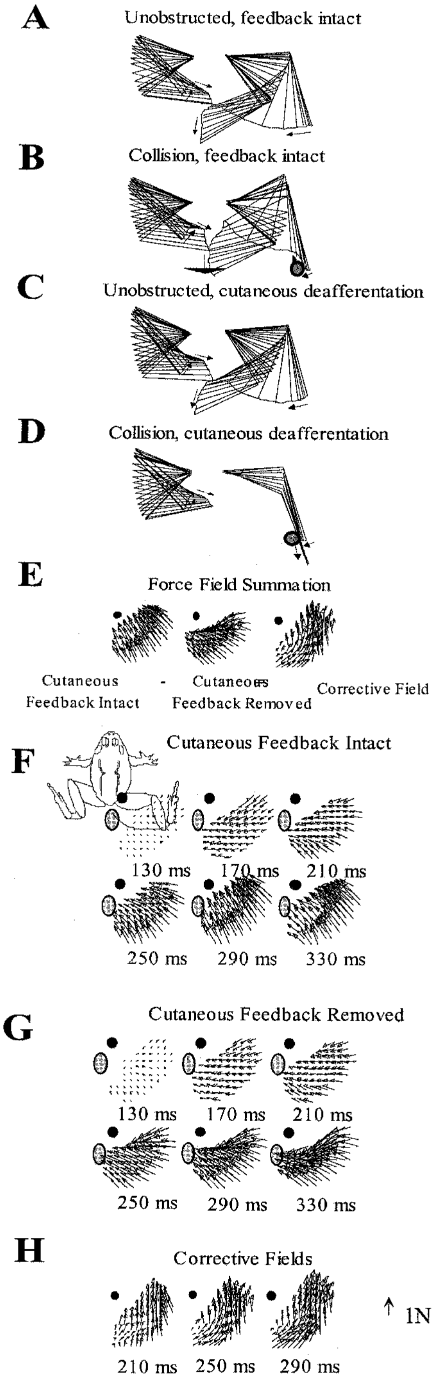

**Figure 1.** Examples of spinally organized responses and their force-field bases (redrawn from Giszter et al., 2000a; Kargo and Giszter, 2000). Upper panels: free-limb kinematics; lower panels: isometric force-field measurements. *A*, normal wipe trajectory. *B*, corrections to obstacles. *C*, loss of skin feedback from the effector limb (right limb) does not alter free trajectory. *D*, Corrections for collisions are abolished by loss of skin feedback. *E*, At each of a grid of ankle locations, the isometric force production is measured at the ankle. The correction response pattern is hypothesized to be due to vector summation of a corrective force-field primitive with the unperturbed pattern. *F*, field pattern with collision detection. *G*, field pattern without correction. *H*, Corrective primitive obtained by subtraction (i.e., *G* from *F* as described in panel *E*). The force pattern is a scaled version of a single pattern at each time point shown, consistent with definitions used for a force-field primitive (see text). Data collected and published in Kargo and Giszter (2000), with support of NIH NS34640 and NS40412.

$$F(x) = \sum_{i=1}^{k} c_i q_i(x) \qquad (4)$$

The $k$ basis fields $q_i(x)$ are subdivided into two groupings. These two groupings consist of **k**/2 conservative or irrotational fields and $k/2$ solenoidal or circulating fields. Thus,

$$F(x) = C(x) + R(x) = \sum_{i=1}^{k/2} q_i(x) + \sum_{i=k/2+1}^{k} q_i(x) \qquad (5)$$

where $C(x)$ is a pure conservative field and $R(x)$ a pure solenoidal field. Circulating fields have curl and can be used to generate energy in closed cycles. In biological measures to date, $R(x)$ is generally found to be sufficiently small that it can be neglected.

Given a set of $j$ sampled (or planned/desired) force vectors $\mathbf{P}_i$ at locations $x_i$ the task of a planner is to find the control vector $\mathbf{c}$, which minimizes the error $e$ given by

$$e = \sum_{i=1}^{j} [F(x_i) - P_i]^2 \qquad (6)$$

Depending on the number of samples ($j$), a minimum norm, an exact, or a least squares approximate solution can be found.

Applying the Mussa-Ivaldi vector field work to the motor system in the nonredundant limb allows approximation of arbitrary smooth vector fields. However, it follows that the planning and choice of the control fields to be approximated must be obtained in some other manner.

Serially redundant manipulators might pose difficulty for the use of this class of models in many biological systems. A study of how far the mechanism of basis field summation might apply to serially redundant planar linkages Mussa-Ivaldi and Gandolfo suggested that in serially redundant linkages a close approximation to vector summation may occur among a large fraction of randomly chosen control primitives. Mussa-Ivaldi (1997) extended these analyses to human-like movement trajectory construction. Use of force-field construction for motion generation in a nonconvex work space can be used for obstacle avoidance and navigation (see Khatib et al., 1999, and POTENTIAL FIELDS AND NEURAL NETWORKS).

More recently, Kargo and Giszter (2000) have proposed on experimental grounds that the primitives should ideally be considered as viscoelastic fields of specific durations (therefore wavelet-like in behavior) and that the approximation problem for biological motor control can be formulated as

$$F(r, \dot{r}, \mathrm{t}) = \sum_i A_i \cdot a(b_i t + \tau_i) \cdot \Phi_i(r, \dot{r}) \qquad (7)$$

where $A_i$ are scalar amplitude parameters, parameters $b_i$ control frequency of a fixed waveform given by function $a$, $\tau_i$ is a phase parameter, and $\phi_i(r, r')$ are the viscoelastic force-field primitives.

Collections of primitives might be used in several ways. Planning and calculating how to combine primitives to approximate a desired field structure is one task that the CNS could perform for each behavior and perhaps each individual instance. In principle, arbitrary field structures and field time courses can be generated by the techniques of basis field approximation. However, as discussed, this flexibility implies that planning the details of these processes must be deferred to other mechanisms. In biological terms, collections of primitives could also be used in low-level motor behaviors driven by CPG oscillators, reflex stimuli, and simpler reinforcement and decision systems to elaborate simple protective actions and perhaps to bootstrap higher motor organization in mammals. Alternative models can be developed in this framework (Giszter et al., 2000b; see also Eliasmith and Anderson, 2000). Clearly, motor primitives could be used in each of these ways in biological systems.

Ideal primitives should provide specific stability guarantees in movement construction and execution. The biologically identified motor primitives simulate passive systems. When they are examined in viscoelastic terms, it is speculated that they may also represent contracting systems, which provide specific stability guarantees when combined in different arrangements (see Slotine and Lohmiller, 2001). The relationship of primitives to contracting systems awaits experimental testing.

It is also important to relate the motor primitives and elements discussed above to rhythmicity and CPGs (see Kiehn, Hounsgaard, and Sillar, 1997). Recently, Sternad et al. (2001) have strongly argued the need for use of limit cycle oscillating "primitives" in human and robot movement construction to synthesize timing. CPGs and limit cycle systems (see MOTOR PATTERN GENERATION) are a huge area that can be mentioned only briefly in this context. The relationship of timing or phasing systems to the force-field primitives discussed above is unclear in the biological data. The role of oscillation and timing in motor learning is clearly significant (Sternad et al., 2001). Kargo and Giszter (2000) have argued for a separation of rhythm and sequence generation from the force-field motor primitives used in execution. Several investigators are actively examining oscillating or "limit cycle primitives" and stability guarantees for these (e.g., Slotine and Lohmiller, 2001; Eliasmith and Anderson, 2000). It is possible that a hierarchy of different types of modules may form the basis of rapid motor development, flexible movement construction, and motor learning.

How force-field primitives are initially constructed and established in a motor system is an important issue that has also recently been considered. Todorov and Ghahramani have advanced the notion that the biological primitives that have been observed can be predicted as the result of a developmental process of system identification of a compact basis. The basis set that is obtained is able to jointly represent the limb dynamics and sensorimotor relationships in the neural control (unpublished work in progress; see also Mataric, Zordan, and Williamson, 1999, and Fod, Mataric, and Chadwicke Jenkins, 2002).

## Motor Primitives in Real Behaviors: Biological Motor Control

### *Wiping Motor Pattern Construction and Control Using Force-Field Primitives*

The task of wiping movements consists of locating a stimulus on the body surface and executing an action that removes it. The task involves many elements of sensorimotor behavior seen in more complex and voluntary acts. The animal subdivides the task as follows: (1) It moves together the body segment on which the target stimulus is located and the effector limb, closing the kinematic chain, and (2) it executes a movement that removes the irritant. These subtasks require the frog to transform skin location, limb configuration, and body scheme to (a) select an appropriate effector, (b) select a set of postures and limb trajectories for the effector, and (c) generate a set of appropriate muscle activations to control and move the effector through these postures and trajectories. Each stage involves ill-posed problems; that is, there is a set of many possible solutions to the problem, from which one must be selected.

A wiping strategy normally consists of a sequence of trajectories and postures. As an example, the kinematic postures and transitions (note, for example, placing and aiming) that are observed in wipes to the opposite hindlimb are summarized in Figure 1*A*. For some types of wipes, particular phases are optional and need not be executed during each cycle. Thus, in wiping to the back, extension may be omitted, flexion may be omitted, and whisk and flexion may be blended in both intact and spinal frogs (see Berkinblit, Feldman, and Fookson, 1986). It is clear that body scheme information is used to control wiping. This frequently involves active posturing of target limbs. Initial experiments on force-field primitives suggested a linkage of force-field primitives and elements of reflex behaviors such as wiping (Giszter et al., 1993). This linkage is now much more firmly established. Both flexion withdrawal and wiping (Giszter et al., 2000b) have been shown to be composed of sequences and combinations of force-field primitives. In wiping, hip and knee extensor deletions in the motor pattern (which were first observed by Stein's group in turtle scratch; see SCRATCH REFLEX) represent deletions of specific force-field primitives (Kargo and Giszter, 2000). An example of kinematic corrections and the isometrically measured correction force-fields taking this form are redrawn from Giszter et al. (2000b) (based on original work in Kargo and Giszter, 2000) and shown in Figure 1.

Rapid online corrections of wiping trajectories (Figure 1*B*) can be shown to occur by inserting specific force-field primitives into the ongoing behavior as a result of obstacle collisions (Figure 1*F*; Kargo and Giszter, 2000). The fields without correction (Figure 1*G*) can be subtracted from those in Figure 1*F* (e.g., as in Figure 1*E*) and lead to a fixed structure field (Figure 1*H*). Setup and adjustment of the motor pattern and trajectory and response to muscle vibration can all be described as amplitude or phase modulation of force-field primitives that are combined by the spinal cord of spinalized frogs according to the rule in Equation 7 above with parameter $b$ fixed for all primitives, that is,

$$F(r, \dot{r}, t) = \sum_i A_i \cdot a(t + \tau_i) \cdot \Phi_i(r, \dot{r}) \qquad (8)$$

### *Descending Control and Force-Field Primitives*

d'Avella and Bizzi have extended the spinal results to less reduced or intact preparations and have shown that a small basis set of muscle patterns and force patterns observed in the spinal frog represent a major fraction of the basis for vestibular correction (Bizzi et al., 2000) and intact behaviors.

## Force-Field Primitives in Mammals

Force-field primitives of properties closely resembling the frog data are found in rat (Tresch and Bizzi, 1999) and cat, respectively. This framework in mammals suggests a new generation of functional electrical stimulation neuroprostheses stimulating either motor pools or interneuron pools to recruit single muscles or ensemble primitives (see Giszter et al., 2000b, for review). The relationship identified interneuron systems such as the C3–C4 and L3–L4 interneurons (found in the cervical [C3–C4] and lumbar [L3–L4] segments of mammalian spinal cord) remains to be explored.

## Primitives in Voluntary Movement and in Motor Adaptation

Decomposition of human motor acts into a few summed elements has now been achieved by various laboratories (see publications of Sanger et al., cited in Kargo and Giszter, 2000). The use of the idea of motor primitives in describing effects in motor learning has gained support from the work of Thoroughman and Shadmehr and of Matsuoka and Bizzi (see Giszter et al., 2001a). How these elements used in learning and adaptation relate to spinal structures remains to be seen. The relationship of the primitives used to approximate and generalize the control of a trajectory in a novel environment and the primitives that are established as a basis set in reflexes in spinal cord of "lower" animals is clearly an important area. The higher-level elements of motor learning may represent more spatially localized patterns of recruitment, activation, and combination of the whole limb spinal primitives. However, it is also likely that completely novel primitives are elaborated in development and learning, for example, in motor cortex and cerebellum, to augment the spinal "bootstrap" or reflex behaviors and expand the domain of movement possibilities through life in a variety of ways (see Giszter et al., 2001a). How the construction and plasticity of primitives are organized in mental development and then later during the learning of novel motor acts or after trauma in adults is a fascinating and important area of investigation.

# Motor Theories of Perception

*Carol A. Fowler, Bruno Galantucci, and Elliot Saltzman*

## Introduction

Motor theories of perception propose that there is recruitment of the motor system or of motor competence (i.e., knowledge) in perception. Perhaps the best known motor theory of perception is Liberman's motor theory of speech perception (see Liberman, 1996, for a history and overview of the motor theory). Within speech science, despite its prominence, the theory has been judged implausible on several grounds. However, in the larger field encompassing studies of perception, action, and their coupling, it is given more credence. It is instructive to consider why the judgments differ between speech experts and experts in the broader domain.

In the following, we outline the motor theory of speech perception and describe some of the findings underlying its development. Next we offer reasons why speech scientists have doubted especially one of its two central claims, namely, that the speech motor system participates in speech perception. Then we suggest why the reasons are not sufficient to refute the claim, and we show that it acquires credibility when it is set in the larger context of investigations of perception, action, and their coupling. In addition, we summarize research that suggests a neural system consistent with Liberman's largely undeveloped ideas about neural support for speech perception. The discovery of mirror neurons in primates (Rizzolatti and Arbib, 1998) provides an existence proof of neuronal perceptuomotor couplings.

## The Motor Theory of Speech Perception

Although in alphabetic script, consonants and vowels are discrete, their expression in acoustic speech signals is not. This is because speakers coarticulate speech gestures; that is, they produce the articulatory gestures of successive consonants and vowels in a temporally and spatially overlapping manner. Gestures are linguistically significant actions of the vocal tract. More specifically, they are equivalence classes of articulatory patterns controlled with respect to linguistically significant goals defined in an abstract task space. Consequences of coarticulation are evident, for example, during production of the word *to* when activation of the vowel /u/ 's lip protrusion gesture overlaps the activation of the consonant /t/'s lingual gesture (compare *tea*). Due to coarticulation, acoustic speech signals are highly context sensitive, and they lack a discrete segmental structure.

Liberman developed a motor theory of speech perception when he and his colleagues found that speech percepts track articulation more closely than the acoustic signals to which articulation gives rise. Two experimental findings were especially telling. One was that, in the synthesized syllables /di/ and /du/, the critical acoustic cues for /d/ were quite different, owing to the effects of coarticulation by the different vowels. Indeed, the cues were audibly distinct when presented in isolation to listeners. However, the gestures for /d/ are the same in natural productions of the two syllables, and the consonants sound alike. A complementary finding was that the same acoustic cue was identified as /p/ before /i/ and /u/, but as /k/ before /a/. Because of coarticulation, to generate the cue before /i/ or /u/ requires production of /p/, whereas to generate it before /a/ requires production of /k/.

Both findings suggested to Liberman that when articulation and acoustic patterns diverge due to coarticulation, perception tracks articulation, a central claim of the motor theory. Subsequently, many other findings (see Liberman, 1996, for a review) converged on the same conclusion. A notable one is the McGurk effect (McGurk and MacDonald, 1976), in which a video of a speaker mouthing one syllable, say, /da/, is dubbed with a different acoustic syllable, say, /ma/. Listeners hear a syllable (/na/ in the example) that reflects integration of gestural information from both modalities.

In Liberman's view, recovery of articulation in speech perception implies recruitment of the motor system. Such motor recruitment is required because of coarticulation in speech production. Speech information must be transmitted rapidly, and the gestural overlap provided by coarticulation permits efficient packaging of consonants and vowels. However, coarticulation has other consequences, including context sensitivity in acoustic information for phonetic segments. Therefore, two specializations, one for coarticulating and one for perceiving coarticulated speech, are needed, and, because neither specialization is useful without the other, they had to coevolve. Moreover, given the motor character of the percept, and Liberman's view that this reflects recruitment of the motor system in perception, the inference was plausible that the specializations were one and the same: a phonetic module. By using gestures as a common currency for talkers and listeners, the module helps guarantee achievement of parity between them—that is, sufficient equivalence between phonological messages sent and received, a necessity for successful communication.

## Speech Science: The Implausiblity of the Motor Theory

Following are grounds on which the motor theory of speech perception has been judged implausible, and then some reasons why we reject each argument.

1. Many speech scientists (e.g., Ohala, 1996) deny that speech percepts have a motor character, and they have no other reasons to suppose that the speech motor system is involved in perceiving speech.
2. Liberman and colleagues wrote very little about how the speech motor system might participate in speech perception, and the mechanism that they typically alluded to (analysis by synthesis) is not obviously workable at the rates at which consonants and vowels are perceived.
3. Listeners' perception of speech gestures need not imply that the speech motor system is recruited in speech perception. This is because the acoustic signal, having been caused by the gestures, and taking distinctive forms for distinct gestures, provides information about them. Listeners perceive gestures because that is what the information in acoustic speech signals is about.

We will address the first objection here only by remarking that, in our opinion as in Liberman's, evidence in favor of perceiving motor gestures is substantial and unrefuted. For example, we know of no studies that refute the evidence we cited in the previous section in favor of the claim that, when articulation and acoustic patterns diverge, perception tracks articulation. As for the other two objections, however accurate they may be, neither refutes the motor theory's claim of motor system recruitment in speech perception. As for the second objection, even if the particular mechanisms proposed by Liberman and colleagues are not the ones that support speech perception, it does not follow that no mechanism involving a production-perception link does the job. As for the last objection, even though acoustic speech signals provide information about speech gestures, that does not preclude a perceptual mechanism in which the speech motor system or motor competence participates in decoding the acoustic signal.

## The Broader Scientific Field: The Necessity for Motor Theories?

In the broader scientific field, central theoretical ideas of Liberman's motor theory recur (e.g., Viviani and Stucchi, 1992), and there are research findings suggesting motor involvement in perception. We review one example of a theoretical view that shares critical ideas with those of Liberman and then summarize a few of the research findings.

### *A Related Idea*

Prinz (e.g., 1997) addresses an issue that arises in the study of perceptually guided action and that is very much like the one we have labeled parity. In speech, *parity* refers to the relation between messages sent and perceived. The messages must characteristically be the same; otherwise communication fails. Prinz has raised the same issue in asking how perception can guide action under the common assumption that percepts are representations of sensory information, and planned actions are coded in purely motor terms; that is, they lack a common currency. He proposes instead that percepts and actions share a common code. Further, consistent with the motor theory's identification of gestures as the common currency of talkers and listeners, and with the hypothesis that gestures are represented in the task spaces of talkers and listeners (SPEECH PRODUCTION), Prinz's *action effect principle* invokes a common code that represents not the proximal stimulus, but the relevant distal event properties. (*Proximal* refers to the signals that stimulate the sense organs, whereas *distal* refers to the environmental events that causally structure the proximal stimuli). Prinz's research shows, for example, that when stimuli that guide responses in some tasks share distal features with responses, response times are affected.

### *Research Findings*

The larger context of evidence, to which we alluded earlier, in which the motor theory gains plausibility includes evidence from communication systems of other animals, evidence of motor recruitment in perception of motion, and findings of mirror neurons. In each domain, we provide illustrative examples.

*Communication systems of other animals.* Male crickets produce mating calls to attract females. Females respond to the calls by moving toward the male, but they do not produce calls themselves. However, males and females show a remarkable symmetry. Different varieties of crickets produce different calls, and females prefer the calls of their own type. When crickets are hybridized by mating the male of one type to the female of another, the male's call exhibits components from the calls of both parental types. Remarkably, female hybrids prefer the hybrid call to the call of either parental type (Hoy, Hahn, and Paul, 1977). This suggests a genetic correspondence between neural systems supporting call production in males and call perception in females.

Evidence of perception-action coupling can be found within individuals as well as between them. In zebra finches, the neural system supporting call production also responds to components of auditorily presented songs (Williams and Nottebohm, 1985). A major path for song production in the zebra finch brain begins at a "higher vocal center" (HVc), which projects to the robustus archistriatum (RA) and from there to the tracheosyringeal portion of the hypoglossal nerve (nXIIts). nXIIts innervates the muscles of the syrinx. The HVc and nXIIts both respond to tone bursts, and motor neurons in nXIIts are differentially responsive to different components of perceived songs. Hauser (1996) concludes that "in order for birds to perceive the proper acoustic features of a song syllable, the percept must be converted into a series of motor actions required to produce the sound" (pp. 148–149).

*Evidence in humans for motor recruitment in perception outside the speech domain.* The tangential velocity of curved movements made by humans is proportional to curvature according to a two-thirds power law, decreasing with increases in curvature (e.g., Viviani and Stucchi, 1989). Viviani and Stucchi have shown that observers' judgments of the shapes of ellipses being drawn on a computer screen (judgments as to whether the major axis is oriented vertically or horizontally) are affected not only by the form's shape, but also by its velocity profile. When ellipses were drawn with constant velocity—a profile characteristic, in natural drawing, of a circular form—perceivers' judgments were poor. Tracings of ellipses that adhered to the two-thirds power law were judged accurately. An implicit proprioceptive-motor, rather than visual, task (Viviani, Baud-Bovy, and Redolfi, 1997) provided similar results. Blindfolded participants' right arms were moved in elliptical trajectories that did or did not preserve the two-thirds power law. With the left arm, participants tried to reproduce the movement of the right arm. Shapes of reproduced trajectories were more accurate when ellipses traced by the right arm conformed to the two-thirds power law than when they did not. Together, these data show that motor competence, here knowledge about velocity constraints on biological movements, is brought to bear on perception of motion.

Other evidence for linkages between the motor and perceptual systems comes from experiments that manipulate the similarity between a stimulus-response pair and measure its facilitatory or inhibitory influence on motor performance (see Prinz, 1997, for a review). For example, Stürmer, Aschersleben, and Prinz (2000) had participants produce a grasping gesture (first close the hand, then open it) or a spreading gesture (first open then close). The task-relevant stimuli for the movements were color changes on a hand that was displayed on a computer monitor, with different colors signaling each task. The visible hand also produced a task-irrelevant gesture on each trial, starting and ending from a neutral half-open position. In one case, it closed and then opened; in the other, it opened and then closed. Although participants were told to ignore the irrelevant information, selecting their responses only on the basis of the color change, their response latencies were faster when their movements matched the irrelevant ones. That perception of a hand gesture interacts with the execution of a similar or dissimilar hand gesture provides strong evidence that the perceptual and the motor systems share a common currency.

*Mirror neurons.* The foregoing evidence, like the evidence underlying the motor theory of speech perception, suggests access to the motor system or to motor knowledge in perception. Recent findings of mirror neurons may reveal part of a neural mechanism that permits and promotes such access.

Rizzolatti and colleagues (see Rizzolatti and Arbib's, 1998 review) have found neurons in the premotor cortex of the monkey (area F5) that respond both when the monkey performs a given action and when it perceives a similar action performed by another monkey or by a human. Many mirror neurons are quite specific in firing during the performance of, say, one manual grasping movement but not another. Many of them exhibit the same specificity in the observed actions that stimulate them to fire.

There is evidence for mirror neurons in humans. Fadiga et al. (1995) used transcranial magnetic stimulation (TMS) of the motor area, in which stimulation provoked muscle activity in the fingers. During TMS, participants observed several events or situations: someone grasping an object, the stationary object itself, someone tracing shapes in the air with the arm, or the dimming of a light. The investigators found more TMS-induced muscle activity in the fingers when participants were observing grasping than when they were observing any other of the events. The modulation of muscle activity was specific to the actions observed. Fadiga et al. concluded that "in humans there is a neural system matching action observation and action execution" (p. 2609).

The finding of mirror neurons reveals neural systems that underlie perception-action coupling in monkeys and perhaps in humans as well. From the perspective of the motor theory of speech perception, it is intriguing that the neurons were found in an area of the monkey brain that includes the homologue of Broca's area in humans, which is involved in language use. The findings, therefore, lend credence to the motor theory's claim of a production-perception coupling in speech.

## Discussion

The motor theory of speech perception has inspired analogous theories in other domains. Yet the theory was motivated by requirements of speaking and listening that Liberman considered special to speech. Is speech special in respects that should discourage efforts to generalize some of its proposals to other domains? We suspect not.

As we have noted, talkers and listeners must characteristically achieve parity to communicate successfully (Liberman, 1996), and parity achievement requires use of a common currency by talkers and listeners. That the speech percept has a motor character suggests that this common currency is defined in gestural task space: listeners *detect* the proximal acoustic signal, but they *perceive* the distal gestural activities of talkers. According to the motor theory, gesture perception is fostered by motor recruitment in perception.

This is not very different from what is required for successful nonlinguistic transactions with the environment, including those with other actors. Although proximal energy patterns stimulate the sense organs, animals must perceive the distal possibilities afforded for action (e.g., Gibson, 1979; see also GRASPING MOVEMENTS: VISUOMOTOR TRANSFORMATIONS). For actions to be felicitous, parity is required among perceived possibilities for action, real possibilities for action, and action itself. This is real-world, functional perception-action coupling. Plausibly, neural-motor recruitment in perception fosters achievement of these parities as well as those of linguistic communication.

In much cognitive science research, perception and action are assumed to be sufficiently distinct and autonomous that they can be studied independently. However, consideration of the relations between animals and their environments uncovers no principled way to draw such a sharp distinction. Perception-action couplings are central to the design of animals. Understanding the real-world settings in which cognitive activity occurs reveals that it could not be otherwise.

## Introduction

Natural systems are based on parallel, distributed processing at many different levels. At the neural level, interconnected and concurrently acting neurons propagate signals among themselves such that coherent behavior emerges from their joint activity. Within the brain, different neural subsystems combine and exchange signals to work together to yield an overall intelligent nervous system. Beyond the boundaries of a single intelligent entity are other such entities, which together make up societies that achieve more than the individual entities can. Thus, what constitutes an "individual" can be highly subjective: what is an individual to one researcher may, to another, be a complex distributed system comprised of finer-grained agents. In this context, an agent's "granularity" corresponds to the amount of processing it does between interactions with others.

Research in artificial neural networks (ANNs) has concentrated on the finer-grained levels of intelligence evidenced in the brain, drawing on neurophysiology and psychology as sources of inspiration when trying to build computational models of such natural systems. Research in brain theory has dealt with different levels, from neurons to brain regions to humans. Finally, research in multiagent systems has focused on coarse-grained levels of individuality and interaction, where the goal is to draw on sociological, political, and economic insights to develop multiagent systems composed of autonomous interacting agents (Weiss, 1999). As such, there is ample room for comparison between the ANN, brain theoretic, and multiagent systems approaches. Much can be gained by comparing the different techniques used in these fields of study. Specifically, agents in multiagent systems must interact with each other. This interaction is often facilitated by the use of agent models. That is, agents either have or learn models of the agents with which they interact. Agents that learn models of other agents can do so by observing their past behavior. These models allow agents to avoid dealing with malicious or broken agents. In a system with many learning agents, we can expect agents to build nested models of the other agents—that is, models that include an agent's models of other agents, and so on. We might expect agents to build deeper and deeper nested models of each other in an effort to outguess each other. However, while there is some amount of deep-model escalation—agents building nested models of each other to greater and greater depths—some research (Vidal and Durfee, 1998) shows that these deeper models exhibit decreasing returns. By using their models of each other, the agents loosely organize themselves into self-reinforcing communities of trust.

Learning agents can use any type of learning, including ANNs. Although there has been very little research into this topic, ANNs seem like a promising learning technique because of their flexibility and ability to generalize. An agent that uses ANNs could learn about the "tags" that identify a cheating agent by extrapolating from a few examples. This would allow the agent to avoid unproductive future interactions with other agents that it has never met. Such behavior, when enacted by all the agents in the system, would speed up system convergence and discourage cheating agents more rapidly. Furthermore, the dynamics generated by a system composed of many learning agents are not unlike the dynamics of an ANN. Some of the same problems of credit assignment and propagation of rewards arise in both of these systems, even if the protocol details are different.

Brain theory can be related to multiagent systems at many levels. At one level brain theory considers neurons as agents. That is, it considers them as a basic behavior unit. Unlike agents in a system, neurons do not engage in complex interactions with other neurons. However, neurons have predefined rules of encounter. For example, a neuron can "count on" the signals of a particular input line carrying specific information. These simple rules enable coordination of the system of neurons. Similar rules are often used by multiagent systems to achieve coordination. At a higher level, brain theory considers brain regions as agents. These agents are more complex and might start to derive a benefit by considering other brain regions as agents and trying to build models of them or trying to interact with them using multiagent techniques. At an even higher level, brain theory considers people as agents. At this level we might wonder if the theories developed for the construction and control of artificial multiagent systems might be useful in either explaining or guiding collective human behaviors.

We can also contrast the various abstraction levels in brain theory to the two organizational varieties in multiagent systems: top-down and bottom-up. In a top-down approach, one or a few agents monitor the global performance of the organization and detect when a particular organizational structure is needed. Most typically, roles in the new organization are assigned (often through a contracting style of protocol) and the new organization is adopted (Corkill and Lesser, 1983). Alternatively, in a bottom-up approach, an agent monitors its own performance, decides when a change (such as to the tasks it itself performs) is in order, and unilaterally makes that change. This in turn could cause other agents to change what they are doing, and reorganization propagates throughout the network (Ishida, Gasser, and Yokoo, 1992). These techniques are similar to the brain theory studies of bottom-up organizational emergence as seen in neurons and the top-down organizational rules as developed and imposed by humans in their organizations.

In this article we will begin by categorizing the different types of agent interaction protocols that are being studied in multiagent systems, from cooperative problem solving among cooperative agents to coordination protocols for autonomous selfish agents. These will be explained in detail in later sections of this article, including brief overviews of the latest research in these areas. We conclude this article by summarizing some of the similarities and differences between multiagent systems and the fields of brain theory and neural networks, highlighting some potentially important areas for cross-fertilization between them.

## Agent Coordination

A central concern in distributed artificial intelligence (DAI) is the development of interaction protocols for the coordination of agents. System designers build protocols that determine how, when, and what the agents will communicate to each other. A good protocol should achieve the expected global goals while maintaining some independence between agents. The degree of independence depends on the particular application. For example, if the agents are robots in a large field, then we can expect them not to interfere with each other as long as they keep their distance. However, if these same robots are charged with the task of lifting a large object, then much tighter coordination will be needed. The amount of independence depends on the type of tasks the agents must achieve and on their interaction opportunities within the environment.

Agents often use commitments and conventions in order to coordinate (Jennings, 1994). *Commitments* are pledges from an agent that it will try to achieve a specified task. Commitments help other agents plan their actions without interfering with each other. *Conventions* specify when commitments can be broken and what the agents should do when this happens. In a typical system we can expect that unforeseen circumstances might force an agent to drop certain commitments, especially if the world the agent inhabits is changing. Conventions tell the agent how it can renege on its commitments without causing undue distress to the system.

DAI systems can be roughly separated into two categories: systems in which all agents share a common goal, and systems in which each agent has its own goals. When all agents have the same goal, the interaction protocol enables balanced task decomposition and allocation. That is, the interaction protocol divides and distributes the tasks among the agents so as to avoid overloading any resource or agent, handing agents overlapping or conflicting tasks, and leaving tasks unhandled. When all the agents have different goals, then a coordination protocol must be designed to align their interests with the designer's global system goal. We discuss these types of systems, and their protocols, in the next sections.

## Cooperative Problem-Solving Systems

In a cooperative distributed problem-solving system (Bond and Gasser, 1988), agents work together to solve problems that require them to cooperate. Research in this area takes two major forms.

One of these forms is represented by the functionally accurate/cooperative (FAC) paradigm (Corkill and Lesser, 1983), where problem solvers individually solve their local subproblems and share their partial results so that, over time, increasingly complete results get formed and the system solves the entire problem. Success is achieved when one or more agents construct and share a hypothesis that satisfies the solution criteria. Of course, the wholesale exchange of all partial results can bog down a system quickly, and so substantial effort has gone into the development of techniques by which cooperating agents could model each other to be smart about which results to share. These models have included organizational structures (Corkill and Lesser, 1983), partial global plans (Durfee and Lesser, 1991), and the TAEMS framework (Decker and Lesser, 1995). Another approach is to include team considerations from the beginning, which has led to research into team-oriented programming (Tambe and Zhang, 1998).

A complementary perspective on cooperative problem solving has viewed the process as sharing tasks rather than results. As embodied in the Contract-Net protocol (Smith, 1980), the task-sharing perspective sees the coordination problem as associating tasks to be done with the right agents to do them. In Contract-Net, for example, an agent with a large task to do would decompose it into smaller tasks, and then attempt to contract these out to the most suitable agents by announcing each subtask, collecting bids, and awarding the subtask. Because agents choose to bid on the tasks they receive, the assignment of tasks to agents involves mutual selection. A similar specialization occurs in the evolutionary structuring of the brain into specialized regions. Task sharing can also be coupled with result sharing, such that organizational roles could be contracted out, FAC would follow, and then tasks to implement the solution could be contracted out.

Continuing research in cooperative distributed problem solving has served to extend and refine the basic paradigms of task and result sharing, involving, among other things, the introduction of planning to the process, and the formulation of negotiation strategies for reaching a compromise between what different agents want that maximizes the overall system performance. Note, however, that in this discussion the emphasis has been on the overall system rather than an individual. The assumption is that agents in these systems are built with an implicit goal of doing whatever they need in order to improve the performance of the entire system. Although this assumption is often reasonable when building real systems, since we can design such agents, it does neglect the issue of how to get individual agents, each with its own selfish goals, to solve problems cooperatively. This issue has been the focus of a variety of research activities more recently, as the next section explains.

## Selfish Agents

Cooperative problem solving has been shown to be generally beneficial from a systemwide perspective, but many DAI researchers are concerned with how such cooperation might emerge when an agent can only see benefits to itself. In other words, what is the knowledge and reasoning that agents employ in making smart decisions about when to work together? Once they have adopted the goal of working together, then they can employ cooperative problem solving techniques to actually accomplish their joint activities.

One of the most fruitful fields for insights when investigating how selfish agents can still work together for their mutual benefit is economics. In fact, the use of economic techniques for coordinating multiagent systems is a very active area of research. The techniques used include voting, bargaining, and auctions (Weiss, 1999, chap. 9). Each technique has different strengths and weaknesses. They are all concerned with the making of rational decisions by a group of distributed agents, each with its own goals. These techniques usually involve several communication steps as well as rational decision making by the agents. They are very useful techniques for structuring the interactions between agents because they aggregate the individual agents' desires to form a global decision or allocation.

Auctions, for example, are very efficient methods for matching buyer and seller agents that are interested in the same good or service. The use of a single exchange currency allows an agent to externalize its utility with a single number that is understood by all other agents. If there are enough agents participating in the auction, then both buyers and sellers are generally guaranteed a fair price. Finally, the auction acts as a location service where all agents that are interested in the item can find each other and interact using the auction's bidding protocol, thereby eliminating the need for agents to find and try to talk directly to each other.

There are, however, some problems with auctions that echo the problems studied by economists. For example, just like their human counterparts, intelligent agents might be able to collude with each other and manipulate the auction's price to their benefit. This problem can be circumvented by changing the type of auction or by increasing the number of participants. A lying auctioneer who does not assign the winnings to the correct agent might also break an auction. Finally, auctions assume that all agents are trading exact instances of the same item. That is, they do not consider the possibility that one agent's products are of a higher quality than another agent's products. Economists often ignore minor differences in the quality of a good or, if the difference is great enough, they state that the different quality goods should simply be considered different goods altogether.

Even in the presence of agents that cheat or offer different quality goods, a stable system can often be achieved by allowing agents to use models of other agents. For example, if the agents see each other as rational, then they can make a deal allowing them to cooperate (Rosenschein and Genesereth, 1985). Alternatively, they can evaluate the performance of alternative strategies to select the cooperative strategy from a purely selfish view (Gmytrasiewicz, Durfee, and Wehe, 1991), leading to self-organization for their mutual benefit. Finally, they can use learning techniques to build models of other agents (Vidal and Durfee, 1998) and use these models to guide interactions.

Organization theory (Malone, 1987) has also looked at the problem of how organizations form and why individuals are willing to become parts of an organization. In joining an organization, an individual forgoes some of his freedom because he has now committed to performing some set of actions for others in the organization. He has also accepted dependencies on others. The positive side of the resulting web of commitments (Gasser, 1991) is that, when the agents abide by their responsibilities and while the circumstances under which the organization was formed hold, the payoff to members of the successful organization is higher than those members could have gained individually. So organization, under the right circumstances, is the rational thing to do. The remaining challenge, then, is in developing computational mechanisms by which individuals can detect that the circumstances are right for organizing and for performing the organizational self-design.

## Discussion

Given the information above, and the larger context in which this article is written, we now wish to delve deeper into the relation between multiagent systems, brain theory, and ANNs. They differ in many respects. One respect is clearly the granularity of computation relative to communication. Multiagent systems generally assume that communication is time consuming, error prone, and costly. Thus, communication decisions are made judiciously, and messages among entities in multiagent systems are at the symbol rather than signal level, encoding much richer semantic content.

Because communication is at such a premium, and because envisioning the impact of a message requires a model of the hearer of that message, agents in multiagent systems usually have explicit models of other agents, including their interests, abilities, and expectations. Decision making in agents is thus a complex process of mapping potential actions (including communication acts) into explicit models of the anticipated activities of others, leading to a wide range of behaviors. Often, to anticipate the actions of another, an agent will execute its inferencing processes on its model of that other agent, drawing conclusions about what the other agent could be thinking or doing by "putting itself in the other's shoes."

In brain theory, this implies that an agent should be able to ignore its current state and instead to "think" as if it were another agent. Because such projection requires an agent to be able to disconnect from its own reality and superimpose that assumed of another, this implies that models of the mind must provide a higher-level override capability to control the processing of the parallel brain regions and schemas. In this way, the same machinery that an agent uses to control its own actions can be used to predict those of others.

In ANNs the individual units are generally simpler, signal-processing elements, and the complexities arise from the sheer number of interconnections and the ways that those interconnections evolve over time. In multiagent systems, the primary concern has been to endow agents with knowledge about protocols, conventions, common goals, and so on right from the start, so that they can immediately interact efficiently; interaction is usually too expensive and slow to depend on "learning" how to interact. In many approaches to ANNs, the focus is precisely on learning, because interaction is cheap and fast in the tightly coupled, signal-propagating architecture assumed. Thus, in ANNs, important performance criteria include trainability, convergence, and robustness. Multiagent systems share the robustness criterion, but rather than the capability to learn, they focus on performance in terms of correctly and quickly coordinating activity to work as an effective team from the outset, making maximum use of resources at all times.

For example, having mobile robots learn to coordinate their movements by allowing them to learn from colliding is generally infeasible, since collisions can lead to disablement of the robots. In a multiagent approach (Montgomery and Durfee, 1993), the robots each plan their behaviors and then engage in a dialogue to efficiently isolate and resolve conflicting actions. Following a predominant paradigm in AI, the robots essentially engage in a distributed search through the space of joint behaviors, using a hierarchical representation to focus their search. Through the distributed hierarchical search, the agents can balance the costs of coordination with its benefits, to attain an appropriate level of coordination. As problems scale up, moreover, the agents can employ abstractions to represent teams of agents as single entities. Mobile robots performing deliveries, for example, are clustered into geographic teams such that a robot models only the other members of its team, and coordinates with other teams through the decisions of team leaders. Properties of the task and of the agents, known ahead of time by the agents, dictate appropriate decomposition and task-abstraction strategies that, in the best case, can reduce the time to solution from exponential in the single-agent case to logarithmic in the multiagent case.

However, even thought agents are usually endowed with the needed interaction protocols, it is often the case that these protocols leave the agent with many possible choices. For example, the fact that agents must interact using a Contract-Net protocol says nothing about which tasks the agents should bid on, or how much they should bid. In fact, the correct choice might depend on the current state of the system and of the other agents. These problems have led to the study of learning agents within multiagent systems. As mentioned earlier, this is an area where multiagent systems and ANNs share some similarities. Both of them try to understand the behavior of systems composed of adaptive agents. In the multiagent case the agents are more complex and loosely connected, whereas in ANNs the units are simpler and have fixed connections but can interact much more often. Still, many of the same mathematical tools used to understand the emergent behaviors in ANNs could be used to understand and engineer multiagent systems.

Another critical similarity between multiagent systems and ANNs is an emphasis on emerging intelligence—on the whole being more than the sum of its parts. From relatively simple neural units, complex patterns of activity can arise in neural networks; from cooperation and competition among schemas, intelligent behavior results; from rational choices among individuals, societies and civilizations (to anthropomorphize) emerge. As was alluded to at the outset of this article, all systems are distributed if you look closely enough, and it is the fact that the collection is more than the sum of its parts that allows us to call it a system rather than a collection of component parts. Whether simple or complex, communicating signals or symbols, distributed systems are a ubiquitous framework encompassing all of these studies. As such, these studies have common ground for sharing ideas and insights.

As a specific example of the opportunities in a cross-disciplinary study, a key concern in multiagent systems, as in ANNs, is in how to propagate global feedback such that individual entities can modify their behavior correctly. Multiagent systems suffer from the same credit/blame assignment problems as neural networks and schema systems. If the system as a whole performs well or poorly, which entities, and which interactions among entities, were responsible?

Propagation algorithms that have been developed for neural networks, multiagent systems composed of learning agents, and feedback loops that support reorganization in multiagent systems raise many common concerns. So far, the similarities and potential overlaps between the multiagent systems and ANN algorithms have not been widely studied.

Similarly, multiagent systems, brain theory, and ANNs are all concerned with timely and appropriate communication among computational units. The thresholding computations used in neural networks and the cooperative/competitive links among brain regions have analogues in multiagent systems that decide when a result is good enough to share, and how much to believe results received from others. Such analogies are, to date, not firmly understood, and represent opportunities for cross-fertilization.

# Muscle Models

*Thomas G. Sandercock, David C. Lin, and W. Zev Rymer*

## Introduction

Muscle is a remarkable mechanical actuator that transduces chemical energy into force and motion, thereby providing power to move the skeleton. Because of the complexity of this transduction and the intricacies of muscle microstructure and architecture, no comprehensive models have yet been able to predict muscle performance completely. For this reason, muscle models are widely used to fulfill a variety of more narrowly defined objectives, ranging from attempts to promote understanding at the molecular level to more practical simulations of whole-muscle behavior. These practical simulations are typically used as part of a broader study of basic musculoskeletal biomechanics or for issues of understanding neural control mechanisms.

Muscle models can be usefully classified in order of increasing complexity. The more elaborate models generally have a wider range of application and can give more accurate results. However, this increase in fidelity is achieved at the cost of an increase in the mathematical complexity, involving parameters that are often not known initially and are not readily measured. Aside from the mechanisms of force generation, many other processes, such as activation, potentiation, and fatigue, also play an important role. In the absence of a single model that captures all these features, models are usually simplified to include only those behaviors that are deemed of interest in a particular application. This article outlines three major model classes and provides guidelines for their application:

1. *Input-output models*. The simplest of models are "black box" input-output models that attempt to capture very specific behavior over a restricted range of operation. Such models commonly use linear transfer function descriptors to transform neural excitation into force.
2. *Lumped parameter mechanical models*. The next level in complexity is typified by lumped parameter mechanical models. These are often composed of combinations of linear mechanical elements such as springs and dashpots to create fairly simple viscoelastic analogs of muscle. Nonlinear relations representing hyperbolic force-velocity behavior and tendon properties can also be incorporated. Such models are usually termed "Hill models." The parameters characterizing the elements of these models are usually directly measurable by experiments. Model inputs may be neural excitation or length and force perturbations, while outputs may include muscle force, stiffness, and the time course of muscle length changes.
3. *Cross-bridge models*. More sophisticated "cross-bridge" models attempt to reproduce the dynamics of molecular processes that are responsible for force generation in muscle. These models incorporate mathematical descriptions of the dynamics of cross-bridge populations, their driving chemical reactions, and the resulting mechanical consequences. Such models usually require knowledge of numerous parameters and rate functions for the underlying reactions. Most of these parameters are not directly measurable, making the fitting of the model to a specific muscle or experimental situation difficult. Again, inputs can consist of neural excitation pulses or mechanical perturbations, while various outputs can be obtained from such a model, ranging from mechanical variables to thermodynamic information.

We next summarize briefly the relevant basic physiology of muscle. See McMahon (1984) for more details.

## Muscle Architecture

A muscle is composed of many long, thin cells, or fibers, arranged parallel to each other. Most fibers terminate in microtendons, which merge to form a common tendon that connects to the skeleton. Because of this parallel organization, the total force a muscle can produce is proportional to the summed cross-sectional area of all the fibers. The fibers are, in turn, composed of several thousand parallel myofibrils. Each myofibril is composed of repeating microscopic units (2–3 $\mu$m in length) called sarcomeres, which are the basic contractile units of muscle. Since sarcomeres within a fiber are linked in series and contract together, many key muscle properties, such as the maximum speed at which a muscle can shorten, are proportional to the length of the fiber. For this reason, muscle contractile properties are often normalized by both the muscle cross-sectional area and the fiber length (Zajac, 1989).

Muscles come in an array of sizes and shapes, reflecting differences in fiber length, fiber number, and fiber orientation. There are also systematic differences in biochemistry and metabolic properties. See Alexander (1981) for a discussion of muscle and tendon architecture and Burke (1981) for a discussion of muscle fiber and motor unit specialization.

## Input-Output (System) Models

At the simplest level, muscle may be treated as a linear system, usually of second order, with a single input and single output (SISO). In fact, since muscle has many simultaneous inputs—primarily neural activation, but also length, force, temperature, and so on—additional constraints on the system are required to apply linear systems approaches.

For example, Mannard and Stein (1973) modeled isometric cat soleus muscle as a linear system, with a neural pulse train input and a force output. Here, motor axons were excited by a random electrical pulse train, and the resulting force data were well fitted by a critically damped, linear, second-order system. Essentially, this muscle acted as a low pass filter, with a cutoff of 5 Hz. Difficulties with the linear systems approach became apparent when slight changes were made in the experiment. By changing the amplitude of the input (mean stimulus rate to the ventral roots), system gain changed by more than a factor of 4, and the cutoff frequency ranged from 8 to 2 Hz. Changing muscle length also changed the system parameters. Thus, the linear approximation assumed by this model holds true only for closely specified conditions.

There are several other nonlinearities in muscle that limit the usefulness of the linear systems approach. First, active muscle behaves quite differently when it is shortening than when it is lengthening—behavior that is inconsistent with linear system properties. For example, if active muscle is stretched rapidly, force may drop precipitously after an initial region of high stiffness, giving rise to muscle "yield." Second, muscle force shows marked hysteresis when measured during increasing neural activation compared with decreasing activation.

Because a SISO linear system model is at best an approximation, the model must be identified for the specific application for which it is used. Attempts to identify a more broadly applicable model by using nonlinear system techniques generally fail because muscle is quite nonstationary and the system changes before it can be fully characterized. Advances in nonlinear techniques may make this a viable approach. For now, the linear systems approach has the advantage of its well-developed theoretical background, which allows relatively simple system identification techniques to be implemented.

## Lumped Parameter Models

The earliest experimentally based descriptions of muscle resulted in muscle models that were composed of viscoelastic elements. The most widely applicable of these models is that of A.V. Hill and can be described as follows: Muscle is composed operationally of three elements: (1) a contractile element (CE) that acts as an active force generator, (2) an elastic element (SE) that represents the combined stiffness of tendon and cross-bridges in series with the force generator, and (3) a second elasticity in parallel with the previous two elements (PE) that represents the passive tissue contributions to muscle force (Figure 1*A*).

Hill (1938) characterized the CE by applying a series of constant force inputs (i.e., an "isotonic load") to active muscle. Muscle responds to such an input by shortening with an initially constant velocity. Smaller loads result in larger velocities. Plotting a number of such force-velocity pairs demonstrates this trade-off (Figure 1*B*), which can be fitted well with a hyperbola of the form

$$V_{CE} = \frac{b(P_o - F)}{F + a}, \qquad F \leq P_o \tag{1}$$

where $F$ is the applied isotonic force, $V_{CE}$ is the resulting initial velocity of shortening, $P_o$ is the maximum isometric (velocity equal to zero) force, and $a$ and $b$ are empirical constants. Equation 1 has been found to describe the steady-state force-velocity behavior of a wide variety of skeletal muscles during shortening. The constitutive relation for the CE embodies this hyperbolic force-velocity trade-off.

The series elasticity is usually modeled as a purely linear spring of stiffness $k$, and the passive elasticity often takes the form of an exponential function that increases with extension. The total muscle length is the sum of the lengths of the CE and SE. The contribution of the PE depends on the precise muscle geometry but is often important only at long muscle lengths and is thus frequently neglected in practice. When passive tension is neglected, a single, first-order, ordinary differential equation expresses the dynamics of this model with force, $F$, as an output:

$$\frac{dF}{dt} = k_{SE}(V_M - V_{CE}) \tag{2}$$

where $V_M$ is the velocity of the end of the whole muscle, $V_{CE}$ is the contractile element velocity from Equation 1, and $k_{SE}$ is the series elastic stiffness. The $V_{CE}$ property described by Equation 1 applies only to shortening muscle and only when the muscle is operating in a length range at which isometric force does not vary. Modifications to this standard model extend its applicability to situations in which large length excursions occur. For example, length dependence (Figure 1*C*) can be incorporated into the force-velocity relation (Equation 1) by changing $P_o$ to reflect the isometric force available at the current muscle length and scaling the parameters $a$ and $b$ by this factor as well. A length-dependent nonlinear SE stiffness can also be included.

In contrast, it is necessary to define an entirely new force-velocity relation to describe behavior during lengthening contraction, that is, when the muscle is forced to lengthen by an external load that exceeds its active force-generating capacity. One such relation (Mashima et al., 1972) is given by

$$V_{EC} = \frac{b'(P_o - F)}{2P_o - F + a'}, \qquad F > P_o \tag{3}$$

where $a'$ and $b'$ are empirical constants. Such an extended model has been shown to perform well for complex motions involving both eccentric and concentric contractions at full activation (Krylow and Sandercock, 1997).

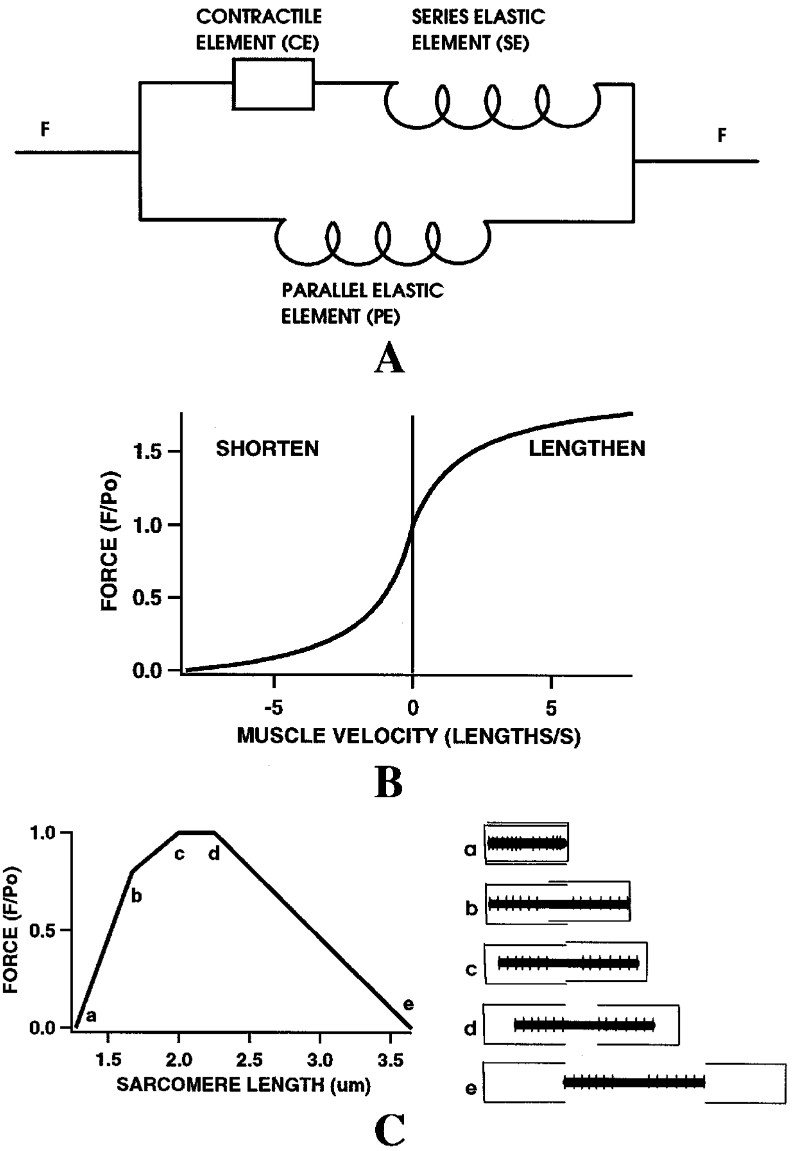
## Cross-Bridge Models

The main components of the sarcomere are two sets of interdigitating protein filaments called thin filaments (made up partly of actin) and thick filaments (made up largely of myosin) (Squire, 1981). When suitably activated by calcium ions and in the presence of adenosine triphosphate (ATP), large populations of molecular projections (cross-bridges) on the thick filaments interact with receptor sites on the actin to produce force and relative motion between the two sets of filaments. Each cross-bridge is believed to act independently, interacting cyclically with successive actin sites to produce a ratchet-like action. The forces thus produced between the two filaments are in a direction to cause each sarcomere to shorten. The actin and myosin filaments are approximately inextensible, and sarcomere shortening occurs because of the relative sliding of the filaments past each other (sliding filament theory).

Muscle force exhibits a pronounced length dependence that can be explained by the sliding filament theory. As muscle length changes, the relative overlap of the actin and myosin filaments in each sarcomere changes because of telescoping of the sarcomere structure, and this overlap determines the maximum number of available cross-bridges at any given muscle length. Figure 1*C* shows the idealized length-tension curve measured during steady-state isometric contraction when the muscle is fully active.

In contrast to lumped parameter models, which try to reproduce macroscopic behavior with discrete mechanical elements, cross-bridge models strive to incorporate the known microstructure of the sarcomere together with biochemical kinetics of muscle protein to predict macroscopic variables such as whole muscle force, stiffness, shortening velocity, energy consumption, heat liberation, and

**Figure 1.** Schematic representations of (*A*) Hill model structure, (*B*) the force-velocity relation for both concentric and eccentric regions, and (*C*) isometric force-length relation and the corresponding sarcomere geometry responsible for this effect.



so on. The prototypical scheme for this type of model (Huxley, 1957) idealizes the interaction of actin and myosin as consisting of two possible cross-bridge states—either bound or unbound—and derives equations that describe the evolution of the distribution of bond lengths for the population of bound cross-bridges. The cross-bridges are assumed to act independently as linear springs, producing force in proportion to their extension, when bound to actin. It is necessary to define simplified chemical reactions that describe the transitions between the states and the form of the rate functions that determine the extent and directions of these reactions. Since the chosen rate functions depend explicitly on the cross-bridge length, the reactions are coupled directly to mechanical events of the cross-bridge cycle as well as to external perturbations imposed on the muscle by loading conditions. See McMahon (1984) and Zahalak (1981, 1992) for more details.

## Tendon Properties

An idealized structure is often assumed for the tendon, in which muscle is connected to a linear series elastic element with high stiffness. In fact, the tendon is far from being simply an inextensible link, and its mechanics modify muscle output significantly. For example, under some conditions, the muscle fibers can shorten while the complete muscle-tendon structure lengthens. The tendon can be used to store energy, as was demonstrated in the Achilles tendon of the wallaby (Alexander, 1981), where its energy storage plays an integral role in efficient jumping locomotion. Although tendon is often simply modeled as an ideal spring, the mechanical properties of tendon are more complex. Its force-length curve depicts an initial compliant region, followed by a reduced compliance, and is often described as exponential, exponential-linear, or a quadratic function of length. When a tendon is stretched and released, the measured force shows a pronounced hysteresis that is a complex function of its history. Nonlinear tendons have been incorporated as the series elastic elements in Hill-type models, providing some improvement in model accuracy.

The cross-bridges that generate force in a muscle are themselves often modeled as ideal springs. They can be lumped together and modeled as an elasticity in series with the tendon to define a global muscle stiffness. For example, in cat soleus muscle, which is considered to have a short, stiff tendon, half of its compliance (the reciprocal of stiffness) is attributed to the tendon when the muscle is fully activated. In muscles with longer tendons, the compliance of the tendon even predominates at high activation. At lesser activation levels, fewer attached cross-bridges result in the sarcomeres becoming the primary source of compliance in the muscle. Experiments show muscle stiffness increases approximately linearly with activation. This important mechanical property of muscle is often incorrectly represented in lumped parameter models.

## Models of Activation

Muscle receives neural input in the form of discrete action potentials. Through a complex sequence of events, each action potential results in a release of calcium from stores in the sarcoplasmic reticulum. This calcium binds to regulatory proteins and allows cross-bridge cycling to proceed. The calcium is quickly sequestered, deactivating the actin-binding sites and allowing the muscle to relax. The frequency of action potential arrival at the muscle determines the degree of muscle activation. At low frequencies, muscle responds with discrete force transients (twitches). At high frequencies, isometric force fuses into a smooth contraction (tetanus) that rises to maximal levels (Figure 2).

The muscle models presented earlier need to be coupled with a model of activation to be fully comprehensive. These models fall into two basic categories: (1) models based on an estimated mean level of neural excitation to the muscle and (2) models that translate a sequence of discrete action potentials into muscle activation. When simulating voluntary movement, models based on estimated mean excitation are preferable because the true excitation is never known, and little is accomplished by trying to estimate the action potential sequence to all motor units in the muscle. However, when muscle is stimulated by a known action potential train, modeling of the discrete action potentials is necessary to reproduce the ripple occurring in an unfused tetanus.

The most widely used activation model uses the rectified and filtered electromyogram (REMG) to estimate the input to a muscle (Deluca, 1979). The electromyogram signal is recorded by using either surface or intramuscular electrodes and results from the complex summation of electric fields produced by each muscle fiber action potential. The REMG provides a measure of the total number of action potentials to the muscle. It often has a linear or exponential relationship to isometric force, and the output of this relationship can serve as the input to a Hill-type or cross-bridge model. Unfortunately, the relationship between the REMG and force varies in different muscles, for different recording electrodes, or even with the placement of the electrodes. Furthermore, because of its stochastic properties, an ensemble average of the REMG is needed for rapidly changing levels of excitation. At best, REMG is a crude approximation of neural drive.

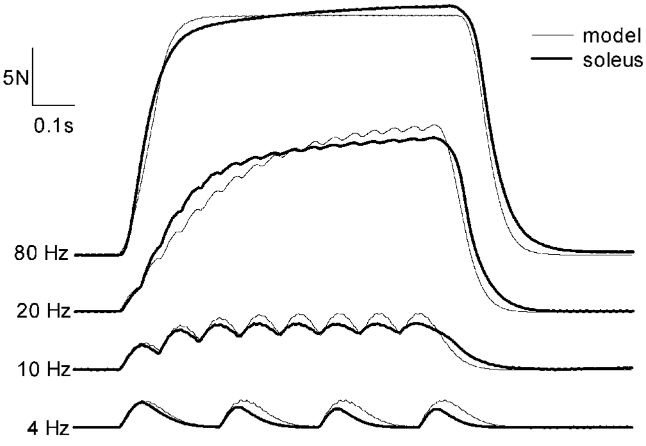


**Figure 2.** Cat soleus force responses for increasing rates of synchronous stimulation. At low stimulus rates, force pulses are responses to individual stimulus pulses. Force pulses fuse to produce smooth traces as the rate approaches 40 Hz. Simple Hill model predictions using the activation scheme given by Equation 4 show similar behavior.

The second approach to modeling activation is to approximate the physiological events after the arrival of an action potential at the muscle. Unfortunately, the complexity of the events precludes an accurate and simple model. In addition, activation is strongly influenced by muscle length. Well-documented activation-related phenomena can more than double or halve the force measured from a muscle stimulated by identical pulse trains. See Burke (1981) for discussions of potentiation, doublets, sag, and fatigue.

A simple model to transform a time sequence of action potentials into activation for a Hill-type model is described by

$$\begin{aligned} x(t) &= \sum_n \delta(t - t_n) \\ \dot{r}(t) &= -C_1 r(t) + C_2 x(t) \\ \dot{y}(t) &= \begin{cases} -C_3 y(t) + r(t), & y(t) \leq 1 \\ -C_3(t), & y(t) > 1 \end{cases} \end{aligned} \tag{4}$$

where $x(t)$ is the input, $\delta(t)$ are unit impulses representing action potentials at times $t_n$, and $C_1$, $C_2$, and $C_3$ are constants. Activation, $y(t)$, is used to scale the force-velocity relationship: $P_o$, $a$, $b$, $a'$, and $b'$ in Equations 1 and 3 are multiplied by $y(t)$. The results of the model applied to cat soleus (Figure 2) show good agreement with the experimental data measured during isometric conditions. However, the model shows substantial errors (up to 50% of maximal muscle force) with low firing rates and high velocity length changes. The largest errors can be attributed to the separation of activation and contractile properties inherent in a Hill-type model (Sandercock and Heckman, 1997). More sophisticated activation models coupled with a cross-bridge model (Zahalak, 1992) address this problem but have not yet been shown to reduce the overall error for widely varying muscle conditions.

Furthermore, during natural contraction of a muscle, slow-fatigue-resistant motor units are active at low forces, and fast-fatigable motor units are recruited only for stronger contractions (Burke, 1981). Because the mechanical properties of these motor units are strikingly different, the overall mechanical properties of a muscle probably change substantially with activation. A muscle model might address this by changing the muscle parameters with increasing activation or by treating the fast and slow motor unit populations separately and combining the results. This problem has received little attention, yet is likely to be a significant source of error in existing models.

## Discussion

As we outlined in the Introduction, the choice of a particular type of model is determined by the intended use of the resulting information. Linear system-type muscle models can provide intuitive insights in the frequency domain that are not easily obtained from the other methods, but muscle's inherent nonlinearities make such models locally applicable at best. Cross-bridge-type models are essentially the only choice to study molecular mechanisms. To study whole muscle or multiple muscle systems, both cross-bridge and Hill-type models offer possibilities, although Hill-type models are much more accessible. Cross-bridge models are capable of a wider range of behaviors, but they pay the price by needing more parameters. Because of the difficulty in estimating these parameters, cross-bridge models are rarely used to study control of multimuscle movement. Hill-type models are by far the most widely used for this application.

A Hill model that is extended to include eccentric contraction and large muscle length changes does a fair job predicting muscle behavior and is the most practical solution for many requirements but has at least two major weaknesses. First, the extensions to Hill-type models for lengthening contractions fit well only under limited conditions and cannot predict muscle "yield." Second, when activation is coupled with the Hill model, the model has no mechanism to handle varying cross-bridge persistence observed with different movement histories. Systematic methods to identify the parameters in a simplified cross-bridge-type model could make it the method of choice.

It is not known how accurate a muscle model must be to effectively study control of movement. Since muscle is a nonstationary system, with crucial time- and history-dependent properties, it is difficult, even under carefully controlled laboratory conditions, to get the identical response to the same input. Perhaps neural control systems make such differences unimportant. Conversely, Lehman (1990) has shown that predicted neural control signals are very sensitive to the muscle model structure. Here, activations necessary to reproduce experimental wrist motions were calculated by using three different muscle models: a linear viscoelastic model, a Hill model with constant SE stiffness, and a Hill model with activation-dependent stiffness. The most complex muscle model predicted control signals that most closely resembled the actual EMG signals. Other nonlinear properties of muscle, the very ones that make modeling difficult, may be advantageous for function and thus may be required to help us understand the control of movement.

# Neocognitron: A Model for Visual Pattern Recognition

*Kunihiko Fukushima*

## Introduction

The *neocognitron* (Fukushima, 1980, 1988b, 1991) is a neural network model for deformation-resistant visual pattern recognition.

In primary visual cortex, neurons respond selectively to local features of a visual pattern, such as lines or edges in particular orientations. In the inferotemporal cortex, cells exist that respond selectively to certain figures such as circles, triangles, or squares, or even human faces. Thus, the visual system seems to have a hierarchical architecture in which simple features are first extracted from a stimulus pattern, then integrated into more complicated ones. In this hierarchy, a cell in a higher stage generally has a larger receptive field and is more insensitive to the position of the stimulus. This kind of physiological evidence suggested the network architecture for the neocognitron.

The neocognitron is a hierarchical network consisting of many layers of neuron-like cells. There are forward connections between cells in adjoining layers. Some of these connections are variable and can be modified by learning. The neocognitron can acquire the ability to recognize patterns by learning. Since it has a large power of generalization, presentation of only a few typical examples of deformed patterns (or features) is enough for the learning process to be successful. It is not necessary to present all of the deformed versions of the patterns that might appear in the future. After learning, the neocognitron can recognize input patterns robustly, with little effect from deformation, changes in size, or shifts in position. It is even able to correctly recognize a pattern that has not been presented before, provided the pattern resembles one of the training patterns.

The principle of the neocognitron can be used in various kinds of pattern recognition systems, such as systems recognizing handwritten characters (Fukushima, 1988b, 2002; Fukushima and Wake, 1991).

## The Network Architecture

The neocognitron has a multilayered architecture, as shown in Figure 1, in which each rectangle represents a two-dimensional array of cells. Each cell receives its input connections from only a limited number of cells situated in a small area on the preceding layer. The density of cells in each layer is designed to decrease with the order of the stage.

The lowest stage of the hierarchical network is an input layer $U_0$, consisting of a two-dimensional array of receptor cells. Each succeeding stage has a layer $U_S$ consisting of "S-cells," followed by another layer $U_C$ consisting of "C-cells." Thus, in the whole network, layers of S-cells and C-cells are arranged alternately.

Each layer of S-cells or C-cells is divided into subgroups, called "cell-planes," according to the features to which they respond. The cells in each cell-plane are arranged in a two-dimensional array. Each rectangle drawn with heavy lines in Figure 1 represents a cell-plane. The connections converging to the cells in a cell-plane are homogeneous and topographically ordered. In other words, the connections have a translational symmetry such that each of the cells of a cell-plane shares the same set of input connections. This condition of translational symmetry holds for both fixed and variable connections. The modification of variable connections is always done under this condition.

S-cells are feature-extracting cells. They resemble simple cells in the visual cortex in their response. Connections converging to these cells may be modified by learning. After learning, S-cells are able to extract features from input patterns. In other words, an S-cell is activated only when a particular feature is presented in its receptive field. The features extracted by the S-cells are determined during the learning process. Generally speaking, local features, such as lines in particular orientations, are extracted in the lower stages. More "global" features, such as parts of a training pattern, are extracted in higher stages.

C-cells, which resemble complex cells in the visual cortex, are inserted in the network to allow for positional errors in the features of the stimulus. The connections from S-cells to C-cells are fixed and invariable. Each C-cell receives signals from a group of S-cells that extract the same feature, but from slightly different positions (Figure 2). The C-cell is activated if at least one of these S-cells is active. Even if the stimulus feature is shifted in position and another S-cell is activated instead of the first one, the same C-cell keeps responding. Hence, the C-cell's response is less sensitive to shifts in the position of the input pattern.

The layer of C-cells at the highest stage is the recognition layer: the response of the cells in this layer is the final result of pattern recognition by the neocognitron.

## Principles of Deformation-Resistant Recognition

In the whole network, with its alternate layers of S-cells and C-cells, the process of feature extraction by the S-cells and toleration of positional shift by the C-cells is repeated. During this process, local features extracted in lower stages are gradually integrated into more global features. Finally, each C-cell of the recognition layer at the highest stage integrates all the information of the input pattern and responds only to one specific pattern. Figure 2 illustrates this situation schematically.

Tolerating positional error a little at a time at each stage, rather than all in one step, plays an important role in endowing the network with the ability to recognize even distorted patterns. Figure 3 illustrates this situation. Let an S-cell in an intermediate stage of the network have already been trained to extract a global feature consisting of three local features of a training pattern "A," as shown in Figure 3*A*. The cell tolerates a positional error of each local feature if the deviation falls within the dotted circle. Hence, the S-cell responds to any of the deformed patterns shown in Figure 3*B*. The toleration of positional errors should not be too large at this stage. If large errors are tolerated at any one step, the network may come to respond erroneously, such as by recognizing a stimulus like Figure 3*C* as an "A" pattern.

Since errors in the relative position of local features are thus tolerated in the process of extracting and integrating features, the same C-cell responds in the recognition layer at the highest stage, even if the input pattern is deformed, changed in size, or shifted in position.

## Self-Organization of the Neocognitron

The neocognitron can be trained to recognize patterns through either unsupervised or supervised learning. Various training methods have been proposed, and this section introduces two of them.

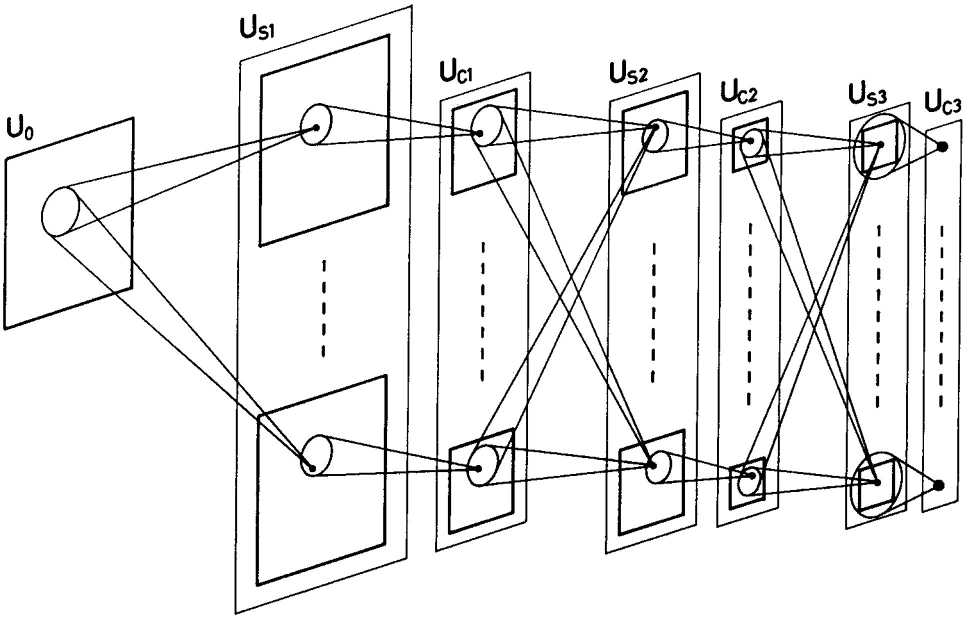

**Figure 1.** The network architecture of the neocognitron. Each rectangle drawn with heavy lines represents a "cell-plane." The cells in each cell-plane are arranged in a two-dimensional array.

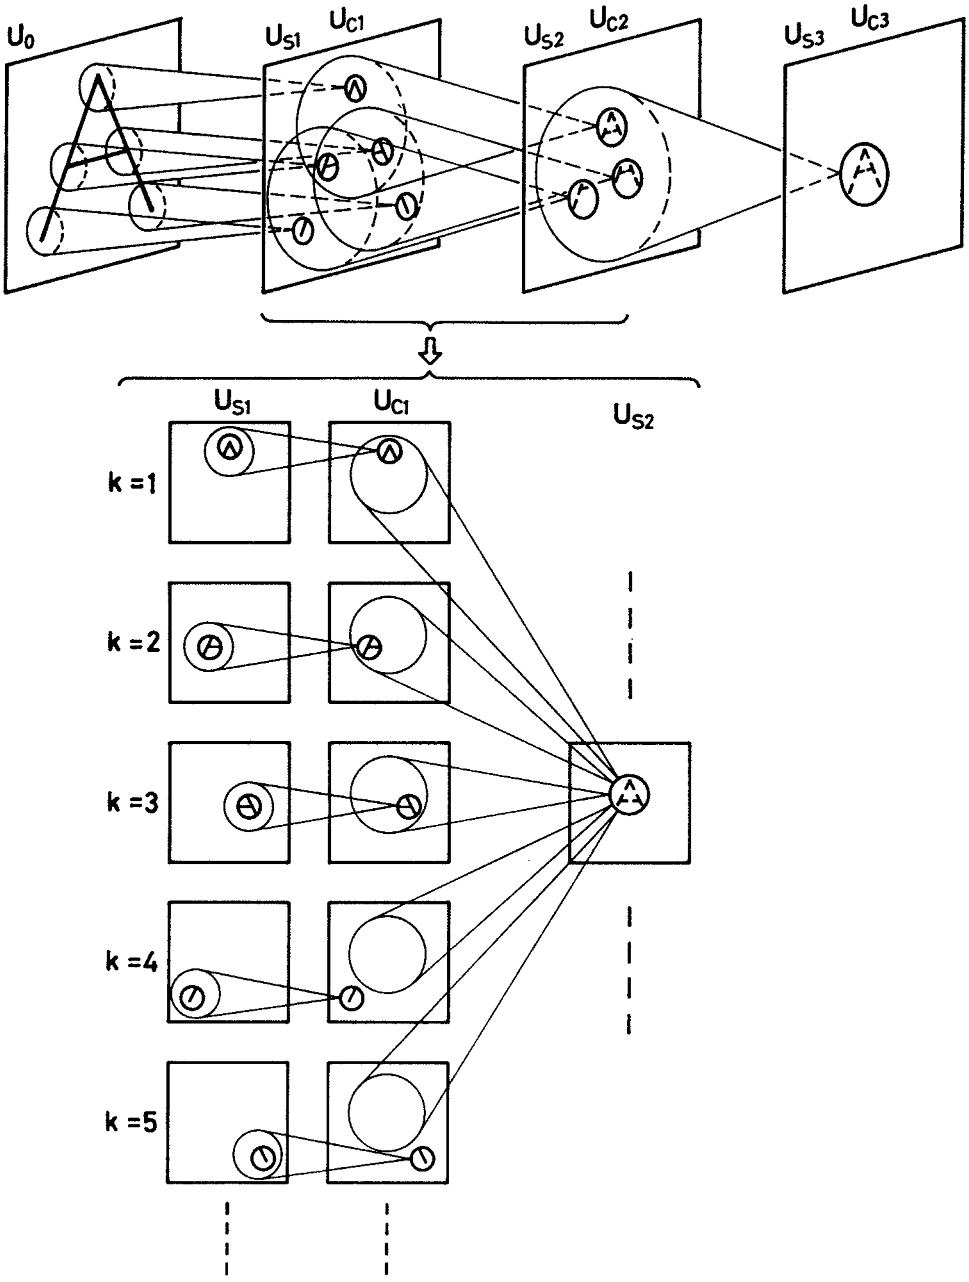

**Figure 2.** Illustration of the process of pattern recognition in the neocognitron (Fukushima, 1980). As shown in the upper half of the figure, local features extracted in lower stages are gradually integrated into more "global" features. The lower half of the figure is an enlarged illustration of a part of the network. The cell-plane with $k = 1$ in layer $U_{S1}$ consists of S-cells that extract Λ-shaped features. Since the stimulus pattern "A" contains the Λ-shaped feature at the top, an S-cell near the top of this cell-plane is active. A C-cell in the succeeding cell-plane ($k = 1$) in $U_{C1}$ has excitatory input connections from S-cells situated in the circle and is activated if one of these S-cells is active. Only one cell-plane is shown in $U_{S2}$ in this enlarged illustration. Each S-cell in this cell-plane detects the existence of features $k = 1, 2, 3$ in $U_{C1}$, and at the same time the absence of features $k = 4, 5$.

In the case of unsupervised learning, the self-organization of the network is performed using two principles. The first principle is a kind of "winner-take-all" rule (see Winner-Take-All Networks): among the cells situated in a certain small area, only the one responding most strongly has its input connections reinforced. The change of each input connection to this maximum-output cell is proportional to the intensity of the response of the cell from which the relevant connection leads.

Figure 4 illustrates this process, showing only the connections converging to an S-cell. The S-cell receives variable excitatory connections from a group of C-cells of the preceding stage. The cell also receives a variable inhibitory connection from an inhibitory cell, called a V-cell. The V-cell receives fixed excitatory connections from the same group of C-cells as does the S-cell, and always responds with the average intensity of the output of the C-cells.

The initial strength of the variable connections is very weak and nearly zero (Figure 4*A*). Suppose the S-cell responds most strongly of the S-cells in its vicinity when a training stimulus is presented (Figure 4*B*). According to the winner-take-all rule just described, variable connections leading from activated C- and V-cells are reinforced, as shown in Figure 4*C*. The variable excitatory connections to the S-cell grow into a "template" that exactly matches the spatial distribution of the response of the cells in the preceding layer. The inhibitory variable connection from the V-cell is also increased at the same time, but not strongly, because the output of the V-cell is not as large.

After the learning, the S-cell acquires the ability to extract a feature of the stimulus presented during the learning period. Through the excitatory connections, the S-cell receives signals indicating the existence of the relevant feature to be extracted. If an

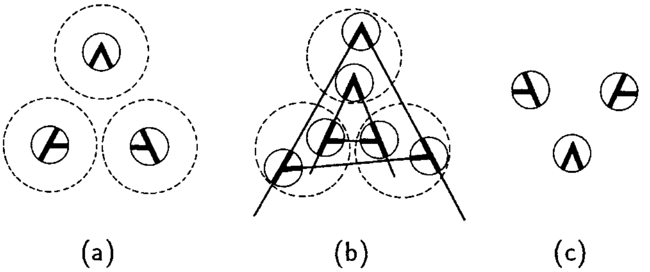

**Figure 3.** Illustration of the principle for recognizing deformed patterns (Fukushima, 1988a). An S-cell, which has already been trained to extract a global feature consisting of three local features as shown in part *a*, tolerates a positional error of each local feature if the deviation falls within the dotted circle. Hence, the S-cell responds to any of the deformed patterns shown in part *b*. The toleration of positional errors should not be too large at this stage. If large errors are tolerated at any one step, the network may come to respond erroneously, such as by recognizing a stimulus like the one in part *c* as an "A" pattern.

irrelevant feature is presented, the inhibitory signal from the V-cell becomes stronger than the direct excitatory signals from the C-cells, and the response of the S-cell is suppressed (Fukushima, 1989).

Once an S-cell is thus selected and reinforced to respond to a feature, the cell usually loses its responsiveness to other features. When a different feature is presented, a different cell usually yields the maximum output and has its input connections reinforced. Thus, a "division of labor" among the cells occurs automatically.

The second principle for learning is introduced in order that the connections being modified always preserve translational symmetry. The maximum-output cell not only grows by itself, it also controls the growth of neighboring cells, working, so to speak, like a seed in crystal growth. To be more specific, all of the other S-cells in the cell-plane, from which the "seed cell" is selected, follow the seed cell, and have their input connections reinforced by having the same spatial distribution as that of the seed cell.

Although the neocognitron can thus be trained by unsupervised learning, supervised learning is still useful when we want to train a system to recognize, for instance, handwritten characters, which should be classified not only on the basis of similarity in shape but also on the basis of certain conventions. In the case of supervised learning, the "teacher" presents training patterns to the network and points out the positions of the features that should be extracted. The cells whose receptive field centers coincide with the positions of the features take the place of the "maximum-output cells" and become seed cells. The other process of reinforcement is identical to that of the unsupervised learning and occurs automatically.

It is another advantage of the neocognitron that these learning methods, both supervised and unsupervised, require extremely short training times compared with other learning algorithms such as backpropagation. In an extreme case of unsupervised learning, for example, three presentations of a training set consisting of one training pattern from each category was sufficient to train the network to recognize 10 numeric characters robustly (Fukushima and Wake, 1992).

The optimal scale of the neocognitron changes depending on the set of patterns to be recognized. If the complexity of the patterns is high, the total number of stages in the hierarchical network needs to be large. Conversely, the necessary number of cell-planes in each stage of the network increases with the number of categories of patterns to be recognized. However, the increase in scale is not proportional. For example, if we compare a system recognizing 35 alphanumeric characters with a system recognizing 10 numerals, the number of characters to be recognized increases 3.5 times, but the number of cells increases only 1.9 times (Fukushima and Wake, 1991). This results from the fact that the local features extracted in the lower stages are common, and they usually are contained in many patterns of different categories. Although the number of cells is large in these systems, the number of parameters required to describe the network is quite small, because all of the cells in each cell-plane share the same set of input connections.

## Selective Attention Model (SAM)

Although the neocognitron has considerable ability to recognize deformed patterns, it does not always recognize patterns correctly when two or more patterns are presented simultaneously. The *selective attention model* (SAM) has been proposed to eliminate these defects (Fukushima, 1986, 1987, 1988a). In the SAM, backward (i.e., top-down) connections were added to the conventional neocognitron-type network, which had only forward (i.e., bottom-up) connections.

When a composite stimulus consisting of two patterns or more is presented, the SAM focuses its attention selectively on one of the patterns, segments it from the rest, and recognizes it. After the identification of the first segment, the SAM switches its attention to recognize another pattern. The SAM also has the function of associative recall. Even if noise or defects affect the stimulus pattern, the SAM can recognize it and recall the complete pattern from

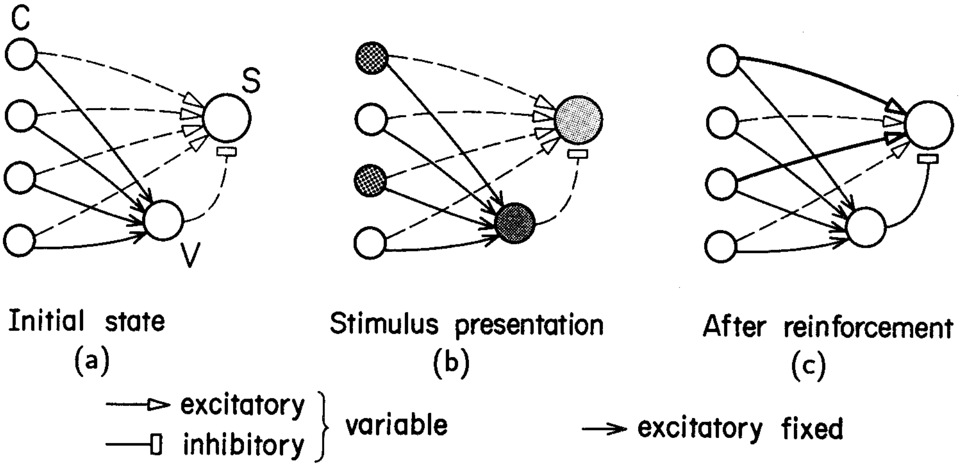

**Figure 4.** The process of reinforcement of the forward connections converging to a feature-extracting S-cell (Fukushima, 1988a). The density of the shadow in the circle represents the intensity of the response of the cell. *a*, The initial state before training. *b*, Stimulus presentation during the training. *c*, The connections after reinforcement.

which the noise has been eliminated and defects corrected. These functions can be successfully performed even for deformed versions of training patterns that have not been presented during learning.

The SAM has some similarity to the Adaptive Resonance Theory model (q.v.; see also Carpenter and Grossberg, 1987), but the most important difference between the two is the fact that the SAM has the ability to accept patterns deformed in shape and shifted in position, while the adaptive resonance theory does not, in principle, have such functions. With the SAM, not only the recognition of the patterns but also the filling-in process for defective parts of imperfect input patterns work on the deformed and shifted patterns themselves. The SAM can repair the deformed pattern without changing the basic shape and location of the deformed input pattern. The deformed patterns themselves can be repaired at their original locations, thus preserving their deformation.

The principles of the SAM can be extended to be used for several applications: for example, the recognition and segmentation of connected characters in cursive handwriting of English words (Fukushima and Imagawa, 1993), and the recognition of Chinese characters (Fukushima, Imagawa, and Ashida, 1991).

# Neocortex: Basic Neuron Types

*Maria Toledo-Rodriguez, Anirudh Gupta, Yun Wang, Cai Zhi Wu, and Henry Markram*

## Introduction

The neocortex is functionally parcellated into vertical columns (~0.5 mm in diameter) traversing all layers (layers I–VI). These columns have no obvious anatomical boundaries, and the topographic mapping of afferent and efferent pathways probably determines their locations and dimensions as well as their functions (Peters and Jones, 1984; White, 1989). Multiple columns overlap, suggesting that the underlying neural microcircuits are designed to enable universal computation. These apparently omnipotent and stereotypical microcircuits are composed of a daunting variety of precisely and intricately interconnected neurons (Douglas and Martin, 1998; Somogyi, 1998; White, 1989), that differ in terms of their anatomical, electrophysiological, and molecular properties (Cauli et al., 1997; DeFelipe, 1993; Gupta, Wang, and Markram, 2000; Kawaguchi and Kubota, 1997; Peters and Jones, 1984; Thomson and Deuchars, 1997). This neuronal diversification may provide a foundation for maximizing the computational abilities of the neocortex.

## Basic Neuron Types—Anatomy

### *Excitatory Neurons*

Excitatory neurons constitute by far the majority of neocortical cells (70–80%) and consist mainly of two types of neurons (Peters and Jones, 1984; Somogyi, 1989; White, 1989):

- *Pyramidal cells* (PC; Figure 1A1), the most commonly occurring neocortical neuron (located in layers II–VI), are characterized by a single, prominent, vertically oriented dendrite emerging from the apex of their mainly pyramidal-shaped somata (apical dendrite), several (~4–6) more or less horizontally radiating basal dendrites, and long descending axons that project to other cortical and subcortical areas. The apical dendrite traverses through several layers, allowing PCs to sample multiple layer-specific inputs, before fanning out into a terminal tuft (often reaching layer I). The basal dendrites mainly remain within the layer of the cell body (sometimes entering adjacent layers), spanning the full diameter of the cortical column. PC axons give rise to a local columnar cluster that may spill over into neighboring columns before continuing to the white matter. Additionally, long vertical and horizontal collaterals project across layers and columns, sometimes forming secondary axonal clusters. PCs are therefore “local circuit neurons” as well as “projection neurons.”
- *Spiny stellate cells* (SSC; Figure 1A1), found almost exclusively in layer IV of the primary sensory areas, are characterized by multiple short dendrites (contained within a layer and column) radiating from spherical somata (stellate appearance). Their axons produce a local axonal cluster of columnar extent within layer IV, before projecting either loosely or in tight bundles to arborize extensively in layers II/III. Some collaterals descend toward layers V/VI. SSCs are mainly “local circuit neurons,” al-

**Figure 1.** Anatomical and Electrophysiological Diversity of Neocortical Neurons. *A*, Schema, summarizing the main anatomical properties of neocortical excitatory (A1) and inhibitory (A2–5) neurons. Each neuron type is labeled by three-letter abbreviation (for explanation, see text). Dendrites: thick, light gray; axon: thin, black lines; black dots: axonal boutons. Spines omitted for clarity. Neurons oriented with pia facing upward and white matter (WM) downward. Note the presence of a prominent, vertical dendrite directed toward WM on some interneurons (A2–4). Inhibitory interneurons (A2–5) are mainly distinguished by the structure of their axonal arbor (see text) and typically innervate selective domains [A2: (peri-) somatic; A3,4 dendritic; A5: axonal] of their target cells. *B*, Representative samples of the most common discharge responses of neocortical excitatory (B1) and inhibitory (B2) neurons to standardized intrasomatic step-current injections. B1: Excitatory cells typically display regular-spiking (RS) discharge behavior. B2: Inhibitory interneurons display a vast repertoire of discharge responses, displaying either bursts (b-), delays (d-), or neither burst/delay (classical, c-) at step-onset, and accommodation (AC), non-accommodation (NAC), stuttering (STUT), or irregular spiking (IS) at steady-state. Scale bar (20 mV; 500 ms) applies to all traces.

though in few cases they have been shown to project to other cortical areas (Douglas and Martin, 1998).

Whereas PCs and SSCs are easily distinguished by multiple morphological features, both types of excitatory neurons share several *functional* properties, that have been amply used to distinguish them from inhibitory neurons (White, 1989): (1) their dendrites are typically densely studded with small membranous protuberances known as spines (hence they are also known as spiny neurons; see Dendritic Spines); (2) they release glutamate from their presynaptic terminals (boutons), which form asymmetric (excitatory) synapses mainly onto the spines of other excitatory neurons (see Neocortex: Chemical and Electrical Synapses); (3) their somata invariably receive *only* symmetrical (inhibitory) synapses.

## *Inhibitory Neurons*

Inhibitory neurons constitute 20–30% of the neocortical cells and are highly heterogeneous (Peters and Jones, 1984; Somogyi, 1989; White, 1989; Figure 1A2–5). They are easily distinguished from excitatory neurons by their lack of an apical dendrite, low spine densities (hence they are also known as smooth and/or sparsely spiny neurons), beaded dendrites, and axonal arbors that remain almost exclusively within a column (hence they are also known as local circuit neurons or interneurons; but see exceptions discussed later in this article). Instead of an apical dendrite projecting toward the pia, many interneurons have a prominent dendrite (with more branches) extending toward the white matter (WM). Moreover, the initial course of their axons, which either originate from the soma or a primary dendrite, is often toward the pia (instead of toward the WM, which characterizes the axon trajectory of excitatory neurons). Inhibitory neurons release GABA at their symmetric synapses, and their cell bodies invariably receive *both* excitatory and inhibitory synapses. Most types of interneurons may display various soma shapes (ovoid, spindle-shaped, triangular, inverted pyramidal) and dendritic morphologies (bipolar, bitufted, and multipolar), but each type characteristically displays unique features in its axonal structure. Details of the axonal arborization (White, 1989), as well as the preferential placement of synapses onto different target-cell domains (Somogyi, 1989; Somogyi et al., 1998), have therefore provided the foundation for classifying interneurons. This selective innervation allows each type of interneuron to effect its target cells in a compartment-specific and potentially independent manner (see Perspective on Neuron Model Complexity).

Inhibitory neurons that selectively innervate:

- the (peri-) somatic region of their target cells, may affect the strength and gain of summated synaptic potentials (see Single-Cell Models), the timing of action potential (AP)-generation and hence the concerted action of populations of target cells (see Synchronization, Binding and Expectancy)
- the dendrites of their target cells, may influence dendritic processing and integration of synaptic inputs (see Dendritic Processing), generation and propagation of dendritic APs, and synaptic plasticity (see Hebbian Synaptic Plasticity)
- the axon initial segment of their target cells, may affect both the generation and the "gating" of APs (see Axonal Modeling)

Most interneuron types, although mainly studied in layers II–V, are also found in layer VI, whereas layer I is characterized by its own distinct set of interneurons (see discussion later in this article). Moreover, it is currently not known whether additional subtypes, specific to layer VI, exist, although this lamina is characterized by a multitude of ill-defined local circuit neurons (~8–12 types) that still await precise description (Peters and Jones, 1984). The following describes the most common types of interneurons located in rat somatosensory cortex (layers II–V), based on a very large data set with considerable emphasis on quantitative morphometric analysis (see, for example, Wang et al., 2002). These basic interneuron types are found across different neocortical areas and species. Minor structural variations of these interneuron types (depending on neocortical layers, regions, age, and species) will not be considered here.

*Interneurons that preferentially target somata and proximal dendrites.* Basket cells (BCs), probably the most frequently encountered neocortical interneurons, are distinguished by their preferential innervation of somata (20–40%) and proximal dendrites (onto shafts and spines) (Kisvarday, 1992). BCs in general give rise to several beaded, mainly aspiny, dendrites. They are composed of three main subclasses, that differ in the structure of their axonal arborizations (Wang et al., 2002), each of which appears to be differentially distributed throughout layers II–VI.

- *Large basket cells* (LBC, Figure 1A2) produce a *sparse* local, mainly intralaminar and intracolumnar, axonal cluster composed of few, long and straight branches of low bouton density (BD) before generating their characteristic conspicuous long-range horizontal collaterals, that traverse multiple columns and some vertically projecting collaterals that may cross all layers (Somogyi, 1989). LBCs are therefore “local circuit” as well as inhibitory “projection” neurons.
- *Small basket cell* (SBC, Figure 1A2) give rise to a characteristic *dense* local, intralaminar and intracolumnar, axonal cluster composed of frequent, short, and curvy axonal branches with high BD. Occasionally SBCs may generate a few far-reaching collaterals projecting across layers and columns. A special subtype of SBC, termed *Clutch Cell*, has been observed in layer IV of the visual cortices of cat/monkey (Kisvarday, 1992). These cells are medium-sized, multipolar cells that typically produce large bulbous terminals, which often “clutch” somata of their target cells.
- *Nest basket cell* (NBC, Figure 1A2) give rise to a *sparse to dense* local, mainly intralaminar and intracolumnar, axonal cluster composed of infrequent, long, and smoothly bending axonal branches of low BD. They may occasionally produce a few far-reaching collaterals projecting across layers and columns. In addition, NBCs exhibit a characteristically simple dendritic arbor with few short and infrequently branching dendrites (Gupta et al., 2000; Wang et al., 2002).

*Interneurons that preferentially target dendrites.* Interneurons that preferentially target dendrites, usually give rise to beaded, aspiny, or sparsely spiny dendrites. Importantly, their overall “axonal fields” are preferentially vertically oriented (except NGCs, see the following discussion).

- *Bitufted cells* (BTC, Figure 1A3) display ovoid somata that emit two dendritic tufts from opposite poles that are preferentially vertically oriented and may emit an additional oblique dendrite (Somogyi, 1989). Their axonal arborizations are characterized by long, vertically oriented collaterals of low BD that may extend through all layers and mainly branch in a bifurcating manner. Their axonal ramification is mostly intracolumnar, although in some cases they may extend into neighboring columns.
- *Bipolar cells* (BPC, Figure 1A3) typically produce the simplest dendritic and axonal arborization of all interneurons, as both dendrites and axons branch very infrequently at shallow angles. The two long, vertically oriented, primary dendrites of BPCs are emitted from the opposite poles of their small spindle-shaped somata, and may span all cortical layers occasionally forming a dendritic tuft in layer I (Peters and Jones, 1984). The axon of BPCs typically emerges from a primary dendrite (usually the lower dendrite) before ramifying vertically across multiple or all layers. It is characterized by a very low number of boutons that are typically placed onto the dendritic shafts of rather restricted population of target neurons. Some BPCs in layers II–V have been shown to form asymmetrical synapses, preferentially onto spines, suggesting that they are excitatory (eBPCs, not shown; White, 1989).
- *Double bouquet cells* (DBC, Figure 1A3) are interneurons that like BPCs appear to consist of two classes. Inhibitory DBCs, that appear to be preferentially located in layers II/III, display bitufted or multipolar dendritic morphologies and typically produce a thin axon that bifurcates to give rise to a characteristic, mainly descending, “horsetail-like,” tight fascicular axonal bundle. The collaterals forming these narrow columnar bundles of high BD are typically much thicker than the main stem, and may extend across all layers. A local axonal ramification of different densities may occasionally be formed. Some double bouquet cells in layers II–V that generate *both* ascending and descending axonal collateral bundles have been shown to form asymmetrical synapses onto target cells, suggesting that they are excitatory (eDBCs, not shown; White, 1989).
- *Neurogliaform cells* (NGC, Figure 1A3) are very small cells that produce dense, spherical dendritic, and axonal fields confined within a single layer and column (densest fields of all interneuron types). They typically produce a large number of thin, radiating dendrites that are short, aspiny, finely beaded, and rarely branched. Their very thin axons, branches intricately to produce a very dense and highly intertwined arborization (spiderweb-like appearance) that is studded with tiny boutons. NGCs target mainly dendritic shafts (Somogyi, 1989) and are also found in layer I.

*Interneurons that preferentially target dendrites and dendritic tufts*

- *Martinotti cells* (MC, Figure 1A4) display a more elaborate dendritic arbor than most interneurons, which is formed by beaded and sparsely- to medium-spiny dendrites. Their local and quite dense axonal cluster (mainly intralaminar and intracolumnar) is formed by collaterals that branch at wide angles before projecting up to layer I, where they spread across many columns, forming *spiny boutons*. MCs are “similar” to LBCs in that they are “local circuit” as well as inhibitory “projection” neurons. However, due to their innervation of distal dendrites and tufts, the form of their inhibitory impact is expected to differ substantially from that of LBCs.
- *Neurons exclusive to layer I* are believed to mainly innervate the dendritic tufts of target neurons and encompass several interneuron types. *Cajal-Retzius cells* (CRC, Figure 1A4) display large somata, long horizontal dendrites, and horizontally projecting axons, which characteristically give rise to numerous short ascending and some descending terminal fibrils. *Small layer I cells* (not shown) are neurons with short processes that constitute a heterogeneous group of multipolar interneurons with varying axonal arborizations. These have been subdivided into small neurons with poor or rich axonal plexus, respectively (Peters and Jones, 1984).

*Interneurons that preferentially target axons*

- *Chandelier cells* (ChC, Figure 1A5) are characterized by a local axonal cluster with a "chandelier-like" appearance resulting from the terminal axonal portions forming short vertical bouton arrays ("candlesticks") onto the axon initial segments of target neurons (mainly PCs; Somogyi et al., 1998). Their local axonal clusters—mainly confined within a single layer and column—are formed by collaterals of high BD that frequently branch at shallow angles. ChCs give rise to mostly aspiny, beaded, infrequently branching dendrites that may span one or several layers.

## Basic Neuron Types—Electrophysiology

Neocortical neurons display diverse intrinsic electrophysiological properties that result mainly from differences in their ion channel composition and constellation. Ion channels are state dependent and therefore a neuron's passine and active properties may change according to different conditions (see Ion Channels: Keys to Neuronal Specialization). However, for standardized stimulation and recording conditions, neuronal discharge responses are stable and can serve as a reliable "marker" of their biophysical identity. Electrophysiological diversity indicates that identical spatiotemporal patterns of synaptic inputs will be differentially integrated and transformed into fundamentally different AP-patterns (and hence different synaptic outputs) and may therefore profoundly increase the computational repertoire of neural circuits (see Spiking Neurons: Computation with).

### *Excitatory Neurons*

Excitatory neurons have been shown to display limited diversity in their discharge responses. Differences in their discharge properties have been described by three distinct features: (1) kinetic properties of single APs, (2) discharge response to intrasomatic threshold, and (3) supra-threshold current injections (Amitai and Connors, 1995; Connors and Gutnick, 1990; see Table 1). Discharge responses to supra-threshold current injections have proven to be the most useful parameter in distinguishing subclasses of both excitatory as well as inhibitory neurons (see the following discussion).

By far the most common discharge response observed for both PCs and SSCs has been described as *regular-spiking* (RS, see Figure 1B1). Sustained supra-threshold currents cause these cells to fire repetitively with a progressive decrease in firing frequency [progressive increase in inter-spike intervals (ISIs)], generally referred to as *spike train adaptation* or *accommodation*. Differences in the degree of accommodation have led to subclassification into RS1 (weak accommodation; *most common behavior*; see Figure 1B1) and RS2 cells (strong accommodation; behavior of PC- and SSC-subpopulations; see Table 1) (Connors and Gutnick, 1990). Some PCs and SSCs have been shown to display *intrinsic bursting* behavior (IB; not shown; see Connors and Gutnick, 1990). These neurons discharge with a cluster of three to five APs riding on a slow depolarizing wave (referred to as a burst), followed by an after-hyperpolarization, and then by either single spikes or bursts at more or less regular intervals (referred to as regular spiking and repetitive bursting, respectively). Other much less common discharge behaviors have been observed for subpopulations of PCs (see Table 1), including *chattering* (CHTs; not shown; Gray and McCormick, 1996) and *rhythmic firing* (RF; not shown; Amitai and Connors, 1995). CHT-cells usually display repetitive long clusters of APs to sustained supra-threshold current injections that, when made audible, sound like chattering. RF-cells discharge continually without accommodation.

### *Inhibitory Neurons*

Inhibitory neurons display a much larger repertoire of discharge behaviors compared to excitatory neurons (see Figure 1B2; see Table 1), and their electrophysiological (sub-) classification has been gradually refined over the last decade. Initially only a single discharge behavior, known as *fast-spiking* (FS), was described for *smooth or sparsely spiny neurons* throughout layers II-VI. FS-cells generate *single* APs with characteristics distinct from that of spiny (excitatory) neurons (faster rise rates (RR) and fall rates (FR), distinct fast afterhyperpolarizing potentials (fAHP); Connors and Gutnick, 1990) and discharge *repetitively* at high frequencies with little or negligible accommodation to sustained supra-threshold currents. Since other discharge behaviors were not observed initially for smooth cells, it was believed that interneurons represent a homogenous population of characteristically fast-spiking (referring to both the brevity of single APs and the resulting high discharge rate) neurons. Subsequent studies, mainly carried out in layers II/III and V, however, gradually demonstrated, that interneurons could display several other discharge patterns: (1) *burst spiking nonpyramidal* cells (BSNP) originally described as *low-threshold spiking* cells (LTS), typically display burst-like discharges after a hyperpolarizing pre-pulse (see Kawaguchi and Kubota, 1997); (2) *late-spiking* cells (LS) respond with a slow ramp depolarization and a late onset of discharge after a step current pulse (Kawaguchi and Kubota, 1997); (3) *regular spiking nonpyramidal* cells (RSNP) displaying discharge patterns similar to the RS response of PCs (Kawaguchi and Kubota, 1997); and (4) *irregular spiking* cells (IS) typically discharge with an initial burst of APs followed by an irregular spiking response (Cauli et al., 1997). IS cells have been further divided into two subclasses (IS1 and IS2) according to the duration of the initial burst.

Attempts to assign distinct electrophysiological discharge patterns to specific anatomical interneuron types have been made (Kawaguchi and Kubota, 1997; Thomson and Deuchars, 1997). Unfortunately, in many cases, the precise morphological identites of the electrophysiologically classified neurons could only be determined in *fractions* of the recorded cells: some MCs and DBCs were shown to display BSNP behavior, whereas LS behavior was observed for some NGCs and IS behavior for some interneurons with bipolar morphology (Cauli et al., 1997). Finally, DBCs, MCs, and BPCs may also display RSNP behavior, indicating that the same anatomical type may display more than one discharge pattern (see Table 1).

Interneuron discharge patterns, however, display an even richer diversity of behaviors. Recent studies—aimed at understanding the *functional* position of a large number of morphologically identified interneurons within the neocortical microcrocuitry—adopted a simple classification scheme that encompasses previous schemes (Gupta et al., 2000; see Table 1) and considers both the *steady-state* and the *onset* response to sustained somatic current injections (Figure 1B2). According to this scheme, neocortical interneurons are categorized into five main classes with three subclasses each, according to the discharge response at steady-state and onset phase, respectively. These interneuronal discharge patterns are stable for (1) different baseline membrane potentials and (2) durations and amplitudes (several times threshold) of step current injections (Gupta et al., 2000; Wang et al., 2002):

- *Nonaccommodating* cells (NAC, Figure 1B2) fire repetitively without frequency accommodation (no or minimial change in ISIs). The steady-state discharge frequency increases steeply as a function of the injected current amplitude, allowing NACs to reach very high firing frequencies. Their APs are very brief and characteristically display a deep fAHP. NACs are the most frequently encountered cells in all layers

**Table 1.** Electrophysiological Classes of Neocortical Excitatory and Inhibitory Neurons

Electrophysiological Classes of Excitatory Neurons

| Supra-Threshold Responses | AP Characteristics | Threshold Responses | Morphological Type of Excitatory Neuron (*) |
|---|---|---|---|
| RS1 | fast RR and fast FR | single AP | PC (layer II–VI); SSC |
| RS2 | fast RR and fast FR | single AP | subpopulations of PC (layer IV–VI) and SSC |
| IB | fast RR and fast FR | burst | subpopulations of PC (layer V) |
| CHAT | nd | nd | subpopulations of PC (layer II/III) |
| RF | nd | bistable: no or nonaccommodating response | subpopulations of PC (layer V) |

Electrophysiological Classes of Inhibitory Neurons

| Main Classes | Subclasses | Other Classification Schemes | Morphological Type of Interneuron (*) |
|---|---|---|---|
| NAC (layers I–VI) | b-NAC | FS | LBC, NBC |
| | d-NAC | FS; LS | LBC, NBC, SBC, BTC, NGC, ChC |

| | s-BST | BSNP | BPC, DBC |
| | I-BST | BSNP | BPC, DBC |

Interneuron classification: main classes and subclasses defined according to discharge responses at steady-state and onset-phase to intrasomatic current injections, respectively (see text; see Figure 1B2). Abbreviations explained in text; nd: not determined/detected so far; (*) morphological types listed according to sequence of description in text and not according to frequency of occurrence; (**) some authors have suggested to distinguish between accommodating FS-cells (FS-cells) and non-accommodating FS-cells (classical FS-cells or CFS; see Thomson and Deuchars, 1997).

- *Accommodating* cells (AC, see Figure 1B2) fire repetitively with a decrease in discharge frequency (the gradual increase in ISIs preventing high firing rates) and are the second most frequently observed electrophysiological class.
- *Stuttering* cells (STUT, see Figure 1B2) fire high frequency AP-clusters (with no or minimal accommodation) intermingled with unpredictable periods of silence (“morse-code”-like discharges). Cells displaying stuttering near threshold and fast spiking at slightly higher depolarizations are not considered STUTs.
- *Irregular spiking* cells (IS, see Figure 1B2) discharge single APs in a random manner throughout a depolarizing pulse, but do not form distinct clusters of APs.

Each of these main classes displays an array of stereotypical onset responses, which have been used for subclassification. They either discharge with:

- a *burst* (a high-frequency cluster of three or more APs), that *seamlessly* merges into the steady-state response (b-subclass, see Figure 1B2),
- a distinct *delay* before discharging to a current pulse (d-subclass, see Figure 1B2). The duration of the delay decreases progressively as the amplitude of current injection increases. Delayed discharging cells characteristically show significantly higher action potential thresholds than the b- and c-subclasses, or
- neither a burst nor a delay (referred to a *classical* response). The “onset” phase of these cells (c-subclass, see Figure 1B2) is therefore indistinguishable from the steady-state phase.

A fifth main class of *bursting* cells (BST; less frequent than the above main classes), with three subclasses, was recently observed (not shown). The onset response of BST cells is characterized by a high-frequency cluster of three to five APs riding on a slow *depolarizing wave* followed by a strong *slow* AHP, that causes a *clear separation* of the onset burst response from the consecutive steady-state responses, even at high current injections. The peak amplitudes of these APs decrease during the bursts in most cells. These burst properties differ fundamentally from those that define the b-subclasses of NAC-, AC-, STUT-, and IS-cells. BST-cells may be subclassified according to their steady-state discharge response into

- *r-BST* cells, which characteristically discharge *repetitive* burst (r = repetitive),
- *s-BST* cells, which characteristically fail to discharge after their initial burst due to a more pronounced, complex of powerful AHP (s = single), or
- *i-BST* cells, which characteristically discharge an accommodating train of APs (i = initial).

Recent computational studies have addressed the mechanisms of bursting behavior in neocortical PCs (see Oscillatory and Bursting Properties of Neurons). Similar studies for the other types of discharge behaviors in both excitatory and inhibitory neurons are eagerly awaited, especially in light of the profound effects, that different discharge properties may have on the behavior of neural circuits (i.e., van Vreeswijk and Hansel, 2001).

## Basic Neuron Types—Molecular

Neocortical neurons express a variety of intracellular molecules including classical neurotransmitters (glutamate, GABA, acetylcholine, and catecholamines), neuropeptides, and calcium-binding proteins (CaBPs), as well as a multitude of different cell-surface molecules (neurotransmitter receptors, etc.). While these molecular species are found throughout the neocortex, each neuron only expresses some of these molecules and in specific combinations

**Table 2.** Molecular Classes of Excitatory and Inhibitory Neocortical Neurons

Molecular Classes of Excitatory Neurons (Glutamate +)

| Calcium Binding Proteins | Neuropeptides | Anatomical Identity | Electrophysiological Identity |
|---|---|---|---|
| CB | — | PC | RS |
| — | SOM | PC | RS |
| — | CCK | PC | RS |
| CB | CCK | PC | RS |

Molecular Classes of Inhibitory Neurons (GABA +)

| Calcium Binding Proteins | Neuropeptides | Anatomical Identity | Electrophysiological Identity |
|---|---|---|---|
| CB | — | LBC, NBC, BTC, MC, DBC | c-AC, c-NAC, d-NAC |
| PV | — | ChC, LBC, NBC | c-NAC, d-NAC, c-STUT, d-STUT |
| CR | — | BPC, DBC, CRC | c-AC |
| CB + PV | — | LBC, NBC | d-NAC |
| — | NPY | LBC, MC, NBC | c-AC, c-NAC, d-NAC, c-STUT |
| — | VIP | DBC, BPC, SBC | c-AC, b-NAC, c-IS, b-IS |
| — | SOM | MC, BTC, NBC | c-AC, c-NAC, b-AC |
| — | CCK | LBC, BTC, MC, NBC, SBC | b-NAC, c-AC, c-NAC, c-STUT |
| CB | SOM | MC | c-AC |
| PV | SOM (*) | NBC | c-AC |
| CR | VIP | BPC, BTC | b-IS |
| CB | NPY + SOM | MC | c-AC |

Excitatory neurons (shown to express glutamate) and inhibitory neurons (shown to express GABA or GABA producing enzymes GAD 65 and/or GAD 67), located throughout layers II–VI, have been sorted according to the detection of CaBPs, neuropeptides, and their co-expression. Abbreviations explained in text. In all cases listed, consistent expression profiles have been determined at both the protein and mRNA level, except (*), in which co-expression of SOM and PV was only detected at the mRNA level (compare Cauli et al., 1997, Wang et al., 2002, with Kawaguchi and Kubota, 1997). Note that the expression profiles are listed separately for *either* the anatomical *or* electrophysiological identities of the inhibitory neurons. Detailed information regarding expression profiles of SSCs not available to date.

(DeFelipe, 1993), allowing the use of expression and co-expression patterns for neuronal classification. Of these "molecular markers," the (co-) expression of the most common CaBPs (calbindin, CB, parvalbumin, PV and calretinin, CR) and neuropeptides (neuropeptide Y, NPY, vasoactive intestinal peptide, VIP, somatostatin, SOM, cholecystokinine, CCK) has been most extensively studied (Cauli et al., 1997; DeFelipe, 1997; Kawaguchi and Kubota, 1997; Wang et al., 2002). The functional significance of this molecular diversity is currently not fully understood, although some of the above-mentioned "markers" (i.e., synaptically released neuropeptides) have been implicated in modulating synaptic transmission and/or neuronal excitability.

Table 2 summarizes molecular expression profiles of neocortical neurons (mainly layers II–VI; except CRC, see previous discussion) for the most commonly investigated CaBPs and neuropeptides, based on studies of protein- or mRNA-expression (mainly rodent neocortex). Whereas, *every* molecular expression profile detected at the protein level has been confirmed at the mRNA level, some mRNA-expression profiles have not been detected at the protein level (compare Cauli et al., 1997 and Wang et al., 2002, with Kawaguchi and Kubota, 1997). In general, neocortical excitatory neurons (mainly PCs) have been shown to differ from inhibitory neurons, (1) in that the percentage of PCs expressing CaBPs and/or neuropeptides is considerably lower and (2) in that they typically display a much more restricted set of expression profiles.

## Discussion

This article outlines the main properties defining the basic cell types in the neocortex. The most striking feature of neocortical neurons is their immense anatomical, electrophysiological, and molecular diversity. All anatomical cell types can display multiple discharge patterns and molecular expression profiles. Different cell types are synaptically interconnected according to complex organizational principles to form intricate stereotypical microcircuits. It is still unknown how afferent and efferent pathways determine the locations, dimensions, and functions of these seemingly omnipotent microcircuits that underlie the formation of functional columns. The major challenge for neural network models is to incorporate and account for the cellular diversity, which may explain the universal computational capability of these stereotypical microcircuits.

# Neocortex: Chemical and Electrical Synapses

*Jay R. Gibson and Barry W. Connors*

## Introduction

Synapses are specialized sites of communication between neurons. Our goal here is to summarize the diverse functional properties of synapses in neocortex. Synapses in the neocortex tend to be small, but their structure and biochemistry are complex. This intricacy befits their rich and highly dynamic functions. Short-term dynamics allow synapses to serve as temporal filters of neural activity; long-term synaptic plasticity provides specific, localized substrates for various forms of memory; modulation of synaptic function by neurotransmitters provides a mechanism for globally altering the properties of a neural circuit during changes of behavioral state. An important point is that each of these functions—short- and long-term plasticity and modulation—has diverse forms that vary between synapses, depending on their site within the cortical circuit.

Synapses come in two distinctly different types, chemical and electrical, both of which exist in neocortex. Chemical synapses are by far the most abundant. They use a chemical neurotransmitter that is packaged presynaptically into vesicles, released in quantized (vesicle-multiple) amounts, and binds to postsynaptic receptors that either open an ion channel directly or activate a G protein–coupled receptor. Electrical synapses are simpler in both structure and function. Their essential element is a protein called a *connexin;* 12 connexins form a single intercytoplasmic ion channel, and a cluster of such channels constitutes a *gap junction*. Electrical synapses provide a direct pathway that allows ionic current or small organic molecules to flow from the cytoplasm of one cell to that of another.

Our description of the neurons and synapses in the neocortex will follow the very simplified diagram shown in Figure 1. This represents only the input stage of the circuit, but it serves to outline the range of synapse functions seen throughout neocortex; we neglect synaptic connections between cortical layers and areas, as well as the output pathways. Most of the data discussed here originated in studies of sensory and motor neocortices of adolescent and adult rats, mice, guinea pigs, and cats.

## Excitatory and Inhibitory Cells

To make sense of the diversity of neocortical synapses, it is essential to understand the nature of the neurons that they interconnect. Neocortical neurons are either excitatory or inhibitory; i.e., their axons form presynaptic terminals that release the excitatory transmitter glutamate or the inhibitory transmitter $\gamma$-aminobutyric acid (GABA). Excitatory neurons include virtually all pyramidal cells and the spiny stellate cells of layer 4 (Figure 1, center). The somata of pyramidal cells exist in all layers below layer 1, and they extend an apical dendrite toward, and often into, layer 1. Pyramidal cells are the output neurons of the neocortex, and their axons often project to other brain areas. Spiny stellate cells are small, locally interacting cells confined to layer 4. Excitatory cells usually produce action potentials that have "regular spiking" characteristics, although subsets may have intrinsic bursting properties (Connors and Gutnick, 1990; see also Oscillatory and Bursting Properties of Neurons).

The inhibitory neurons tend to have relatively few spines on their dendrites (Thomson and Deuchars, 1997). Many classification schemes have been proposed for inhibitory interneurons based on

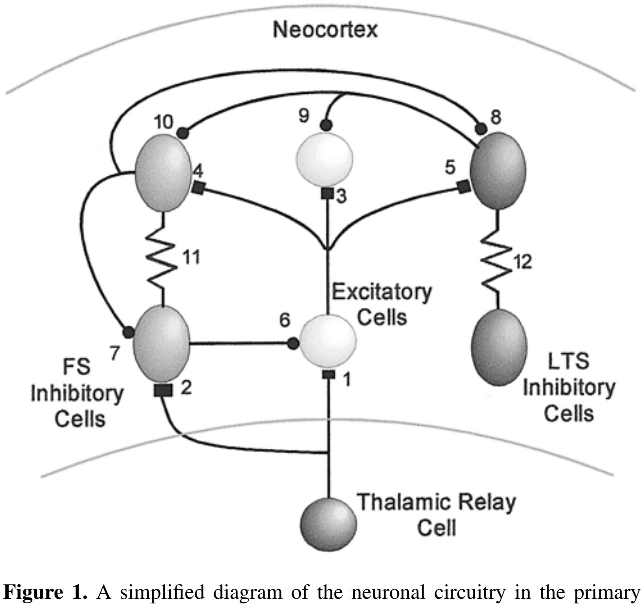

**Figure 1.** A simplified diagram of the neuronal circuitry in the primary input layer of sensory neocortex. Chemical synapses are represented by rectangles (for excitatory synapses) or dots (for inhibitory synapses), and electrical synapses are represented by zig-zags. The numbers refer to specific synaptic connections that are described in the text.

their dendritic and axonal morphology, the genes they express, their electrophysiological properties, and their synaptic physiology (e.g., Kawaguchi and Kubota, 1997; Gupta, Wang, and Markram, 2000; see also Neocortex: Basic Neuron Types). The number of inhibitory cell types and the criteria for distinguishing them are not universally agreed upon.

The majority of inhibitory neurons can be divided into three basic classes. The first expresses the $Ca^{2+}$-binding protein parvalbumin, and constitutes about 50% of all GABAergic neurons. Physiologically these cells are often called "fast spiking" (FS) because of their exceptionally short-duration action potentials, which can fire at high rates with little or no adaptation (Figure 1, left). Morphologically, many FS cells are either classical basket cells, with axons that make synaptic contacts onto somata or proximal dendrites, or chandelier (axo-axonic) cells, which synapse exclusively onto the initial axon segments of pyramidal cells. The second largest class of inhibitory neurons expresses the $Ca^{2+}$-binding protein calbindin, as well as the neuroactive peptide somatostatin; these neurons constitute about 17% of GABAergic neurons. Physiologically, at least some are "low-threshold spiking" (LTS) cells; their tonic firing shows adaptation, and they can fire rebound spikes in response to hyperpolarization (Figure 1, right). LTS cells often have vertically oriented dendritic patterns, and probably include many of the sparsely spiny, bitufted cells and Martinotti cells. A third class of cells stains for the $Ca^{2+}$-binding protein calretinin and for vasoactive intestinal polypeptide (VIP), and they also constitute about 17% of GABAergic neurons. Their physiological properties include irregular or intermittent firing patterns in response to steady current stimuli, and morphologically they are usually vertically oriented bipolar cells.

## Neurotransmitters and Their Receptors

The excitatory neurotransmitter glutamate binds to two types of iontropic receptors: non-NMDA and NMDA (Ozawa, Kamiya, and Tsuzuki, 1998). The binding of glutamate induces a conformational change in the receptor, which biases an ion channel toward an open state, allowing the passage of ions. Currents passing through these channels usually have a reversal potential around 0 mV. Because the transmembrane potential of a cell is usually much more negative than this, channel opening results in net inward current flow and transient membrane depolarization: the excitatory postsynaptic potential (EPSP). Usually, both types of glutamate receptors exist at the same excitatory synapse. Non-NMDA receptors can be further subdivided into AMPA receptors and kainate receptors. AMPA receptors mediate the vast majority of fast glutamatergic EPSPs, while the functions of kainate receptors are poorly understood. Most AMPA receptor channels are permeable to $Na^+$ and $K^+$ and have linear current-voltage relationships, but many excitatory synapses on inhibitory cells also include AMPA receptor subtypes that are permeable to $Ca^{2+}$ and have a more nonlinear current-voltage relationship. In response to synaptically released glutamate, AMPA receptor-mediated currents have an extremely fast onset, and a decay time constant of roughly 3 ms.

NMDA receptor-mediated responses, in contrast, are slow; their decay time constants are about 40 ms. They are also highly permeable to $Ca^{2+}$, in addition to $K^+$ and $Na^+$. NMDA receptors have a nonlinear voltage dependence, with highest conductance at potentials positive to about $-30$ mV. The voltage dependence of the NMDA channel is caused by extracellular $Mg^{2+}$ ions, which block the channel due to electrostatic attraction; membrane depolarization releases this attraction. As a consequence, at standard excitatory synapses containing both NMDA and AMPA receptors, synaptic release of glutamate always opens AMPA receptors, whereas NMDA receptors are open only during the conjunction of glutamate release and relative depolarization of the postsynaptic membrane. This property allows NMDA receptors to act as coincidence detectors, sensing the simultaneous activation of presynaptic glutamate release and postsynaptic activation of the cell through other synaptic inputs. The opening of NMDA receptors, and the subsequent influx of postsynaptic $Ca^{2+}$ they provide, is thought to mediate many forms of long-term synaptic change.

Fast inhibitory synaptic transmission in neocortex seems to be exclusively mediated by the neurotransmitter GABA (Connors, 1992). GABA binds to ionotropic $GABA_A$ receptors, inducing the opening of channels permeable to $Cl^-$. $Cl^-$ reversal potentials tend to be about $-70$ mV in mature neocortical neurons. If the postsynaptic membrane is positive to this potential, inhibitory activation evokes a transient hyperpolarization—an inhibitory postsynaptic potential (IPSP)—owing to the influx of $Cl^-$. An inhibitory effect may result either from this shift in membrane potential, or from a current "shunt" caused by the increase in membrane conductance to $Cl^-$. Synaptically triggered $GABA_A$ currents have a decay time constant of about 10 ms in cerebral cortex.

So far, we have only discussed synaptic transmission mediated by ionotropic receptors, i.e., receptors that are also ion channels. There are also many examples of synaptic transmission mediated by metabotropic receptors, i.e., receptors that activate G proteins, which in turn interact with downstream effector proteins. All neurotransmitters known to exist in neocortex activate specific metabotropic receptors. These include the two most important neurotransmitters that activate ionotropic receptors, glutamate and GABA, as well as other neuromodulators. Metabotropic responses tend to start more slowly than ionotropic responses (tens to hundreds of milliseconds versus fractions of a millisecond), last much longer (hundreds of milliseconds to seconds versus a few milliseconds), and can occur in both postsynaptic cells and presynaptic terminals. Postsynaptically, responses can be inhibitory, excitatory, or both. Most notable is the slow IPSP mediated by the $GABA_B$ receptor, which is generated by an increase in $K^+$ conductance (Connors, 1992). Presynaptic metabotropic effects modify, and usually depress, the subsequent release of neurotransmitter.

## Functional Properties of Chemical Synapses

The effectiveness of a chemical synapse is determined by several factors, including the probability of transmitter release (which can range widely, from near zero to almost one), the mean number of transmitter quanta released (which for many neocortical synapses is a maximum of one quantum per presynaptic terminal), the dynamics of the release process, and the history of prior activity. These factors often interact. We will describe how the functional properties of synapses vary between different pathways in neocortex; numbers in boldface refer to specific synapses in Figure 1. When we speak of a "unitary" synaptic response we mean the postsynaptic response to the firing of a single presynaptic cell or axon. One axon may make multiple synaptic contacts onto a single postsynaptic cell, so the strength of a unitary response is strongly determined by the number of synaptic contacts per axon, in addition to the physiological factors listed above. The "short-term dynamics" of a synapse refers to its time-varying changes in strength during repetitive activation over relatively brief intervals (milliseconds to seconds). Synapses may show short-term depression or facilitation, or a combination of the two.

### *Thalamic Input*

Thalamic inputs are the conduit by which all specific information enters the neocortex. Thalamocortical axons form relatively strong excitatory synapses onto excitatory cells (**1**) and FS inhibitory cells (**2**), but not LTS cells (Figure 1; Gibson, Beierlein, and Connors, 1999). The strongest responses are generated in cortical layers 4 and 6, where most thalamic axons terminate. Unitary thalamocortical connections generate relatively large-amplitude EPSPs, with high reliability and practically no failures, and the responses show pronounced short-term depression (Figure 2*A*; Gil, Connors, and Amitai, 1999). Unitary thalamocortical EPSPs onto excitatory cells activate an average of roughly seven synaptic release sites, but unitary inputs to FS cells are twice as strong, with occasional single-axon responses surpassing 12 mV (FS mean = 4 mV, excitatory cell mean = 2 mV). Electron microscopic observations show that thalamocortical synapses terminate primarily on the soma and proximal dendrites of FS cells, and on the proximal dendritic spines of excitatory spiny stellate cells in layer 4 (Somogyi et al., 1998).

### *Intracortical Excitatory Synapses*

The probability and strength of excitatory synaptic contacts vary widely and depend on the nature of the targets. Estimates suggest that the typical unitary connection between two excitatory cells (**3**) comprises about two to eight synaptic contacts, on average about half that of the average thalamocortical connection (Gil et al., 1999). These synapses target mostly dendritic spines (85%). There are exceptions. For example, a specific population of layer 6 spiny cells projects only 30% of its synapses onto spines (Somogyi et al., 1998). The amplitude of unitary intracortical EPSPs range from less than 0.5 mV up to 9 mV. The larger the response, the more reliable it tends to be. Failure rates are higher in connections with relatively small unitary responses (Thomson and Deuchars, 1997).

The dynamics of synapses between excitatory cells range from moderately depressing to weakly facilitating. The short-term dynamics of these intracortical connections depend on the maturity of the cortex. For instance, in the adolescent rat (14–17 days postnatal), excitatory synapses between layer 5 pyramidal cells show clear depression, but by postnatal day 28 the same synapses are either weakly depressing or slightly facilitating.

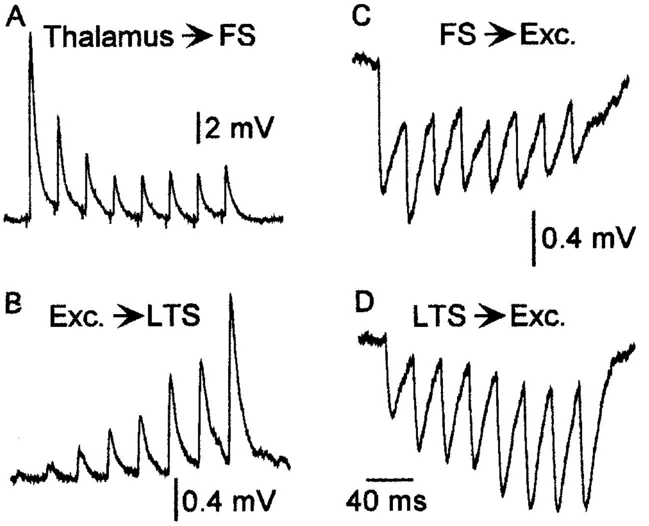

**Figure 2.** Variability in the strength and short-term dynamics of specific synaptic connections. In each case the presynaptic cell was activated at 40 Hz to test the dynamics of the postsynaptic response. *A*, The excitatory synapses from thalamocortical axons onto FS inhibitory cells (connection **2** in Figure 1) tend to be relatively strong and reliable, but depress during activation at high frequencies. *B*, The intracortical synapses from excitatory cells onto LTS inhibitory cells (**5**) tend to be quite unreliable when first activated, but strongly facilitate at frequencies above about 20 Hz. *C*, Inhibitory synapses from FS cells onto excitatory neurons (**8**) tend to be strong and reliable, and show moderate depression. *D*, Inhibitory synapses from LTS cells onto excitatory neurons (**9**) are moderately strong, and often facilitate during high-frequency activation. (Data from M. Beierlein, J. R. Gibson, and B. W. Connors.)

Excitatory cells also synapse onto inhibitory cells, but the properties of the synapses vary with the postsynaptic inhibitory cell type. When excitatory axons fire at a rate above 5 Hz, EPSPs onto FS inhibitory cells (**4**) generally depress (Thomson and Deuchars, 1997). At low frequencies of stimulation (<0.2 Hz), unitary EPSPs onto FS cells are relatively reliable, with low failure rates. Unitary EPSP sizes can range from a few $\mu$V to 12 mV, and they have a distinctly shorter duration than EPSPs in excitatory cells (Thomson and Deuchars, 1997). Axons from excitatory cells make about one to four synapses onto a single FS cell, and yield a response about 1 mV in amplitude. Most of these synapses terminate on dendrites, with fewer onto the soma.

The intracortical excitatory synapses that terminate on LTS inhibitory cells (**5**) have unusual dynamics, showing very strong short-term facilitation when activated at frequencies above 20 Hz (Figure 2*B*). At low-frequency stimulation (<1 Hz), EPSPs onto LTS cells have high failure rates, despite the likelihood that unitary connections are mediated by as many as three to 12 synapses. At higher frequencies, after facilitation develops, unitary EPSPs can be as large as 3 mV. Thus, inhibitory LTS cells may be activated only when local excitatory cells fire at high and sustained rates, suggesting that they serve as a "governor" on the cortical circuit, helping to prevent runaway excitation.

Metabotropic glutamate receptors (mGluRs) are expressed by various types of neurons in neocortex, both pre- and postsynaptically. Postsynaptic effects mediated by these receptors presumably require relatively large rates of glutamate release. Electron microscopy has localized mGluRs to the marginal regions of the subsynaptic membrane (Somogyi et al., 1998). Responses mediated by mGluRs are relatively slow, lasting hundreds of milliseconds. Some types of excitatory cells apparently depolarize when mGluRs are activated, while others hyperpolarize; it may be that responses vary with the neurons' laminar location. Activating mGluRs depolarizes FS and LTS cells, but LTS cells are more strongly excited. Glutamate can also act on mGluRs expressed on presynaptic terminals. Activation of presynaptic mGluRs usually inhibits further transmitter release, reducing the amplitude of the postsynaptic response.

Fast, ionotropic excitatory synaptic transmission in neocortex is subject to long-term synaptic plasticity. Long-term potentiation (LTP) and long-term depression (LTD) occur primarily at excitatory synapses onto excitatory cells, but generally not at synapses onto inhibitory cells. Some forms of LTP and LTD depend on the opening of NMDA channels, while other forms of LTD depend on activation of the metabotropic glutamate channel.

### *Inhibitory Synapses*

Inhibitory cells may inhibit excitatory neurons or other inhibitory neurons. The connection specificity depends on the cell types involved (Thomson and Deuchars, 1997; Kawaguchi and Kubota, 1997; Somogyi et al., 1998). Calretinin-expressing interneurons preferentially inhibit other interneurons in visual cortex, but the functional properties of their synapses are unknown. FS (parvalbumin-expressing) cells frequently synapse onto excitatory cells (**6**), other FS cells (**7**), and onto LTS cells (**8**), where they tend to form synapses on the soma or dendritic shafts. Unitary axonal connections of up to 20 synapses have been described, from a single basket (FS) cell onto the soma and proximal dendrites of spiny cells and other inhibitory interneurons. Responses mediated by FS-derived synapses are very reliable, but tend to depress during repetitive activation (Figure 2*C*). The unitary IPSPs of these synapses have peak amplitudes of about 2 mV when the postsynaptic cell's membrane potential is just below firing threshold. Some neocortical areas have an FS-like interneuron, called the axo-axonic cell, whose synapses exclusively and precisely target the axonal initial segments of pyramidal cells. The IPSPs of the axo-axonic connection have not been characterized in neocortex, but a similar connection in hippocampus displays short-term depression (Thomson and Deuchars, 1997).

Anatomical studies show that LTS-like (somatostatin-expressing) cells tend to synapse on the more distal dendritic shafts and spines of excitatory cells (**9**) and on distal dendritic shafts of FS cells (**10**). In one example, an LTS cell made ten synapses onto a single pyramidal cell—six onto spines and four onto dendritic shafts. Interestingly, recordings from neurons in layer 4 imply that LTS cells rarely make chemical synapses upon one another. The short-term dynamics of inhibitory synapses from LTS cells differ from those of FS cells. LTS-to-spiny cell IPSPs are fairly stable at 10 Hz and slower, while at 40 Hz and above they often show moderate facilitation (Figure 2*D*).

The computational consequences of inhibitory synapses can be complex, and synaptic location can play a role (Vu and Krasne, 1992). For example, activation of distal inhibition may shift the preferred input of the postsynaptic cell to a more proximal position. Proximally placed inhibition may be most effective for controlling the precise timing of action potentials and subthreshold activity. Postsynaptic inhibition can be divisive or subtractive in overall quality, depending on whether the inhibitory synapse is near the soma or farther out on the dendrites, respectively.

Activation of single inhibitory neurons tends to induce pure $GABA_A$ receptor-mediated IPSPs in both excitatory and inhibitory cells. However, strong stimulation, which activates multiple inhibitory cells and yields large quantities of GABA release, can evoke an additional, and much longer-lasting, IPSP that is mediated by $GABA_B$ receptors (Connors, 1992). Most $GABA_B$-mediated inhibition has been studied in excitatory cells, and its possible role in regulating inhibitory neurons is unknown. $GABA_B$ receptors are also located presynaptically on both GABA- and glutamate-releasing terminals. When these receptors are activated, they inhibit evoked transmitter release.

## Electrical Synapses

Electrical synapses have been directly demonstrated only between inhibitory neurons in the neocortex (Gibson et al., 1999; Galarreta and Hestrin, 2001), although there is indirect evidence that they may be more widespread early in development. Electrical synapses allow ionic current to pass directly between cells, equally well in both directions, with little or no voltage or time dependence. Recordings from two electrically coupled LTS cells are shown in Figure 3. Current steps of opposite polarity applied to $LTS_1$ induced either depolarization plus a train of action potentials, or a hyperpolarization ($V_1$); the voltage of $LTS_2$ responded in parallel with either strongly attenuated action potentials riding on a slower depolarization, or a slow hyperpolarization, respectively ($V_2$). The electrical synapses of inhibitory cells have an average "coupling coefficient," or attenuation factor, of about 0.1 for low-frequency signals; this decreases to about 0.01 for faster signals such as action potentials. Thus, a single presynaptic spike of 90 mV induces an electrical PSP that is typically less than 1 mV at its peak.

The functional significance of electrical synapses in neocortex is currently being studied. In general, electrical synapses promote synchronous electrical activity among the interneurons they connect. The electrical synapses between interneurons are located at dendrodendritic or dendrosomatic sites of contact (Tamas et al., 2000). This constrains them to closely neighboring cells, and indeed the most strongly connected inhibitory cells have somata within 100 $\mu$m of each other. Extensive sampling of neuron pairs in layer 4 (Gibson et al., 1999) showed that, with rare exceptions, FS cells formed electrical synapses only with other FS cells (**11**), and LTS cells only with LTS cells (**12**). Thus, electrical synapses are a molecular and functional marker that serves to define and distinguish the boundaries between the FS and LTS inhibitory networks. It is also possible that the connexin-based channels of electrical synapses mediate the passage of small organic signaling molecules between interneurons.

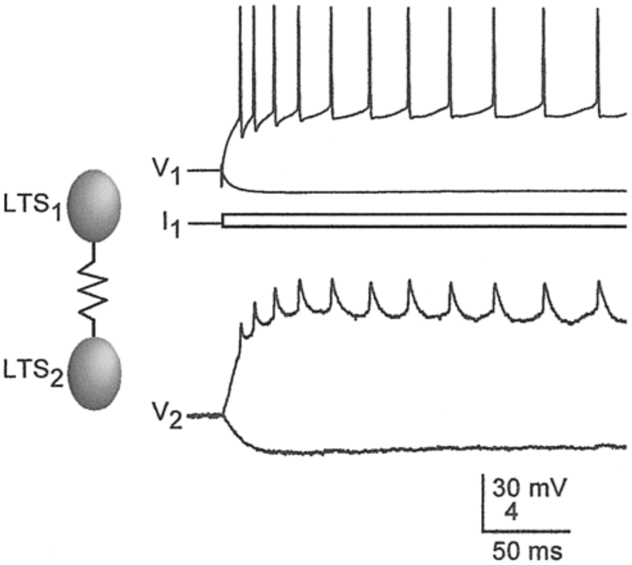

**Figure 3.** An electrical synapse between two LTS inhibitory neurons. Recordings on the top right show the superimposed responses of the first cell ($LTS_1$) as it was directly stimulated by two steps of injected current, depolarizing and hyperpolarizing. Responses from the second cell ($LTS_2$), on the lower right, were generated by current flowing through the electrical synapse from $LTS_1$. Notice that action potentials were more strongly attenuated than low-frequency voltage components. Voltage calibration is 30 mV for top traces, 4 mV for lower traces. (Data from J. R. Gibson, M. Beierlein, and B. W. Connors.)

## Neuromodulation

Modulators such as acetylcholine, norepinephrine, serotonin, dopamine, and histamine can modulate presynaptic and postsynaptic neocortical function via G protein–coupled receptors. In general, these modulators are released throughout most or all of the neocortex from synaptic terminals whose axons originate extracortically, and the rates of modulator release depend strongly on behavioral state (Steriade, McCormick, and Sejnowski, 1993).

The two best-studied neuromodulators are acetylcholine and norepinephrine, and many of their effects are similar. Via postsynaptic actions, they can both depolarize and hyperpolarize excitatory cells, depending on the receptor subtypes that they activate, and they can also modulate spiking patterns via more subtle actions. Acetylcholine and norepinephrine depolarize both FS and LTS interneurons, but they are more effective at inducing LTS cells to surpass action potential threshold. Presynaptic effects of these modulators usually suppress transmitter release, resulting in smaller PSPs together with a reduction in short-term depression.

## Discussion

There seem to be distinct rules governing the synaptic connections among neurons in the neocortex. First, connections are specific; for example, thalamocortical synapses are strong and common onto FS interneurons but quite weak and rare onto LTS interneurons, and electrical synapses only interconnect interneurons of similar type. Second, the functional characteristics of synapses, such as efficacy, short-term dynamics, and location, vary with the identity of the pre- and postsynaptic neurons that participate in making the synapse. Third, synaptic function can be modulated by the common transmitters intrinsic to neocortex, glutamate and GABA, and by transmitters such as acetylcholine and norepinephrine that are mainly released by extrinsic neurons whose activity depends on behavioral state. The computational consequences of these complex synaptic properties are rich (e.g., Markram et al., 1998; see also Temporal Integration in Recurrent Microcircuits and Temporal Dynamics of Biological Synapses), although far from fully understood.

# Neural Automata and Analog Computational Complexity

*Hava T. Siegelmann*

## Introduction

Computational theory has developed hand in hand with the field of neural computation. The Turing machine was suggested in 1935 as a model of a mathematician who solves problems by using a specifiable algorithm. McCulloch and Pitts demonstrated the first computational model of a neuron, where they explicitly sought to provide a "brain" for the Turing machine. They proposed to model the nervous system as a finite interconnection of logical devices. Following the development of von Neumann's universal model of computation based on the principle of the McCulloch-Pitts neuron, the digital approach prevailed in the field of cybernetic research.

In the last few decades, continuous, rather than digital, neural network models have been emphasized. Unlike the output values 0, 1 of the McCulloch-Pitts neuron, these models calculate continuous values. This was key to the development of the backpropagation algorithm that learns neural parameters; it enabled the foundation of machine learning, engineering tools such as optimal controllers, and adaptive technologies.

The connection between neural networks and computation, or more generally between physical systems and computation, is formalized by computational theories that describe features and capabilities of computational process. Automata are the basic mathematical abstractions used in such formalization.

A digital automaton has a set of internal states $\Omega$, it receives a string of input symbols belonging to an alphabet $\Sigma$, and it moves from state to state according to the transition rules until the computation ends. Current neural automata are quite different from classical automata. Whereas classical automata describe digital machines, neural models frequently require a framework of analog computation. In these terms, a physical system, beginning from an initial state (input), evolves in its state space according to an update equation (the computation process) until it reaches some designated state (the output).

Properties that distinguish analog from digital computation include the following:

1. Analog models are defined on a continuous phase space, while the phase space of a digital model is inherently discrete.
2. Physical dynamics is characterized by the existence of real constants that influence the macroscopic behavior of the system. In contrast, in digital computation all constants are in principle accessible to the programmer.
3. The motion of a physical system has local continuity. Unlike the flow in digital computation, analog models do not include locally discontinuous statements such as if $x > 0$ then compute one thing and if $x > 0$ continue in another computation path.
4. Continuous time dynamics is part of some analog systems.
5. A system composed of analog components may be sensitive to external noise.

In this article, we first review some work on analog and neural computation, and then focus on analog computation under noise. The fundamental question is, how should computational models described by networks of continuous neurons be characterized? The need for theories describing the operations and capabilities of machines that are analog or adaptive arises when one wants to describe and analyze nature's computation, as well as the already developing analog chips and adaptive technologies.

## Analog Computation

Blum, Shub, and Smale (1989) introduced a discrete-time computational model that operates in each time step on real-valued registers. The BSS model is considered a model of computation over the real numbers, rather than a model of analog computation, because it lacks the property of local continuity (item 3 above). Hybrid models of computation behave similarly. These models combine discrete- and continuous-time dynamics, usually by means of ODEs that are governed by finite automata. Because of their finite automaton component, hybrid systems also do not adhere to local continuity. A coupled map lattice is the analog version of a cellular automaton. This model is composed of an infinite lattice of variables with a local homogeneous transition rule, and can be defined generally enough to include practically any discrete-time model. The general-purpose analog computers, by Shannon (1941) and by Pour-el (1974), are based on continuous-time operators and include integrators. Unlike their name, these models are not universal and not very general.

Of special interest in physical computation are analog systems based on dissipative dynamics. Dynamical systems are called dissipative if their dynamics converge to attractors. When a dissipative system has energy (Lyapunov) functional, the attractors are fixed points; otherwise, more complex attractors may appear. Dissipative systems are mainly popular in neural modeling of memory, such as in the Hopfield and other related models. The meaningful attractors of these networks, where information is stored, are all simple: either stable fixed points or limit cycles. There are various models of neural activity that report chaos, such as in the olfactory, though they are typically not being considered in computational terms.

The dynamics of dissipative systems can be thought of as computation: either the initial state or parameter values can be considered the input to a computational problem, the evolution along the trajectory is the computation process, and the attractor describes the solution. We realized (Siegelmann and Fishman, 1998) that while fixed points can be computed efficiently, chaotic attractors could only be computed efficiently by means of nondeterminism. The inherent difference between fixed points and chaotic attractors led us to propose that, in the realm of dynamical systems, efficient deterministic computation differs from efficient nondeterministic computation: Pd <> NPd.

A general theory of computation for dissipative dynamical systems was developed in Siegelmann, Ben-Hur, and Fishman (1999). This theory interprets the evolution of dissipative dynamical systems, both discrete and continuous in state space and in time, as a process of computation, and it relates the computational complexity to the true relaxation time. Prior to this work, no tool existed with which to analyze continuous-time algorithms and analog VLSI systems; ODE-based algorithms could only be analyzed by means of time discretization, which could result in loss of the main characteristics of these systems. We exemplified our theory with popular computer science problems, showing, e.g., a continuous algorithm for the maximum network flow problem that has linear time complexity, an algorithm for MAX that converges in logarithmic time, and a probabilistic continuous algorithm for the linear programming problem, which for a Gaussian distribution over instances of LP converges in linear time.

The analog recurrent neural network consists of a finite assembly of simple processors (or neurons), each of which computes a scalar—real-valued, continuous function, or activation, of an integrated input (Siegelmann and Sontag, 1994). This activation function is nonlinear and monotonic with bounded range, reminiscent of neural responses to input stimuli. The scalar value produced by a neuron is, in turn, broadcast to the successive neurons involved in a given computation. The existence of feedback loops in the interconnection graph allows the processing of arbitrarily long data with a fixed size network. A related model is the network of spiking neurons (see SPIKING NEURONS, COMPUTATION WITH, and INTEGRATE-AND-FIRE NEURONS AND NETWORKS). There, the neurons output binary values only, but the time intervals between consecutive spikes are considered exact analog value. The computational analysis of the two models is similar under the transformation of neural value and time interval.

## Neural Automata

Unlike the von Neumann computer model, the structure of neural networks is not separated into a memory region and a processing unit; memory and processing are strongly coupled. Each neuron is part of the processing unit, and the memory is implicitly encoded in the mutual influence between any pair of neurons. The influence can be represented by a real number weight. The status of the weights prompts two different views of the neural mode according to whether the weights are perceived as unknown parameters or as fixed constants. When the weights are considered unknown parameters, the network is a semiparametric adaptive technology, able to approximate input-output mappings by means of parameter estimation/learning. When the weights are considered constant (after or without a process of adaptation), the networks can perform exact computations rather than mere approximations. We next consider the latter case.

In the McCulloch-Pitts neuron, the potential is updated by

$$u_i(t) = \sum_{j \in \mathrm{in}(i)} w_{ij} x_j(t - 1) \tag{1}$$

where in($i$) is the set of presynaptic neurons of $i$ and $w_{ij} \in \mathbb{R}$ is the weight on the edge directed from neuron $j$ to neuron $i$. The activation value is updated by

$$x_i(t) = \mathcal{H}(u_i(t) - c_i) \tag{2}$$

where $c_i$ is the firing threshold of neuron $i$ and $\mathcal{H}$ is the binary response function

$$\mathcal{H}(x) = \begin{cases} 0, & x < 0 \\ 1, & x \geq 0 \end{cases}$$

In the analog recurrent network, the activation function is continuous, e.g., the sigmoid $\sigma(x) = 1/(1 + e^{-x})$, or the *saturated-linear function*:

$$\sigma(x) = \begin{cases} 0, & x \leq 0 \\ x, & 0 < x < 1 \\ 1, & x \geq 1 \end{cases} \tag{3}$$

The update equation of the basic analog neuron is

$$x_i(t) = \sigma(u_i(t) - c_i) \tag{4}$$

where $u_i$ is defined as in Equation 1. Despite the similarity to the McCulloch-Pitts neurons, these two models are very different in their dynamical behavior and their computational power.

An asynchronous version of the analog neuron uses a potential, as in spiking neurons or integrate and fire neurons. Let $\mathcal{F}_j(t)$ be the set of firing times of neuron $j$ until time $t$, and let $\varepsilon_{ij}$ be a kernel function. The update equation of the neuronal potential is

$$u_i(t) = \sum_{j \in \mathrm{in}(i)} \sum_{\tau \in \mathcal{F}_j(t)} w_{ij} \varepsilon_{ij}(t - \tau) \tag{5}$$

Some variants of this model take into account the refractory period as well.

### *Preliminaries: Language Recognition*

The computer science approach of characterizing the discernibility between different inputs employs the concept of formal languages.

Let $\Sigma$ be a set of symbols, e.g., $\{0, 1\}$, called an *alphabet*. Finite sequences of symbols in $\Sigma$ are called *strings*. The set of all strings over $\Sigma$ is denoted by $\Sigma^*$. A subset of $\Sigma^*$ is called a *formal language*.

There are various ways to associate languages with automata, which are mostly equivalent. In this chapter we focus on language recognition. A *recognizer* reads an input string and decides whether the string is a correctly formed string of its language. Such a device has two types of halting states: accepting states and rejecting states. The language recognized or accepted by the automaton is the set of all input strings for which a computation ends in an accepting state. Thus, each automaton defines a language. Languages are divided into classes according to the type of automata that are needed to recognize them or the "difficulty" of recognizing them. Two types of automata are said to be equivalent if they accept the same class of languages.

A finite network of McCulloch-Pitts neurons has a finite memory only. This is far less than what one expects from a general digital computer. Even tasks like "decide whether there are more 0's or more 1's in a given binary input string" is not possible in a predefined size of memory. The formal description of a digital computer is in terms of the Turing machine. This consists of a control box with a finite memory coupled to a tape that is indefinitely expandable. The input is given by the initial state of the tape; the output is read off the tape if and when the Turing machine halts. Only with this extra tape are the languages recognized by digital machines captured mathematically.

To perceive neural automata as language recognition machines one needs to define an input-output convention. Two possibilities are outlined here. In the first the input is static, appearing in a designated set of neurons at the beginning of the computation. In the case of Boolean neurons, a finite network cannot encode an arbitrary number of symbols. (In this input convention one needs to consider a series of networks with an increasing number of input neurons.) In this article we consider mainly another input convention, where input arrives as a stream of symbols appearing consecutively on the input channels. This allows us to use a single network to recognize a language with strings of arbitrary length. In this convention, Equation 1 for the potential becomes

$$u_i(t) = \sum_{j \in \mathrm{in}(i)} w_{ij} x_j(t - 1) + \sum_{j \in I} b_{ij} I_j(t - 1) \qquad (6)$$

where $I$ is the set of input channels, $I_j(t)$ is the value of input channel $j$ at time $t$, and $b_{ij}$ are the weights that connect the input channels to the rest of the network. There are various possible conventions for halting a computation of an analog machine, such as convergence to a fixed point, or, as we will consider here, a designated neuron reaching some value. Acceptance is then decided from the value of another neuron. In asynchronous models, the input stream arrives in a predetermined sequence of times $t_{\mathrm{in}}^1$, $t_{\mathrm{in}}^2$, . . . at the input neurons.

### *Computational Power*

Deterministic networks of Boolean McCulloch-Pitts neurons were studied first. Minsky (1967) showed that Boolean networks can simulate any combination of Boolean gates, and thus in particular, finite automata. Sima and Wiedermann (1998) have quantified the size of a network required to recognize a particular regular language. They also characterized the Hopfield languages—the languages recognized by Boolean automata with symmetric interconnections—as a strict subset of regular languages. If a series of Hopfield networks is considered in the static input convention, the computational power is much higher.

Analog recurrent neural networks have been analyzed in a series of papers and in Siegelmann (1999). Although the structure and dynamics of analog recurrent neural automata are very different from those of the von Neumann machine, the automata were found to compute exactly like the digital computer when their parameters took rational values. Moreover, in the absence of noise, and if the networks took real-valued weights, they became more powerful than digital computers and recognized nonrecursive (super-Turing) languages. In particular, the efficient computation class is "P/poly."

To explain the extra power stemming from the real weights, two more results were obtained (Siegelmann, 1999). In one, the complexity, or information content, of the weights was measured by a variant of resource-bounded Kolmogorov complexity, taking into account the time required for constructing the numbers. With Balczar and Gavald, we showed a full and proper hierarchy of nonuniform complexity classes associated with networks having weights of increasing Kolmogorov complexity, of which the classes "P" and "P/poly" are the two extreme cases.

Second, we proposed a new model that, although it seems digital, is still hypercomputational. This model is a network with rational weights only. In addition to the neurons, it includes a binary coin that outputs 0/1 with a probability $p$ that is a real number. Although $p$ is a real number, it is never accessed by any neuron (the coin is binary, so the other neurons receive from it digital values only). The computational power of this type of network is still hypercomputational (though less than "P/poly"). That is, the real value does not have to be explicit, but any process that is affected by a real number brings on nonrecursive computation.

All of the results mentioned in this section assume a noise-free environment.

## Noisy/Probabilistic Analog Automata

The two classes of language that have arisen in noisy analog models are known as *regular* and *definite*. *Regular* languages are those accepted by finite automata. A language is called *definite* if for some integer $r$, any two strings coinciding on the last $r$ symbols are either both or neither in the language. Definite languages are reminiscent of short-term memory. If the alphabet is finite, then definite languages are also regular; otherwise, they are not comparable with them.

Models of noisy analog neural networks were recently examined (e.g., Casey, 1996; Maass and Orponen, 1998; Maass and Sontag, 1999). The networks appeared to compute either regular or definite languages. Similarly, earlier models of probabilistic automata and circuits (e.g., Rabin, 1970; Paz, 1971; Pippenger, 1990) were found to compute sometimes regular and sometimes definite languages, depending on the properties of the probabilistic transition rules. These results make one wonder which details of the stochastic systems are essential for the computational power and which details are "accidental" aspects of the specific models. In particular, can one describe a general mechanism leading to the generation of these two classes of languages?

This challenge was partially met by Roitershtein and Siegelmann (1999), who proposed a general framework of stochastic computation. This framework, called *Markov computational systems* (MCS), includes all of the models just mentioned. Furthermore, it provides a natural way to introduce probabilistic counterparts of many diverse computational systems, such as topological automata, networks with nonfixed (e.g., growing) dimensions, hybrid systems that combine discrete and continuous variables, cellular automata, coupled map lattices, and the Blum, Shub, and Smale (1989) model.

In our generalization, the internal states of an automaton are substituted by distributions of states, and the transition function that guides the movement is substituted by operators, using an "operator theoretic" framework. The alphabet can be any set (e.g., real numbers) and so is the state space (e.g., not necessarily Euclidean or even metric).

*Definition 1.* An operator $P$ acting in the space of finite measures defined on a measurable space $(\Omega, \mathcal{B})$ is said to be a *Markov operator* if for any probability measure $\mu$, the image $P\mu$ is again a probability measure. A *Markov system* is a set of Markov operators defined on an alphabet $\Sigma: \quad T = \{P_u : u \in \Sigma\}$.

A Markov system $T = \{P_u : u \in \Sigma\}$ is associated with a computational system, as follows. At each computational step $t = 0, 1, \ldots,$ the system receives an input symbol, $u_t \in \Sigma$, and updates its state, $x_t \in \Omega$. Let $\mu_t(A)$ be the probability of finding $x_t$ in the set $A$. Then the evolution of the system is governed by the update equation, $\mu_{t+1} = P_{u_t}\mu_{t.}$

For an input sequence $w = w_0w_1 \cdots w_n \in \Sigma^{n+1}$, define a Markov operator $P_w = P_{wn} \ldots P_{w1}P_{w0}$. If the probability distribution on the initial states is given by the probability measure $\mu_0$, then the distribution of states after $n+1$ computational steps on the input $w = w_0, w_1, \ldots, w_n$ is defined by

$$P_w\mu_0(A) = P_{w_n} \cdots P_{w_1}P_{w_0}\mu_0 \tag{7}$$

Let $\mathcal{A}$ be the set of "accepting" probability distributions, and let $\mathcal{R}$ be the set of "rejecting" probability distributions. We need the condition

$$\text{dist}(\mathcal{A}, \mathcal{R}) = \inf_{\mu \in \mathcal{A}, \nu \in \mathcal{R}} \|\mu - \nu\|_1 = \rho > 0 \tag{8}$$

where $\|\cdot\|_1$ is the total variation norm $\|\mu\|_1 = \sup_A \mu(A) - \inf_A \mu(A)$. Then, a Markov computational system is defined to accept or reject the input according to the distribution it has after reading the input string.

### Quasi-compactness and Regular Languages

$T = \{\text{P}_w : w \in \Sigma^*\}$ is considered quasi-compact when:

1. The alphabet $\Sigma$ is finite.
2. The operators $P_w$ are "close to being compact" in the sense that there exist $r > 0$ and $\delta < 1$ such that for every input string $w$ of length $r$, there exists a compact operator $Q_w$, which satisfies $\|P_w - Q_w\|_1 \leq \delta$.

We proved the correlation between quasi-compact operators and the recognition of regular languages. Special cases of automata that satisfy the above condition are the probabilistic automata of Rabin (1970) and the noisy model of Maass and Orponen (1998). Various conditions leading to quasi-compactness were shown.

### Weak Ergodicity and Definite Languages

Probabilistic computational models with the power to recognize definite languages have their roots in Rabin's (1970) pioneering work on probabilistic automata. Paz (1971) generalized the method and introduced the notion of weak ergodicity for automata having a denumerable state space. Maass and Sontag (1999) focused on analog recurrent neural nets perturbed with additive Gaussian-like noise of a certain type. We pinpointed the underlying connection of this chain and formalized its ultimate generalization. For this, we redefined weak ergodicity to describe all probabilistic systems that mix their probability distributions to the extent that they approach the uniform distribution. More formally,

*Definition 2.* A Markov system $\{P_u, u \in \Sigma\}$ is called *weakly ergodic* if for every $\alpha > 0$, there is an integer $r = r(\alpha)$ such that for any string $w$ with length larger than $r$ and any two probability distributions $\mu$, $\nu$,

$$\|P_w\mu - P_w\nu\|_1 \leq \alpha \tag{9}$$

Let $\mathcal{M}$ be defined with a weakly ergodic operator set. Then it recognizes only definite languages.

*Remark 1.* Weakly ergodic systems are robust with respect to perturbations of the system parameters and under some types of external noise.

# Neuroanatomy in a Computational Perspective

*Almut Schüz*

## Introduction

This article is intended to help the modeler get a feel for real brains. It provides an introduction to basic principles of brain organization and to network structures within the brain. By focusing especially on the cerebral cortex, the article shows how quantitative neuroanatomy can contribute to brain theory.

## The Role of Neuroanatomy in Brain Theory

In simple organisms in which the sensory organs are connected by direct pathways and effectors (muscles, glands), tracing such pathways may provide a sufficient explanation of behavior. However, in the course of evolution, the number of neurons has increased considerably and the pathways between input and output have become less and less direct.

The human brain contains between $7 \times 10^{10}$ and $8 \times 10^{10}$ neurons (Haug, 1986). Most of them belong to the cerebellar cortex (approximately $5 \times 10^{10}$) and the cerebral cortex (approximately $1.5 \times 10^{10}$). Many other parts of the human brain, such as the first relay station of the optic nerve in the thalamus, contain about $10^6$ neurons. The corpus callosum, the main fiber bundle that connects the two hemispheres, consists of about $10^8$ fibers. For a comprehensive collection of neuroanatomical measures, see Blinkov and Glezer (1968).

In small mammals, the numbers of neurons are reduced by a factor of about 1000 compared to the human brain. The cerebral cortex of the mouse, for example, contains about $10^7$ neurons, and the corpus callosum of the mouse contains about $10^5$ fibers. But even with these reduced numbers, a complete assessment of the neuronal network would be a hopeless undertaking.

However, the high number of neurons is not the main obstacle to understanding the neural mechanisms underlying higher brain functions. The situation is complicated by the fact that most connections in the brain are not one to one. In most nerve networks, it is beyond practical means to trace the anatomical pathways in detail. Many neurons receive input from thousands of other neurons and distribute their output to just as many. Physiologically, even if a direct anatomical connection between two neurons were demonstrated, whether the activity of neuron A leads to the activation of neuron B largely depends on what else is going on in the network.

Thus, in complex nerve networks, the task of neuroanatomy is not so much to study all of the connections in detail, but rather to show the typical structural properties that characterize a specific part of the brain. These properties provide clues to the understanding of its specific function, as will be shown later for the cerebral cortex.

## White and Gray Matter: Projection Versus Computation

One general principle of construction in the brain is the spatial separation of long axons (composing the "white" matter) from the synaptic tissue in which the signal exchange between neurons occurs—the "gray" matter. Over short axons running within the gray matter, a neuron can reach other neurons within a radius of a few hundred microns, up to a few millimeters at most; but through the white matter, neurons can reach cells located in the centimeter range and in distant regions of the brain and spinal cord.

The largest mass of white matter in the human brain is that of the cerebral cortex. The white matter of the hemispheres consists largely of fibers that connect different parts of the cortex to each other. Apparently, one of the principles of cortical connectivity is the rich projection of the cortex onto itself. In contrast, the thin sheet of white matter accompanying the cerebellar cortex indicates that local computation plays a major role in this part of the brain (Braitenberg, Heck, and Sultan, 1997).

## White Matter, Brain Size, and Connectedness

Large brains have comparatively more cortical white matter than do small brains. For example, 42% of the human neocortex (white and gray matter taken together) is white matter, while in the hedgehog the white matter content is only 13% (Frahm, Stephan, and Stephan, 1982). Clearly, if one wants to connect a large cortex in a style similar to one with fewer neurons, the fiber mass has to increase more than proportionately to the number of neurons. The question is whether the increase in white matter with brain size indicates an increasing, decreasing, or constant degree of interconnectedness. The answer is either decreasing or constant, depending on whether one is focusing on individual neurons or on groups of neurons. The percentage of neurons of the cortex reached by an individual neuron is definitely lower in larger cortices than in smaller ones. However, if one defines compartments the size of the largest dendritic trees in each species, and if one postulates a complete set of connections between all the compartments, the relative increase in white matter corresponds to a roughly constant interconnectedness (Braitenberg, 2001).

In a similar way, Mitchison (1992) showed that if the neurons in the cortex were not organized into spatially distinct areas connected through the white matter, but were merged into one huge piece of gray matter, the volume of the human cortex would have to increase by a factor of 10 to maintain the same degree of connectedness.

Not only the number of connections but also time delays play a role in the interconnectedness of various parts of a network. In a large brain, distant elements may not be able to collaborate efficiently owing to delays in the transmission from one point to the other. Since conduction velocity depends on the thickness of an axon, this problem could theoretically be solved by an appropriate increase in the diameter of the longer axons in larger brains. However, this remedy is self-defeating; thicker fibers would further increase brain size and therefore increase time delays, which would in turn require thicker fibers, and so on. Starting with a brain as large as the human one, such a series would converge at a volume approximately 50% larger if one wanted interhemispheric signals to travel twice as fast as they do (Ringo et al., 1994). As a way out of this dilemma, Ringo et al. (1994) have proposed a higher degree of functional specialization of cortical regions in larger brains.

## Overall Connectivity of the Brain

There are no isolated parts of the brain; there are fiber connections, direct or indirect, from any part of the brain to every other. Nevertheless, the brain is highly structured. Some parts (e.g., the cerebral cortex and the thalamus) interact directly with each other by way of reciprocal connections. Other parts may be arranged in loops, such as (1) the cerebral cortex–basal ganglia–thalamus (ventral anterior nucleus)–cerebral cortex loop and (2) the cerebral cortex–pontine nuclei–cerebellum (ventral lateral nucleus)–thalamus–cerebral cortex loop.

Such loops may traverse the same part of the brain and remain separate, as is the case for the two loops just mentioned when they pass through the thalamus. At other places, cross-talk may occur.

As a matter of fact, the cortical regions involved in these two loops overlap (Rouiller et al., 1994). In addition, shortcuts to the main stream may exist, parallel routes through further relay stations may accompany part of a loop, or subloops may be added to the main loop (see Basal Ganglia). Depending on the neurons involved, a signal can be fed back either negatively or positively onto the place of its origin. Positive feedback can also be transmitted by way of disinhibition when two inhibitory stations are connected in series. This type of positive feedback characterizes the cortico-cortical loop through the basal ganglia.

The projections between the various parts of the brain mostly suggest parallel processing in the sense that large regions of one part are connected to large regions of another by thousands or millions of fibers.

Sometimes, the projections from one part of the brain to another form patterns that suggest special kinds of computation. For example, the projections may be organized such that neighborhood relationships are maintained (e.g., the retinotopic projections in the visual system). In other cases, complex, patchy divergent, or convergent patterns may occur, suggesting a combination of inputs from different sources and/or distribution of inputs to disparate loci (e.g., projections from the various regions of the cerebral cortex to the basal ganglia).

The projections can also differ in that they may be point to point in some cases (sometimes one point to several points), while in others the terminal arbors of the axons may be smeared over large regions of the target structure. In a sense, this anatomical distinction corresponds to an important functional difference. Relatively restricted terminal arbors are typical for pathways that are involved in computation, such as those between the specific thalamic nuclei and the cerebral cortex or between cortical neurons. In contrast, huge terminal arbors extending over large portions of the brain and coming from small nuclei in the brainstem (e.g., the locus coeruleus) are involved in the global regulation of the level of activity, providing the background on which the information processing takes place (see Emotional Circuits).

## Geometry of the Gray Matter

Some of the structural features of the various parts of the brain are easily recognized at both the macroscopic and the microscopic level. The gray matter can either form lumps (often called nuclei) or show a two-dimensional, layered arrangement as in the so-called cortices. With respect to function, the latter type suggests that the same kind of operation is performed over the whole surface. One would expect such an arrangement, for example, in the processing of two-dimensional pictures. Indeed, this type of arrangement is found in centers for visual processing in all vertebrates, as well as in many invertebrates. Among the cortices, further distinctions can be made (Figure 1). In the cerebral cortex, the plane is isotropic in the sense that different directions cannot be distinguished in the histological picture. In contrast, in the cerebellar cortex, two perpendicular dimensions of the cortical plane are organized in completely different ways. Most of the axons run in a laterolateral direction, while the dendritic trees of the same layer extend in planes perpendicular to this.

A mixture of these two types also exists. In the hippocampus, the dendrites and some axonal systems are spread in all directions of the plane, while other axonal systems (mossy fibers, Schaffer collaterals) superimposed onto these run in one direction only. Furthermore, the serial reentrant arrangement of the latter is suggestive of cyclic operation (Figure 1*C*).

In contrast to cortices, geometry does not seem to play an important role in many nuclei. Their fine structure appears to be isotropic in all directions (Figure 1*D*).

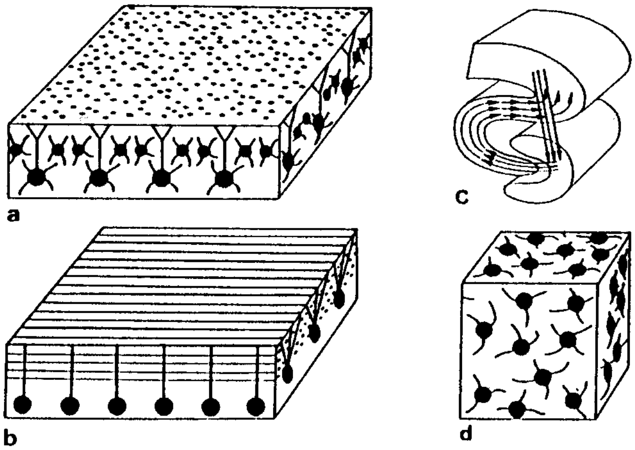

**Figure 1.** Different types of geometry in the gray matter. *A*, The structure in the horizontal plane is isotropic and different from that in the vertical plane (as in the cerebral cortex). *B*, All three planes of sectioning are different from each other (as in the cerebellar cortex). *C*, In the hippocampus, the horizontal (folded) plane is isotropic, but overlaid by a subpopulation of fibers that run in one direction only. These are, furthermore, arranged such that a cyclic operation is suggested. *D*, All three dimensions are equal. [Modified from Braitenberg, V., and Schüz, A., 1993, Allgemeine Neuroanatomie, in *Neuro- und Sinnesphysiologie* (R. F. Schmidt, Ed.), Berlin: Springer.]

## Histology and Connectivity

Different parts of the brain differ with respect to density and size of neurons, shape of axonal and dendritic trees, or arrangement in layers. But in spite of our detailed knowledge of such structural features, it is difficult to grasp the underlying principles of connectivity. What are the rules, for example, behind the felt of axons stained in Figure 2? To how many neurons do they belong and where do they come from? Is what we see in Figure 2 an intermingling of separate circuits, or are these fibers part of the same network?

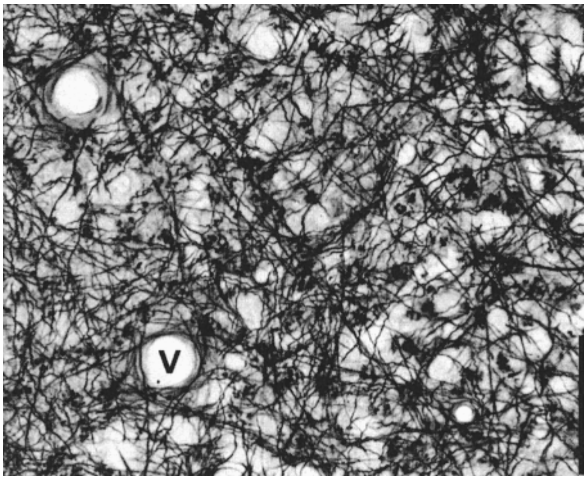

**Figure 2.** Axonal net. Light micrograph of the visual cortex of a monkey (area 17). A horizontal section is shown through layer IV. Only axons are stained. V indicates a blood vessel. The bar equals 50 $\mu$m.

## Specific Versus Statistical Connectivity

One crucial problem springs to mind in view of a fiber felt as shown in Figure 2: the degree to which the target of an individual fiber is defined. This question is relevant to the anatomist in determining at what level of detail to analyze the structure. The theoretician, too, must decide whether to base a model on a certain well-defined connectivity or on a random network. (For a more comprehensive treatment of this topic, see Arbib, Érdi, and Szentágothai, 1998).

In Figure 3, three possibilities are depicted. In Figure 3*A*, neurons of type A connect to neurons of type B in a strictly defined manner. There is specificity between types (A, B) and between individual neurons ($A_{1/1}$ and $A_{2/1}$ to $B_1$; $A_{1/2}$ and $A_{2/2}$ to $B_2$; etc.). A prerequisite for this kind of connectivity is that the neurons can be labeled individually, either by their geometric arrangement or by some other means, such as a chemical marker. On the other hand, the specificity could be restricted to types of neurons (e.g., A connects to B only) without further specification, as shown in Figure 3*B*). In this case, it is no longer crucial whether a certain neuron A connects to a particular neuron B rather than to its neighbor.

In the third case (Figure 3C), there is no specificity whatsoever. The neurons of both types are intermingled and connect to the cells they happen to meet.

All three types of connectivity are realized in nature. An example of the first kind is the visual system of the fly. There, the photoreceptors are arranged in strict geometric order and connect to the first optic ganglion in a completely determined manner.

The second kind of network describes the situation in the cerebellar cortex. There, it is determined how the various types of neurons are connected. The granule cells, for example, connect to the other four cell types of the cerebellar cortex, but not to other granule cells; basket cells contact only Purkinje cells; and so on.

The network in Figure 3*C* comes close to the situation in the cerebral cortex. With the exception of the chandelier cells, which have been found to connect to pyramidal cells only, pyramidal and nonpyramidal cells connect to each other and often in the expected proportion, although interesting biases also occur (see White, 1989). The overall connectivity depends, then, on the density of neurons, on their ramification patterns, on the location of their terminal arbors, and on the relative numbers of the various cell types. These constraints, which are of a probabilistic nature, are in part genetically determined and in part refined by activity-dependent self-organization (see Self-Organization and the Brain).

## Statistical Neuroanatomy

One approach to the question of connectivity in complex nerve networks is a quantitative assessment of the various components shown by the different histological methods (cell bodies, synapses, axons, etc.). How such data can be used to determine the structural properties of a network and to constrain neural models accordingly was shown in detail for the cerebral cortex (see Braitenberg and Schüz, 1998, and references therein). The main points are briefly summarized here.

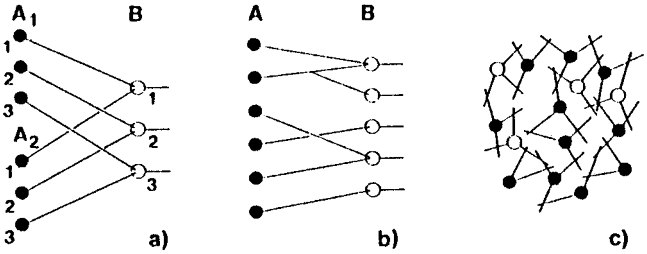

**Figure 3.** Three networks illustrating various degrees of specificity. *A*, All connections are determined. *B*, The connections are specified only with respect to type, not with respect to individual neurons. *C*, There is no specificity. [From Schüz, A., 1992, Randomness and constraints in the cortical neuropil, in *Information Processing in the Cortex* (A. Aertsen, and V. Braitenberg, Eds.), Berlin: Springer, fig. 1, p. 4. Reprinted with permission.]

## Basic Structure of the Cerebral Cortex

Some of the quantities that have been measured are shown in Table 1 (*a–m*). They refer to the mouse cortex and are corrected for tissue shrinkage. The letters *n–s* show further quantities that can be derived from those. A number of these quantities require some explanation.

The *relative density of axons* (Table 1, *q*) is defined as follows. Imagine a piece of cortex punched out perpendicularly to the cortical surface and just large enough to contain the local axonal tree of an individual neuron within the gray matter. If the total length of this individual axon is divided by the sum of the lengths of all axons within this volume, the relative axonal density is obtained. It quantifies the axonal contribution of an individual neuron to the

**Table 1.** Quantitative Anatomy of the Mouse Cerebral Cortex

| | |
|---|---|
| *Measured quantities* | |
| *a*: Volume (iso- and allocortex) | 2 × 87 mm$^3$ |
| *b*: No. of sensory input fibers | $<10^6$ |
| *c*: Density of neurons | 9.2 × 10$^4$/mm$^3$ |
| *d*: Percent pyramidal cells | 85% |
| *e*: Density of synapses | 7.2 × 10$^8$/mm$^3$ |
| *f*: Percent type I synapses | 89% |
| *g*: Percent synapses on spines | 75% |
| *h*: Density of axons | 4 km/mm$^3$ |
| *i*: Density of dendrites | 0.4 km/mm$^3$ |
| *j*: Length of axonal tree | 10–40 mm |
| *k*: Length of dendritic tree | 4 mm |
| *l*: Range of axonal tree (pyramidal cell) | 1 mm |
| *m*: Range of dendritic tree | 0.2 mm |
| *Deduced quantities* | |
| *n*: (*a, c*) Total no. of neurons | 1.6 × 10$^7$ |
| *o*: (*c, e*) Synapses/neuron | 8000 |
| *p*: (*e, h*) Synapses/length of axon | 200/mm |
| *q*: (*h, j, l*) Relative density of axons (pyramidal cells) | $10^{-5}$ |
| *r*: (*i, k, m*) Relative density of dendrites (pyramidal cells) | $10^{-3}$ |
| *s*: (*p, q, r*) Probability of synapses between two pyramidal cells 0.2–0.3 mm apart | 0 synapses, $p = 0.9$ |
| | 1 synapse, $p = 0.09$ |
| | 2 synapses, $p = 0.004$ |
| *Conclusions* | |
| *t*: (*b, n*) No. of neurons ≫ no. of input fibers | |
| *u*: (*d, f, g*) Most connections between neurons of one kind | |
| *v*: (*f*) Most connections excitatory | |
| *w*: (*o, s*) Great divergence and convergence | |
| *x*: (*s*) Connections very weak | |
| *y*: (*u–x*) Mixing machine | |
| *z*: (*t, u, g*) Memory rather than computation | |
| *z′*: (*y, z*) Associative memory with formation of cell assemblies | |

Modified from Braitenberg and Schüz (1998). The numbers represent measurements on light and electron micrographs from the cortex of the mouse (*a–m*), quantities that can be deduced from those measurements (*n–s*), and conclusions that can be drawn for the connectivity (*t–x*), as well as the functional interpretation (*y–z′*). The letters in parentheses indicate from which other quantities the corresponding quantity or conclusion can be derived.

neuropil within which it ramifies and is a measure for the intermingling of axons belonging to different neurons. The *relative density of dendrites* ($r$) is derived similarly by dividing the dendritic length of an individual neuron by the sum of the lengths of all dendrites present in the volume within which the dendritic arbor ramifies.

The *probability of synapses between two pyramidal cells* ($s$) is determined on the basis of $p$–$r$ and the assumption that a synapse between two neurons is made wherever the axon of one touches a dendrite of the other. The probability of this occurrence decreases with distance, i.e., with decreasing overlap between the two neurons.

From these data, some properties of cortical connectivity can be inferred (Table 1, $t$–$x$). A functional interpretation is also given in Table 1 ($y$–$z'$).

In short, the network of the cortex consists mainly of one type of neuron, the pyramidal cells (including the spiny stellate cells), which are connected by excitatory synapses. Most of these synapses are located on dendritic spines. Since synapses on spines are assumed to be modifiable in strength, one may conclude that one of the main tasks of the cortex is storage of information.

Nonpyramidal cells (about 15%) are interspersed among the pyramidal cells. They are inhibitory. Pyramidal and most kinds of nonpyramidal cells connect onto each other. The inhibitory neurons, however, contribute only about 11% of the synapses in the cortex. The number of synapses contributed by input fibers is small compared with the number of synapses that connect cortical neurons to each other. Most pyramidal cells have a local axonal tree, which connects them to other neurons in their neighborhood, as well as a far-reaching axonal tree, which, in most cases, connects them to another region of the cortex through the white matter.

The low relative axonal and dendritic densities have interesting implications. In the mouse, the local axonal tree of an individual pyramidal cell is interwoven with the dendrites of $10^5$ other neurons and competes with axons from approximately $5 \times 10^5$ other neurons ramifying in the same territory. Geometric considerations suggest that multiple synapses (more than 2 or 3 between any pair of neurons) account for only a small percentage of the whole synaptic population of a neuron. This makes it probable that the 8000 synapses of a pyramidal cell connect to thousands of different neighbors. Thus, theories based on a probabilistic connectivity, as sketched in Figure 3*C*, seem to be appropriate.

For the most part, the knowledge gained from the mouse cortex applies to mammals in general. Some of the numbers in Table 1 differ with brain size according to known rules *(a–c, j–m)*; others seem to be constant *(d–i)*. For some, the dependence on brain size is not yet clear *(q–s)*, but the differences and uncertainties are not strong enough to affect the conclusions about the basic connectivity and function of the cortex.

## Basic Function of the Cortex

This description of cortical structure fits Hebb's theory of cell assemblies remarkably well. This theory postulates that meaningful events are represented by groups of neurons that are connected more strongly to each other than to other neurons. These groups are formed through a learning process (see HEBBIAN SYNAPTIC PLASTICITY). The learning is assumed to strengthen the connections between neurons that are often activated together, a process known as *associative storage* (see ASSOCIATIVE NETWORKS).

For such cell assemblies to form, a large number of neurons of the same type must be connected into a network. What is crucial is an initial connectivity that is sufficiently rich to allow as many constellations of neuronal activity as possible to be detected and learned in the connections. The fact that the individual pyramidal cell seems to strive toward a large number of different synaptic neighbors, together with the large mass of corticocortical fibers, indicates that the cortex is well suited for this task. The excitatory and modifiable synapses that are implicit in Hebb's theory are also present in the cortex. The fact that individual neurons are weakly connected through one or only a few synapses implies that only correlated activity of many neurons can activate another neuron. This implication is also in agreement with the theory of cell assemblies.

The linkage of the structure of the cortex with the theory of cell assemblies has led to more precise formulations of this concept. It permits estimates of the storage capacity of the cortex and the size and internal structure of cell assemblies (Palm, 1993) and allows concrete ideas to develop about the regulation of their dynamics through the hippocampus (Miller, 1991) or the striatum (Miller and Wickens, 1991).

## Other Basic Principles of Connectivity

The connectivity of the cortex contrasts with that of other parts of the brain. The *cerebellar cortex* differs from the cerebral cortex primarily in its complete lack of positive feedback connections within the cortex and in its strict geometric order, which indicates computation along quasi-one-dimensional lines (Figure 1). These and other structural features suggest that the cerebellar cortex plays a role in the detection of sequences, a view supported by recent experimental evidence (Braitenberg et al., 1997). In addition, the cerebellar cortex stands out by virtue of its very large number of granule cells, which exceeds the number of neurons in the rest of the brain. Their small size and large numbers suggest a combinatorial richness of mossy fiber inputs that may be essential for the subtleties of motor coordination (Arbib et al., 1998).

Another contrasting network is the *striatum*. Although the cerebral cortex and the striatum have a number of features in common, a fundamental difference is that the cortex operates primarily on the basis of mutual excitation of neurons, while mutual inhibition seems to play an essential role in the striatum. There, more than 90% of the neurons (the medium spiny neurons) are GABAergic and, in addition to providing the output, make axon collaterals within the striatum. Thus, while the dominating principle in the cortex seems to be cooperation, the internal connectivity of the striatum suggests competition between neurons (Miller and Wickens, 1991; Wickens and Oorschot, 2000).

A basic difference also exists between cortex and *thalamus*. As in the cortex, most of the neurons in the thalamic relay nuclei are excitatory. However, in contrast to the neurons in the cortex, the lack of axon collaterals within the relay nuclei indicates that the excitatory neurons in the thalamus do not make synapses with each other (Steriade, Jones, and Llinás, 1990).

## Homogeneity Versus Heterogeneity of Brain Structures

Some parts of the brain show local anatomical variations; others do not. For example, the cerebellar cortex exhibits no obvious differences over its whole extent.

In the striatum, compartments known as striosomes can be detected with histochemical methods. They differ from the surrounding matrix not only in their histochemistry but also in their input-output organization. The medium spiny neurons, the main cell type, are located in both regions but tend to avoid crossing the boundaries between striosomes and matrix (Penny, Wilson, and Kitai, 1988).

In the cerebral cortex, local differences on a large scale are the basis of its division into areas. These differences are of a kind that influences the statistics of the connectivity between neurons (density of neurons in the various layers; size, shape, and density of dendritic and axonal fields). Cortical areas can differ along two coordinates: the coordinate of hierarchy and the coordinate of modality. Hierarchy is reflected, for example, in the degree of myelination. Overall myelination diminishes with increasing distance from the primary sensory and motor areas. The existence of a well-developed layer IV in primary sensory fields is another example. In addition, the size of the local axonal fields of pyramidal cells, as well as the size of basal dendritic trees, increases with distance from the periphery, at least in the visual system (for details, see Schüz and Miller, 2002). The coordinate of modality is reflected in the fact that primary areas not only share commonalities that set them apart from higher cortical areas, but also differ one from the other. Such differences characterize the most conspicuous neocortical areas: the primary visual cortex in primates, with its particularly prominent layering; the somatosensory cortex in some rodents, with the barrel field (see SOMATOSENSORY SYSTEM); and the primary motor cortex, with its huge corticospinal neurons.

Some histological methods, particularly the cytochromoxidase method and tracer methods, also reveal substructure *within* cortical areas—usually, bands or patches a few hundred microns in diameter, which are best known in the visual system (Arbib et al., 1998; see also OCULAR DOMINANCE AND ORIENTATION COLUMNS; VISUAL CORTEX: ANATOMICAL STRUCTURE AND MODELS OF FUNCTION). To a large extent, this phenomenon is the result of the alternating insertion of input bundles from different sources (via the white matter) into a relatively homogeneous internal network. Intracortical axonal ramifications of pyramidal cells, however, may also exhibit a patchy distribution, particularly in large brains. These patches connect columns with similar functional properties. In contrast to the situation in the striatum, the dendritic trees seem to freely cross borders between columns, an arrangement that suggests a maximization of diversity in neuronal connections (Malach, 1994; see also Dinse and Schreiner in Schüz and Miller, 2002).

# Neuroethology, Computational

*Dave Cliff*

## Introduction

Over the past decade, a number of neural network researchers have used the term *computational neuroethology* to describe a specific approach to neuroethology. *Neuroethology* is the study of the neural mechanisms underlying the generation of behavior in animals, and hence it lies at the intersection of neuroscience (the study of the nervous systems) and ethology (the study of animal behavior); for an introduction to neuroethology, see Simmons and Young (1999). The definition of computational neuroethology is very similar, but is not quite so dependent on studying animals: animals just happen to be biological *autonomous agents*. But there are also nonbiological autonomous agents, such as some types of robots and some types of simulated embodied agents operating in virtual worlds. In this context, autonomous agents are self-governing entities capable of operating (i.e., coordinating perception and action) for extended periods of time in environments that are complex, uncertain, and dynamic. Thus, computational neuroethology can be characterized as the attempt to analyze the computational principles underlying the generation of behavior in animals and in artificial autonomous agents. For the sake of brevity, in the rest of this article autonomous agents will be referred to simply as agents, and computational neuroethology will be abbreviated to CNE.

CNE can be distinguished from classical computational neuroscience by its increased emphasis on studying the neural control of behavior within the context of neural systems that are both embodied and situated within an environment. The “computational” nature of CNE comes not so much from treating neural systems as inherently computational devices, but rather in the use of sophisticated computer-based simulation and visualization tools for exploring issues in neuroethology.

Put most simply, CNE involves the use of computational modeling in trying to understand the neural mechanisms responsible for generating "useful" behaviors in an agent. The word useful is rather imprecise; it is more common to talk of *adaptive* behaviors. In the ethology literature, an adaptive behavior is usually defined as a behavior that increases the likelihood that an animal will survive long enough to produce viable offspring. Often implicit in this definition is the assumption that the animal's environment is sufficiently unforgiving (or hostile) that if the animal does nothing, it will die before it can reproduce. In studying artificial agents, the utility of behavior is frequently evaluated by less harsh criteria, such as observed behaviors scored according to some metric that indicates how close they come to satisfying some set of performance objectives or criteria.

Neural networks that generate adaptive behavior should not be confused with adaptive neural networks, where connection strengths may alter as a result of experience. Adaptation or plasticity may itself give rise to new or improved adaptive behaviors, but there are many cases of adaptive behaviors that are genetically determined (e.g., "hardwired" behaviors such as reflexes and instincts).

When CNE is approached in the context of adaptive behavior research, it becomes clear that the neural system is just one component in the *action-perception cycle*, where an agent's actions may alter what information it perceives concerning its environment, and where those alterations in perceived information may lead to changes in the agent's internal state, and where those changes in state may in turn affect further actions, thereby affecting what information is subsequently perceived, and so on. Thus, crucially, the agent's nervous system, body, and environment all combine to form a tightly coupled dynamical system. This is a notion long stressed by Arbib:

> In speaking of human perception, we often talk as if a purely passive process of classification were involved—of being able, when shown an object, to respond by naming it correctly. However, for most of the perception of most animals and much of human behavior, it is more appropriate to say that the animal perceives its environment to the extent that it is *prepared* to *interact* with that environment in some reasonably structured fashion (1972, p. 16).

As defined thus far, CNE may not seem to be particularly distinguishable from most work in neural network research. After all, many people in computational neural network research might argue that their work will, ultimately, lead to understanding of the neural mechanisms underlying the generation of (some) adaptive behaviors. For example, face recognition is an adaptive behavior in humans and could probably be classed as an adaptive behavior in, say, a security robot. So why can't a backpropagation network that learns to distinguish between photographs of human faces (for example) be classed as work in CNE?

## Motivations

Typically, artificial neural network models employ homogeneous groups of highly idealized and simplified neuron models (called *units*), connected in a regular fashion, that exhibit some form of "learning" or adaptation. The large majority of such models can be described in essence as mapping or transforming between representations: input data are presented to the network in a particular format, and the network is judged successful when its outputs can be interpreted as a correct representation of the results of performing the desired transformation. In almost all cases, the input and output representation formats are prespecified by the experimenter (although this is not entirely true of unsupervised learning networks, and there are a number of artificial neural network models that draw inspiration from biological data in their choice of input and output representations). If such networks are to be employed in artificial agents, or are to be of use in understanding biological agents, then this can only be so under the (often unspoken) assumption that, eventually, it will be possible to assemble a "pipeline" of such input-output transducer networks that links sensory inputs to motor outputs, and produce adaptive behavior. The most significant issue here is the heavy dependence on a priori intermediate representations, which may not be justifiable: neural sensorimotor pathways generating adaptive behaviors might not be neatly partitioned into representation-transforming modules; such pathways may not exhibit any patterns of activity identifiable as a representation in the conventional sense, and even if they do, there is no guarantee that they will be in strong accordance with representations chosen a priori by modelers.

This should not be mistaken for an argument against representation or for a denial of the vital role played by internal states in the generation of adaptive behaviors; it is simply an awareness of the dangers of being misled by a priori notions of representation. One of the safest ways of avoiding these dangers is to model, as far as is possible, *entire* sensorimotor pathways (i.e., the complete sequence of neural processing, from sensory input to motor output) involved in the generation of adaptive behavior. This requires that the agent be studied *while situated in an environment*: most sensorimotor processing for adaptive behavior involves dynamic interaction with the environment, and a situated agent is part of a closed-loop system, because certain actions can affect subsequent sensory inputs. Thus, the sensorimotor pathway should not be viewed as a "pipeline" transforming from a given input representation to a desired output representation, but rather as one link in the action-perception cycle.

When such an approach is adopted, the true nature of the representations and processing necessary for the generation of relatively complex adaptive behaviors is more likely to be revealed, and the validity of any a priori assumptions is clarified.

Naturally, it is beyond the state of the art to attempt to model complete sensorimotor pathways in humans or other large mammals, but experimental work in the neuroethology literature provides a wealth of data from less intellectually able animals, such as arthropods (the animal class that includes insects, spiders, and crustacea), amphibia, and other "simple" vertebrates such as eels or salamanders. Such animals are used as the domains of study in some CNE research, but in other work, simple idealized models are rigorously studied, in a manner akin to Galileo's models of perfect spheres rolling down inclined frictionless planes.

The argument that a priori commitment to certain representations or architectures for sensorimotor processing can lead to surprisingly wrong conclusions can be illustrated by reference to a classic series of thought experiments devised by Braitenberg (1984). Braitenberg described specifications for a series of simple mobile vehicles operating in a world with simplified kinematics. The series of vehicles starts with an elementary device that performs primitive heat-seeking behavior and progresses through vehicles that exhibit positive or negative taxes (i.e., orientation toward or away from a directional stimulus) and primitive forms of learning, pattern detection, and movement detection, culminating in vehicles that exhibit chaotic dynamics and predictive behavior. The internal control mechanisms of all the vehicles are rigorously minimal. The simpler vehicles contain nothing more than wires connecting sensors to actuators, while the more advanced ones employ nonlinear threshold devices with delays and pseudo-Hebbian adaptation.

Braitenberg notes that the psychological language indicative of intentional mental states has compelling intuitive appeal in describing the observed behavior of the vehicles. He ascribes *fear, aggression, love, values and taste, rules, trains of thought, free will,* *foresight, egotism*, and *optimism* to his vehicles. But he also demonstrates that whereas such terms may be very useful at the level of description of an external observer, the internal causal mechanisms could be surprisingly simple and, crucially, could contain nothing that can meaningfully be said to either "represent" or "implement" these intentional mental states. That is to say, the intentionality is in the eye of the beholder, not in the workings of the agent. For further discussion of these issues, see Cliff and Noble (1997).

While Braitenberg's vehicles are nothing more than thought experiments, they provide insight into possible organizational principles in natural and artificial creatures, and demonstrate the limits of applicability of intentional terminology. Further discussion of the utility of agent models in biology can be found in Dean (1998).

To summarize, research in CNE can be characterized as placing increased emphasis on modeling entire adaptive behavior–generating sensorimotor pathways in embodied agents, where those agents are situated in environments that supply sensorimotor feedback. Such an approach lessens the chances of making untenable assumptions concerning issues of representation and processing. Moreover, in order to study such pathways where there is reliable biological data, it may often be necessary to focus attention on relatively simple animals, such as arthropods or amphibia. For further discussion of the rationale for CNE, see Beer (1990) and Cliff (1990).

It is important to note that there is a tradition of related work in the artificial neural network literature. Research on reinforcement learning for control tasks is most close; see Reinforcement Learning in Motor Control.

## Selected Current Research Projects

Two specific longstanding CNE research programs are discussed in this section: the work of Arbib's research group on visuomotor behavior in simple vertebrates, and Beer's work on the neural foundations of adaptive behavior in even simpler agents (i.e., cockroaches) and in abstract idealized agents. Before delving into these bodies of work, it is useful to consider where they sit in the CNE canon, and to point to CNE research that resides at other points in that space.

For the purposes of framing, there are three major axes along which work in CNE can be categorized. In no particular order, they are the degree of reliance on computer software simulation, the degree of concentration on a specific animal species or class, and the extent to which semiautomated design techniques are employed.

The degree of reliance on computer simulation in CNE research projects varies from the complete, where all work is carried out using software simulations, to the minimal, where the CNE model takes the form of an operational physical robot, with the model neurons (individually or at the network level) being constructed from electronic circuits. Examples of the former include work by Arbib (1987) and Beer (1990), while many examples of the latter are discussed by Webb (2001). Note also that Beer went on to use robot platforms in continuations of his work that was initially software-only (Beer et al., 1992) while Arkin (see Reactive Robotic Systems) made similar use of Arbib's works. A comprehensive review of the merits of using physical robots (rather than computer software) as simulations of animals has recently been published by Webb (2001), with copious references to work in this field; see also Biologically Inspired Robotics.

The extent to which CNE research projects concentrate on a specific animal species or class varies from, at one extreme, CNE studies of one specific species (e.g., Beer, 1990) through generic CNE studies of several species of animals within the same order (e.g., Arbib's 1987 work on anuran visual control of action), to the other extreme, where neural mechanisms underlying the generation of adaptive behavior in wholly abstract and idealized agents is explored within the CNE methodology (e.g., Beer, 2002).

Finally, with the continuing falls in the real cost of processor power and memory and disk storage, there has been an increased tendency over the past decade to move away from hand-designed computational/robot models and toward models that are the product of automated or semiautomated design processes. The use of evolutionary computation techniques such as genetic algorithms in particular (see Evolution of Artificial Neural Networks) has proved fruitful. At the hands-on extreme, there are CNE models where each artificial neuron's parameters (e.g., its time constants, thresholds, and connectivity to other components) are specified by the designer of the model (see, e.g., Arbib, 1987; Beer, 1990), whereas at the hands-off extreme the modeler sets up a (usually truly vast) space of possible network designs and then uses an evolutionary search process to identify points in that design space that best satisfy some performance metric (i.e., the fitness evaluation function). Examples of this latter approach include Isjpeert (2001) and Beer (2002).

### *Computational Frogs, Toads, and Salamanders*

Probably the most mature body of work in CNE is the research program led by Arbib for two decades on a family of models of visually mediated behavior in simple vertebrates. In the initial years of this project the focus was on visuomotor activity in frogs and toads; see Arbib's 1987 paper for a review of the project with peer commentary and his 1997 publication for a discussion of how this work integrates with studies of monkeys and of rats. Arbib named his simulation model *Rana computatrix*, the computational frog, in homage to W. Grey Walter's seminal *Machina Speculatrix* robots from the 1950s.

The *R. computatrix* models are faithful to the known biology, and there is an interplay between the experimental and theoretical work: an initial first approximation model was extended and refined in a number of stages, leading to a family of models.

Arbib's approach involves defining a number of functional *schemas*. Schemas can be modeled by interacting layers of neuron-like elements or by nets of intermediate-level units; the network models can be related to experimental data concerning neural circuitry, and the development process iterates (Arbib, 1987, p. 411 *ff.*). Further details can be found in Schema Theory.

The primary focus in the *R. computatrix* models has been on how frogs and toads use vision to detect and catch prey, in environments that include obstacles and barriers. Arbib has developed a series of schema-based models that account for depth perception as interaction between accommodation and binocular clues, and at the lowest level the schemas are plausibly based on known details of the relevant neurological data.

One of the more striking results from this work, with reference to Marr's well-known theory of vision, is the indication that, at least in frogs and toads, there are different perceptual mechanisms for different visual stimuli. That is, the depths to prey and to barriers are extracted from the optic array by different processing channels and are integrated in the sensorimotor pathways much later than Marr's theory might suggest. Arbib and Liaw (1995) went on to demonstrate how lessons learned from the *R. computatrix* project could inform the design of visually guided robot systems.

In more recent work, Ijspeert and Arbib (2000) have reported on experiments in which a sophisticated simulation of a 3D multisegmented biomechanical model of a salamander's body is controlled by a complex neural network model. The network is composed of separate central pattern generators (CPGs; see Locomotion, Vertebrate) for the body and the limbs, each of which may be activated and modulated by descending tonic inputs. Ijspeert and Arbib use this simulation system to explore the neural circuitry underlying the generation of visually steerable salamander locomotion behaviors in water and on land. One notable aspect of this work in relation to the earlier studies of anuran circuitry is that, while the gross morphology of the CPG circuits is decided by the experimenters, a genetic algorithm is used to determine the fine details of the CPG circuits' internal connectivity and parameter values, the intersegmental coupling, and the coupling between the limb CPG and the body CPG. Thus, unlike the hands-on incremental modeling employed in the *R. computatrix* models, the salamander model is the product of a semiautomatic evolutionary design process.

### *Computational Cockroaches and* Vehicles *Redux*

Beer's 1990 book, *Intelligence as Adaptive Behavior*, contains both methodological arguments for CNE and details of experimental work on his model of a computational cockroach, *Periplaneta computatrix*, which is a simulated hexapod agent embedded in an environment, inspired by neuroethological studies of the cockroach *Periplaneta americana*. The real cockroach uses chemotaxis as one of several strategies to locate food sources. If its path along an odor gradient is blocked by an obstacle, it performs stereotyped "edge-following" behavior. The artificial cockroach is controlled by a heterogeneous neural network that was inspired by biological data and has been used to study issues in locomotion, guidance, and behavioral choice.

The primary external sensory input was simulated chemosensory information: patches of food in the environment gave off odor gradients detectable under an inverse square law relating distance to odor intensity. The neural nets also received mechanosensory input from proprioceptors in the limbs and tactile sensors that signaled the presence of food under the mouth. The simulation model included elementary kinematics: if the artificial cockroach failed to adopt a stable position for a sufficient length of time, it fell down.

Results from the simulation sessions demonstrated behavior in the model that was highly similar to behavior in the real animal, and Beer subsequently performed "lesion" experiments by selectively deleting connections or units from the *P. computatrix* control network. Again, the results obtained with the artificial system were in agreement with the biological data.

*P. computatrix* was inspired by biological data, but it was not intended as a biological model. The various behaviors were generated by heterogeneous neural networks. The neuron model employed by Beer was more faithful to biology than many of the "formal neurons" used in conventional artificial neural network research: the units involved differential equations modeling membrane potentials, which gave his model neural assemblies a rich intrinsic dynamics. For further details, see Locomotion, Invertebrate.

The central focus in Beer's (1990) work was on designing architectures composed from such neural units that could act as controllers for the various behaviors that *P. computatrix* should exhibit. Thus, there was no treatment of learning in the initial body of work on the cockroach. Subsequently, Beer reported on work that extended the original *P. computatrix* simulation model, testing it by allowing it to control walking in a real hexapod robot (Beer et al., 1992).

In the robot implementation, the control network was still simulated (i.e., the units in the neural network were not realized physically), but the sensorimotor connections to the artificial neural network were interfaced to physical sensors and actuators by means of analog-digital and digital-analog converters. Beer et al. reported that in all cases, the response of the physical robot was highly similar to that previously observed in simulation. The implementation did, however, reveal one problem in the controller that had not been examined in the simulation. This problem, involving disturbances in the crossbody phasing of the legs, was easily rectified, but nevertheless this demonstrates that simulation models cannot be trusted to perfectly replicate any physical implementation they may ultimately be intended for.

For a wider unified perspective on this work, see Locomotion, Invertebrate; Visuomotor Coordination in Frog and Toad; and Locomotion, Vertebrate.

Subsequent to his work on *P. computatrix*, one line of research that Beer has pursued is, in comparison, radically simplified, divorced from any specific animal, and yet in its simplicity it reaches to the core of fundamental issues in cognitive science and adaptive behavior research. Rather than be constrained (and potentially confused) by biology, Beer (2002) developed a series of simple idealized embodied and embedded model agents, each of which is capable of "minimally cognitive" behaviors. Beer defines a minimally cognitive behavior as one that is just above the threshold for raising issues of genuine interest to cognitive science (see also Cognitive Modeling: Psychology and Connectionism).

Beer's minimal agents exist in a two-dimensional world, but can only move along a bounded horizontal baseline. Various geometric shapes such as circles or diamonds drop from above, toward the agent's baseline. In each experiment, the intention is that the minimal agents use their sensors to detect the nature of whatever geometric shape or shapes is or are currently falling toward it, and thereby generate behavior "appropriate" to the current situation. The definition of appropriate behavior depends on the experiment but may, for example, be as apparently trivial as "intercept circular objects and avoid diamond-shaped ones." To achieve this sensorimotor coordination, each minimal agent is equipped with a small continuous-time recurrent neural network (CTRNN) (see Recurrent Networks: Learning Algorithms).

The CTRNN for each minimal agent has a small number (e.g., seven) of fixed-orientation ray-casting "visual" proximity sensors (each of which sends a straight limited-length ray out at a particular angle to the agent's body and reports on how far the ray traveled before it intercepted an object, if at all). Each sensor feeds onto a small number (e.g., five) of fully interconnected "interneurons," and all of these in turn feed onto a small number (e.g., two) of "output" neurons—one for moving to the left and one for moving to the right. Thus, a typical minimal agent may have 14 units and perhaps 70 connection weights in its CTRNN.

Any particular design for a CTRNN sensorimotor controller for one of Beer's minimal agents specifies the time-constant, bias, gain, and input weights for each neuron. Rather than design appropriate networks by hand, Beer employs a "hands-off" genetic algorithm to explore a very large space of possible network designs, evaluating each design on a measure of its observed behavior. To halve the size of the search space, Beer imposed a bilateral symmetry requirement. Other than this enforcement of symmetry, there is very little a priori commitment to any particular CTRNN solution. Over a reasonably small evolutionary experiment (e.g., 2,000 generations with a population size of 100), minimal agents evolve that reliably score well on the experiment's evaluation function, and that also generalize well to situations not encountered in the evolutionary adaptation period.

So far, so simple. Yet, in a series of papers published since 1996, Beer and his colleagues have reported on the evolution of CTRNNs for sensorimotor control in minimally cognitive agents that have been evaluated on the basis of their ability to perform a variety of increasingly sophisticated behaviors. These behaviors include orientating toward and reaching for objects, discriminating between objects, judging the passability of openings relative to the agent's own body size, discriminating between visible parts of the agent's body and other objects in the agent's environment, predicting and remembering the future location of falling objects so that they can later be intercepted "blind," and switching attention between multiple objects as they fall. All of these behaviors are achieved with the same simple agent CTRNN architecture outlined above.

This array of cognitively interesting behaviors achieved by Beer's minimally cognitive agents prompts the question of what, precisely, is happening at the mechanistic level within the evolved CTRNNs to generate these behaviors. And at this point we return to the arguments and issues explored in the opening sections of this article. Beer presents concrete analyses of the CTRNNs of these agents, demonstrating a full understanding of their mechanistic activity from a *dynamical systems* perspective; and yet, as he points out, this analysis is of little or no use in attempts at elucidating an understanding from a *computational* (and hence *representational*) perspective: there is nothing readily identifiable in the CTRNNs that represents a circle or a diamond, or the action of intercepting or of avoiding. Rather, a full explanation of the behavior exhibited by one of Beer's minimally cognitive agent's CTRNNs can only be given in the context of the dynamics of that agent's embodiment and of the environment in which it is situated. See Beer (2002) and Cliff and Noble (1997) for further details.

## Discussion

Computational neuroethology studies neural mechanisms that generate adaptive behaviors, and hence requires that embodied agents be studied within the situated context of their environmental and behavioral niches.

From the descriptions given in this article, some patterns emerge: the animal-specific CNE projects mentioned are dependent on the availability of fairly detailed neuroethological data. Such data invariably come from invasive in vivo experimentation, and the neuroanatomy of "simpler" animals such as arthropods or simpler vertebrates is particularly amenable to such techniques. For arthropods in particular, certain neurons performing particular functions are readily locatable in different individual animals of the same species. Although there are manifest obstacles preventing the collection of such data from more complex vertebrate subjects, research in these areas is making significant progress. Furthermore, by definition, any truly *general* principles underlying the neural generation of adaptive behaviors are those that are common to a number of species, so only cross-species studies will help identify general principles (Cliff, 1990, p. 37).

Yet surely the most general principles of all are those that apply to all agents within a certain class of cognitive or behavioral niches, regardless of the hardware (or software) that those agents are implemented in. In this respect, Beer's minimally cognitive agents are highly cogent. Until the representation-manipulating explanatory language that has traditionally been brought to bear on the supposed neural behavior-generating mechanisms of "complex" animals (including humans) can be demonstrated to be routinely applicable to "simpler" agents (including Beer's *vehicle*-like minimal agents), the rigor and limits of that explanatory language will remain in doubt.

# Neuroinformatics

*Michael A. Arbib*

## Introduction

Some define the term "neuroinformatics" as the use of databases, the World Wide Web, and visualization for the storage and analysis of neuroscience data, but we here broaden the definition to include the role of computational models in structuring masses of data. From the perspective of this *Handbook*, the key challenge for neuroinformatics is to integrate insights from synthetic data obtained from running a model with data obtained empirically from studying the animal or human brain. Moreover, we must integrate all levels from molecules to compartments and neurons up to biological neural networks and on to the behavior of organisms. One must thus maintain an architecture for a federation of empirical databases in which the results from diverse laboratories can be integrated, providing an environment in which we can make quantitative verifiable or disprovable predictions from the model to the database.

Neuroscience integrates anatomy, behavior, physiology, and chemistry. Each vertebrate has hundreds of brain regions, discriminated from other regions by gross anatomy, cytoarchitectonics, input and output connections of the region, and detailed neurophysiology. Then, for a variety of behaviors—whether they be eye movements, aspects of motor control, performance on memory tasks, and so on—we may seek to characterize the regions of the brain that are most involved in such behaviors and then characterize the firing of particular populations of neurons in temporal correlation with different aspects of the task. In such modeling studies, we seek to understand what must be added to the available database on neural responsiveness and connectivity to explain the time course of cellular activity, and the way in which they mediate between sensory data, the animal's intention, and behavior. But we also seek to use insights from these studies to better understand the human brain.

Shepherd et al. (1998) review the contribution to neuroinformatics tools for integrating, searching, and modeling multidisciplinary neuroscience data made by researchers supported by the Human Brain Project, a consortium of U.S. federal research agencies led by the National Institute of Mental Health. Kötter (2001) reviews current issues in the representation, integration, and analysis of neuroscience data from molecular to brain systems levels, including issues of implementation, standardization, management, quality control, copyright, confidentiality, and acceptance, with particular emphasis on integrative neuroinformatics approaches for exploring structure-function relationships in the brain. Arbib and Grethe (2001; hereafter *CtB*) present an integrated approach to neuroinformatics whose delineation will structure much of this article.

## Federating a Variety of Databases

A database on the neurochemistry of synaptic plasticity might be constructed as a view of plasticity data within various databases for different brain regions. An atlas of brain regions can be used to structure data both on the location of single cells (a link to a neurophysiology database) and for standardizing slice-based data (such as stains of receptor activity in a neurochemistry database). In short, neuroinformatics requires a *federation* of databases with tools for linking data from diverse databases to answer complex questions (Heimbigner and McLeod, 1985; Liao and McLeod, Chapter 5.1 of *CtB*). Databases in such a federation may be of one or more of the following types.

### Article Repositories

Many publishers now offer their journals on-line. Even if articles migrate from linear text to hypertext, such narratives about the data—"This is the recent experiment that I did," "Here is my review," and so on—will often provide the way for humans to get started in understanding what is going on in some domain, even if they will eventually search specific data sets of the kind described below.

### Repositories of Empirical Data

This is where we get data from different laboratories and make them generally available by linking each data set to the *protocol* that produced it: information (like that in the Methods section of an article but in a more algorithmic form) on the hypotheses being tested, the experimental methods used, and so on.

### Summary Databases

In these databases are assembled the assertions, summaries, hypotheses, tables, and figures that encapsulate the state of knowledge in a particular domain. Assertions in summary databases can be linked through the database federation not only to primary literature, but also to models or empirical data. However, in many fields, there is no consensus as to just which hypotheses have been firmly established. Different reviewers may therefore assign different confidence levels to different primary data, and these will affect the confidence level of assertions in the summary database.

### Model Repositories

These repositories will not only provide access to computational models, but also link each model to empirical and summary databases to provide evidence for hypotheses in the model or data to test predictions from simulation runs made with the model. We have viewed the protocol as a way to delineate the structure of an experiment. When we design a model, we often give an interface that mimics the protocol so that operations on the model capture the manipulations the experimenter might have made on the nervous system. This makes it easy for somebody who is not expert in modeling to nonetheless evaluate a model by seeing how it runs in a variety of situations.

### NeuroCore and Time Series Databases

Neuroscience provides many examples of time series data. For example, the time series data for a single experiment for a study of classical conditioning of a rabbit's eyeblink (see CEREBELLUM AND CONDITIONING) might include for each trial traces showing the movement of the eyelid and a display of firing of a single neuron. The firing data might then be aggregated across trials in a histogram. This example motivates the database issues: How do we store time series? How do we register data with time stamps to facilitate interesting processing of sets of data? How do we link each firing pattern to the position in the brain of the neuron it is taken from? We again see the need to store the protocol as well as, making explicit what hypotheses were being tested, what experimental methods were used, and what conditions were required to elicit each data set.

NeuroCore (Grethe, Mureika, and Merchant, Chapter 3.2, in *CtB*) provides a core schema, an extendible object-relational database schema implemented in Informix. The schema (structure of data tables, etc.) for each NeuroCore database is an extension of the core database schema that has links to repositories of neuroanatomical and neurochemical concepts and provides an extendible specification of items needed in most experimental records, such as research subject, experimental manipulation, structure of the research data, and the statistics performed on the data. There is a slot for research data and a standard extension for handling time series data. NeuroCore comes with a Java applet called the Schema Browser, which allows one to learn the structure of a particular laboratory's database by showing, for each familiar core table, the extensions particular to that laboratory.

### Mediator Systems and Common Ontologies

In a cooperative federated database system, the challenge is to provide conceptual links between data sources to begin to address the problem of data integration: assisting users by selecting, restructuring, and merging information from different databases and providing an integrated view of the information. Each database in the federation has its own *ontology* (the collection of concepts and their relationships used to describe information units in the database). But these ontologies may use terms differently (a "cell" in one may be a "neuron" in another and a "neuron" or a "glia cell" in yet another). If we seek a direct translation between each pair of ontologies, then $n$ ontologies require $n(n - 1)$ translators. However, if we can define a common ontology and translate back and forth between it and the other ontologies, then only $2n$ translators are required. With a common ontology that serves the basis of mutual understanding among participants in the federation, information is shared via what are called *mediators*. These support import (folding remote information into local environments), export (registering information to share), discovery (searching for relevant information), and browsing (navigating through information sources).

Kahng and McLeod (Chapter 5.1 of *CtB*) show one way to dynamically build a common ontology. Their motivation is that it is extremely difficult to reach total agreement on an ontology if there are many participants and that the ontology should be allowed to change dynamically as the federation evolves.

The model-based mediation architecture offered by Ludaescher, Gupta, and Martone (2001) employs F-logic as a data and knowledge representation and reasoning formalism. Integrated database views are defined and executed at the level of conceptual models rather than at the usual level of database schemas or XML. To semantically correlate across databases with little or no overlap in their schemas, they introduce domain maps, which are semantic nets of terms and relationships used to mediate across sources; for example, Purkinje cell "is a" neuron; cerebellum "has a" cerebellar cortex. The mediator then uses these rules to navigate through the various levels of brain analysis to allow for complex queries that span multiple levels of resolution and multiple data sources. Sources of domain knowledge include existing ontologies such as those provided by brain atlases and the Unified Medical Language System (UMLS) project of the National Library of Medicine (http://www.nlm.nih.gov/research/umls/), but the aim is to provide tools to allow different groups of users to tailor their own extensions to the ontology.

## Modeling and Simulation

Consider modeling the role of neural circuitry of certain brain regions in a given set of tasks. For each brain region, a survey of the neurophysiological data calls attention to a few basic cell types with firing characteristics that are strongly correlated with some aspect of that task. For example, in eye movement tasks, some cells fire most strongly near the onset of the target stimulus, others seem to be active during a delay period, and others are more active near movement initiation. The data tell the modeler what the activity of the cells should be in a variety of situations, but in many cases, experimenters do not know in any quantitative detail the way in which the cell responds to its synaptic inputs, nor do they know the action of the synapses in great detail. In short, the available empirical data might not be rich enough to define a *causally complete* model. Therefore, to get the model to run, the modeler has to make a number of hypotheses about some of the unknown connections, weights, time constants, and so on. The modeler may even have to postulate cell types that experimenters have not yet looked for and show by computer simulation that the resulting network will indeed perform in the observed way when known experiments are simulated, in which case it must match both external behavior and the key data on model populations that were based on cell populations with measured physiological responses. What raises the ante is that (1) the modeler's hypotheses suggest new experiments on neural dynamics and connectivity and (2) the model can be used to simulate experiments that have never been conducted with real nervous systems.

A few years from now, new models will both examine the interactions of a larger number of brain regions and analyze cells within each region in increasing detail. There is no way we would be able to keep cognitive track of these models if we had to look at everything at once. One approach (e.g., Arbib, Chapter 2.1, in *CtB*) is to represent complex models in an object-oriented way, using a hierarchy of interconnected modules. A module might be an interconnected set of brain regions; each region in turn might itself be a module composed of yet smaller modules that represent arrays of neurons sharing some common anatomical or physiological property. In any case, a module is either decomposable, in which case this "parent module" is decomposed into submodules known as its child modules, or the module is a "leaf module" that is not decomposed further but is directly implemented in the chosen programming language. There are basically two ways to proceed for a complex model. We can get a hierarchical view of the overall model, or we can zoom in on subsystems and study them in detail.

### *Multilevel Simulation*

As recently as 2000, a detailed model of chemicals reacting and diffusing around a single synapse could require a full day of workstation processing to simulate just a few seconds of synaptic activity. There may be of the order of 10,000 synapses on a "typical" neuron, millions of neurons in a single region, and hundreds of regions in a brain. Clearly, any simulation methodology that required one to simulate every synapse in such detail would be doomed to failure. No short-term increase in computer power will allow us to reduce the simulation of a second's activity in a system with $10^{15}$ synapses from $10^{15}$ hours or minutes down to a single second. A major challenge for work in multilevel simulation is thus to undertake detailed simulation at one level to validate a (possibly context-dependent) approximation that can be used in far more efficient large-scale simulations at the next level.

Neurosimulation: Tools and Resources, NSL Neural Simulation Language, GENESIS Simulation System, and NEURON Simulation Environment present tools bridging from circuits in interacting brain regions down to compartmental models of individual neurons. For example, a NSL model might employ a neuron module that is far simpler than a corresponding compartmental model developed in NEURON but that has been validated by careful studies to yield an economical but effective approximation to it. Or a GENESIS modeler might want to check that a model of a compartment provides a satisfactory approximation to a far more detailed model of neurochemical details for the neuron. All this raises two important challenges for the neural simulation community. One is to increase the range of tools currently available for comparing model to model as well as model to data (with the parameter search methods that this implies). The other is to develop "wrapping" technology so that modules developed by using one simulator can indeed be used to replace objects (whether to simplify them or attend to crucial new details) in an existing model developed by using another simulator.

Young, Hilgetag, and Scannell (2000) offer one example of modeling at the highest level, far removed from the details of neural circuits (see also Covariance Structural Equation Modeling). They developed a formal framework for inferring function from structure in which knowledge of connectivity is necessary but not sufficient. They applied this framework to inferences about a simple network that reproduces intact, lesioned, and paradoxically restored orienting behavior. Lesion effects could be used to infer which structures contributed to particular functions in this simple network. Clearly, such an approach can complement, but not replace, attempts to link high-level data from lesion effects or brain imaging to the analysis of detailed neural circuitry. Synthetic Functional Brain Mapping reviews methods for calibrating human brain imaging against simulations of monkey neurophysiology; while Kötter et al. (2002) simulate activity propagation in the primate visual cortex with the aim of relating neuronal activity to cortical activation patterns and relating onset response latencies to the structure of the underlying anatomical network.

Usui (2002) describes the NRV (Neuroinformatics Research in Vision) project, which aims to construct mathematical models for each level of the visual system (single neuron, retinal neural circuit, visual function), build resources for neuroinformatics, and develop a new vision device based on brain-type information-processing principles. A mathematical model of a retinal neural circuit will be constructed from neurophysiological experimental data and from the characteristics of single neurons. This circuit will form the basis for a "virtual retina" that encompasses everything from the light energy conversion mechanism in a photoreceptor to the encoding mechanism of impulse sequence in a ganglion cell, which is the retinal output. The results of this project will be made available in a database, the VISIOME Platform, that integrates morphological and physiological knowledge and mathematical models with related studies and references.

Arbib (1995) formulated the challenge of building databases that link models developed with different simulators to each other and to empirical databases, and Bischoff-Grethe, Spoelstra, and Arbib (Chapter 6.2 in *CtB*) explore the integration of one such model repository, Brain Models on the Web, with a summary database. Goddard et al. (2001) further develop the theme that software tools are needed that support discussion, development, and exchange of computational models. They describe methodologies that focus on these tasks and discuss the use of templates, declarative forms of model description equivalent to object-oriented classes and database schemas, to describe models ranging from neuron cell membranes to neural networks. The paper introduces NeuroML, a markup language for neuroscience that is defined syntactically using templates, with a component designed to support communication between modeling-related tools.

## Neuroanatomy

One way to integrate data from diverse experiments on the brains of a given species is to register the data—whether the locations of cells recorded neurophysiologically, the tract tracings of an anatomical experiment, or the receptor densities revealed on a slice of brain in a neurochemical study—against a standard brain atlas. Just as people have different faces, so do rats and other animals have different brains, and therefore there is a registration problem: Given a location in an individual brain, what is the best bet as to the corresponding location in the "standard" brain?

Part 4 of Arbib and Grethe (2001) offers a number of approaches to atlas-based databases. The core of the work is NeuARt, a neuroanatomical viewer for the rat brain based on the Swanson atlas (Swanson, 1998). It also present NeuroSlicer, a tool for registering 2D slice data against a 3D model of the rat brain reconstructed from the Swanson atlas, as well as the design of an atlas-based database of neurochemical data. The Swanson atlas contains 73 plates representing cross sections of one-half of the rat brain. These are not uniformly spaced but rather were chosen to exhibit many crucial features of the rat's neuroanatomy. Each plate contains a photomicrograph of a stained brain section on the left and Swanson's representation of that section on the right, in which he draws boundaries separating different brain regions and labels the regions. Many of the curves dividing one nucleus from another correspond obviously to boundaries in the cell densities visible on the micrograph. Others cannot be seen from that particular micrograph and can be revealed only by a variety of staining techniques or by the incorporation of physiological and other data. It therefore requires great skill on the part of the anatomist to draw those nonobvious divisions, and in fact even expert neuroanatomists may disagree. Therefore, although there is much agreement between the Swanson atlas and the other leading atlas of the rat brain, the Paxinos-Watson atlas (Paxinos and Watson, 1998), there are also disagreements. Thus we have the future challenge not only of registering data against a particular choice of atlas, but also of facing the issue of how to update such data sets as future anatomical research resolves certain disagreements and leads to more reliable demarcation of boundaries.

NeuARt allows one to view any template of the Swanson atlas through a Web browser, together with any data overlays retrieved from the database. A Display Manager allows one to see these different results, and a Viewer Manager allows one to customize the Display Manager to one's needs. The Query Manager provides forms that make it easy to request anatomical information from the Informix database; the results of these queries are described textually by a Results Manager, and the user can maintain a set of results of interest. The Level Manager allows one to choose which level (template) of the brain to examine, and the Active Set Manager then shows which results of the query have data that are relevant for that set. These can then be displayed by clicking on the appropriate elements.

Another approach to preparing neuroanatomical data is to flatten computer images of monkey or human cerebral cortex. As we know from atlases of the world, such flattening requires cuts if it is to preserve areas of the surface and then can preserve only local, but not global, spatial relationships. Nonetheless, when data about cortex rather than deep brain structures is paramount, display of data on such a flattened map of cortex allows one to take in patterns at a glance in a way that is impossible if one must scroll slice by slice through the pages of a conventional brain atlas. Van Essen et al. (2001) describe three software programs for carrying out surface-based analyses of cerebral cortex: SureFit (Surface Reconstruction by Filtering and Intensity Transformations) is used primarily for cortical segmentation, volume visualization, and initial surface generation; Caret (Computerized Anatomical Reconstruction and Editing Toolkit) provides a range of surface visualization and analysis options plus capabilities for surface flattening, surface-based deformation, and other surface manipulations; and SuMS (Surface Management System) provides a version control system that is capable of handling large numbers of surface and volume data sets. With built-in database management system support, SuMS provides rapid search and retrieval capabilities across all the data sets while also incorporating multiple security levels to regulate access.

Of course, the problem of linking data to neuroanatomy is not limited to vertebrates, let alone mammals. Jacobs and Theunissen (2000) examine the anatomical basis for the representation of stimulus parameters within a neural map and examine the extraction of these parameters by sensory interneurons in the cricket cercal sensory system. Their modeling of the cricket cercal system makes crucial use of their identified neuron database (http://cns.montana.edu/research/neurosys/).

We close this section with the work of Toga and Thompson (2002) on the collection of images of normal and diseased human brains brain in vivo and post vivo. They stress that the design of appropriate reference systems for human brain data presents considerable challenges, since these systems must capture how brain structure and function vary in large populations, across age and gender, in different disease states, and across imaging modalities, not to mention comparison across species. This work requires new approaches in computer vision, partial differential equations, and statistical field theory to detect and visualize disease-specific patterns. They survey the types of maps relevant to mental disorders, including maps that capture dynamic patterns of brain change in dementia.

### *The NeuroHomology Database*

The term "homology" is a central one in comparative biology, referring to characteristics of different species that are inherited from a common ancestor. Defining homologies between brain structures requires a process of inference from distinct clusters of attributes. Bota and Arbib (Chapter 6.4 of *CtB*) introduce the concept of *degree of homology*. To define a neural structure, neuroscientists use numerous attributes, including gross morphology, relative location, cytoarchitecture, types of cell responses to different ways of stimulation, and function. In similar fashion, Bota and Arbib employ eight criteria for determining the degree of homology of two brain structures: the morphology of cells within each brain structure and the relative position, cytoarchitecture, chemoarchitecture (neurotransmitters that are found within a brain structure), myeloarchitecture, afferent and efferent connections, and function of each of a pair of brain structures from two species. If two brain structures have common cell types, chemoarchitectonics, and cytoarchitectonics and common connectivity patterns, then one should expect that those two brain structures have the same function or related functions. This is the case for the primary visual area (area 17). In each major mammalian species, area 17 can be delimited on the basis of myeloarchitecture (heavy myelination) and cytoarchitecture (the presence of a granular layer IV), the presence of a single and systematic visuotopic map, a well-defined pattern of subcortical afferents, small receptive fields, and the presence of many orientation-selective neurons with simple receptive fields. Bota and Arbib not only discuss the homology criteria that can be established between pairs of brain structures across species, but also introduce the NeuroHomology (NHDB) summary database. This database contains three interconnected entities: Brain Structures, Connections, and Homologies. A user who wants to find whether there is any homology between structures X and Y from two different species can also find the definitions of structures X and Y according to different sources, as well as the afferents and efferents of these two structures. More important, the latest version of NHDB has three inference engines: one for combining data of differing reliability on the connections between two brain regions, one for comparing neuroanatomical data for a given species when the data come from the different parcellations provided by different brain atlases, and one for estimating the degree of homology according to multiple criteria.

## Discussion

The full development of neuroinformatics will provide an environment that helps the user pass back and forth between empirical data and related models, even though these are distributed across a federation of databases. Mediation technology will help to integrate these databases despite their diversity of ontologies and database schemas. In particular, a variety of brain atlases will provide reference platforms for a host of data within a species, with the analysis of homologies supporting the linkage of data across species. Future standards activity will provide modelers using a variety of simulation environments with tools to develop interfaces that make it easy for nonprogrammers to run basic "experiments" with the models and add to the database comments on the comparison of simulation results with available empirical data, to install models, to create versions of both models and parameter sets, and to freeze models in various interesting states for later analysis under varying conditions. A crucial aspect in all this is to catalyze a truly cumulative style of modeling in neuroscience by facilitating the *reusability* of modules within current neural models, with the pattern of reuse fully documented and tightly constrained by the linkage with a federation of databases of empirical neuroscientific data.

# Neurolinguistics

*Barry Gordon*

## Introduction

Neurolinguistics began as the study of the language deficits occurring after brain injuries but now encompasses all aspects of language and the brain, normal as well as disturbed. To help place neural modeling efforts in perspective, this chapter is intended as an overview of current understanding of language and its putative neural bases.

Recent reviews of neurolinguistics and its methods can be found in Berndt (2001) and Brown and Hagoort (1999). Speech perception is reviewed in SPEECH PROCESSING: PSYCHOLINGUISTICS; speech production in LANGUAGE PROCESSING, SPEECH PRODUC-

TION and Levelt (2001). Gordon (1997) provides an example of a detailed, multilevel analysis of one language function, the visual naming task.

## First-Order Model of Speech/Language and Neuroanatomy

There is now general agreement concerning what constitutes actual language and what does not, what major functional abilities underlie speech and language, how these are interconnected, and their approximate neuroanatomic dependencies. Collectively, this first-order model can summarize many features of normal ability as well as developmental and acquired disorders. A century and a half of intensive study has also identified many errors that might occur in the experimental and theoretical analysis of behavior-brain relationships. Understanding these pitfalls is useful for interpreting current evidence and for modeling attempts in the future.

### *Language and Language Development*

Babbling, grunts, shouts, and other emotional expressions are not language; they occur in non-human primates and are not affected by the same brain lesions that may abolish almost all language abilities. Even curses, idiomatic expressions, and singing may also be spared by such lesions. The language and related speech capabilities that are the focus of this chapter are propositional (i.e., both symbolic or referential, and created from combinations of elements). Although language can express concepts and reasoning, concept formation and reasoning do not necessarily depend on language.

All normal individuals have the capability to rapidly acquire language (LANGUAGE ACQUISITION). Some of this capability is expressed neonatally and even in utero. An extensive search for genes that might be responsible for language capabilities has produced several candidates and much controversy.

Until recently, it was thought that this facile ability to acquire language might atrophy in most people after approximately five years of age. New evidence, both empirical and theoretical, suggests that at least some of the apparent loss of plasticity could be the result of entrapment by the first-learned language. With special training or stimuli, some phonological limitations may be overcome.

### *Functional Architecture*

It is generally agreed that the complex overt functions of language and speech are the byproduct of various combinations of internal subprocesses (stages). Different overt functions may use these stages in different arrangements, and with different demands. Figure 1 is a schematic of these stages and their inputs, outputs, and interconnections. Every normal auditory/oral language user has functional modules for auditory phonemic perception, auditory word recognition (phonologic word-form recognition), lexical-semantics, abstract word form retrieval (which may or may not involve syntactic information, depending on the account), phonological word-form retrieval, and production of articulatory patterns. The process of learning to read and to write also establishes language-specific capabilities within the visual and motor systems. In the case of an alphabetic language such as English, this includes stages that perform abstract visual letter- and word-form recognition. These stages are connected to phonemic, phonologic word-form, and lexical-semantic processes. Output (in English) maps from phonologic and subphonologic word-forms to the written forms. Language communicated by gesture (such as American Sign Language) requires its own specialized visual recognition and manual production mechanisms, which also communicate with core language faculties (Crone et al., 2001). Figure 2 shows the approximate neuroanatomic associations of some of these stages in normal right-handed individuals.

In normal right-handed individuals, core functions required for speech and language are almost always (>99%) the responsibility of the left (dominant) hemisphere. In left-handed individuals (who make up ~13% of the population), or even those who are right-handed but with a family history of left-handedness, the core functions can be in the right hemisphere, or more bilaterally distributed. The lateralization of speech and language is under genetic control.

## Lesion Effects and Classic Syndromes

A large part of the evidence for this lateralization, parcellation, and mapping of language functions has come from individuals with

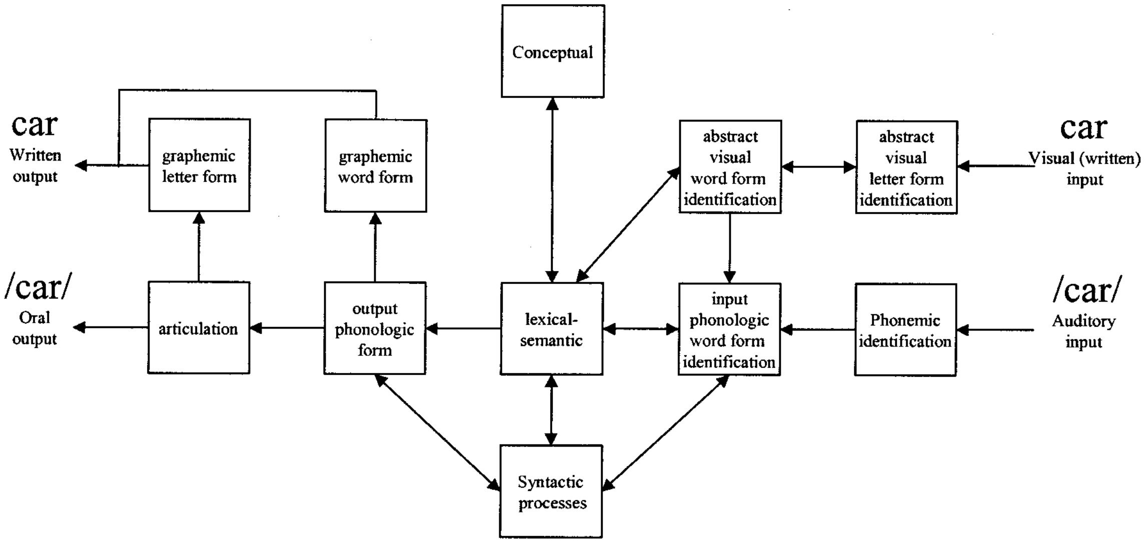

**Figure 1.** Schematic of larger-scale functional modules and interconnections involved in speech/language and related functions. Visual confrontation naming uses visual inputs analogous to those used for reading; see Figure 4. (Copyright IA, Inc. Used with permission.)

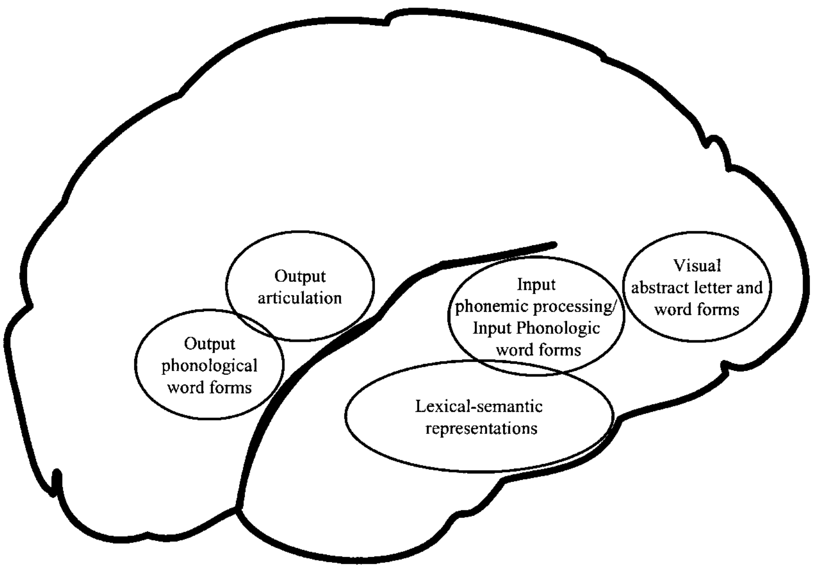

Output articulation
Output phonological word forms
Input phonemic processing/ Input Phonologic word forms
Visual abstract letter and word forms
Lexical-semantic representations

acquired brain injuries. The common forms of brain injury that occur in adults tend to produce somewhat distinctive patterns of impairment in language and speech (collectively termed "aphasia"), particularly in the late (>6 month) period after the injury. *Broca's aphasia* is typified by slow, effortful, halting speech, frequently described as telegraphic and agrammatic because function words and grammatical endings are often omitted. These individuals may appear to have good comprehension of speech, but it is now appreciated that their comprehension of syntax is also impaired. Lesions associated with Broca's aphasia are typically in the anterior regions of the left hemisphere, including the posterior inferior frontal lobe (Broca's area), but are more extensive than this area. The pattern of deficits in Broca's aphasia contrasts with that of *Wernicke's aphasia*, in which speech is fluent and well articulated but often empty of specific meaning (as in "Jabberwocky"). Content words (nouns and verbs) are often misused or not recognizable (neologisms). Grammatical function words and endings are present but used incorrectly (with errors in inflections, and with nongrammatical (paragrammatic) constructions). These deficits are found in both production and comprehension as well as in reading. Individuals with Wernicke's aphasia are usually found to have lesions that include the posterior superior temporal lobe and adjacent parietal lobe (Wernicke's area) of the dominant hemisphere. In addition to these syndromes, a number of other relatively distinctive ones have been described, with varying degrees of anatomic lesion specificity.

Aphasic deficits reveal themselves as either complete failures to perform a function or as delays and/or errors in performance. Among the errors commonly observed are those that sound like the intended target (such as "bot" for "dot") (*phonemic paraphasias*) and those with a meaning similar to the intended target (as in "door" for "exit") (*lexical* or *semantic paraphasias*). Normal individuals also make most, if not all, of the errors made by aphasic individuals, as Freud and others pointed out, but aphasic individuals make them with a much higher frequency.

## The Expanded First-Order Model

Aphasic syndromes and the errors that normal and aphasic individuals may make have not changed in the past hundred years. As a result, the basic block diagrams of the models explaining them have not changed much (compare Figure 3), but critical details are now different. Methodological errors have been identified, and additional methods and subject groups have been used. As a result, finer details have been added. In addition, speech and language are now recognized as the products of interactive dynamic systems, with major implications for modeling normal and abnormal performance and for understanding their neural substrates.

### *Methodological Refinements*

Broca's aphasia, Wernicke's aphasia, and the other aphasic syndromes are now understood to be collections of more than one fundamental deficit. For example, Broca's aphasia is a variable mix of difficulties in comprehension of syntax (Imaging the Grammatical Brain) and deficits in word retrieval, production of syntax, and articulation. These independent functions happen to cooccur in Broca's aphasia because the typical brain injury that causes the syndrome, vascular infarction, affects all the different regions responsible at once. Similarly, Wernicke's aphasia has now been reinterpreted as a variable mixture of deficits in phonemic speech

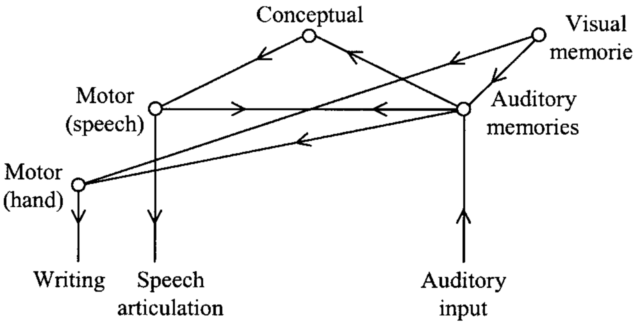

**Figure 3.** An example of a classical model of speech/language functions: Lichtheim's 1885 model, redrawn and labeled for brevity. Note that the modern meanings of the labels may not correspond exactly to the meanings Lichtheim originally intended. (Copyright IA, Inc. Used with permission.)

perception, the input phonological word system, lexical semantics, and word retrieval processes, perhaps also with syntactic deficits.

It is now understood that analysis of functions and functional architecture must to be strictly separated from analysis of the neural structures and mechanisms that may be responsible for those functions, at least in the initial stages of investigation. The flaw in assuming otherwise can be seen even with machines that are designed to perform basic functions. It is likely to be even more necessary to keep functions and structures separate for systems such as speech/language, which evolved from simpler beginnings by mutation and opportunistic adaptation. The correspondence between functional and neural levels in such cases is likely to be extremely convoluted.

Lesions remain a valuable source of information. Their utility has increased with the investigation of hyperacute strokes and follow-up studies (Hillis et al., 2002) and with the use of methods for inducing temporary "lesions" in humans, such as intracarotid amobarbital injection, transcranial magnetic stimulation, and direct cortical electrical stimulation (Berndt, 2001). However, it is now clear that lesions do not produce simple effects on neural tissue or on function. For example, functional and neuroanatomic reorganization often occurs in the minutes to months after a lesion, blurring lesion effects and neuroanatomic associations.

Besides lesion methods, there are now observational (correlational) methods for identification of the neural activity associated with language performance. These include regional cerebral metabolic studies (PET), regional cerebral blood flow (PET and functional MRI), and electrophysiological methods, such as evoked potentials, magnetoencephalographic recording, and direct cortical electrical recording (Berndt, 2001). To use these methods effectively, it is necessary to determine how the quantities measured correspond to brain activities, and in turn how brain activities are related to task performance. These methods allow examination of the whole brain (or large portions) at once and most involve little or no risk, so they can be performed in normal subjects as well as those with cerebral injuries.

Neurolinguistics now draws on a wide range of subject groups. Normal subjects have been studied more intensively, because it is now better understood that there are wide variations in normal abilities, that different languages may make different demands on mental functions, and that special training (such as literacy) can affect language and related functions. Individuals with developmental disorders that cause language functions to be affected disproportionately (e.g., autism) or relatively spared (e.g., William's syndrome) have provided valuable data concerning what components comprise language abilities and what sequence of steps is required to learn language (DEVELOPMENTAL DISORDERS).

Tasks used to probe language functions have been refined in light of the theoretical understanding of what it takes to accomplish a particular task and what components are of interest in any particular experiment. Traditional subtractive logic and additive factors logic have been found to have limitations. More subtle manipulations, such as word frequency, may be needed to affect a single stage of interest (Levelt, 2001). Techniques such as speeded reaction can induce informative errors and response patterns.

## *Amplifications and Controversies*

The schematics presented in Figures 1 and 2 need to be expanded in several ways to be brought into conformity with current understanding. The parcellation of functions at large scale remains correct, and so do their approximate neuroanatomic associations. However, it is clear that even the classical processing chains have many more subfunctions than once thought. Furthermore, in many normal individuals, the nondominant hemisphere can perform many language-related functions. Figure 4 gives an outline of the subprocesses involved in the relatively straightforward task of naming visual objects and of their hemispheric associations. Moreover, processes and regions apart from those traditionally thought to be involved in language are now known to contribute to language abilities. For instance, metaphor and emotion are important for language but are not affected by lesions in left hemisphere language areas; instead, they seem to depend on the non-dominant hemisphere.

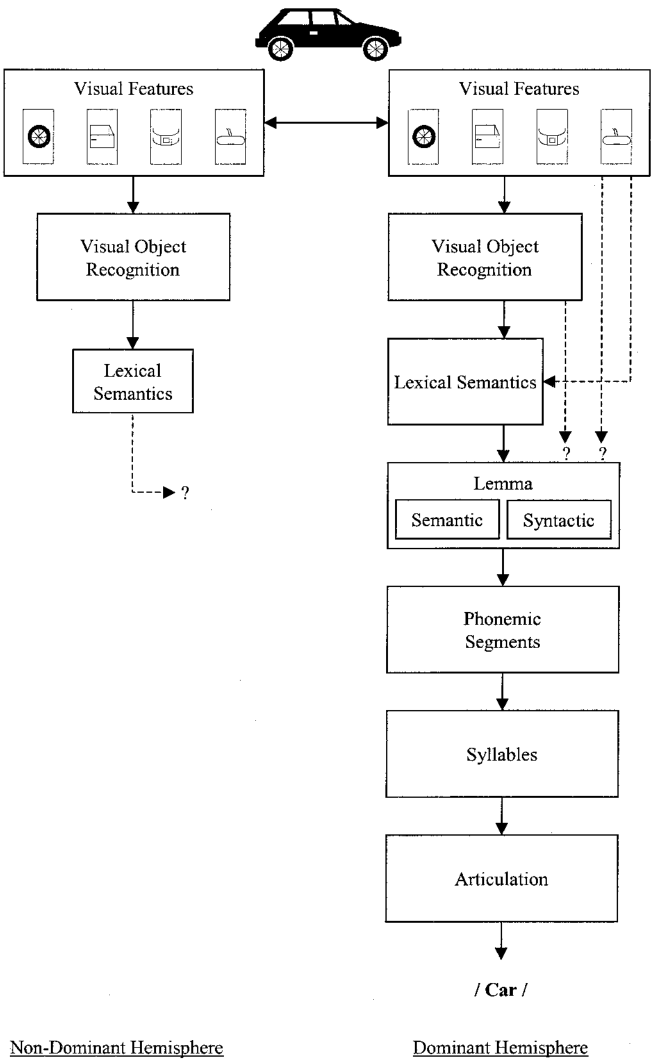

**Figure 4.** Supplemental detail for Figure 1, for the visual confrontation naming task. The processes identified here are used by other tasks as well; see Gordon, 1997. The bihemispheric distribution of these processes is illustrated. (Copyright IA, Inc. Used with permission.)

What functions are subdivided, the nature of the processing performed in these subfunctions, and the neuroanatomic associations of any particular subfunction, are all active areas of inquiry. Some important current debates include the following:

Speech perception and its functional anatomy alone are far more complex than presented here; additional information can be found in Hickok and Poeppel (2000) and in SPEECH PROCESSING: PSYCHOLINGUISTICS. Figure 1 separates input phonology from output phonology, although some have argued these are identical (Martin, Lesch, and Bartha, 1999). Working memory and sensory-specific memory stores (such as auditory-verbal memory) are also important for speech and language processing (but see Martin et al., 1999).

Syntactic functions are clearly important for both comprehension and production. Some consider syntactic abilities to be the product of a relatively small set of functions (IMAGING THE GRAMMATICAL BRAIN), whereas others have suggested that syntactic abilities are the product of a much larger and more variegated collection of processes (Dick et al., 2001).

There is no consensus on the nature of conceptual and semantic abilities. Much evidence favors the existence of modality-specific semantic capabilities, connecting to an amodal repository of additional semantic knowledge. However, both extremes (only modality-specific semantic processes, or only an amodal semantic system) have also been argued.

It is also now understood that, in any one individual, the areas devoted to specific language functions are likely to be smaller in extent, and more variable in location, than the maps derived from chronic studies of large numbers of individuals (Gordon et al., 2001). As a result, when it is necessary to have precise localization in any one individual (as in patients requiring focal cerebral excisions for treatment of seizures or tumors), detailed, individualized mapping is necessary (Gordon et al., 2001).

## Dynamic Processing Considerations

Perhaps the most important addition to the modern understanding of how language is represented and processed in the brain is an understanding of its dynamic properties. That language is the product of complex, interacting, dynamic systems may explain the richness of language abilities and hitherto intractable problems such as how word and sentence information might be integrated online. Furthermore, what is known or should be known about these dynamics will need to be explained by any theory of the neural processes responsible for them. What follows is a synthesis of the inferences and assumptions that have been made concerning the dynamics of processing of the cognitive information relevant to speech/language and related functions.

### *Between-Stage Information Flow*

The approximate sequence of the flow of information between stages is shown in Figure 1. Auditory speech perception somewhat precedes lexical semantic comprehension; visual perception of a picture somewhat precedes its comprehension and the generation of its name. However, the times involved in each stage are relatively long compared to the time required for the overall process, so there is considerable overlap in processing between stages (cascaded processing).

In addition, there is almost certain to be extensive feedback between stages (only shown for the most likely ones in Figure 1), both at adjacent levels and at greater psychological (and neural) distances. Many potential neuroanatomic mechanisms for such feedback are known to exist, and some have been shown to be operational (with the most compelling examples coming from the visual domain).

### *Dynamics of Within-Stage Processing*

There is fair agreement that processing within a stage is not a step function; it has a rise and fall that can be measured by behavioral as well as by more interventional techniques (Hart et al., 1998). Although the data on durations of processing are difficult to interpret, it certainly appears that speech perceptual processes can be accomplished in as little as 20–50 ms (or less), whereas lexical-semantic selection involved in a function such as naming may take 200–400 ms.

### *Unitary Representations and Activation*

It has been widely assumed that the contents of any particular stage are some form of unitized, independent representations. The terminology of these unitized representations is confusing (Gordon, 1997). In cognitive science, they are often termed "nodes." However, these are not the nodes of connectionist networks. Nor do these unitized representations almost ever correspond to the activity of single neurons, either in actuality or in theory (although they could, if there really were "grandmother cells"). Here, we will use the standard cognitive science terminology of "nodes."

What information these unitized representations convey has not been settled. They may correspond to features that have already been psychologically identified (e.g., the /ba/ part of the phonological representation of /bat/, or the {round} semantic feature of a lexical-semantic representation of {ball}). Others have assumed that what they represent is much less transparent.

Nodes are generally assumed to have a number of characteristics and properties (although not every theorist who uses nodes necessarily endorses or uses all of the ones listed here; see Gordon, 1997):

Except for perhaps very basic perceptual and motor features, nodes are not preexisting; they must be created by experience.
Once created, nodes persist in latent form, available for activation.
The latent strength of a node is greater, depending on its experiential frequency. Experiential frequency is probably a surrogate for memory; the strength of a node is a form of memory, increased by frequency of exposure and by all the other mechanisms that consolidate learning (such as salience).
Nodes can be converted from a latent to an active (activated) state.
Nodes are activated by virtue of their connections to other nodes ("spreading activation").
The degree to which a node is activated is determined by several factors:
  By how well the input(s) match the node's receptive pattern. Inputs can be inhibitory as well as facilitatory.
  By the node's latent strength
  By a random component (noise). Noise may be absolute, or it may be correlated with the degree of activation, or both.
Activation of a node grows over time to the maximum determined by the factors listed previously.
After a node has reached maximal activation, its activation may persist for a time or may decay.
It is likely that there is some degree of control over nodal properties, both internal and external to each stage: how easily they are formed, how they activate and decay, and how they can be altered by experience.

There is little direct evidence for nodes, but there are several lines of indirect support. Postulating nodes with properties such as those listed previously has proven to be very useful for understanding many otherwise puzzling phenomena of normal and brain-injured performance (Gordon, 1997). Some brain injuries can be interpreted as though they selectively destroy some nodal representations within a stage (see Gordon, 1997). In other cases, focal brain injuries have been successfully modeled in terms of changes in nodal properties or connection strengths, as in the Dell et al. (1997) and Foygel and Dell (2000) simulations discussed later in this article.

### *Processing by Constraint Satisfaction*

The input information available to a stage is very likely to underspecify the correct output, particularly at the beginning of processing. Evidence exists from several different levels of language processing (speech perception, reading, and sentence-level comprehension, among others) that all possible candidate representations are activated initially. With continued input, and with input from other stages, the candidate set is winnowed down to the correct one. The specifics of this process are debated, but it is likely that such dynamic, interactive computation plays a critical role in many known examples of language processing. Dynamic processing by interactive constraint satisfaction may also explain how multiple sources of information can interact in the course of comprehension and production. See, for example, Arbib and Caplan (1979), Lesioned Networks as Models of Neuropsychological Deficits, and Optimality Theory in Linguistics.

## Possible Neural Bases

As depicted in the schematic of Figure 2, some stages or collections of stages seem to be the product of relatively discrete areas of the cerebral cortex. Connections between stages seem to correspond to short- and long-range subcortical white matter pathways.

How the cognitive elements (nodes) of psychological theorizing correspond to actual neuronal activity is not known for certain. However, the attractor states that can occur in neuronal networks with feedback are viable candidates for behaving as nodes are posited to behave (Lesioned Networks as Models of Neuropsychological Deficits). A single neural network can have multiple attractor states. The sculpting of connections to create an attractor can be equated with the learning of a node. The width of a basin of attraction of a neural activity state may be the neural counterpoint of a node's similarity relations (its receptive field). The depth of a basin of attraction, as well as its width, may correspond to frequency ("strength"). The process of "activation" of a cognitive node may correspond to the evolution of neural activity toward the attractor. Attractor dynamics have proven to be very useful in modeling a number of language and related functions (see, for example, McLeod, Shallice, and Plaut, 2000; also Computing with Attractors; Neurological and Psychiatric Disorders). However, attractors are not the only emergent features of neural network activity that might be candidates for nodes (see, for example, Structured Connectionist Models).

## Models of Speech/Language Functions

Many modeling efforts in neurolinguistics have been concerned with the consequences of relatively large-scale assumptions about stages and connections. Examples of models that have incorporated both stage- and substage-level assumptions are those used by Dell et al. (1997) and by Foygel and Dell (2000). Dell et al. (1997) simulated picture naming using semantic, lexical, and phonologic stages. Each level represented its information as nodes, with properties similar to those discussed earlier. Spreading activation drove production. Parameters that replicated normal performance were derived from control data. Then, to model the picture naming performance of aphasic subjects, two parameters were altered for each aphasic subject: one governed how much activation spread, and one determined how rapidly activation declined. There was a "fairly good" fit between simulated and actual performance with just these assumptions (as characterized by Foygel and Dell, 2000). In addition, Dell et al. (1997) were able to capture much of the pattern of recovery of patients in terms of changes in these same parameters back to their normal values. Even so, Foygel and Dell (2000) have suggested that the data used by Dell et al. (1997), and other cases in the literature, might be better explained by alterations in two other parameters: the connection strengths (weights) between semantic and lexical units, and those between lexical and phonological units.

Modeling efforts by Dell and his colleagues represent one motivation for this chapter's method of review. Modeling efforts are likely to be most productive when they are informed by a good knowledge of existing data and theoretical explanations and also by a realistic understanding of when those data and explanations may be incomplete or arguable. Lesioned Networks as Models of Neuropsychological Deficits provides additional perspectives on modeling attempts.

## Discussion

The emergent complexity of language functions is a daunting challenge for both its experimental investigation and for modeling attempts. However, it is also encouraging, because it makes it more likely that the same fundamental building blocks and processes that are identified in other domains of brain function will be applicable to understanding language, and vice versa.

# Neurological and Psychiatric Disorders

*Eytan Ruppin and James A. Reggia*

## Introduction

In the last decade it has become natural to ask how neural modeling may be harnessed to investigate the pathogenesis and potential treatment of brain disorders, and in what ways it may complement more traditional research methodologies. Indeed, early attempts in this direction have been extensively developed in recent years.

The interest of the psychiatric and neurological communities in neural network modeling probably reflects the belief that, although the gathering of neurobiological data has led to much progress in our understanding of basic brain mechanisms, we do not appear to have come much closer to understanding how these mechanisms result in behavior. Neural modeling is a methodology that is precisely aimed at bridging this gap, by studying the relation between the "microscopic" pathological alterations of the underlying neural networks and the "macroscopic" functional and behavioral disease manifestations that characterize the network's function.

To study brain or cognitive disorders computationally, one first has to construct a model network that is capable of performing some basic functions, such as controlling movements or storing and retrieving information. Thereafter, by lesioning the intact network's structural components or disrupting its dynamic mechanisms, the specific neuroanatomical and neurophysiological findings assumed to characterize the pathogenesis of the disease can be modeled, and the resulting changes in the behavior of the network can be examined. It is then also possible to search for mechanisms that may counteract the damaging effects of the simulated pathological alterations.

Neural models are limited in that they necessarily simplify the biological phenomena occurring in the nervous system and are generally constrained in size. The simulated lesions in such models are substantial simplifications of abnormal events occurring within the brain and/or in cognitive processes. Nevertheless, such computer-based models complement traditional methods of studying brain disorders in substantial and important ways. The size and location of simulated brain damage can be controlled precisely and can be systematically varied over arbitrarily large numbers of experimental "subjects" and information processing tasks. Further, the computational experiments are open to detailed inspection in ways that biological systems are not.

Neural models of brain and cognitive disorders, like neural network models in general, vary widely in the level of realism with which they aim to model the underlying phenomena. This is true both with regard to the level of biological detail employed in describing the individual building blocks themselves (the neurons and their interactions), and also with regard to the description level of the network's architecture, i.e., to the extent the latter aims to reconstruct a specific brain region. In general, computational studies addressing neuropsychological or cognitive disorders tend to describe more abstract models, fairly removed from specific brain architectures, compared with the models addressing neurological and psychiatric disorders. Models of neuropsychological disorders are reviewed in LESIONED NETWORKS AS MODELS OF NEUROPSYCHOLOGICAL DEFICTS. Here we review some computational studies of a few major neurological and psychiatric disorders. In addition to studies of Alzheimer's disease, Parkinson's disease, and stroke reviewed in this chapter, neurological modeling studies have addressed a wide variety of other disorders, including multi-infarct dementia, migraine, and delirium. Our review of psychiatric disorders focuses on schizophrenia and affective disorders, but preliminary computational modeling studies have also addressed paranoid disorders, dissociative disorders, and others. For recent papers describing these studies the interested reader is referred to Reggia, Ruppin, and Berndt (1996); Reggia, Ruppin, and Glanzman (1999); and Parks, Levine, and Long (1998).

## Neurological Disorders

Many models of memory impairment have addressed various aspects of Alzheimer's disease (Horn et al., 1993, Hasselmo, 1994), the most common dementing illness. The essential clinical feature of Alzheimer's disease is a broad-based intellectual decline from previous levels of functioning, but memory impairment is a major clinical hallmark of the disease. These models have examined two main hypotheses concerning the pathogenesis of the disease. One hypothesis has been that *failure of neuronal synaptic compensatory mechanisms* (which in normal subjects successfully counteracts synaptic degenerative changes) plays a primary role in Alzheimer's pathogenesis (Horn et al., 1993). Variations on the rate and exact functional form of synaptic compensation were used to define various compensation strategies, and these could account for the observed variation in the severity and progression rate of Alzheimer's disease. The second hypothesis has focused on *synaptic runaway*, a pathological exponential growth of synaptic connections that may occur due to interference by previously stored memory patterns during the storage of new patterns (Hasselmo, 1994). Several factors can lead to the initiation of synaptic runaway, but once it occurs, its increased metabolic demands or excitotoxic effects could presumably be sufficiently severe to cause neuronal degeneration, parallel to that found in Alzheimer's disease. Interestingly, the pattern of spread of pathological damage in Alzheimer's disease fits well the hypothesis of synaptic runaway.

Recent work on modeling Alzheimer's disease has focused on more realistic models incorporating spiking neurons. These models share the view that the hippocampus (and more generally, medial temporal lobe structures) plays a primary role in consolidation of memories in the cortex. Extending their previous work, Hasselmo and his co-workers have studied a fairly realistic model of the hippocampus, both in terms of its subdivision into various substructures and in terms of accounting for several known neuromodulatory effects on hippocampal memory processing. The latter enables one to address the cholinergic disturbances that are assumed to play an important role in memory and learning dysfunction in Alzheimer's disease. The possible role of cholinergic neuromodulation of the hippocampus in Alzheimer's disease has also been recently addressed by Menschick and Finkel (1998). Their work is performed in a realistic compartmental model of associative memory, and discusses the pathogenesis of memory decline in Alzheimer's disease in dynamic terms that emerge from such spiking models, identifying a cascade of malfunctions occurring at multiple levels.

Models of stroke (sudden focal brain damage due to impaired regional blood flow) have been developed to address the events occurring immediately following the acute stroke event, and also later on during the chronic, reorganization phase. Naturally, these models differ in the kind of computational framework involved. Models of acute focal stroke encompass a combined neural/metabolic description that traces the temporal evolution of several variables that play a critical role in ischemic stroke (Revett et al., 1998). This work has examined the hypothesis that *cortical spreading depression* waves play a primary role in the spread of damage into the penumbral perinfarct region from the infarct core. It successfully reproduced several experimental dependencies and has made testable predictions about the number, velocity, and duration of spreading depression waves. In contrast, studying chronic reorganization after focal stroke has been based on models simulating map formation in the cortex (Goodall et al., 1997). These models involve the projection of high-dimensional data on a two-dimensional cortical surface, and generate computational maps that mimic cortical "maps" representing relevant aspects of the external world (e.g., the homunculus in primary somatosensory or motor cortex). When a lesion is introduced into the simulated map, the model reorganizes such that the sensory surface originally represented by the lesioned area spontaneously reappears in adjacent cortical areas, as has been seen experimentally in animal studies. Two key hypotheses emerged from this modeling work. First, that postlesion map reorganization is a two-phase process, consisting of a rapid phase due to the dynamics of neural activity and a longer-term phase due to synaptic plasticity. Second, that increased perilesion excitability is necessary for useful map reorganization to occur. Similar self-organizing models, but based on cortical deafferentation, have been used recently to support a theory of *phantom limb* experiences (Spitzer et al., 1994). This latter work presented an interesting solution, in neural network terms, to the ongoing controversy about the relative weight of central versus peripheral nervous system alterations in the pathogenesis of these disturbing symptoms.

Parkinson's disease is an important motor and cognitive degenerative disorder. Its primary pathology has been traced to the degeneration of nigral dopaminergic neurons projecting on the striatum, and it has been a subject of quite a few modeling studies in recent years (see Basal Ganglia and Dopamine, Roles of). Again, the pathogenesis of the disease can be studied at different levels. In a more high-level model, Contreras-Vidal, Teulings, and Stelmach (1998) describe the activation of many of the pathways known to exist in basal ganglia in terms of a system of coupled differential equations, composing a gross-scale representation of basal ganglia structures as single dynamical variables. This model was able to produce handwriting patterns that were comparable to handwriting changes observed in Parkinson's patients before and after L-DOPA treatment. On a lower-level of description, Kotter and Wickens (1998) have presented a more detailed, realistic model of the striatum, including effects of dopamine on the various receptor subtypes. This work suggests that dopamine therapy would tend to reverse only a subset of the changes produced by dopamine depletion, resulting in striatal dynamics that are significantly different from those encountered in the normal, premorbid state.

## Psychiatric Disorders

Neural models have been created for a wide range of psychiatric disorders, but most of the work has focused on schizophrenia and affective disorders.

Schizophrenia is a clinically heterogeneous disorder with a broad spectrum of manifestations. Its symptoms include both "positive symptoms," such as hallucinations, delusions, disorganized speech and behavior, and "negative symptoms," such as loss of fluency of thought and speech, impaired attention, abnormalities in the expression and observation of emotion, and loss of volition and drive. The course of the illness tends to be marked by exacerbations and remissions, but the persistence of the impairment may give the disease a "dementia-like" quality in more advanced stages. The pathogenesis of schizophrenia is unknown. Perhaps the most enduring biochemical explanation of the pathophysiology of schizophrenia is the dopamine hypothesis, which postulates the coexistence of hypodopaminergic activity in the mesocortical system, resulting in negative symptoms, and hyperdopaminergic activity in the mesolimbic system, resulting in positive symptoms. Structural and functional imaging and neuroanatomical postmortem studies are providing converging evidence of the involvement of specific brain regions in schizophrenia, such as the prefrontal areas, temporal lobes and the temporo-limbic circuitry, and subcortical circuitry. Integrative pathophysiological hypotheses have been proposed, but so far no single explanatory mechanism has prevailed.

Neural modeling of schizophrenia has taken two main paths, reflecting the view of schizophrenia as composed of positive symptoms that arise due to temporo-frontal pathology, and negative symptoms that are a result of prefrontal abnormalities. The first avenue has concentrated on modeling schizophrenic positive symptoms in the framework of an associative memory attractor network (Hoffman, 1987). In this framework, pathological alterations in an attractor neural network modeling excessive synaptic pruning can lead to the formation of *parasitic attractors*, whose cognitive and perceptual manifestations may play an important role in the emergence of schizophrenic delusions and hallucinations, by altering speech perception and production processes. In this line of research, Ruppin, Reggia, and Horn (1996) have modeled a frontal module as an associative memory neural network receiving its inputs from degenerating temporal projections and undergoing reactive synaptic regeneration. They have shown that while preserving memory performance, compensatory synaptic regenerative changes coupled with Hebbian activity-dependent synaptic changes may eventually lead to a *biased* retrieval distribution that is strongly dominated by few memory patterns, resembling the concentration of psychotic delusions and hallucinations on very few cognitive and perceptual themes.

Building upon their work on modeling the neuromodulatory effects of catecholamines on information processing, Cohen and Servan-Schreiber (1992) have presented a modeling study of the performance of normal subjects and schizophrenics in three attentional and language processing tasks. These tasks are important indices of cognitive dysfunction in schizophrenia, and are related to schizophrenic negative symptoms. In all of the tasks modeled, a backpropagation algorithm was used to train the networks to simulate normal performance. Although each task was modeled by a network designed specifically for that task, the networks used rely on similar information processing principles and share a common module for representing context, which is identified with the prefrontal cortex. The hypothesized neuromodulatory effects of dopamine on information processing were modeled as a global change of the input gain. Simulations demonstrated that a change in the gain of neurons in the context module can quantitatively account for the differences between normal and schizophrenic performance in the tasks examined. Postulating that the prefrontal cortex plays a central role in establishing context (see Braver and Cohen in Reggia et al., 1999), it has been proposed that dopamine might regulate context information in prefrontal cortex by providing an appropriate gating signal. Their model provides a mechanism for flexible updating of stored information, and is able to accurately simulate the performance breakdown of schizophrenics in the Continuous Performance Test.

More recently, Hoffman et al. have addressed the pathogenesis of schizophrenic positive symptoms from a neurodevelopmental perspective. They show that although the process of synaptic pruning can improve generalization of previously learned information, when taken to excess it would result in spontaneous percepts (hallucinations) and in "hyperpriming," both seen in schizophrenia (Hoffman and McGlashan, 1997). This provides an interesting view of the pathogenesis of a disease by a normal developmental process that is taken "much too far." Recent work has investigated the role of the prefrontal cortex in the pathogenesis of schizophrenia using more biologically realistic spike response neurons (see Reid and Willshaw in Reggia et al., 1999). They show that the ability of the prefrontal cortex to hold working memory information may be disrupted by changes in dopaminergic activity, reduced GABAergic activity, and reduced prefrontal connectivity, which have all been implicated in schizophrenia. As in the case of neural models of dementia and Alzheimer's disease, the general trend is to move from simplistic models employing McCulloch-Pitts binary neurons to networks using compartmental models of neurons and more realistic descriptions of synaptic transmission.

Attractor neural networks have also been considered as a framework for modeling cognitive manifestations of manic-depressive disorder. Manic bouts are characterized by a distinctly elevated, expansive or irritable mood, accompanied by "hyperactivity" symptoms. In contradistinction to schizophrenic positive symptoms, Hoffman (1987) has suggested that manic "hyperactivity" arises not as a result of structural damage leading to the formation of pathological attractors, but due to an increase in the noise levels resulting in enhanced rate of transition between attractors.

Past work related to major depression has concentrated on modeling learned helplessness, an experimental psychological model of depression, in an adaptive resonance network. More recently, a general model aimed at explaining how cognitive, emotional, and motor processes might influence one another has been presented (see Grossberg, in Reggia et al., 1999). Grossberg postulated opponent processing modules to control reinforcement learning in response to positive and negative reenforcers. Taking yet another approach to modeling major depression, it has recently been shown that the affective interference of depression might produce network overtraining and result in a network that responds excessively to negative stimuli and reinforces the dark obsessions characteristic of rumination.

## Discussion

The conceptual and methodological challenges tackled by the studies surveyed here serve to illustrate the early stages of coalescence of a field that ambitiously endeavors to study the pathogenesis of brain disorders computationally. There is a large gap between the conceptual and modeling levels utilized in "realistic" computational studies of brain disorders versus more abstract ones. This gap arises in part because of the different disorders and phenomena addressed. It also reflects the long-standing controversy in the literature between more realistic "bottom-up" models and simpler, conceptual "top-down" models. In our current state of knowledge of the workings of the brain there is certainly room for both kinds of models.

The work reviewed in this paper demonstrates that neural models are a potentially useful methodological tool for examining the feasibility of theoretical hypotheses within a computational context. They can offer new insights into the experimental data, and may unify previously unrelated observations. Even the much simplified models reviewed here are sufficiently complicated to generate interesting and nontrivial predictions, as the feedback structure of the systems and processes involved makes the study of lesioned models a difficult and considerable challenge.

Future challenges and prospects of modeling brain disorders include:

1. *Modeling new experimental data*: Recent advances in several experimental techniques have yielded a number of promising developments. Of special interest to neural modelers are the developments in techniques that provide information on neural and synaptic degenerative processes. Those include neuroanatomical morphometric and immunochemical methods and magnetic resonance spectroscopy. Much hope for further advancement relies on the rapid development of functional imaging techniques, but a significant discrepancy remains between the scale of the distributed networks of brain activation revealed by current functional imaging studies and the scale of current neural models.
2. *Developing neural models of more complex cognitive functions*: current work has concentrated on making use of available neural modeling tools. This has restricted the cognitive phenomena studied to memory-related processes, and to learning relatively simple tasks in a supervised manner. The development and incorporation of more sophisticated neural models is probably an essential step towards capturing more complex phenomena. Promising venues include models of reinforcement learning, multimodular associative memories, and multilayered recurrent networks.

The studies reviewed here are just the "end of the beginning." As more becomes known about the normal functioning of brain and cognitive systems, we shall be in a much better position to model their abnormalities. Some of the research projects in this field demonstrate another, perhaps not less promising, potential value of computational studies of brain disorders: to use the constraints imposed by such studies to learn more about the normal functioning of the brain by way of "reverse engineering." Computational modeling helps us to formulate our ideas precisely and study their consequences by making them explicit within simulation and analytical models. As such, we believe it will continue to develop as a fundamental research approach, working in a complementary manner with other research methodologies.

# Neuromanifolds and Information Geometry

*Shun-ichi Amari*

## Introduction

A neural network is specified by its architecture and by a number of parameters consisting of connections or synaptic weights, together with bias terms or thresholds. These parameters are modifiable, and learning or self-organization is carried out by changing them. Let us denote all of these parameters by a vector $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_n)$, where $n$ is the number of the parameters, and consider the parameter space where $\boldsymbol{\theta}$ is its coordinate system. Any neural network of this architecture is specified by a point $\boldsymbol{\theta}$ in the parameter space, so that we identify the parameter space with the set of all the neural networks.

Neural networks are regarded as stochastic nonlinear systems. Some models are intrinsically stochastic, because of the stochastic nature of neural firing. These models include Boltzmann machines (see SIMULATED ANNEALING AND BOLTZMANN MACHINES) and Bayesian or belief-propagation networks (see BAYESIAN NETWORKS). Some are deterministic but work in the noisy environment, so that its behaviors are not free from stochastic fluctuations. A typical example is a multilayer perceptron.

Learning takes place in the parameter space, and a learning process is represented by a trajectory. Here an important problem arises: What is the geometrical structure of the parameter space, and how do learning behaviors depend on its structure? Information geometry, which originated in studies of the manifolds of probability distributions, can be used to answer these questions (Amari and Nagaoka, 2000). It defines a Riemannian metric and a pair of dual affine connections. It gives a geometrical framework to elucidate problems related to stochastic phenomena, so that it is useful not only for statistical inference and information theory but also for neural networks.

This article introduces geometrical structures in the parameter space of neural networks known as neuromanifolds and elucidates how the dynamical behaviors of neural learning are related to the underlying geometrical structures. We use multilayer perceptrons and Boltzmann machines as examples. Geometrical ideas are also applied to support vector machines (Burges, 1999; Amari and Wu, 1999), boosting methods (Lebanon and Lafferty, 2001), and many others. The principles and practical implementations of natural gradient learning (Amari, 1998) are described first.

## Neuromanifold of Multilayer Perceptrons

Let us consider a multilayer perceptron consisting of one hidden layer with $h$ hidden neurons and one output neuron. Let its inputs, $x_1, \ldots, x_k$, be denoted by an input vector $\mathbf{x} = (x_1, \ldots, x_k)$. The $i$th hidden neuron receives $\mathbf{x}$ and calculates its weighted sum, $u_i = \mathbf{w}_i \cdot \mathbf{x} = \Sigma w_{ij}x_j$, where $\mathbf{w}_i = (w_{il}, \ldots, w_{ik})$ is the synaptic weight vector. It then emits a nonlinear sigmoidal function $\varphi(u_i)$ as its output, where $\varphi(u) = \tanh(u)$ is the hyperbolic tangent.

The output neuron summarizes all the outputs of the hidden neurons with weights $\mathbf{v} = (v_1, \ldots, v_h)$, and emits its output. The sum is disturbed by Gaussian noise $n$, so that the overall input-output relation is written as

$$y = \sum_{i=1}^{h} v_i\varphi(\mathbf{w}_i \cdot \mathbf{x}) + n \tag{1}$$

The parameter space of the multilayer perceptron is specified by the set of all the parameters $\boldsymbol{\theta} = (w_{11}, \ldots, w_{1k}, w_{21}, \ldots, \ldots w_{hk}; v_1, \ldots, v_h)$. It can be seen that each point $\boldsymbol{\theta}$ corresponds to the nonlinear function $f(\mathbf{x}, \boldsymbol{\theta}) = \Sigma v_i\varphi(\mathbf{w}_i \cdot \mathbf{x})$ of the perceptron. However, since the behavior of each perceptron is represented by the probability distribution of the output $y$ given $\mathbf{x}$,

$$p(y|\mathbf{x}, \boldsymbol{\theta}) = \frac{1}{\sqrt{2\pi}} \exp\left\{-\frac{1}{2}(y - f(\mathbf{x}, \boldsymbol{\theta}))\right\}^2 \tag{2}$$

we may identify each point $\boldsymbol{\theta}$ with the above probability distribution.

We first address the problem of the identifiability of the parameters of neural networks. When two networks with different parameters $\boldsymbol{\theta}$ and $\boldsymbol{\theta}'$ have the same input-output behavior, it is not possible to identify the parameters from the behaviors. Such networks are said to be equivalent. Two types of unidentifiability are known (Chen, Lu, and Hecht-Nielsen, 1993):

1. *Permutation*: Permutation of the number of hidden units does not change a network's behavior.
2. *Sign change*: Sign change of both $\mathbf{w}_i$ and $v_i$ at the same time does not change its behavior, because $v_i\varphi(\mathbf{w}_i \cdot \mathbf{x}) = -v_i\varphi(-\mathbf{w}_i \cdot \mathbf{x})$.

The above transformation induces the following equivalent networks (Rüger and Ossen, 1997): When the synaptic weight vectors $\mathbf{w}_i$ and $\mathbf{w}_j$ are equal, the two hidden neurons can be merged into one neuron, where $v' = v_i + v_j$ gives a new connection weight to the output neuron without changing its behavior. Hence, on the submanifold defined by $\mathbf{w}_i = \mathbf{w}_j$, two networks are equivalent when $v_i + v_j$ are equal. It also happens that, in the submanifold defined by $v_i = 0$, whatever value $\mathbf{w}_i$ takes, $v_i\varphi(\mathbf{w}_i \cdot \mathbf{x}) = 0$. Hence, whatever $\mathbf{w}_i$ is, the behaviors are the same, and this neuron can be removed. The same holds when $\mathbf{w}_i = 0$. We call these submanifolds defined by $\mathbf{w}_i = \mathbf{w}_j$ or $v_i|\mathbf{w}_i| = 0$ the critical submanifolds. Parameters are not identifiable on critical submanifolds.

When we consider equivalent networks as one object, the equivalent points in the neuromanifold will be merged into one point. For example, the submanifold defined by $v_i = 0$ reduces to one point. The reduced manifold has singularities on which dimensions are reduced. This causes a singular topological structure in the reduced neuromanifold.

It is usual to use the Kullback-Leibler divergence (Cover and Thomas, 1991) as a measure of divergence defined by two probability distributions $p(\mathbf{x})$ and $q(\mathbf{x})$:

$$KL[p(\mathbf{x}) : q(\mathbf{x})] = E_p\left[\log \frac{p(\mathbf{x})}{q(\mathbf{x})}\right] = \int p(\mathbf{x}) \log \frac{p(\mathbf{x})}{q(\mathbf{x})}\, d\mathbf{x} \tag{3}$$

where $E_p$ is expectation with respect to $p(\mathbf{x})$. This quantity is nonnegative and is equal to 0 when and only when $p(\mathbf{x}) = q(\mathbf{x})$, but it is not symmetric; that is, $\mathrm{KL}[p : q] \neq \mathrm{KL}[q : p]$ in general. The KL divergence is related to information theory. Let $X$, $Y$ be two random variables whose joint probability is $p(x, y)$ and whose marginal distributions are $p_X(x)$ and $p_Y(y)$, respectively. The probability distribution $p_X(x)p_Y(y)$ is different from $p(x, y)$ except for the case in which $X$ and $Y$ are independent. How much are the random variables $X$ and $Y$ related? This is measured by the Shannon mutual information $I[X : Y]$, which is equal to the KL divergence, in this way:

$$I[X : Y] = KL[p(x, y) : p_X(x)p_Y(y)] \tag{4}$$

When the probability distribution is given by a parametric form $p(\mathbf{x}, \boldsymbol{\theta})$ (or conditional distribution $p(y|\mathbf{x}, \boldsymbol{\theta})$, in the present case), the KL divergence $D(\boldsymbol{\theta} : \boldsymbol{\theta}')$ is given in the parameter space by

$$D[\boldsymbol{\theta} : \boldsymbol{\theta}'] = KL[p(y|\mathbf{x}, \boldsymbol{\theta}) : p(y|\mathbf{x}, \boldsymbol{\theta}')] \tag{5}$$

When the two points are close, we put $\boldsymbol{\theta}' = \boldsymbol{\theta} + d\boldsymbol{\theta}$. Then, by Taylor expansion, we have the quadratic form

$$KL[p(y|\mathbf{x}, \boldsymbol{\theta}) : p(y|\mathbf{x}, \boldsymbol{\theta} + d\boldsymbol{\theta})] = \tfrac{1}{2}\, d\boldsymbol{\theta}^T G d\boldsymbol{\theta} \tag{6}$$

where

$$G(\boldsymbol{\theta}) = E\left[\frac{\partial}{\partial \boldsymbol{\theta}} \log p(y|\mathbf{x}, \boldsymbol{\theta}) \frac{\partial}{\partial \boldsymbol{\theta}} \log p(y|\mathbf{x}, \boldsymbol{\theta})^T\right] \tag{7}$$

is a matrix called the Fisher information matrix, and the quadratic form is regarded as the square of the distances between two nearby points $\boldsymbol{\theta}$ and $\boldsymbol{\theta} + d\boldsymbol{\theta}$. Here, $\partial/\partial\boldsymbol{\theta}$ is the gradient and T denotes transposition of a column vector.

The Fisher information matrix is a measure concerning how much information is obtained by observing a random variable, in order to estimate the underlying distribution. On the other hand, the Shannon information matrix is a measure concerning how much information is obtained concerning random variable $X$ when another random variable $Y$ is observed. Hence, they are used for different purposes, although they are derived from the same KL divergence.

A manifold is said to be Riemannian when the square of the distance between two nearby points is given by a quadratic form like that in Equation 6, based on a symmetric positive matrix $G$. The matrix is called the Riemannian metric.

The neuromanifold is a Riemannian space, having the Fisher information matrix $G$ as its Riemannian metric. It is positive-definite in general, but it degenerates on the critical submanifolds of the neuromanifold of multilayer perceptrons, that is,

$$d\boldsymbol{\theta}^T G d\boldsymbol{\theta} = 0 \tag{8}$$

on a critical submanifold, when $d\boldsymbol{\theta}$ is the direction of unidentifiability. This reflects the fact that the distance between two equivalent points is 0. Such a manifold may be said to be pseudo-Riemannian. Hence, the Riemannian structure accounts for the topological singularity in the reduced manifold.

The gradient of a function $f(\boldsymbol{\theta})$ represents the direction of the steepest change of the function $f$ in a Euclidean space. "The steepest" implies that, when $\boldsymbol{\theta}$ changes by $d\boldsymbol{\theta}$ with a small fixed length, say $|d\boldsymbol{\theta}|^2 = \varepsilon^2$, the change of $f$, $\Delta f = f(\boldsymbol{\theta} + d\boldsymbol{\theta}) - f(\boldsymbol{\theta})$, is largest in the direction of the gradient $d\boldsymbol{\theta} \propto \nabla f(\boldsymbol{\theta})$. In the case of a Riemannian space, the distance is defined by the quadratic form given in Equation 6. The steepest direction is then given by the natural or Riemannian gradient (Amari, 1998).

$$\tilde{\nabla} f = G^{-1} \nabla f \tag{9}$$

## Natural Gradient Learning in a Neuromanifold

Learning takes place in a neuromanifold by modifying the current parameters $\boldsymbol{\theta}$, depending on the current input and output pair $(\mathbf{x}_t, y_t)$ at time $t = 1, 2, \ldots,$ in a training set of examples. Let $l(\mathbf{x}, y; \boldsymbol{\theta})$ be a loss function that is to be minimized through learning. A popular loss is the square of errors of the outputs. The backpropagation learning rule is given by the gradient method

$$\Delta\boldsymbol{\theta} = -\eta \nabla l(\mathbf{x}, y; \boldsymbol{\theta}) \tag{10}$$

However, backpropagation learning is very slow. The error rate decreases quickly in the early stages of learning, but soon the decrement becomes very small. Such a position is called a plateau, and it takes a long time to get rid of it. Plateaus are not local minima but saddle points.

It is known from the statistical-physical method that plateaus result from the permutation symmetry of the hidden neurons and thus are ubiquitous (Rattray and Saad, 1999). Moreover, a learning trajectory is usually attracted to such a saddle point, and convergence slows greatly. Such a phenomenon is caused by the geometrical structure of the neuromanifold, corresponding to its topological and metrical properties.

Plateaus mostly occur on critical submanifolds where the parameters are not identifiable. A change in the parameters around a critical submanifold causes only a negligibly small improvement in its behaviors. However, if we take the metrical structure into account, the gradient should be replaced by the Riemannian one, the natural gradient. Then, the plateau phenomenon given rise to by unidentifiability disappears. The natural gradient learning rule is given by

$$\Delta\boldsymbol{\theta} = -\eta G^{-1} \nabla l(\mathbf{x}, y; \boldsymbol{\theta}) \tag{11}$$

where $\eta$ is a learning rate (Amari, 1998). It should be noted that $G$ is singular on a critical submanifold, so that $G^{-1}$ diverges there. This has an effect of preventing the parameters $\boldsymbol{\theta}$ from approaching critical submanifolds, thus avoiding plateaus.

This method is equivalent locally to the Newton method, implying superlinear convergence. However, the merit of natural gradient learning lies not only in the speed with which local convergence can be achieved but also in the avoidance of plateaus in the learning process, which is the main obstacle slowing convergence. In general, natural gradient learning differs from a second-order method such as Newton's in that natural gradient learning depends on both the Riemannian structure and the cost function, while the second-order method takes only the second derivatives of the cost function.

In general, it is difficult to calculate and invert the Fisher information matrix $G$. In order to overcome this difficulty, the *adaptive natural gradient method* has been proposed (Amari, Park and Fukumizu, 2000) in which the inverse $G^{-1}$ is estimated by an adaptive method, by changing the current $G^{-1}$ into $G^{-1} + \Delta G^{-1}$,

$$\Delta G^{-1} = \eta' G^{-1} \nabla l (G^{-1} \nabla l)^T \tag{12}$$

where $\eta'$ is another learning rate.

In the special case of the squared loss, the adaptive natural gradient method is equivalent to the adaptive version of the Gauss-Newton method, although the motivation is quite different. However, the adaptive natural gradient method is used for many other types of learning problems, including the Kullback-Leibler loss (Park, Amari, and Fukumizu, 2000), Independent Component Analysis (q.v.) (Hyvarinen et al., 2001), and others.

## Information Geometry of Boltzmann Machines and EM Algorithm

We now introduce a more advanced theory of information geometry, in which a manifold has a pair of dual affine connections in addition to the Riemannian metric (Amari and Nagaoka, 2000). We will defer the mathematical details in favor of an intuitive explanation. For the manifold consisting of probability distributions, a Riemannian metric is given by the Fisher information matrix. How is a geodesic defined in such a manifold? The Riemannian geodesic is given by the shortest path connecting two points. Two other types of geodesics, called the *e*-geodesic and *m*-geodesic, are introduced as follows:

Given two probability distributions $p(x)$ and $q(x)$, the *e*-geodesic connecting them is a curve $r_e(x, t)$ given by

$$\log r_e(x, t) = (1 - t) \log p(x) + t \log q(x) + c(t) \tag{13}$$

where $t$ is the parameter of the curve and $c$ is a normalization constant. In other words, an *e*-geodesic connects two distributions linearly in the logarithmic scale. Such a curve is an exponential family. The *m*-geodesic connecting them is given by

$$r_m(x, t) = (1 - t)p(x) + tq(x) \tag{14}$$

In other words, it connects two distributions linearly, giving a mixture family.

We next define the orthogonality. In a Riemannian manifold, two curves $\boldsymbol{\theta}_1(t)$ and $\boldsymbol{\theta}_2(t)$ that intersect at $t = 0$, $\boldsymbol{\theta}_1(0) = \boldsymbol{\theta}_2(0)$ are orthogonal at the intersection when the inner product of their tangents $\dot{\boldsymbol{\theta}}_1(0)$ and $\dot{\boldsymbol{\theta}}_2(0)$ is 0:

$$\langle \dot{\boldsymbol{\theta}}_1, \dot{\boldsymbol{\theta}}_2 \rangle = \dot{\boldsymbol{\theta}}_1^T G \dot{\boldsymbol{\theta}}_2 = 0 \tag{15}$$

Here $\dot{\boldsymbol{\theta}}_i = (d/dt)\dot{\boldsymbol{\theta}}_i(t)$ represents the tangent of curve $\boldsymbol{\theta}_i(t)$. In the present case, the two curves $r(x, t)$ and $q(x, t)$, $r(x, 0) = q(x, 0)$ are orthogonal when

$$\langle \dot{r}(x, 0), \dot{q}(x, 0) \rangle = \int \frac{\dot{r}(x, 0)\dot{q}(x, 0)}{r(x, 0)}\, dx = 0 \tag{16}$$

The following is a fundamental theorem of a dually flat manifold (Figure 1).

**Generalized Pythagoras Theorem**. For three distributions $p(x)$, $q(x)$, and $r(x)$, when the *m*-geodesic connecting $p$ and $q$ intersects the *e*-geodesic connecting $q$ and $r$ orthogonally at $q$,

$$KL[p : q] + KL[q : r] = KL[p : r] \tag{17}$$

The Boltzmann machine (see Simulated Annealing and Boltzmann Machines) is a recurrently connected stochastic neural network whose behavior is directly connected with a probability distribution. Hence, its performance is elucidated by information geometry. The state of a Boltzmann machine is specified by vector $\mathbf{x} = (x_i)$, where $x_i$ is 1 when the $i$th neuron is excited and is 0 otherwise. The state changes stochastically at discrete times. The next state $\mathbf{x}'$ is determined as follows. Choose one neuron, say $j$, randomly. Then, $x'_j$ (the $j$th component of $\mathbf{x}'$) is determined to be equal to 1 with probability related to $u_j = \Sigma w_{ji} x_i$, where $\mathbf{w} = (w_{ji})$ are the connection weights between neurons $i$ and $j$. Here, $w_{ji} = w_{ij}$ and $w_{ii} = 0$ are assumed. The state transition of a Boltzmann machine is described by a symmetric Markov chain. Its stable distribution is explicitly given by

$$p(\mathbf{x}; \mathbf{w}) = c \exp\{-E(\mathbf{x})\} \tag{18}$$

$$E(\mathbf{x}) = -\tfrac{1}{2} \sum w_{ij} x_i x_j \tag{19}$$

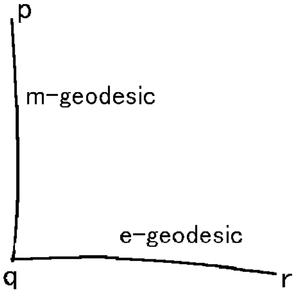

**Figure 1.** Pythagorean relation in information geometry.

When the Boltzmann machine is working for a long period, state $\mathbf{x}$ appears with relative frequency $p(\mathbf{x}; \mathbf{w})$. A Boltzmann machine is used to simulate an environmental information source that generates signal $\mathbf{x}$ with relative frequency $q(\mathbf{x})$. To this end, we need to train a Boltzmann machine by modifying the synaptic connections $\mathbf{w} = (w_{ij})$ such that $p(\mathbf{x}; \mathbf{w})$ approximates $q(\mathbf{x})$, by using the training data $D_T = \{\mathbf{x}_1, \ldots, \mathbf{x}_T\}$.

A Boltzmann machine has visible neurons and hidden neurons, where the hidden neurons control the behaviors of the visible neurons. We first explain the simplest case without hidden neurons. Let $S$ be the set of all the probability distributions over the state set $X = \{\mathbf{x}\}$. Since there are $2^n$ states over $n$ neurons, a probability distribution $q = \{q(\mathbf{x})\}$ over these states specifies $2^n$ probabilities $q(\mathbf{x})$ for all $\mathbf{x} \in X$. Since

$$\sum_{\mathbf{x} \in X} q(\mathbf{x}) = 1 \tag{20}$$

holds, $q$ has $2^n - 1$ degrees of freedom. Geometrically, this implies that $S$ is a $(2^n - 1)$-dimensional manifold. The probability distributions $p(\mathbf{x}; \mathbf{w})$ realized by Boltzmann machines are of the form given by Equation 18, having only $0.5n(n + 1)$ degrees of freedom $\mathbf{w} = (w_{ij})$. Therefore, the set $B$ of the probability distributions realized by Boltzmann machines is a $0.5n(n + 1)$-dimensional submanifold included in the larger manifold $S$.

Given a training set $D_T$ from the environment distribution $q$, we need to obtain $p \in B$, which approximates $q$ best. The criterion of approximation is to minimize the Kullback divergence or relative entropy of $q$ and $p$:

$$D(q \| p) = \sum_{\mathbf{x}} q(\mathbf{x}) \log \frac{q(\mathbf{x})}{p(\mathbf{x})} \tag{21}$$

Information geometry elucidates the geometrical structure of $S$ and $B$, and the optimal approximator is easily obtained (Amari, Kurata, and Nagaoka, 1992). Let $\hat{p} \in B$ be the minimizer of $D(q \| p)$. Then, from the Pythagoras theorem, the *m*-geodesic connecting $q$ and $\hat{p}$ is orthogonal to $B$, that is, orthogonal to any curves in $B$. Such a point is called the *m*-projection or $q$ to $B$. Hence the optimal approximator of $q$ is given by its *m*-projection.

In the general case, neurons are divided into two parts, hidden neurons and visible neurons. The state $\mathbf{x}$ is also divided into two parts, $\mathbf{x}_V$ and $\mathbf{x}_H$, $\mathbf{x} = (\mathbf{x}_V, \mathbf{x}_H)$. The stable distribution of $\mathbf{x}_V$ is

$$p(\mathbf{x}_V; \mathbf{w}) = \sum_{\mathbf{x}_H} p(\mathbf{x}_V, \mathbf{x}_H; \mathbf{w}) \tag{22}$$

which is more general than those specified by Boltzmann machines (cf. Equation 18) without hidden units.

The training data $D_T$ are given only to the visible neurons, and no information is available for the states of the hidden neurons. However, it is more flexible to adjust $p(\mathbf{x}_V)$ to fit $q(\mathbf{x}_V)$ of the environment, by modifying the connection weights, including the hidden neurons. Let $S$ be the set of all the joint probability distributions $q(\mathbf{x}_V, \mathbf{x}_H)$. Let $B$ be the joint distributions $p(\mathbf{x}_V, \mathbf{x}_H; \mathbf{w})$ realized by the Boltzmann machines. Since the training data $D_T$ specify relative frequencies $q(\mathbf{x}_V)$ of the visible part only, the marginal distribution $q(\mathbf{x}_V)$ is available from $D_T$. Let $\tilde{D}$ be the set of all the probability distributions $q(\mathbf{x}_V, \mathbf{x}_H)$ whose marginal distribution is specified by the training data $D_T$. We can prove that $\tilde{D}$ is an *m*-flat submanifold in $S$.

The best approximation is to minimize $D\{q(\mathbf{x}_V) \| p(\mathbf{x}_V; \mathbf{w})\}$. A recursive procedure to obtain the best approximation is shown (Amari, 1995). Starting from any initial guess $p_1 \in B$, project it by the *e*-geodesic to $\tilde{D}$, obtaining $q_1 \in B$. Then, project $q_1$ to $B$ by the *m*-geodesic, obtaining a new candidate $p_2 \in B$. Here, two dualistic notions of the *e*-geodesic and *m*-geodesic play a fundamental role. It is interesting that this coincides with the Expectation-Maximization (EM) algorithm known in statistics. Here, the *e*-

projection part corresponds to taking the expected value of the unknown (hidden) frequencies of $q(\mathbf{x}_V, \mathbf{x}_H)$ when the candidate is $p$, as is given by the $E$ procedure in the EM algorithm. The $m$-projection part is maximization of the likelihood, deriving the maximum likelihood estimator $p$ from $q$.

## Conclusion

Information geometry provides a mathematical structure that originated in the study of the intrinsic geometry of manifolds of probability distributions. It gives a Riemannian metric together with a dual pair of affine connections, where generalizations of the Pythagoras theorem and projection theorem hold. It is applied to various stochastic models in many fields of research, including neural networks. Further developments can be found in Watanabe (2001).

# Neuromodulation in Invertebrate Nervous Systems

*Patsy S. Dickinson*

## Introduction

Because animals live in changing environments, behavior and hence nervous system output must be flexible. This flexibility manifests itself in several ways that are important when using either experimental studies or modeling to understand neural network function. First, neurons are not all alike; they show a rich variety of conductances that endow them with different functional properties. Second, these properties and hence the collective activity of the networks to which the neurons belong are not fixed, but are subject to modulation that can change their characteristics and output. Modulation as a result of both locally released neuromodulators and more widely acting hormones differs qualitatively from the moment-to-moment integration of synaptic excitation and inhibition that a neuron receives. Neuromodulators can provoke dynamic changes in neurons or circuits on time scales ranging from seconds to days.

Neuronal membrane properties and synapses, neuromuscular junctions, and muscle properties are all subject to modulation. Together, these modulations allow the same groups of neurons to generate diverse arrays of behaviors and to respond appropriately to a wide variety of sensory stimuli. Frequently, the same modulators act at multiple levels to influence or bias motor output. Because of their relative simplicity and accessibility, invertebrate nervous systems have provided the clearest examples of modulation and its importance to neuronal output.

## Temporal and Spatial Dynamics of Neuromodulation

Neuromodulators act on a variety of both temporal and spatial scales owing to the nature of release and breakdown as well as the mechanisms through which they exert their effects (Figure 1). Some modulators are hormones; thus, they are spatially widespread and show relatively slow temporal changes. In *Aplysia*, for example, the bag cells release several peptides that change the activity of numerous other neurons, and of themselves via autoreceptors, for up to 18 hours (Levitan and Kaczmarek, 2002). Alternatively, other modulators are released at defined neuropilar locations and may be rapidly broken down. In addition to the amines, which often function as modulators, some peptides, such as proctolin in the crustacean stomatogastric nervous systems, are rapidly broken down by peptidases (Nusbaum et al., 2001). Moreover, the same transmitter substance may be released both hormonally and neuronally. At the same time, the cellular mechanisms by which modulators act may selectively potentiate the effects of some modulators. For example, some modulators activate second messengers, which may outlast the presence of the modulator itself. Others may act on relatively short time scales, so cellular properties in a rhythmic network, for example, may vary over the course of each cycle. Because of these dynamics, networks are continuously refined and reconfigured during behavior (Marder, 1997), and such dynamics must be incorporated into models if they are to explain the flexibility observed in behaving animals.

## Factors Determining Variability in Neuromodulator Effects

The effects of a given neuromodulator on its target neuron(s) or network(s) depend on a number of other factors. First, many neuromodulator influences may be dependent on the concentration of

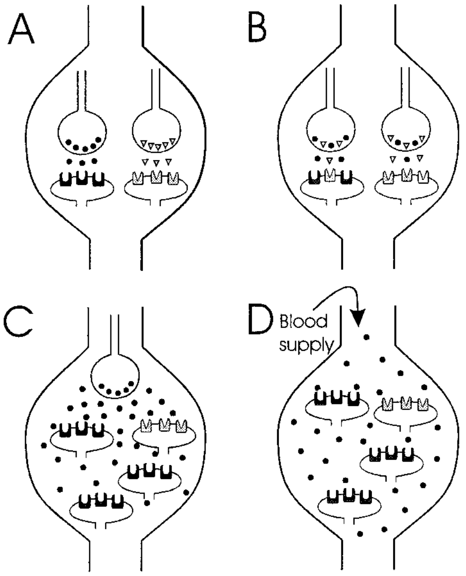

**Figure 1.** Modulatory transmitters can affect other neurons on a number of spatial scales and in a variety of combinations. For example, each of two different modulatory neurons could release a modulator into specific neuropilar regions, resulting in "pointwise" modulation that is limited in both time and space (*A*). Alternatively, two or more co-transmitters (one or both of which are modulatory) could be released from the same synaptic terminals (*B*). The two substances need not act simultaneously on the same postsynaptic terminals. Instead, they could be released by differential spiking frequencies or patterns; moreover, not all postsynaptic neurons necessarily have receptors for both modulatory compounds. A third alternative (*C*) is more widespread release from nonsynaptic sites, such that the transmitter diffuses to influence a larger group of neurons, with a gradient as a function of distance from the presynaptic release site. Finally, modulators can be released into the bloodstream and thus delivered to all neurons (*D*), although they affect only those with appropriate receptors.

transmitter present. In most experiments using bath application, there is a dose-dependent effect. When modulators are released from neurons, the amount of transmitter released can be a function not only of spike frequency in the modulatory neuron, but also of the pattern with which the neuron fires. For example, small molecule transmitters may be released with each spike, but peptides and amines, which are frequently modulatory, may be released only when the neuron fires in high-frequency bursts. Thus, the effect of a modulatory neuron firing tonically at 10 Hz may differ both qualitatively and quantitatively from the effects of the same neuron firing 0.5-s, 40-Hz bursts every 2 s, even though the average spike frequency is unchanged. In the *Aplysia* motor neuron B15, for example, acetylcholine is released with each action potential, but the modulatory peptides (small cardioactive peptides, SCPs) that it contains are released only with elevated (e.g., 25–50 Hz) spike frequencies (Whim, Church, and Lloyd, 1994). Peptide release from this neuron does not depend on spike frequency alone, but rather on complex interactions between spike frequency, burst duration, and interburst interval. Additionally, it should be noted that while peptide release is often pattern sensitive, this is not always the case, as illustrated by another motor neuron in *Aplysia*, which likewise releases the SCPs, but does so even at very low firing frequencies (<1 Hz; Whim et al., 1994).

Second, many modulatory neurons contain more than one transmitter. These co-transmitters may be released differentially as a function of neuronal firing pattern, as described above. Likewise, they may be released differentially at different neuronal terminals (Nusbaum et al., 2001). Additionally, they may act differentially on different postsynaptic neurons as a function of the availability of different postsynaptic receptors. The situation becomes even more complex when we realize that the same neuron can contain co-transmitters that exert opposing effects on the same postsynaptic targets, so they may be excitatory under certain conditions yet be inhibitory under other firing regimes. Finally, the release of modulatory peptides may itself be modulated by other neurotransmitters. In *Aplysia* motor neuron B1, for example, serotonin increases excitability but simultaneously decreases the amount of the SCPs it releases (Whim et al., 1994).

Third, the effect of a given modulator frequently depends on the state of the system when the modulator is applied. Modulators themselves may affect this state, thereby altering the responses of the network to other inputs. In the lobster stomatogastric system, for example, the peptide proctolin by itself has no effect on the cardiac sac pattern. However, if proctolin is applied shortly after red pigment-concentrating hormone (RPCH) is applied, it elicits strong cardiac sac bursting (Dickinson et al., 1997). In formulating models of such systems, it should be remembered that the response of a system to one modulator may not always be identical, but instead may be a longer-term function of the modulatory history of the animal.

## Modulation of Sensory Systems

The sensory information that an animal needs depends on a number of factors, including its activity patterns and motivational state. Thus, the sensitivities of many sensory receptors can be modulated, as is seen for a stretch receptor, the oval organ, in crustaceans. This organ contains three sensory afferents and provides proprioceptive feedback to the gill ventilatory system. Proctolin increases the amplitude of the receptor potential and hence the number of action potentials produced in two of these afferents, whereas octopamine and serotonin decrease these responses. Interestingly, the dendrites within the oval organ itself contain proctolin, suggesting that receptor activity might automodulate receptor sensitivity in that increased activity would induce greater proctolin release, thereby increasing receptor gain (Pasztor, 1989).

In addition to receptor sensitivity itself, the extent to which sensory information is conveyed to central and motor systems is subject to modulatory control. This has been extensively examined in the sensorimotor synapses of *Aplysia* in the context of learning, but is also prevalent on shorter time scales associated with ongoing activity of many motor systems. In a number of locomotive systems in arthropods, for example, it has been shown that reflexes that stabilize posture in a quiet animal can change not only in magnitude, but also in direction when the animal begins to move. Such reflex reversal involves a number of mechanisms at both the presynaptic and postsynaptic levels (Clarac, Cattaert, and LeRay, 2000). Moreover, the strength of the reflex can vary cyclically as a function of the ongoing movement, again underscoring the importance of temporal dynamics in neuromodulation.

## Modulation at Central Levels

Modulators can activate, terminate, or modify rhythmic pattern-generating networks. The detailed outputs of many rhythmic patterns are highly variable; frequency, phase relationships within the pattern, and number of participating neurons are subject to change. Additionally, many neurons and/or muscles participate in more than one behavior. Thus, in modeling networks, the mechanisms by which modulators sculpt specific patterns of activity from more generalized pattern generators must be considered. Getting and Dekin (reviewed in Harris-Warrick and Marder, 1991), who first described such networks as "polymorphic," showed that the same network could be reconfigured by modulatory inputs to produce either escape swimming or reflexive withdrawal in the mollusk *Tritonia*.

### *Intrinsic Versus Extrinsic Neuromodulation*

Until recently, most modulators studied were located in control centers removed from the target network, and hence the release of transmitter was independent of the network and neurons being modulated. It is now clear, however, that neurons within a network may release modulators that act on the same network (Katz, 1998). With such "intrinsic neuromodulation," the pattern of modulator release thus depends on the activity of the network of neurons being modulated. In the CPG network controlling swimming in *Tritonia*, for example, one neuronal type, the dorsal swim interneurons, releases the transmitter serotonin. Serotonin not only reciprocally inhibits the ventral swim interneurons within the pattern generator, but also modulates the strength of other synapses within the network (Katz, 1998). Serotonin levels thus fluctuate dynamically during the course of a swim, and recent models have shown that this intrinsic modulation is a critical component in the production of the swim motor pattern (Frost et al., 1997).

### *Alteration of Intrinsic Properties of Neurons*

Many neurons have voltage-dependent conductances that allow them to generate rhythmic bursts of action potentials in the absence of synaptic input (see Oscillatory and Bursting Properties of Neurons for further details). However, many of these conductances are activated only in the presence of an appropriate neuromodulator. For example, the Anterior Burster neuron in the lobster pyloric network does not oscillate when completely isolated from its network partners and modulatory inputs. However, the isolated neuron oscillates strongly when superfused with any of several neuromodulators (Harris-Warrick and Marder, 1991). The characteristics of these oscillations (burst period, duration, amplitude) are different for each modulator. This diversity results at least partly from the fact that bursting in this neuron can be driven by a number of different voltage-dependent currents, a finding that has subsequently been confirmed by modeling studies (Marder, 1997). Each amine activates a different subset of conductances, resulting in different bursting patterns (Harris-Warrick and Marder, 1991).

Similarly, dopamine and serotonin modulate different currents in *Aplysia* neuron R15 to produce superficially similar changes in bursting, in this case the cessation of spontaneous bursting. However, when silenced by serotonin but not by dopamine, a brief depolarizing input provokes sustained bursting. A modeling study of this system showed that by modulating different currents, both amines silence R15, but dopamine prevents other input signals from activating the neuron, whereas serotonin amplifies synaptic inputs (reviewed in Fellous and Linster, 1998).

Modulators also alter the ability of neurons to generate plateau potentials, the regenerative switch between two stable membrane potentials. At one, the cell is hyperpolarized and silent; at the other, it is depolarized and fires action potentials. Shifts between the two levels occur abruptly when the neuron's membrane potential crosses a threshold value in response to current injection or postsynaptic potentials. The abilities of neurons to generate plateau potentials can be enhanced or suppressed by modulatory inputs. In the stomatogastric system, for example, activity in the Anterior Pyloric Modulator neuron enhances or suppresses the abilities of different neurons to generate plateau potentials. One effect of the changes in plateau capability is an altered sensitivity to synaptic inputs. When plateaus are generated, inputs strong enough to trigger the regenerative shift from one level to the other have greater effects than they would otherwise have, whereas those that are too weak to trigger the shift have little effect (Dickinson and Nagy, 1983). Once the threshold is reached, further increases in synaptic strength have little effect. In network computations, this characteristic effectively decreases the importance of synaptic strength (Marder, 1993). Consequently, the postsynaptic response becomes nonlinear. In addition, the effective duration of synaptic inputs is changed, since, once shifted, the postsynaptic neuron remains at its new level; hence, the effect of inputs sufficient to induce a switch from one plateau level to another long outlasts the stimulus duration (Figure 2).

Changes in the abilities of neurons to generate plateau potentials can have far-reaching effects on network activity. For example, when the plateau properties of the ventricular dilator (VD, a pyloric neuron), are suppressed, the VD no longer fires with the pyloric pattern. Instead, if the much slower cardiac sac pattern is active, the VD fires with this network (reviewed in Harris-Warrick and Marder, 1991).

The roles of different conductances in determining the firing patterns of nonoscillatory neurons have now been examined in the stomatogastric nervous system both in models and in experiments using the dynamic clamp technique. The LP neuron, for example, is modulated by proctolin, and adding the proctolin conductance to the model alters both its activity and other membrane currents in ways that reflect the peptide's biological effects. Modeling has confirmed that even small currents that produce minor changes in membrane potential may have profound effects (Marder, 1993).

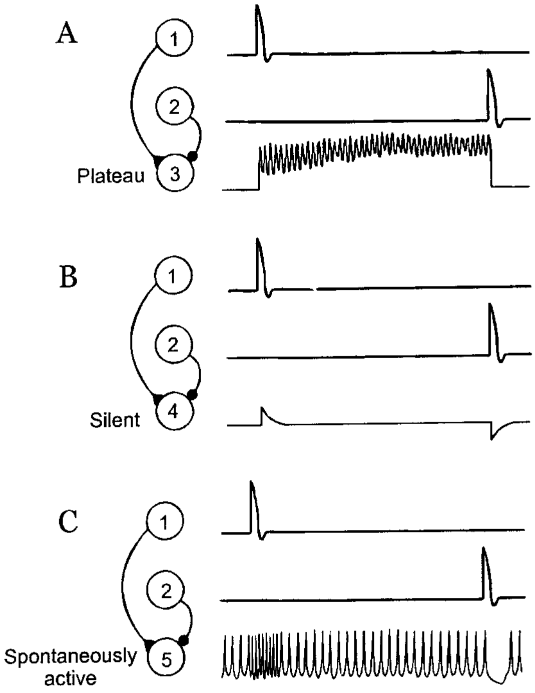

**Figure 2.** Plateau properties in a postsynaptic neuron increase the duration of its response to synaptic input. *A*, When the follower cell, 3, has plateau properties, an excitatory postsynaptic potential (from 1, triangle) triggers a shift to a depolarized plateau, whereas an inhibitory postsynaptic potential (from 2, circle) terminates the plateau. When the follower cell (4, 5) is silent but does not have plateau properties (*B*) or is spontaneously active (*C*), the effect of the same excitatory or inhibitory postsynaic potential lasts for only a short time after the input. (Source: Marder, E., 1993, Modulating membrane properties of neurons: Role in information processing, in *Exploring Brain Functions: Models in Neuroscience* (T.A. Poggio and D.A. Glasser, Eds.), Chichester, Engl.: Wiley, p. 30. Copyright 1993. Reprinted by permission of John Wiley & Sons, Ltd.)

Similarly, it has been possible to determine which K currents are most important for provoking the changes in postinhibitory rebound, and hence phasing of the pyloric pattern, when dopamine is applied to the stomatogastric system (Harris-Warrick et al., 1998).

An intriguing recent finding is the observation that many different modulators, including the peptides proctolin, RPCH, CabTRP, and TNRNFLRFamide and the muscarinic agonist pilocarpine, activate the same membrane current in neurons of the lobster STG. However, while all these modulators activate the pyloric pattern, each produces a different variant of the pattern, owing to the fact that a different subset of pyloric neurons contains receptors for each modulator (Nusbaum et al., 2001).

When modeling networks subject to neuromodulation, one must consider that although a modulator may act on only a subset of neurons in the network, neurons that are not direct targets of the modulator can likewise be affected and can influence the output of the system through their synapses within the network (for further discussion, see Crustacean Stomatogastric System).

### *Alteration of Synaptic Efficacy by Neuromodulators*

The efficacy of both chemical and electrical synapses can be changed by neuromodulator actions. For chemical synapses, changes in the amount of transmitter released or in the responsiveness of postsynaptic neurons can contribute to modulation. In *Aplysia*, for example, changes in synaptic efficacy are largely responsible for the long-term changes that underlie learning (see Invertebrate Models of Learning: *Aplysia* and *Hermissenda*). In the stomatogastric system, RPCH increases the efficacy of the synapses from a single presynaptic neuron onto its follower cells; this increase in synaptic efficacy is sufficient to cause a functional rewiring of two pattern generators and to provoke the generation of a novel rhythm (reviewed in Harris-Warrick and Marder, 1991).

Many synapses in invertebrates release transmitter not only in response to action potentials, but also as a graded function of membrane potential. It has recently been found that graded and spike-mediated transmitter release can be differentially modulated. Thus, for example, dopamine enhances graded synaptic transmission but decreases spike-evoked transmission at the LP-PD neuron synapse of the pyloric network (Harris-Warrick et al., 1998).

Electrical synapses are likewise subject to modulation. Serotonin, octopamine, and dopamine alter electrical coupling in the lobster pyloric system, with coupling at some synapses increased while at other synapses it is decreased. Because the same modulators can change the efficacies of both chemical and electrical synapses between the same neurons, the effective sign of a synapse can be changed. Dopamine, for example, alters synaptic efficacy between several pairs of pyloric neurons that are connected by dual synapses. Under control conditions, the electrical component dominates, and the synapses are largely excitatory. Under dopamine, however, the chemical component dominates, and the synapses are largely inhibitory (Harris-Warrick et al., 1998).

## Modulation of Neuromuscular Junctions and Muscles

Neuromodulators in many systems exert effects on neuromuscular junctions or on muscles themselves. These effects are often consistent with central or sensory effects of the same modulators. Modulators, which are released both from motor neurons and from exogenous sources, can change the amplitude, duration, or speed of muscle contraction or relaxation. These effects result from changes at one or more of three levels: presynaptic effects resulting in altered transmitter release from motor terminals, electrical properties and excitability of the muscle fibers themselves, and excitation-contraction coupling (Harris-Warrick and Marder, 1991).

These multiple steps have recently been incorporated into a model of the "neuromuscular transform" (NMT) by Brezina et al. (Brezina, Orekhova, and Weiss, 2000), who used a dynamical systems approach to examine modulation of feeding muscles in *Aplysia*, both theoretically and in this model neuromuscular system. These authors show that the NMT, which acts as a dynamic, nonlinear filter, limits the range of behaviors that can be produced. In particular, they find that many rhythmic behaviors break down at the level of the NMT when the neuronal cycle frequency driving the muscles increases beyond certain limits. However, neuromodulators in *Aplysia* modify a number of characteristics of the neuromuscular system, including the amplitude of contraction and rate of relaxation in response to neuronal stimulation, thereby altering the constraints on the system. Both intrinsic and extrinsic peripheral neuromodulation occur in this system, and the theoretical framework developed by these authors has shown that intrinsic modulation, which varies with the motor pattern itself, optimizes the performance of a single behavior. In contrast, extrinsic modulation, which is independent of the motor pattern, allows multiple contraction shapes to be generated and hence allows multiple behaviors to be produced using the same neuromuscular system.

## Discussion

Modulation is prevalent in both invertebrate and vertebrate nervous systems, and it occurs at all levels: sensory, central, and motor. Neuromodulators alter the output of a system by changing membrane properties of neurons, synaptic interactions, and intracellular properties such as excitation-contraction coupling in muscles. Moreover, modulatory inputs can act on time scales ranging from seconds to days. Consequently, the properties of individual neurons, as well as the nature and extent of their interactions within networks, are dynamic rather than static, and so the temporal dynamics of such changing properties must be considered if we are to fully understand and appreciate the flexibility of the nervous system. Moreover, these dynamics must be incorporated into models if they are to fulfill their promise in illuminating principles of neuronal functioning. Additionally, the responses of a given system to a specific neuromodulator are not always the same and may depend on the state of the preparation when the modulator is applied or activated. Because a range of substances modulates invertebrate systems, this variability can have important consequences.

Moreover, because the neural circuits that are subject to modulation differ substantially, the same modulator can cause different effects on different systems. Serotonin, for example, enhances swimming behavior in leeches, *Tritonia*, and the pteropod *Clione*. In both leeches and *Tritonia*, one component of this increase is enhanced presynaptic transmitter release. In *Tritonia* and *Clione*, the excitability of pattern-generating neurons is enhanced. In the lobster STG, serotonin causes an overall activation of the pyloric pattern but an inhibition of a number of neurons within the network, so the circuit is effectively limited to three of the eight neuronal types (Levitan and Kaczmarek, 2002).

The specific effects of a given neuromodulator are determined by numerous factors, including (1) the array of neurons expressing receptors for that modulator, (2) the membrane channels (often voltage-dependent) that are altered by the modulator, (3) the membrane potentials of neurons in the circuit, and (4) the interactions of those neurons within the network.

At least partly because of the dynamic nature and complexity brought to nervous systems by modulation, models are being successfully used to test fundamental assumptions underlying mechanisms of neuronal and network function and modulation. Modeling studies have, for example, confirmed that neuromodulators are able to increase and control the computational complexity of networks without increasing their structural complexity. However, it is important to consider neuromodulation as an integral part of models rather than simply as an "add-on" (Fellous and Linster, 1998). Moreover, models will ultimately need to incorporate the more complex aspects of neuromodulation that are now being found experimentally, including, for example, interactions amongst modulators, and the actions of modulators at multiple levels.

# Neuromodulation in Mammalian Nervous Systems

*Michael E. Hasselmo, Bradley P. Wyble, and Erik Fransen*

## Introduction

Neuromodulators change the way in which neural circuits process information. The term *neuromodulation* usually refers to the effect of neurochemicals such as acetylcholine (ACh), dopamine, norepinephrine, and serotonin, and other substances, including neuropeptides (see Hasselmo, 1995; Fellous and Linster, 1998; Katz, 1999; Doya, Dayan, and Hasselmo, 2002). The term neuromodulation does not refer to the rapid transmission of information through the nervous system by excitatory and inhibitory synaptic potentials. Rapid synaptic potentials are caused by neurotransmitters such as glutamate or $\gamma$-aminobutyric acid (GABA) acting on receptor proteins containing ion channels (ionotropic receptors), which cause fast changes in the conductance of the cell membrane to specific ions. In contrast, the neuromodulators primarily activate receptor proteins that do not contain an ion channel (metabotropic receptors). These receptors activate enzymes that change the internal concentration of substances called second messengers. Second messengers cause slower and longer-lasting changes in the physiological properties of neurons, resulting in changes in the processing characteristics of the neural circuit.

The effect of a neurochemical is receptor dependent (Table 1). Thus, a single neuromodulator such as serotonin can have dramatically different effects on different neurons, depending on the type of receptor it activates. Even the distinction between neurotransmitters and neuromodulators has exceptions based on receptor effects: glutamate and GABA can activate slower metabotropic receptor subtypes (mGluR and $\text{GABA}_\text{B}$), whereas some receptors for ACh and serotonin are ionotropic (nicotinic ACh and $5\text{-HT}_3$).

Neural network models are important for understanding the function of neuromodulatory influences, because neuromodulation causes effects that may appear subtle and contradictory in recordings from single neurons but have a significant effect on dynamical properties when distributed throughout a network (Hasselmo, 1995; Fellous and Linster, 1998; Katz, 1999; Doya et al., 2002). The anatomical distribution of fibers releasing neuromodulatory substances in the brain is usually very diffuse, as shown in Figure 1. This allows the activity of a small number of neuromodulatory neurons to influence the functional properties of broad regions of the brain. Neuromodulatory effects are usually slower than effects at ionotropic receptors, causing longer-term changes in functional state.

This review falls into two main sections, the cellular effects of neuromodulators and the functional modeling of neuromodulation. The first section summarizes some of the physiological effects of neuromodulation, including effects on (1) the resting membrane potential of pyramidal cells and interneurons, (2) spike frequency adaptation, (3) synaptic transmission, and (4) long-term potentiation. The second section reviews several different theories of the function of modulatory influences in neural circuits, including (1) noradrenergic modulation of attentional processes, (2) dopaminergic modulation of working memory, (3) cholinergic modulation of input versus internal processing, and (4) modulation of oscillatory dynamics in cortex and thalamus.

## Modeling Cellular Effects of Neuromodulation

A range of different neuromodulatory effects have been modeled in compartmental simulations of cortical pyramidal cells, including

**Table 1.** Some Receptor-Dependent Effects of a Subset of Neuromodulatory Substances

| | | Resting Potential | | | Synaptic Transmission | | | |
|---|---|---|---|---|---|---|---|---|
| Neuromodulator | Receptor Subtype | Pyramidal Cell | Interneuronal | Spike Adaptation | Inhibition | Afferent Input | Feedback | Long-Term Potentiation |
| Acetylcholine | Muscarinic | ↑ | ↑ | ↓ | ↓ | | ↓ | ↑ |
| | Nicotinic | ↑ | ↑ | | | ↑ | | |
| Dopamine | $D_1$ | | ↑ | | ↑ | | ↑ | |
| | $D_2$ | | | | ↓ | | | |
| Norepinephrine | $\alpha$ | | | | ↓ | | ↓ | |
| | $\beta$ | | ↑ | ↓ | | | ↑ | ↑ |
| Serotonin | 5-$HT_1$ | ↓ | ↓ | | | | | |
| | 5-$HT_2$ | | | ↓ | | | | |
| | 5-$HT_3$ | ↑ | ↑ | | | | | |
| Opioids | $\mu$ | | ↓ | | | | | |

changes in resting membrane potential, spike frequency adaptation, synaptic transmission, and long-term potentiation. Many of these effects are described in more detail in reviews of neuromodulation (McCormick, Wang, and Huguenard, 1993; Hasselmo, 1995; Fellous and Linster, 1998; Katz, 1999).

### *Pyramidal Cell Membrane Potential*

Some neuromodulatory agents cause slow changes in resting membrane potential owing to changes in the resting membrane conductance to individual ions. For example, activation of muscarinic ACh receptors causes a slow depolarization of pyramidal cells by decreasing the leak potassium conductance. In contrast, GABA activation of $GABA_B$ receptors and serotonin activation of 5-$HT_{1A}$ receptors causes a slow hyperpolarization by increasing potassium conductance. The time course of this $GABA_B$ effect is modeled in Synaptic Interactions (q.v.).

### *Inhibitory Interneuron Membrane Potential*

Many neuromodulators have a strong effect on the membrane potential of inhibitory interneurons. Depolarization of interneurons as a result of activation of dopaminergic, noradrenergic, cholinergic, and serotonergic receptors has been detected, whereas opioid receptors have a strong hyperpolarizing effect on interneurons.

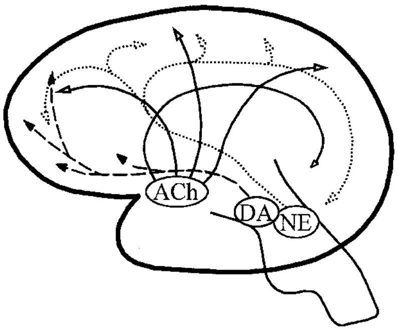

**Figure 1.** Example of the anatomy of neuromodulatory systems. Neurons producing acetylcholine (ACh) are clustered in nuclei of the basal forebrain. This relatively small population of neurons sends diffuse projections to a broad range of brain regions. Similarly, noradrenergic neurons (NE) are clustered in the locus coeruleus, and send diffuse connections throughout the brain. Dopaminergic neurons (DA) are in the ventral tegmental area and substantia nigra and project to nucleus accumbens, striatum, and frontal cortex.

### *Spike Frequency Adaptation*

When injected with current, cortical pyramidal cells fire action potentials initially at high frequencies, but neurons show a rapid decrease in firing frequency, referred to as *accommodation* or *adaptation*. ACh, norepinephrine, and serotonin reduce spike frequency adaptation, allowing higher frequency firing. In models, spike frequency adaptation can be modeled with an increase in intracellular calcium, because of the voltage-dependent calcium influx caused by each action potential. The increasing intracellular calcium concentration activates calcium-dependent potassium currents (also known as $I_{K(AHP)}$), which are reduced by the above neuromodulators.

### *Synaptic Transmission*

Many neuromodulatory substances activate presynaptic receptors, which alter the release of neurochemicals, including glutamate and GABA. Receptors that cause presynaptic inhibition at glutamatergic synapses include the $\alpha$-adrenergic receptors (which are a subtype of norepinephrine receptors), muscarinic ACh receptors, $GABA_B$ receptors, neuropeptide Y receptors, and adenosine receptors. As shown in Table 1, these effects can be selective for specific synapse types.

### *Long-Term Potentiation*

Neuromodulators have been shown to induce long-term potentiation and to enhance long-term potentiation induced by synaptic stimulation. $\beta$-adrenergic receptors and muscarinic receptors appear to actively induce long-term potentiation at specific synaptic connections. Activation of dopamine receptors, muscarinic ACh receptors, metabotropic glutamate receptors, opioid receptors, and $GABA_B$ receptors appears to influence the magnitude of long-term potentiation caused by synaptic stimulation.

## Functional Modeling of Neuromodulation

The cellular effects of neuromodulators can dramatically alter the functional dynamics of neural circuits, in contradiction to the common notion that neuromodulation only slightly increases or decreases the normal function of the network (Hasselmo, 1995; Fellous and Linster, 1998; Katz, 1999). The essential functional role of neuromodulation is illustrated by the breakdown of normal cognitive function by high doses of drugs such as scopolamine (which blocks ACh receptors) and by the important clinical effects of selective serotonin reuptake inhibitors (SSRIs).

Modulator effects are often described in simple colloquial terms such as "memory," "attention," or "reward," but the techniques of computational neuroscience allow a more sophisticated assessment of the specific functional influence of modulators on neural circuits (Hasselmo, 1995; Fellous and Linster, 1998; Doya et al., 2002). This will allow data from specific behavioral tasks to be addressed directly in terms of the dynamics of neural circuits rather than as simple verbal hypotheses.

### *Norepinephrine*

Drugs that enhance the release of norepinephrine and other monoamines have been shown to enhance performance on tests of sustained attention, such as the continuous performance task, in which subjects must detect an infrequent target stimulus in a long series of distractor stimuli. In recordings from monkeys, the enhancement of performance on these tasks has been linked to activity of noradrenergic neurons. The role of norepinephrine in this regard has been modeled using a hybrid model with detailed representation of the spiking activity of noradrenergic neurons in the locus coeruleus, coupled with a more abstract representation of cortical circuits performing the visual detection task (Usher et al., 1999). The cortical model regulates the behavioral response to individual stimuli using competing processing units with sigmoid input-output functions. The gain (slope) of these sigmoid units is increased by noradrenergic modulation. In this model, noradrenergic neurons have a low baseline firing rate, ensuring low gain in the cortical network, and a low false alarm rate. However, these neurons show a brief response to the target stimulus, which transiently increases the gain of the cortical units, increasing the likelihood of generating a response. The phasic level of noradrenergic neuron activity correlates with greater performance accuracy in the model and in experiments (Usher et al., 1999). A tonic increase in noradrenergic activity enhances the response to all stimuli, consistent with general arousal, which allows orienting to all stimuli but decreases visual detection performance.

The change in input-output functions described above could be a reasonable representation of the changes in circuit dynamics caused by norepinephrine. On a cellular level, norepinephrine activates $\beta$-adrenergic receptors, which decrease spike frequency adaptation and enhance postsynaptic responses (see Table 1). At the same time, norepinephrine activates presynaptic $\alpha$-adrenergic receptors, which suppress excitatory transmission. In network simulations of piriform cortex, these effects enhance the response of pyramidal cells to afferent input while decreasing the background activity caused by excitatory transmission between pyramidal cells in the cortex (Hasselmo et al., 1997). Norepinephrine has the apparently contradictory effects of decreasing excitatory synaptic input to interneurons while directly depolarizing these same interneurons. These effects decrease the activity of local circuits in response to weak input but increase their activity in response to strong input, an effect that resembles the change in gain of sigmoid input-output functions utilized in the model described above.

### *Dopamine*

Models of dopamine function include research on reinforcement learning as well as working memory. Dopamine has traditionally been viewed as a neuromodulator signaling reinforcement, but electrophysiological recording of the activity of dopaminergic neurons in the ventral tegmental area demonstrates activity dependent on the expectation of reward rather than on the reward itself. This pattern of activity appears similar to the error signal used in temporal difference learning. Models of the role of dopamine in reinforcement learning are described in more detail in REINFORCEMENT LEARNING and DOPAMINE, ROLES OF.

Experimental data also indicate a role for dopamine in working memory (the capacity to hold information in short-term memory for performance of tasks). Working memory may involve sustained spiking activity in populations of neurons within the prefrontal cortex. This sustained spiking activity can be maintained by excitatory recurrent connectivity or by the intrinsic properties of individual neurons. Detailed biophysical modeling demonstrates how dopaminergic modulation could contribute to both the transition between different activity states, as well as the maintenance of stable spiking activity (Durstewitz, Seamans, and Sejnowski, 2000). In this model, dopamine enhances the maintenance of individual stored items through enhancement of persistent voltage-sensitive sodium currents and the NMDA current. At the same time, dopamine reduces AMPA currents and depolarizes inhibitory interneurons through activation of the $D_1$ subtype of receptor. In the model, this serves to prevent activation of other task-irrelevant memories. Other work from that group showed that the initial response to dopaminergic modulation involved a $D_2$ receptor-mediated suppression of inhibitory synaptic transmission, which could serve to allow activation of prefrontal cortex by multiple inputs, and exploration of the input space. This effect is transient, while the more persistent effects at $D_1$ receptors could allow selection and maintenance of a single memory for a more extended period.

### *Acetylcholine*

The cellular effects of ACh play an important role in the function of cortical networks (Hasselmo, 1995). For example, muscarinic cholinergic antagonists such as scopolamine impair the encoding of new words but not the retrieval of previously encoded words. Models demonstrate how ACh could be important for enhancing encoding of new information in the cortex. As shown in Figure 2, computational modeling demonstrates how cholinergic activation of a calcium-sensitive cation current in layer II pyramidal cells in entorhinal cortex could cause sustained spiking activity such as that observed during the delay period of a delayed non-match-to-sample task (Fransen, Alonso, and Hasselmo, 2002). These mechanisms could allow maintenance of novel information for encoding and working memory.

Computational modeling also demonstrates how the cellular effects of ACh can enhance the encoding of new information patterns by selectively enhancing the response to external sensory stimuli

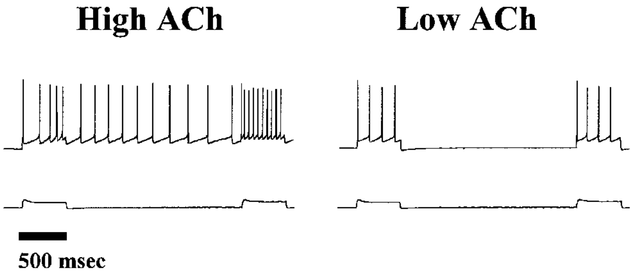

**Figure 2.** A biophysical simulation of an entorhinal cortex layer II pyramidal cell demonstrates that cholinergic enhancement of a calcium-sensitive cation current could allow maintenance of sustained spiking without afferent input. Bottom traces show the timing of depolarizing input, which causes spiking for 500-ms periods separated by a 2,500-ms delay. When cholinergic modulation is present (in a condition of high ACh, left side), the calcium influx during initial spiking causes activation of the cation current. This causes further depolarization, which causes additional spiking and calcium influx. This causes regenerative spiking activity even in the absence of external input. With lower ACh levels (right side), the current is not sufficiently activated and the neuron does not fire during the delay period.

versus internal retrieval (Hasselmo, 1995). This results from cholinergic suppression of glutamatergic transmission at feedback synapses but not at feedforward synapses, coupled with cellular depolarization, which makes neurons more likely to spike in response to afferent input. This causes activity to be clamped to the pattern of afferent input, allowing accurate storage of input patterns without interference from retrieval of previously stored patterns. Cholinergic enhancement of long-term potentiation offsets the reduction of synaptic input at excitatory intrinsic connections, allowing Hebbian synaptic modification of these connections for autoassociative storage of input patterns. On a faster time scale, similar transitions could occur in different phases of each cycle of hippocampal theta rhythm oscillations (Hasselmo, Bodelon, and Wyble, 2002). Theta rhythm appears when an animal is actively exploring the environment or attending to relevant stimuli. The phase with strong afferent input could allow encoding of new sequences without interference from retrieval, while a separate phase of dominant feedback connections could allow retrieval. Loss of this oscillatory modulation could underlie the learning impairments caused by fornix lesions, which damage the modulatory influences pacing theta rhythm.

Low ACh levels allow strong feedback transmission for consolidation. During quiet waking and slow-wave sleep, there is a dramatic decrease in ACh level, which is accompanied by the appearance of sharp wave events in the EEG (Buzsaki, 1989). During sharp waves, associations encoded in hippocampus are theorized to be reactivated, causing activity in hippocampus and neocortex that could mediate the formation of additional traces of the same memory (Buzsaki, 1989; Shen and McNaughton, 1996). The generation of sharp waves becomes more robust and drives neocortical activity more strongly when low levels of ACh release the suppression of excitatory feedback connections, allowing a shift from tonic theta rhythm oscillations to bursts of activity due to excitatory positive feedback.

### *Modulation and Network Oscillations*

Changes in modulatory levels play an important role in setting the oscillatory properties of the EEG and functional properties important for behavior. Microdialysis of neuromodulators during different stages of waking and sleep show dramatic changes in their levels associated with changes in the cortical EEG. High levels of ACh, NE, and 5-HT are present during waking, very low levels of ACh are present during slow-wave sleep, and very low levels of NE and 5-HT coupled with high levels of ACh are present during REM sleep. Computational models have illustrated potential mechanisms for these modulatory influences on cortical dynamics.

Neurmodulation alters the way in which thalamic circuitry regulates low-frequency synchronous oscillations that appear in the neocortex during sleep, including spindle activity and delta waves. Modeling demonstrates that the fundamental frequency of spindle activity could result from the interaction of intrinsic currents in thalamic reticular neurons, which fire bursts due to a low-threshold calcium current and hyperpolarize due to a calcium-activated potassium current. These cells provide rhythmic inhibitory input to thalamocortical relay cells, which then repolarize because of the hyperpolarization-activated nonspecific cation current and fire bursts because of the activation of the low-threshold calcium current (Terman, Bose, and Kopell, 1996; also see SYNAPTIC INTERACTIONS). Cholinergic innervation of thalamic circuits could prevent the generation of spindle and delta wave oscillations by depolarizing neurons through blockade of potassium currents, thereby inactivating the low-threshold calcium current underlying bursting (McCormick et al., 1993). Decreases in cholinergic depolarization would initially cause spindles when both thalamocortical neurons and thalamic reticular neurons are active, but as reticular neurons become less depolarized, their activity decreases, and thalamocortical neurons can oscillate synchronously at delta wave frequencies (Terman et al., 1996).

Neuromodulation plays an essential role in generating the hippocampal theta rhythm (see HIPPOCAMPAL RHYTHM GENERATION). Theta rhythm is primarily paced by rhythmic input from the medial septum, but it can also arise from intrinsic mechanisms in local circuits. In slice preparations of the hippocampus, cholinergic modulation has been demonstrated to induce theta rhythm oscillations (Tiesinga et al., 2001). Simulations demonstrate that the appearance of oscillations in the slice could result from slow depolarization of pyramidal cells, causing spiking activity, which is then synchronized by excitatory synaptic connections, with a time course dependent on the calcium-activated potassium current (Traub, Miles, and Buzsaki, 1992; Tiesinga et al., 2001). Computational modeling provides a means for understanding the role of neuromodulation in regulating a wide range of oscillatory dynamics.

## Discussion

Neuromodulation plays an important role in brain function, as demonstrated by the dramatic behavioral effects of drugs that influence the release of neuromodulators or activate receptors for neuromodulators. Neuromodulators do not just cause slight quantitative changes in network function but can qualitatively alter neural circuits to a completely different functional state. Computational modeling helps us understand the functional role of modulatory effects that may appear contradictory at a cellular level (for example, many modulators simultaneously depolarize neurons while suppressing synaptic transmission). Computational modeling will prove essential to understanding the functional role of diffuse modulatory effects with complex effects on multiple components of neural circuits.

# Neuromorphic VLSI Circuits and Systems

*Stephen P. DeWeerth and Andreas G. Andreou*

## Introduction

Biological systems excel at sensory perception, motor control, and sensorimotor coordination by sustaining high computational throughput with minimal energy consumption. Research in electronic neuromorphic engineering (Mead, 1989) has had two intertwined objectives. The first objective is the use of very large-scale integrated (VLSI) technology as a modeling tool aimed at capturing the behavior of living neurons, networks of neurons, and the complex mechanical-electrical-chemical information processing present in biological systems. The second objective—the subject of this article—is the development of engineered systems based on abstractions of sensory, motor, and brain function.

Neuromorphic VLSI systems employ distributed and parallel representations and computation akin to those found in their biological counterparts. The hardware implementations combine analog and digital circuits to realize a variety of computational primitives and architectures. Unlike traditional analog computing, neuromorphic representations are not linearized a priori, but rather exploit the inherent nonlinearities and dynamics that arise from the physics of the devices and circuits. The bio-inspired approach to the engineering of VLSI microsystems results in the embodiment of computation in complex, *physical* systems that exploit biological inspiration and lie beyond digital computing and that have a wide range of industrial applications (Vittoz, 2002).

The high levels of system integration offered in VLSI technology make it attractive for the implementation of highly complex artificial neuronal systems, even though the physics of the liquid-crystalline state of biological structures is different from the physics of the solid-state silicon technologies. Silicon complementary metal oxide semiconductor (CMOS) transistors are used in their subthreshold region of operation (Vittoz, 1985; Mead, 1989) because in this regime the primary constraint of highly integrated microsystems, power consumption, is all but eliminated. Circuits operating in their subthreshold region also exhibit a diverse set of computational primitives that are continuous, analog functions of time, space, voltage, current, and charge.

In this article, we discuss neuromorphic VLSI viewed at three hierarchical levels: the *device* level, the *circuit/network* level, and the *systems* level. Given the space limitations, we focus primarily on the circuit/network level. We describe a design style that employs mixed-signal (analog/digital), current-mode CMOS circuits that have minimal complexity (Andreou et al., 1991). Our presentation is not a comprehensive overview of the field, even within the bounds of circuits and networks. Rather, it provides a basic foundation in device physics and presents a set of specific circuits that implement certain essential functions that exemplify the breadth possible within this design paradigm.

## Devices

Neuromorphic VLSI circuits and systems are designed with two basic device building blocks available in CMOS technology—transistors and capacitors.

The transistors used in most neuromorphic implementations are devices operating in their *subthreshold* regime. In this regime, the current through the device is an *exact difference* of exponential functions of the drain and source voltages (Vittoz, 1985; Mead, 1989; Andreou et al., 1991). For an *n*MOS transistor, the current is given by

$$I_{\mathrm{DS}} = I_{n0} \cdot S \cdot e^{\kappa_n V_{\mathrm{GB}}}(e^{-V_{\mathrm{SB}}} - e^{-V_{\mathrm{DB}}}) \tag{1}$$

and for a *p*MOS transistor by

$$I_{\mathrm{SD}} = I_{p0} \cdot S \cdot e^{-\kappa_p V_{\mathrm{GB}}}(e^{V_{\mathrm{SB}}} - e^{V_{\mathrm{DB}}}) \tag{2}$$

The terminal voltages $V_{\mathrm{GB}}$, $V_{\mathrm{SB}}$, and $V_{\mathrm{DB}}$, in these equations are normalized to the thermal voltage $U_t = kT/q$, which is approximately equal to 25 mV at room temperature. The constants $I_{n0}$ and $I_{p0}$ depend on the mobility of the carriers (electrons and holes) and other physical properties of the silicon, and are typically in the range of $10^{-15}$ A. The geometry factor, $S = W/L$, where $W$ and $L$ are the width and length of the device, respectively. The constants $\kappa_n$ and $\kappa_p$ take values between 0.6 and 0.9. All of these parameters are fixed by the fabrication process, and thus cannot be modified by the designer or user with the exception of the variable $S$, which can be modified by designing the geometry of the device, and $U_1$, which is a function of operational temperature.

The MOS transistor has excellent circuit properties as a voltage-input, current-output device (a *transconductance amplifier*) with good fan-out capabilities (high transconductance, $g_m = \partial I_{\mathrm{DS}}/\partial V_{\mathrm{GS}}$) and good fan-in capability (extremely high input impedance). Additionally, the exponential voltage-current relationships depicted in Equations 1 and 2 facilitate a powerful synthesis (and analysis) procedure, the *translinear principle* that has also been generalized for MOS circuits (Andreou and Boahen, 1996; Gilbert, 1996).

In addition to CMOS transistors, neuromorphic VLSI systems also utilize capacitors extensively. These capacitors, which are implemented as parallel-plate devices between fabrication layers (e.g., vertically adjacent layers of polysilicon), endow the systems with temporal properties based on the capacitor's ability to store charge (energy). The capacitor equation

$$I = C\,\frac{dV}{dt} \quad V = \frac{1}{C}\int Idt \tag{3}$$

demonstrates that the capacitor integrates input current and represents this integrated value as a voltage.

## Circuits and Networks

The synthesis of computational structures begins at the circuit level and manifests itself as the emergence of *networks.* At the circuit level, conservation laws—the conservation of charge (Kirchoff's current law), $\Sigma_n I_n = 0$, and the conservation of energy (Kirchoff's voltage law), $\Sigma_n V_n = 0$—are used to realize simple constraint equations. These laws, combined with the integration of charge on capacitors, provide a means of implementing functions of both space and time.

The important concept of *negative feedback* is also exploited to implement the inverse of natural functions in the technology and to trade off the gain in the active elements for precision and speed in the circuits. The simplest circuit that exploits the high-gain transconductance of the MOS transistor, its exponential characteristics, and negative feedback is the *diode-connected* transistor. This circuit uses negative feedback to invert the exponential characteristic of the transistor to create a logarithmic current-in, voltage-out configuration.

Current replication and scaling are two additional operations that are used in the implementation of many systems. Current replication is implemented using the *current mirror,* which uses an input transistor to convert an input current logarithmically to a voltage. This voltage is distributed to one or more output transistors, each of which converts this voltage exponentially back into a current that is equal (modulo fabrication offsets and second-order effects) to the input current. Scaling can be accomplished in multiple ways, including transistor sizing and using an additional parameter to control the source of a transistor.

In the remainder of this circuits section, we focus on three computational functions in space and time that are essential to and exemplify the breadth of neuromorphic microsystems: (1) signal aggregation, (2) normalization, and (3) signal quantization. These particular choices certainly do not represent a complete itemization of all of the important neuromorphic circuits/networks, but rather are a representative list. For each of these functions, we discuss both spatial and temporal implementations, and in some cases show circuit schematics and describe the corresponding operation. Finally, we present the issue of the representation and communication of signals among subsystems, which is essential in the implementation of large-scale systems. Throughout this section, we discuss systems that utilize these circuits, networks, and representations as fundamental elements in their implementation.

### *Signal Aggregation*

Signal aggregation is the collection and processing of signals over space and/or time. Spatial aggregation can take many forms, including simple summation, computation of global attributes, and localized aggregation. Temporal aggregation is typically formulated as the integration of charge over time on a capacitor, and includes many temporal filtering functions. The representation of analog signals as currents facilitates the elegant implementation of both spatial and temporal aggregation as a direct result of Kirchoff's current law; thus, aggregation is implemented primarily using currents.

*Spatial aggregation.* One particularly useful circuit for local spatial aggregation is the resistive network (Mead, 1989, chap. 6). It performs linear addition of signals over a confined region of space, such as that observed throughout the nervous system. The basic resistive network depicted in Figure 1A employs voltages and currents. Its node equation is

$$I_j = G \cdot (V_i + V_k - 2V_j) \cong G\nabla^2 V \tag{4}$$

Note that the term $V_i + V_k - 2V_j$ is a first-order approximation to the Laplacian operator $\nabla^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2$, with the internode distance normalized to unity.

The resistive network in Figure 1*A*, although simple, is not amenable to compact VLSI integration because conductances *G* with a large linear range typically consume large amounts of both area and power. However, MOS transistors provide a natural way to exploit the underlying device physics to implement analog VLSI aggregation networks that can be applied to systems, including silicon retinas (Andreou et al., 1995; Vittoz, 2002).

The exponential functions of $V_{\text{SB}}$ and $V_{\text{DB}}$ in Equations 1 and 2 correspond to Boltzmann-distributed charges at the source and drain diffusing through the channel. For the *n*MOS transistor, the exponentials can be conveniently represented as dimensionless quantities of charge

$$Q_S \equiv e^{-V_{\text{SB}}} \quad Q_D \equiv e^{-V_{\text{DB}}} \tag{5}$$

and diffusivity

$$D \equiv S \cdot e^{V_{\text{GB}}} \tag{6}$$

so that the Equation 1 becomes

$$I_{DS} = I_{n0} \cdot D^{\kappa} \cdot (Q_S - Q_D) \tag{7}$$

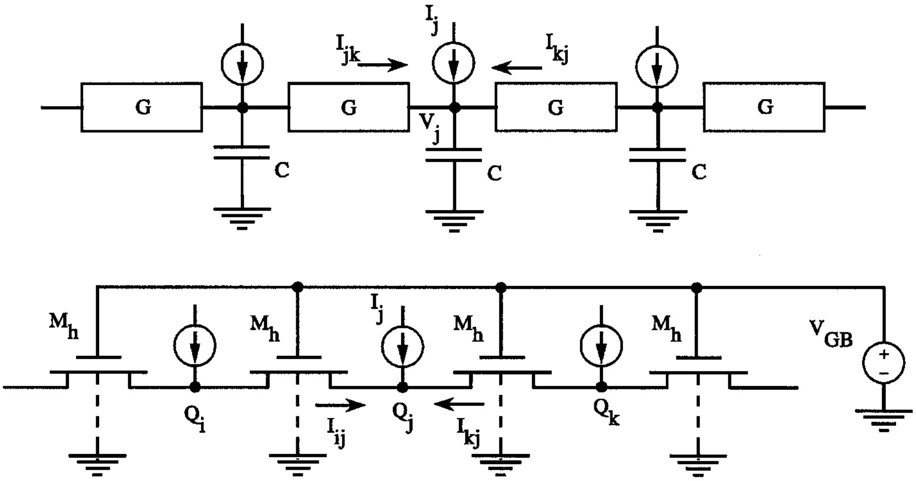

**Figure 1.** *A*, Signal aggregation in space using a linear resistive network. *B*, A network of nonlinear conductances implemented using MOS transistors.

The charge-based representation depicted in Equation 10 suggests that the MOS transistor in subthreshold is a highly linear device in the charge domain. This property can be used to implement the resistive network using MOS transistors, as shown in Figure 1*B*. This network employs charges (positive) and currents through *n*MOS transistors operating in their subthreshold regime. The node equation is

$$I_j = I_{n0} \cdot D \cdot (Q_i + Q_k - 2Q_j) \cong I_{n0} D \nabla^2 Q \qquad (8)$$

assuming that $S$ and $V_{\mathrm{GB}}$ are identical for all transistors in the network. The diffusivity $D$ can be controlled by setting the voltage at the gate of transistor $M_h$ at the desired value.

*Temporal integration.* The aggregation of signals in time is performed using temporal integration circuits that combine a device or circuit that generates a current with a capacitor that integrates that current. The diode capacitor integrator shown in Figure 2 is one of the simplest and most useful of these circuits. The input to this circuit can take the form of a continuously varying current or of a pulse stream generated by quantization circuits such as those described in a subsequent section.

Given subthreshold bias voltages, the input current, $I_1$, and output current, $I_2$, are related as follows:

$$Q \frac{dI_2}{dt} = I_2 \cdot \left(I_1 - \frac{I_2}{A}\right) \qquad (9)$$

where $Q = CU_t/\kappa$ and $A = e^{V_{\mathrm{E}}/U_t}$. This equation demonstrates that the time constant of the circuit can be modified separately from the input current by changing $V_{\mathrm{E}}$.

When a steady-state train of pulses of width $w$ and frequency $f = 1/T$ is applied to this integrator, the nonlinear behavior of the diode capacitor integrator has the following interesting properties: (1) the steady-state current is proportional to pulse-stream frequency $f$, (2) the steady-state current is proportional to pulse width $w$, (3) the steady-state current ripple (error) is independent of current level, and (4) the steady state is reached, for a given precision, after a constant number of pulses.

The diode capacitor integrator has been used in many systems, including silicon retinas that compute motion (Sarpeshkar et al., 1996) and the receiver sections for multichip neuromorphic systems (Boahen, 2000).

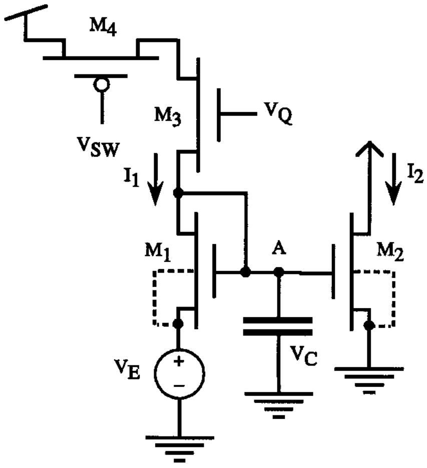

**Figure 2.** Diode capacitor integrator. The input and output signals are currents. The circuit is basically a current mirror with scaling, with the integrating capacitor at node A providing a time history of the input signals.

## Gain Control

Gain control is an important function in biological systems. Many biological signals, especially those in the sensory periphery (e.g., visual and auditory signals), exhibit orders of magnitude of dynamic range. In order to process these signals, it is necessary to modify the dynamic range while not diminishing the information embedded in the signal. This type of normalization occurs in both space and time. Spatial normalization is used to bring a spatially distributed set of signals into a common or prescribed range that is matched to further processing. Temporal normalization typically takes the form of adaptation in which a slow variable that sets the gain of a circuit or network is modified over time to adapt to changes in signal magnitude.

*Spatial normalization.* Spatial normalization can be divided into *global* and *local* operations. Global normalization modifies the gain of all of the signals in a network, serving to shift the global level of these signals. Local normalization serves to perform similar processing but controls gain based on the activity in a local region.

One example of global normalization is the linear, current-mode normalizing circuit (Gilbert, 1996). Using the translinear principle, it can be shown that the output currents of this circuit are related to its input currents through the following expression:

$$I_{On} = \frac{I_T}{\sum I_{In}} \cdot I_{In} \qquad (10)$$

Thus an output current $I_{On}$ in the array is proportional to the corresponding input current $I_{In}$ normalized to the sum of all input currents. The current $I_T$ is a scaling parameter that can be controlled externally. This circuit demonstrates the basic formulation of global normalization: the gain of individual elements is modified based on a global aggregate, in this case the sum (or average) of the input currents. Similar circuits have been created to compute a wide variety of nonlinear normalization functions using the same principle. Local normalization can also be implemented via the addition of resistive elements between the individual nodes, resulting in localized sums of input currents against which the input signals are compared.

*Temporal adaptation.* Normalization in time is accomplished through the combination of “fast” input variables normalized by “slow” adaptation variables. As in the case of spatial normalization, the basic premise of temporal adaptation is the averaging of the input signal—in this case, averaged over time using the slow variable—and the scaling of the input based on this average.

One of the simplest and most widely used adaptive circuits that implements temporal gain control is the adaptive photoreceptor (Delbruck and Mead, 1996). This circuit provides an analog output that has low gain for static signals and high gain for transient signals that vary about an operating point. The circuit’s adaptive function allows the output to represent a large dynamic range of absolute intensities while retaining sensitivity to small inputs. The adaptive photoreceptor has been used extensively in vision chips, including those that compute motion (Sarpeskar et al., 1996) and visual attention (Morris and DeWeerth, 1999).

## Signal Quantization

Signal quantization is seen throughout the nervous systems of animals. Information is transmitted using action potentials, which are temporally quantized forms of the analog membrane potentials from which they are derived. Spatial quantization is also widespread, taking forms such as the *place codings* found in motor maps in areas including colliculus and primary motor cortex. Such quantization is essential to system operation because multidimensional signals must be represented by sets of individual neurons, each of which encodes one piece of a quantized signal.

*Spatial quantization.* One example of spatial quantization is the current-mode winner-take-all circuit (Lazzaro et al., 1989; Andreou et al., 1991), a variation of which is shown in Figure 3. In this circuit, pairs of MOS transistors ($M_{1n}$ and $M_{2n}$) configured as *current conveyers* compete for current supplied to a common line. Each current conveyor sees a voltage $V_T$ at its common node. Consequently, for conveyor $n$, if $I_n < I_0 S e^{\kappa V_T}$, $M_{1n}$ enters its linear region ($V_{\mathrm{DS}} < 4$), turning $M_{2n}$ off at that element. This condition occurs in all but one of the conveyors. At the element with the largest input, negative feedback in transistor $M_{2n}$ adjusts $V_T$ so that $I_n = I_0 S e^{\kappa V_T}$. Thus, the conveyor with the largest input sets the voltage on the common node and conveys the common current $I_T$ to its output. The result is a network that, for normal operation, selects the largest input by generating a non-zero output at only that element. Variants of the basic winner-take-all circuit have been used extensively in systems such as attention-based imagers (Morris and DeWeerth, 1999) and large classifier arrays (Pouliquen et al., 1997).

*Temporal quantization.* Temporal quantization is exemplified by the creation of neural "spikes" (action potentials) as a function of a continuous input current (Mead, 1989, chap. 12). For example, integrate-and-fire neurons convert continuous-value representations of signals into a discrete-value representation. Spiking neuron circuits are used widely in interface circuits to communicate information among different subsystems and is an essential component of the address event representation discussed in the next section. They have also been used extensively as the primary output devices in the pulse-modulated control of motor systems.

### *Representation and Communication*

To construct systems from the circuits and networks described previously, we must have a paradigm for representing and communicating signals over long distances (including between VLSI chips) with potentially significant fan-in and fan-out. The massive connectivity of the brain is impossible to implement directly using VLSI because of wiring limitations within and between microchips. We can, however, exploit the temporally sparse nature of spike codes and the high bandwidth of VLSI systems in order to overcome this connectivity problem by time-multiplexing signals from many connections onto a single high-speed data bus. The resulting *address-event representation* (AER) (Lazzaro et al., 1993) has emerged as a general paradigm for communicating large amounts of data in distributed spatiotemporal architectures. The core paradigm represents individual local activity that is encoded by neural spikes as *events.* Each of these events represents the origin/destination and timing information of a single spike, and is communicated on high-speed data buses throughout the network.

Because AER was originally formulated to emulate the optic nerve and the auditory nerve (Lazzaro et al., 1993), it implements a one-to-one connection topology. To implement more complex neural circuits, convergent and divergent connections are required. For example, architectures have been developed for emulating short and long connections along the spinal cord (DeWeerth et al., 1997), and for memory-based projective field mappings that enable the projection of an address event to multiple receiver locations (Boahen, 2000).

## Discussion

Neuromorphic engineering represents a design paradigm that combines biological inspiration with microsystems technology to facilitate the design and implementation of systems that address a wide variety of tasks that are presently beyond the abilities of today's computer systems but appear accessible and even trivial to the nervous systems of the simplest animals. The field is based on the premise that it is the nonlinearities and dynamics, the circuit architectures, and the basic computational paradigms present in these biological systems—most of which are foreign to traditional engineered systems—that make them successful. The ultimate goal of this field is to abstract these organizational principles by implementing them in real, physical systems in order to create artificial systems that exploit the power of biological computation.

In this article we have discussed neuromorphic electronic systems at three levels of organization: devices, circuits/networks, and systems, with an emphasis on the intermediate level. At the device level, we presented the basic devices—transistors and capacitors—that form the foundation for the other levels. At the circuit/network level, we described a set of essential circuits and networks that are employed as building blocks for a wide variety of systems. A full appreciation of the value of these circuits can be attained only by studying their use in larger systems. For more detailed coverage of this rapidly developing field, readers are referred for such excellent journals as *IEEE Transactions on Circuits and Systems, IEEE Transactions on Neural Networks, IEEE Journal of Solid-State Circuits, Analog Integrated Circuits and Signal Processing, Neural*

# NEURON Simulation Environment

*Michael L. Hines and N. Ted Carnevale*

## Introduction

NEURON is designed to be a convenient and efficient environment for simulating models of biological and artificial neurons, individually and in networks. Great care has been exercised at every point in its development to achieve computational efficiency and robustness while helping users maintain conceptual clarity, i.e., the knowledge that what has been instantiated in the computer is an accurate implementation of one's conceptual model. NEURON's application domain extends beyond continuous system simulations of models of individual neurons with complex anatomical and biophysical properties, and includes discrete-event and hybrid simulations that combine biological and artificial neuronal models. Here we review features of NEURON that are of special interest to prospective users.

## Who Uses NEURON, and Why?

Presently, more than 300 papers have reported research performed with NEURON (see http://www.neuron.yale.edu/neuron/bib/usednrn.html). Among the research topics are descriptions of models of individual neurons and networks of neurons with properties such as complex branching morphology, multiple channel types, inhomogeneous channel distribution, ionic diffusion and buffering, active transport, second messengers, and use-dependent synaptic plasticity. At the cellular level, NEURON has been used to investigate pre- and postsynaptic mechanisms involved in synaptic transmission, the roles of dendritic architecture and active membrane properties in synaptic integration, spike initiation and propagation in dendrites and axons, the effects of developmental changes of anatomy and biophysics, the functional genomics of ion channels, and extracellular stimulation and recording, among other topics. Network models implemented with NEURON have been used to address issues such as the origin of cortical and thalamic oscillations, the role of gap junctions in neuronal synchrony, information encoding in biological networks, visual orientation selectivity, mechanisms of epilepsy, and the actions of anticonvulsant drugs.

NEURON is also being used in neuroscience education at the undergraduate and graduate level at numerous universities across the United States and around the world. Many of these courses are completely homegrown, but one lab manual with exercises has already appeared in print (Moore and Stuart, 2000), and we are involved in a collaboration to develop another set of laboratory exercises for publication. NEURON is particularly well suited to educational applications, since special expertise in numerical methods or programming is not required for its productive use. Furthermore, NEURON runs under MacOS, MSWindows, and UNIX/Linux, and can execute research-quality simulations with reasonable run times on entry-level hardware.

## How Does NEURON Work?

Historically, NEURON's primary domain of application was in simulating empirically based models of biological neurons with extended geometry and biophysical mechanisms that are spatially nonuniform and kinetically complex. In the past decade its functionality was enhanced to include extracellular fields, linear circuits to emulate the effects of nonideal instrumentation, models of artificial (integrate-and-fire) neurons, and networks that can involve any combination of artificial and biological neuron models. The following sections outline how these capabilities have been implemented so as to achieve computational efficiency while maintaining conceptual clarity, i.e., the knowledge that what has been instantiated in the computer model is an accurate representation of the user's conceptual model.

### *Representing Biological Neurons*

Information processing in the nervous system involves the spread and interaction of electrical and chemical signals within and between neurons and glia. These signals are continuous functions of time and space and are described by the diffusion equation and the closely related cable equation (Rall, 1977; Crank, 1979). To simulate the operation of biological neurons, NEURON uses the tactic of discretizing time and space, approximating these partial differential equations by a set of algebraic difference equations that can be solved numerically (numerical integration) (Hines and Carnevale, 1997).

Discretization is often couched in terms of compartmentalization, but it is perhaps better to regard it as an approximation of the original continuous system by another system that is discontinuous in time and space. Simulating a discretized model results in computation of the values of spatiotemporally continuous variables over a set of discrete points in space ("nodes") for a finite number of instants in time. If NEURON's second-order-correct integration method is used, these values are a piecewise linear approximation to the continuous system, so that second-order-accurate estimates of continuous variables at intermediate locations can be found by linear interpolation (Hines and Carnevale, 2001).

In one form or another, spatial discretization lies at the core of all simulators used to model biological neurons, e.g., GENESIS SIMULATION SYSTEM (q.v.). Unlike other simulators, however, NEURON does not force users to deal with compartments. Instead, NEURON's basic building block is the section, an unbranched, continuous cable whose anatomical and biophysical properties can vary continuously along its length. The branched architecture of a cell is reconstructed by connecting sections together, each section having its own anatomical dimensions, biophysical properties, and discretization parameter `nseg`, which specifies the number of nodes at which solutions are computed. This strategy makes it easier to manage anatomically detailed models, since each section in the model is a direct counterpart to a branch of the original cell (Figure 1). Furthermore, neuroscientists naturally tend to think in terms of axonal or dendritic branches rather than compartments.

But even in topologically simple cases, there is still the problem of how to treat variables that are continuous functions of space. Thinking in terms of compartments leads to representations that require users to keep track of which compartments correspond to which anatomical locations. If we change the size or number of compartments, e.g., in order to see whether spatial discretization is adequate for numerical accuracy, we must also abandon the old mapping between compartments and locations in favor of a completely new one.

This is the motivation for another strategy that helps NEURON users maintain conceptual clarity: *range* and *range variables*. Range variables are continuous functions of position along a branch of a cell, e.g., diameter, membrane potential, or ion channel density. NEURON deals with range variables in terms of arc length (normalized distance) along the centroid of each section. This normalized distance, which is called range, is a continuous parameter that varies from 0 at one end to 1 at the other. In NEURON's programming language `hoc`, the membrane potential at a point 700 $\mu$m down the length of a 1,000-$\mu$m-long axon would be called `axon.v(0.7)`, regardless of the value of the axon's discretization parameter `nseg`. Range and range variables allow NEURON itself to take care of the correspondence between nodes and anatomical location. This avoids the tendency of compartmental approaches to confound representation of the physical properties of neurons, which are biologically relevant, with implementational details such as compartment size, which are mere artifacts of having to use a digital computer to emulate the behavior of a distributed physical system that is continuous in time and space.

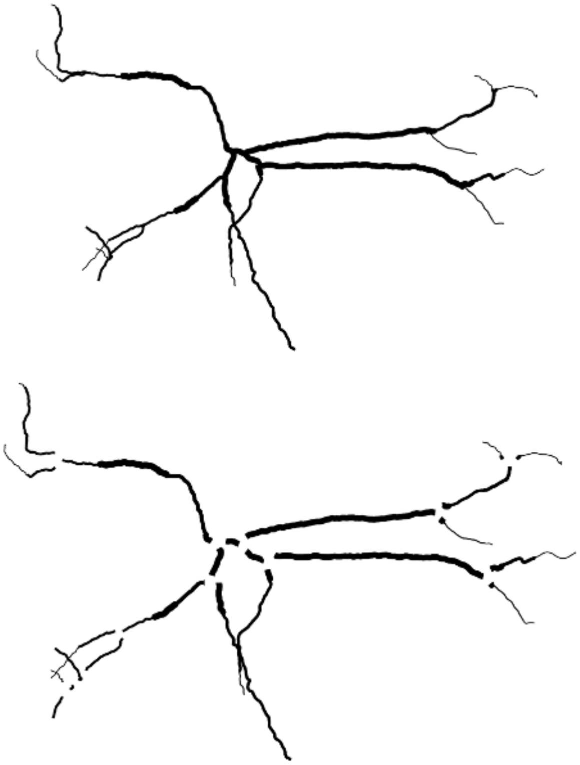

**Figure 1.** *Top*, Morphometric reconstruction of a hippocampal interneuron (data from A. I. Gulyás). *Bottom*, An "exploded" view, in which individual, unbranched neurites have been separated from each other at branch points.

### *Representing Artificial Neurons*

In NEURON, the basic difference between biological and artificial neuron models is that the former may have arbitrarily complex anatomical and biophysical complexity, while the latter have no spatial extent and employ highly simplified kinetics. Indeed, the three built-in classes of artificial spiking neurons are so simple that they are simulated using a discrete-event method, which executes hundreds of times faster than numerical integration methods. If an event occurs at time $t_1$, all state variables are computed from the state values and time $t_0$ of the previous event. Since computations are performed only when an event occurs, total computation time is proportional to the number of events delivered and independent of the number of cells, number of connections, or problem time. Thus, handling 100,000 spikes in 1 hour for 100 cells requires the same time as handling 100,000 spikes in 1 s for one cell. This takes advantage of NEURON's event delivery system, which was originally implemented to facilitate efficient network simulations of biological neurons (see following section).

Three different classes of integrate-and-fire models are built into NEURON. The simplest is IntFire1, a leaky integrator that treats input events as weighted delta functions. When an IntFire1 cell receives an input event of weight $w$, its "membrane potential" state $m$ jumps instantaneously by an amount equal to $w$ and thereafter resumes its decay toward 0 with time constant $\tau_m$.

A step closer to the behavior of a biological neuron is the IntFire2 mechanism, which differs in that $m$ integrates a net synaptic current $i$. An input to an IntFire2 cell makes the synaptic current jump by an amount equal to the synaptic weight, after which $i$ continues to decay toward a steady level $i_b$ with its own time constant $\tau_s$, where $\tau_s > \tau_m$. Thus a single input event produces a gradual change in $m$ with a delayed peak, and cell firing does not obliterate all traces of prior synaptic activation. The firing rate is $\sim i/\tau_m$ if $i \gg 1$ and $\tau_s \gg \tau_m$.

Although IntFire2 can emulate a wide range of relationships between input pattern and firing rate, all inputs produce responses with the same kinetics, regardless of whether they are excitatory or inhibitory. The fact that synaptic excitation in biological neurons is generally faster than inhibition inspired the design of IntFire4. IntFire4 integrates two synaptic current components that have different dynamics, depending on whether the input event is excitatory or inhibitory (Figure 2). Excitatory inputs add instantaneously to an excitatory synaptic current $e$, which otherwise decays toward 0 with a single time constant $\tau_e$; this is analogous to IntFire2 with $i_b = 0$. However, the inhibitory synaptic current $i_2$ is described by the reaction scheme

$$i_1 \xrightarrow{1/\tau_{i1}} i_2 \xrightarrow{1/\tau_{i2}} \text{bath} \tag{1}$$

where an inhibitory input (weight $w < 0$) adds instantaneously to $i_1$, so that $i_2$ follows a biexponential course (a slow rise followed by an even slower decay).

These are not the only kinds of artificial neurons that can be simulated using discrete events. The only prerequisite for discrete event simulations is that all state variables of a model cell can be computed analytically from a new set of initial conditions. Users who have special needs can add other kinds of artificial neuron classes to NEURON with the NMODL language (discussed later).

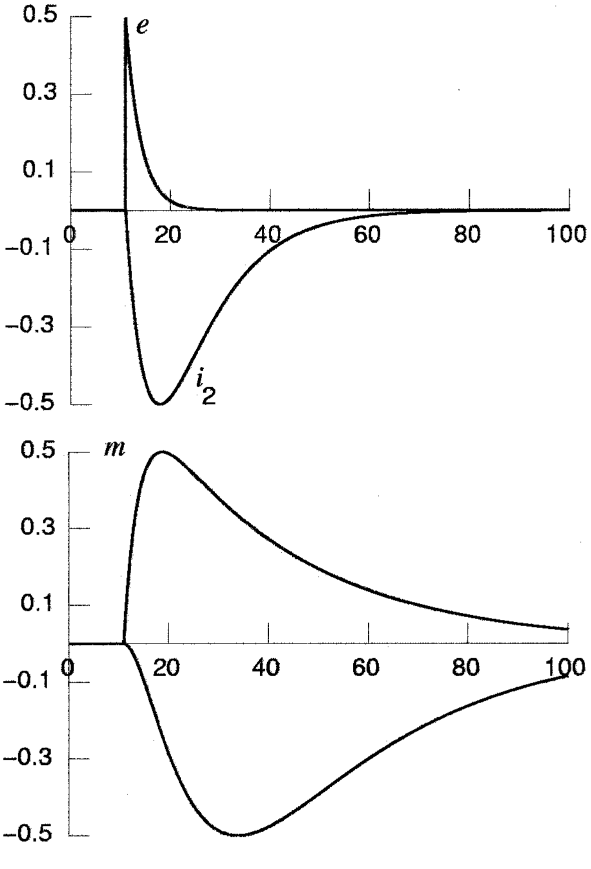

**Figure 2.** *Top*, Current generated by a single input event to an IntFire4 cell with weight 0.5 ($e$) or $-0.5$ ($i_2$). *Bottom*, The corresponding response of $m$. Parameters are $\tau_e = 3$, $\tau_{i1} = 5$, $\tau_{i2} = 10$, and $\tau_m = 30$ ms.

## *Representing Networks*

NEURON can handle networks that involve gap junctions or graded transmitter release, but this discussion is restricted to spiking networks. NEURON's NetCon class and event delivery system are used to manage synaptic communication between any combination of artificial and biological model neurons in a network. The event delivery system can also serve other purposes, such parameter changes on the fly, and it is a key part of the implementation of the built-in integrate-and-fire models, but these topics are beyond the scope of this article.

NEURON's strategy for dealing with synaptic connections emerged from techniques initially developed by Destexhe, Mainen, and Sejnowski (1994) and Lytton (1996). This strategy is based on a very simple conceptual model of synaptic transmission: arrival of a spike at the presynaptic terminal causes transmitter release, which in turn perturbs some mechanism in the postsynaptic cell (e.g., a membrane conductance or second messenger) that is described by a differential equation or kinetic scheme. All that matters is whether or not a spike has occurred in the presynaptic cell; mechanistic details in the presynaptic and postsynaptic cells do not affect transmitter release. This conceptual model separates the specification of the connections between cells from the specification of the postsynaptic mechanisms that the connections activate.

A presynaptic spike triggers an event that, after a delay to account for conduction along the axon, transmitter release, and diffusion time, is delivered to the postsynaptic mechanism, where it causes a change in some variable (e.g., a conductance). Event delivery is computationally efficient because of how synaptic divergence ("fan out") and convergence ("fan in") are handled. Synaptic divergence from model biological neurons is efficient because threshold detection is performed on a per source basis rather than a per connection basis. That is, if a neuron projects to multiple targets, the presynaptic variable is checked only once per time step, and when it crosses threshold an event is generated for each of the targets. Fan-out from artificial neurons is also very efficient, since their discrete event mechanisms do not have to be checked at each time step. However, the greatest computational savings are offered by synaptic convergence onto model biological neurons. Suppose a neuron receives multiple synaptic inputs that are close to each other and of the same type, i.e., each synapse has the same kind of postsynaptic mechanism. Then the total effect of all these synapses can be represented by a single kinetic scheme or set of equations driven by multiple input streams, each of which has its own weight.

The implementation of the event delivery service in NEURON takes into account the fact that the delay between initiation and delivery of events is different for different streams. Consequently, the order in which events are generated by a set of sources is rarely the order in which they are received by a set of targets. Furthermore, the delay may be 0 or $10^9$ or anything in between.

As noted earlier, NEURON separates specification of the connections between cells from specification of the postsynaptic mechanisms that the connections activate. This separation means that NEURON models are compatible with other event delivery systems, such as the parallel discrete event delivery system used by NeoSim (Goddard et al., 2001).

## *Integration Methods*

Users can choose among several different integration methods, but the "best" method for any given problem depends on many factors and may require empirical testing. Every choice involves trade-offs between accuracy, on the one hand, and stability and/or run time, on the other. For more extensive treatments of this topic, see Hines and Carnevale (1995, 1997, 2001).

Two methods use fixed time steps: backward Euler, and a Crank-Nicholson variant. NEURON's default integrator is backward Euler, which is first-order accurate in time, inherently stable, and generally produces good qualitative results even with large time steps. Used with extremely large $\Delta t$, it will find the steady-state solution of a linear ("passive") model in one step, and quickly converge to a steady state for nonlinear models. The Crank-Nicholson (CN) variant employs a staggered time step in order to provide second-order accuracy without having to iterate nonlinear equations. The computational cost of a single time step is practically the same as for backward Euler, but much shorter run times are possible with CN because it can use a larger $\Delta t$ for a given degree of accuracy. However, CN cannot be used with models that involve purely algebraic relations between states, and it can produce spurious oscillations if $\Delta t$ is too large or if the model includes a fast voltage clamp.

Models that work with CN are generally also amenable to CVODE (Cohen and Hindmarsh, 1984), the variable order, variable time step method offered by NEURON. For a given run time, CVODE often yields greater accuracy than CN. CVODE is usually the best choice for network models that involve artificial neurons. NEURON also offers a local variable order, variable time step method in which each cell has its own time step. This can be advantageous for network models in which most cells are silent most of the time.

## Development Environment

Constructing and managing models and controlling simulations can be accomplished with an object-oriented interpreter, a set of GUI tools, or a combination of both. Most common tasks can be performed with the GUI tools, which are especially convenient for exploratory simulations during model development. Where the GUI is inadequate, users can resort to the interpreter, which is based on `hoc` (Kernighan and Pike, 1984). The interpreter is also appropriate for noninteractive simulations, such as production runs that generate large amounts of data for later analysis. Even so, several of the GUI tools are quite powerful in their own right, offering functionality that would require significant effort for users to recreate in `hoc`. This is particularly true of the optimization and electrotonic analysis tools. Thus, the most flexible and productive use of NEURON is to combine the GUI and `hoc` programming, taking advantage of the strengths of both.

Because of the ever-growing number and diversity of ligand- and voltage-gated ionic currents, pumps, buffers, etc., NEURON has a special facility for expanding its library of biophysical mechanisms (Hines and Carnevale, 2000). A user can write a text file that contains a description of the mechanism in NMODL, a programming language whose syntax for expressing nonlinear algebraic equations, differential equations, and kinetic reaction schemes closely resembles familiar notation. This file is then converted into C by a translator that automatically generates code for handling details such as mass balance for each ionic species. The translator output, which includes code that is suitable for each of NEURON's integration methods, is then compiled for computational efficiency. This achieves tremendous conceptual leverage and savings of effort because the high-level mechanism specification in NMODL is much easier to understand and far more compact than the equivalent C code, and the user is not bothered with low-level programming issues like how to interface the code with other mechanisms and with NEURON itself.

NEURON runs under MacOS, MSWindows, and UNIX/Linux, with a similar X11-based look and feel on all platforms. Furthermore, the same `hoc` and NMODL code works under all these operating systems without modification. This facilitates collaborations in a heterogeneous computing environment.

## Distribution, Documentation, and Support

NEURON is available free of charge from http://www.neuron.yale.edu/, along with extensive documentation and tutorials. The UNIX/Linux distribution includes full source code; the MSWin and MacOS distributions employ an identical computational engine and come with the `hoc` code that implements the GUI and the NMODL definitions of the built-in biophysical mechanisms and artificial neuron classes.

The web site also has a sign-up page for joining the NEURON Users' Group, a moderated mailing list for questions and answers, and pertinent announcements such as program updates and courses on NEURON. For the past several years we have presented "executive summary" and intensive hands-on courses at sites in the United States and Europe, and we plan to continue this in the future. NEURON is actively supported by a development team that responds to bug reports and questions about program usage. Indeed, much of the program's current functionality has been stimulated by requests and suggestions from users, and we are grateful to them for their continued interest and encouragement.

## Discussion

The level of detail included in NEURON models can extend from a single compartment with linear membrane, to intricate extended architectures with membrane and cytoplasm that have complex biophysical properties. There are also several classes of artificial spiking neurons. Networks can involve biological neurons, artificial neurons, or both. Models can be simulated with fixed time step or with variable order, variable time step methods. With the variable time step integrator, the built-in artificial neurons are simulated as discrete event models, executing orders of magnitude faster than models of biological neurons do. Users can add new kinds of biophysical mechanisms and artificial neuron classes to NEURON's built-in library. NEURON runs on a wide variety of platforms, is actively supported, and is under continuous development, with revisions and updates that address the evolving needs of users. Because of these features, NEURON is employed in research on topics that range from the biophysical basis of neuronal function at the subcellular level to the operation of large-scale networks involved in consciousness, perception, learning, and memory. It is also increasingly being adopted for neuroscience education.

# Neuropsychological Impairments

*Martha J. Farah*

## Why Model Neuropsychological Impairments?

Neuropsychological impairments are an important source of evidence about the organization of cognition in the normal brain. For example, the finding that amnesic patients retain the ability to learn certain kinds of implicit information led to the idea of multiple memory systems and the distinction between explicit and implicit learning, both key insights in modern memory research (Squire, 1987). However, the inferences that link a neuropsychological impairment to a particular theory in cognitive neuroscience are not as direct as one might first assume. A patient's behavior following brain damage is not necessarily determined by a simple subtraction of one or more components of the mind or brain, with those that remain functioning normally. The brain is a distributed and highly interactive system, such that local damage to one part can unleash new modes of functioning in the remaining parts of the system. Thus, the link between neuropsychological impairments and models of the normal system must take into account not only the subtraction of one of more components of that system, but also changes in the functioning of other components that had previously been influenced by the missing components.

Neural network models of cognition and the brain provide a framework for reasoning about the effects of local lesions in distributed, interactive systems (Farah, 1994). Computer simulations of such models allow us to test hypotheses concerning the normal cognitive system using data from neurological patients, by simulating the candidate systems. The simulations of normal systems can be "lesioned," for example by removing their neuron-like units, or connections between units, and the behavior of the lesioned system can be compared with the behavior of patients.

In many cases a model's behavior after lesioning is somewhat counterintuitive. Indeed, it is often very different from what one would expect by reasoning in terms of simple deletion of parts from a normal system, with minimal interactions among the parts. For this reason, the use of neural networks when interpreting neuropsychological impairments can lead to very different interpretations regarding the nature of the normal system.

## Examples of Neural Network Models in Neuropsychology

The remainder of this article will back up these statements with some specific examples of well-known neuropsychological impairments whose interpretations vis-à-vis the normal brain have been changed dramatically by neural network modeling. In each example the neural networks are highly simplified models of real brain tissue, in the tradition of parallel distributed processing (PDP; Rumelhart and McClelland, 1986).

PDP systems consist of a large number of highly interconnected neuron-like units. These units are connected to one another by weighted connections that determine how much activation from one unit flows to another. Each part of the network functions locally and in parallel with the other parts; hence the first P in PDP. Representations consist of the pattern of activation distributed over a population of units, and long-term memory knowledge is encoded in the pattern of connection strengths distributed among a population of units; hence the D. There are many types of PDP networks with different computational properties. Among the features that determine network type are the activation rule, connectivity, and the learning rule.

PDP models differ from real neural networks, including the human brain, in numerous ways. Even the biggest PDP networks are tiny compared with the brain. PDP models have just one kind of unit, compared with a variety of types of neurons, and just one kind of activation (which can act excitatorily or inhibitorily) rather than a multitude of different neurotransmitters, and so on. Of course, all models are simplifications of reality and possess both theory-relevant and theory-irrelevant features. Among the theory-relevant features of PDP models are the use of distributed representations, the large number of inputs to and outputs from each unit, the modifiable connections between units, the existence of both inhibitory and excitatory connections, summation rules, bounded activations, and thresholds. PDP models allow us to find out what aspects of behavior, normal and pathological, can be explained by this set of theory-relevant attributes. The three examples that follow demonstrate the explanatory work that can be done in neuropsychology with such models.

### *Interpreting Error Types: The Case of Deep Dyslexia*

Neuropsychologists have long assumed that the nature of the damaged component could be inferred from the kind of errors made. In a syndrome known as deep dyslexia, patients make two kinds of errors. They make semantic errors, that is, errors that bear a semantic similarity to the correct word, such as reading *cat* as *dog*. They also make visual errors, that is, errors that bear a visual similarity to the correct word, such as reading *cat* as *cot*. The most straightforward interpretation would seem to be that deep dyslexics have at least two lesions, with one affecting the visual system and another affecting semantic knowledge. However, a consideration of the effects of single lesions in a neural network with attractor states suggests that a single lesion is sufficient to account for these patients' errors. Furthermore, it suggests that mixtures of error types will be the rule rather than the exception when the system that has been damaged normally functions to tranform the stimulus representation from one form that has one set of similarity relations (e.g., visual, in which *cot* and *cat* are similar) to another form with different similarity relations (e.g., semantic, in which *cot* and *bed* are similar).

Hinton and Shallice (1991) trained the recurrent network shown in Figure 1 to produce semantic representations of a set of words, given their printed orthography as input. The grapheme-to-"sememe" (their term for elements of semantic representation) mapping is carried out with the aid of hidden units, and the sememes are interconnected among themselves and connected to a final layer of semantic representation that connects, recurrently, back to the sememes. This pattern of connectivity in the semantic layers creates attractor states for the network. The input to the semantic layers need not be perfectly on target for the semantics of a particular word; as long as it is sufficiently similar to the correct semantics, which is an attractor state, it will be pulled in (i.e., as long as it falls in a region of activation space that slopes downward to the correct activation pattern, it will be transformed into that pattern). Damage to the network, from the removal of units or connections, distorts the shape of the activation space. Figure 2 illustrates the normal attractor structure of a region of activation space containing *cot*, *cat*, and *bed*, and the altered structure following damage to semantics. Whereas before damage, "cat" fell into the *cat* basin of attraction, after damage the edges of the basins have shifted and "cat" falls into the *cot* basin of attraction. Thus, one need not hypothesize damage to visual representations to account for the visual errors in deep dyslexia.

Plaut and Shallice (1993) have demonstrated the generality of Hinton and Shallice's account by replicating their simulation results with a variety of different networks, with different patterns of connectivity and different training procedures. As long as there are attractors that serve to transform input patterns whose similarity relations are based on visual appearance into semantic representations whose similarity relations are based on meaning, the landscape of the activation space will be organized by both visual and semantic similarity, and distortions of that landscape due to network damage will result in both visual and semantic errors.

## *Determining a Processing Sequence: The Example of Neglect Dyslexia*

Patients with left visual neglect omit or misidentify letters on the left side of letter strings. When the letter string is a word, this pattern of performance is termed neglect dyslexia. Surprisingly, neglect dyslexics are more likely to report the initial letters of a word than of a nonword letter string, even when the initial letters of the word cannot simply be guessed on the basis of the end of the word. This seems to have a fairly specific, though surprising, implication for the order in which word recognition and spatial attention occur in the brain. If lexical status (word versus nonword) affects the allocation of attention, then it would seem that word recognition occurs before attention is allocated.

The concept of attractors is helpful here too, in understanding how an impairment in a prelexical attentional process could nevertheless show a lexicality effect. Mozer and Behrmann (1990) simulated neglect dyslexia by damaging the attentional mechanism in a computational model of printed word recognition so that attention was distributed asymmetrically over letter strings. In their model, attention *preceded* word recognition. In fact, it gated the flow of information out of early visual feature maps. Neglect therefore resulted in full information from the right side of a letter string, but only partial information from the left, being transmitted to word representations.

According to this model, the errors that occur with nonword letter strings result from partial visual information about the letter features on the left side of the string, which is not sufficient to identify precisely which letters are present. In contrast, the same partial information about the initial letters of a word, with good-quality information about the remaining letters of a word, will result in an activation pattern that is similar to the activation pattern for that word. Because known words are attractors, the network will settle into the pattern of the word, complete with initial letters. In this way, it is possible to explain why neglect dyslexics read words better than nonwords, without giving up the hypothesis that neglect is a disorder of visual perception that affects stimulus processing prior to the recognition stage.

It is worth noting that computational models make predictions that can be tested empirically. According to this model of neglect dyslexia, if the asymmetry of attention is too extreme, no information about the initial letters will get through to word representations, and the resulting activation state will not fall within the basin of attraction for the word. Behrmann et al. (1990) tested this prediction with a patient who had severe neglect. As predicted, he did not show better perception of the initial letters of words than nonwords. Furthermore, when his attention was drawn to the left, and the attentional asymmetry thereby made less extreme, he

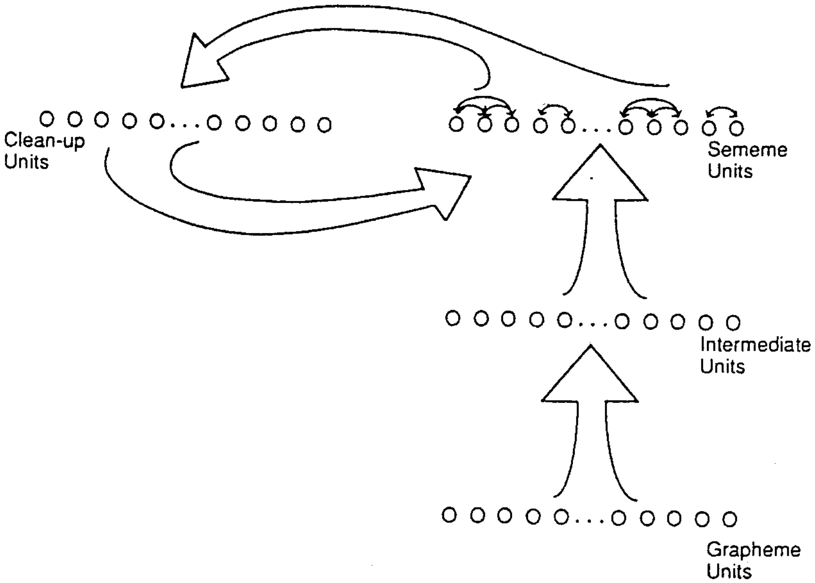

**Figure 1.** Hinton and Shallice's (1991) PDP model of reading, in which visual graphemic representations are associated with semantic representations. Single lesions in this model produce a mixture of visual and semantic errors.

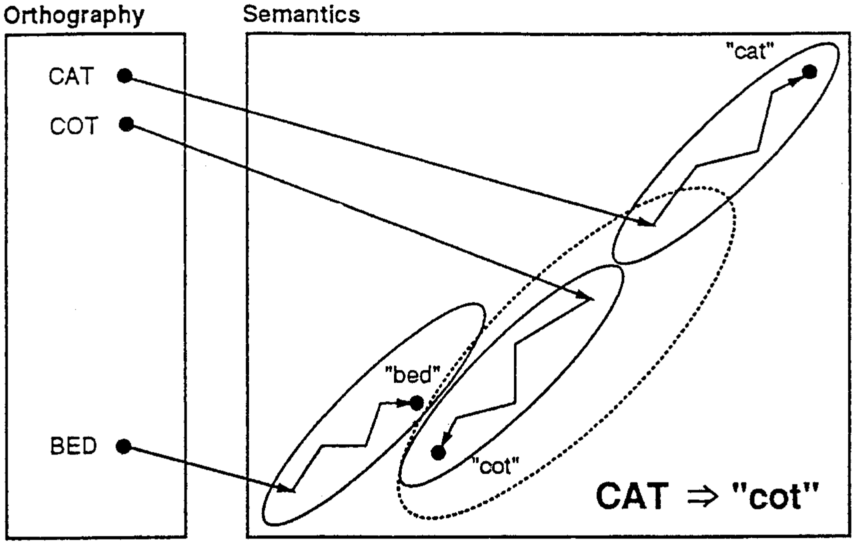

**Figure 2.** Part of the activation space of the Hinton and Shallice model as represented by Plaut and Shallice (1993), showing attractors for three words. After damage to semantic units, the basins of attraction shift from those shown in solid lines to those shown in dotted lines, resulting in visual errors.

showed the usual difference between word and nonword letter strings. Conversely, a patient who normally showed this difference between words and nonwords was stopped from doing so by attentional manipulations that increased his attentional asymmetry.

### *Dissociation Without Separate Systems: The Example of Covert Face Recognition*

Prosopagnosia is an impairment of face recognition that can occur relatively independently of impairments in object recognition. The behavior of some prosopagnosic patients (described below) seems to suggest that recognition and awareness depend on dissociable and distinct brain systems (Figure 3). My colleagues and I built a computer simulation that is able to account for covert recognition in a number of different tasks (Farah, O'Reilly, and Vecera, 1993; O'Reilly and Farah, 1999). The network is shown in Figure 4 and consists of face recognition units, semantic knowledge units, and name units (embodying knowledge of people's facial appearance, general information about them, and their names, respectively). Hidden units were interposed between these layers to assist the network in learning to associate faces and names by way of semantic information. No part of the network is dedicated to awareness.

The first finding to be simulated was that some prosopagnosics can learn to associate facial photographs with names faster when the pairings are true (e.g., Harrison Ford's face with Harrison Ford's name) than when they are false (e.g., Harrison Ford's face with Michael Douglas's name; De Haan, Young, and Newcombe, 1987). This result was initially taken to imply that these patients were recognizing the faces normally, and that the breakdown in processing lay downstream from vision, as shown in Figure 3. However, when some of the face units were eliminated from our model, thus simulating a lesion in the visual system, the network also relearned old face-name pairings faster than new ones. Why should this be? We can think of learning as a process of moving through weight space. After damage, the network is in a high-error region of weight space for both old face-name pairings and new ones, and therefore the network cannot overtly associate any faces with any names. However, that region of weight space is closer to a low-error region for the old pairings than for the new ones, because the residual weights (connecting intact units) have the correct values for the old pairings, and the learning process is therefore shorter.

A second finding, that previously familiar faces are perceived more quickly in the context of a same/different matching task, has also been interpreted as evidence for intact visual face processing (De Haan et al., 1987). However, after lesions to the face units in our model, the remaining face units settled into a stable state faster for previously familiar face patterns. This can be understood in terms of the distortion of the network's attractor structure after damage. The original structure was designed to take familiar face patterns as input and settle quickly to a stable state. After damage,

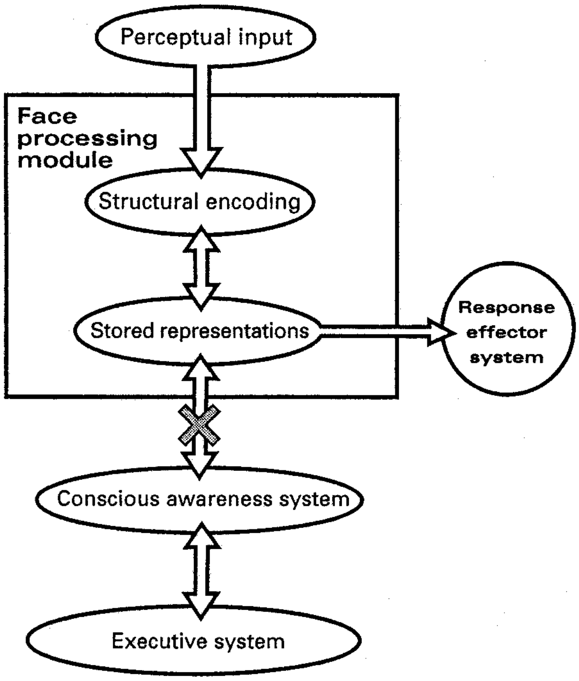

**Figure 3.** A model proposed by De Haan, Bauer, and Greve (1992) to account for covert face recognition in prosopagnosia. A separate mechanism for conscious awareness is hypothesized, distinct from the mechanisms of face recognition, and covert recognition is explained by a lesion at location ×, disconnecting the two parts of the model.

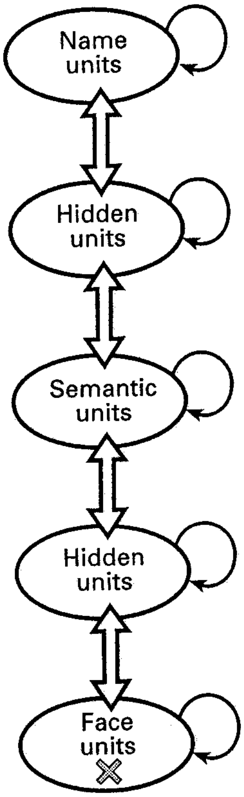

**Figure 4.** A model proposed by Farah, O'Reilly, and Vecera (1993) to account for covert face recognition in prosopagnosia. The dissociation between overt and covert face recognition emerges when the face recognition system is damaged.

these patterns will still find themselves on downward-sloping parts of the energy landscape more often than novel patterns, even if the energy minima into which they roll have changed.

In yet another task, one that requires classifying a printed name as belonging to an actor or a politician, both normal subjects and prosopagnosics are influenced by a face from the opposite occupation category shown in the background, again implying that the face is recognized despite prosopagnosia (De Haan et al., 1987). To simulate this finding, we removed face units until the network's overt performance at classifying faces according to occupation was as poor as the patient's. At this level of damage, wrong-category faces slowed performance in the name classification task. This can be understood in terms of the distributed nature of representation in neural networks, which allows for partial representation of information when some but not all units representing a face have been eliminated. The partial information generally raises the activation of the appropriate downstream occupation units, thus biasing their responses to the printed names, but is not generally able to raise their activations above threshold to allow an explicit response to faces.

# Neurosimulation: Tools and Resources

*Randall D. Hayes, John H. Byrne, and Douglas A. Baxter*

## Introduction

In all scientific fields, including neuroscience, experimental hypotheses are based on models. Often, these models only qualitatively describe the relationships among the elements of a system, such as the molecules that make up a second-messenger cascade or the neurons that make up a network. Mathematical models provide a more rigorous framework within which investigators can organize large amounts of empirical data, test whether current data can account for the behavior of the system, identify critical features that warrant additional experimental investigation, and discover dynamic properties that are not intuitively obvious.

This article reviews neurosimulators, that is, programs designed to reduce the time and effort required to build models of neurons and neural networks. We include programs for modeling networks of spiking neurons as well as programs for kinetic modeling of intracellular signaling cascades and regulatory genetic networks. A comprehensive description of all neurosimulators is beyond the scope of this chapter (see also GENESIS Simulation System, NEURON Simulation Environment, and NSL Neural Simulation Language). Instead, we provide a general picture of the capabilities of several neurosimulators, highlighting some of the best features of the various programs, and refer the reader to more specific information (Bower and Bolouri, 2002; Skrzypek, 1994; Koch and Segev, 1998; De Schutter, 2001). We do not list connectionist simulators in this chapter (see Murre, 1995).

This article also describes ongoing efforts to increase compatibility among the various programs, which serve two purposes. First, compatibility allows models built with one neurosimulator to be independently evaluated and extended by investigators using different programs, thereby reducing duplication of effort. Second, compatibility allows for models describing different levels of complexity (i.e., molecular, cellular, network) to be related to one another.

## General Considerations

General considerations in selecting a simulator program include the hardware capabilities and programming expertise of the lab. Complicated models require fast workstations or networks of desktop computers running portions of the model in parallel (Hammarlund and Ekeberg, 1998). For investigators with limited resources, it may be necessary to simplify a model so that a less powerful computer can run a simulation in a reasonable amount of time. Building a model takes more time than simulating one, so using a simple program to build a simple model can speed up the process even further.

### *Hardware Issues*

Platform requirements for various neurosimulators are listed in Tables 1 to 3. We include a few programs that can run on older, less expensive computers (e.g., *Nodus, MetaModel*). Programs written in Java or Perl (e.g., *CATACOMB, NSL, SNNAP, StochSim*) can run on multiple platforms without modification. Another solution to the problem of computer compatibility is to separate the simulator code, which is less platform sensitive, from the user interface code (e.g., *NEST/SYNOD, CONICAL*). For some simulators, the user can log onto a centralized network server through a web browser (e.g., *iCell, CMISS, Vcell*).

### *Level of Tech Support*

An important issue is how much support the developers provide to the first-time user (see Tables 1 to 3). Most programs distribute manuals, which vary greatly in how complete and up-to-date they are. Buyers of commercial packages may receive personal instruction (e.g., *In Silico Cell, ModelMaker, SABER*). Another option is to attend short courses at workshops or national meetings (e.g., *GENESIS, Mcell, NEURON, SNNAP*). Many developers maintain e-mail lists or bulletin boards, where users can ask questions. Especially useful to the beginner are templates of possible conductances, cells, or circuits. These allow the user to start modeling immediately by modifying an existing file rather than beginning from scratch.

### *Numerical Methods*

*Discrete events.* Connectionist simulators generally use continuous scalar variables to represent firing rate and synaptic weight (see Single-Cell Models). The integrate-and-fire units used by discrete event neurosimulators (e.g., *NeuroImitator, SpikeNET*) are more realistic. They have a membrane potential that sums the cell's inputs over time; a spiking threshold, which determines when the cell will fire; and often a refractory hyperpolarization after the spike. When threshold potential is exceeded, a time-stamped spike event (not an action potential waveform) is generated, and the membrane potential is reset. After some fixed delay representing axonal conduction, the spike event triggers synaptic conductances in postsynaptic target cells. Note that most of the programs that calculate a waveform for each action potential by one of the methods described below also default to fixed axonal delays, rather than propagating the action potential (see Axonal Modeling), to save computing time.

By adjusting the free parameters that control threshold and refractory period, the user can reproduce the firing rates and spike frequency adaptation of a wide range of biological neurons. Because individual conductances contributing to the membrane potential are ignored, discrete event simulators are suitable for studying network behaviors but not the intracellular mechanisms that produce them (see Integrate-and-Fire Neurons and Networks).

*Ordinary differential equations (ODE).* Most simulators represent individual neurons as systems of ODEs, which represent the average change in a dependent variable (usually membrane voltage or concentration) in a well-mixed spatial compartment over one time step of the simulation (Cobelli and Foster, 1998). The dependent variable is recalculated at regular intervals, with the intervals chosen to capture the fastest dynamics of the model (often tens of microseconds). In addition, some simulators (e.g., *BIOQ, NEURON, Surf-Hippo, XNBC*) provide variable time-step algorithms, which recalculate the dependent variable more often when it is changing rapidly and less often when it is changing slowly. These algorithms can shorten the computer time required to simulate large networks.

*Monte Carlo methods.* Other simulators explicitly follow each molecule in the simulation over time (e.g., *BIOQ, CKS, MCELL, StochSim*). At each time step, random numbers are chosen for the

Packages that simulate the electrical activity of cells are in the top half of the table. Packages that simulate chemical reactions are in the bottom half of the table. Methods abbreviated under Spiking Neurons and Chemical Kinetics: ODE = Ordinary differential equations, MC = Monte Carlo, InF = Integrate-and-fire. Abbreviations under Control, Platform, and Support are identical to those in Table 1.

direction and distance each individual molecule diffuses (Stiles and Bartol, 2001). If two or more molecules happen to collide, another random number is compared to a rate constant to determine whether a chemical reaction occurs. These methods are more accurate than ODEs when well-mixed assumptions are violated, such as when a simulation involves small numbers of molecules per spatial compartment. Monte Carlo methods can also be faster than ODEs when complicated three-dimensional structure requires a large number of compartments to meet the well-mixed assumptions of ODEs. The major disadvantage of Monte Carlo methods is the amount of memory required to track every element of a simulation.

## Progression of Complexity

In our experience, users generally prefer to start out using a program through a graphical user interface (GUI), in which the number of choices is restricted and approachable. As they become more proficient, users often dispense with the GUI and begin to interact with the program at the more flexible command-line level or through scripts (lists of commands saved in text files). This allows them to automate common tasks that would otherwise have to be performed step by step. In keeping with this progression, we divide the simulators into three levels of complexity: demonstration pro-

grams, modeling packages specialized for neurobiology, and generalized modeling tools. Each level has its advantages, as described in more detail below.

### *Demonstration Programs*

Demonstration programs are particularly appropriate for students, for researchers who are approaching modeling for the first time, and for quick explorations of experimental hypotheses. They are limited to a few general examples (see Table 1), although those examples can be rich, with parameters for temperature and other common experimental variables (Friesen and Friesen, 1994; Huguenard and McCormick, 1994). Several demonstration programs use virtual experimental rigs, including electronic components such as amplifiers and analog-to-digital converters, perfusion pumps for drugs, and oscilloscopes; this allows users to become comfortable with using the equipment before proceeding to simulated or real experiments (e.g., *cLabs, NerveWorks*). Some programs allow the preset simulations to be modified (e.g., *NeuroSim, VClamp/CClamp*). For example, *NeuroSim* allows the teacher to simplify simulations by hiding irrelevant parameters; this feature can also hide the values of parameters so that students have to deduce them experimentally. A drawback for experimenters is that these demonstration programs generally do not include automated tools to analyze their output or to save their output so that third-party software could analyze it (but see GENESIS SIMULATION SYSTEM and NEURON SIMULATION ENVIRONMENT).

### *Packages Specialized for Simulating Spiking Neurons*

A number of specialized packages are available to simulate the electrical activity of neurons and neural circuits. These packages are more flexible than the demonstration programs discussed above. The trade-off for this richness is an increase in complexity of the software used to build models. For example, *SNNAP* uses a hierarchical parameter tree composed of 26 parameter file types, including conductances (voltage-gated or ligand-gated), modulators, and intracellular pools of ions (Ziv, Baxter, and Byrne, 1994). Each parameter file consists of a single equation, chosen from a list of possibilities. Simulations are controlled through the GUI, although the text of the parameter files can be accessed through an ASCII text editor, a faster and more flexible option for experienced users.

*Individual cells.* Packages vary in the detail with which individual neurons are modeled. The simplest ODE package (*SONN*) models each cell as a single-compartment isopotential sphere, using a fixed set of four differential equations, sufficient to describe the minimal soma capable of bursting behavior. Most other neurosimulators divide a cell into many compartments, each with its own parameters. For example, a dendritic compartment might be electrically passive, whereas an axonal compartment would contain the $Na^+$ and $K^+$ conductances necessary to support spiking. Certain packages can automate creation of multicompartmental three-dimensional structures to some extent by importing anatomical files, either with built-in tools (e.g., *Maxsim, NeMoSys, Surf-Hippo*) or through the use of third-party applications (e.g., *GENESIS, NEURON*).

Packages vary in their analytical capabilities, as well. Most packages can run batches of simulations to systematically vary parameters, saving the results in files to be examined by other tools. Some can also optimize model parameters to fit experimental data (e.g., *GENESIS, NEURON, NeuronC, Surf-Hippo*). *Surf-Hippo* runs scripts that detect spikes or other events in the output of a cell. *XNBC* has menu-based tools for time series analysis.

*Small circuits.* Most packages, whether based on discrete events, ODEs, or Monte Carlo, come with built-in synaptic conductances that can be used to connect neurons into a circuit. The most common "alpha function" synapse has a maximal conductance, a reversal potential, and an exponential time course (see SYNAPTIC INTERACTIONS). In many packages, synaptic conductances can be modulated by intracellular second messengers to produce various profiles of synaptic plasticity (see the "Chemical Kinetics" column in Table 2). Built-in electrical synapses that simulate gap junctions are relatively uncommon (however, see *NeuronC, SNNAP*). *NeuronC* is unusual in that it models the synapse as a series of filters that determine how presynaptic voltage affects postsynaptic voltage to study information transfer across the synapse. In addition to graphs of membrane voltage over time in individual neurons, several packages allow the user to visualize the entire network as a grid of icons in order to examine spatial patterns of activity, such as waves that sweep through the network (e.g., *BioSim, Neuro-Imitator, XNBC*).

*Large networks.* Some packages allow for abstraction beyond integrate-and-fire neurons to reduce the number of network elements. For example, a group of neurons whose interactions form an oscillator or a filter function can be represented as a single unit (e.g., *NSL, SpikeNET*). In some packages (e.g., *SEE, SpikeNET, XNBC*), the user can define populations of identical neurons that project topographically to other populations, which reduces effort in wiring up large networks.

Detailed compartmental modeling of many thousands of neurons requires a package optimized for that purpose, usually running on parallel processors, because of the large number of calculations involved (e.g., *GENESIS, NEST/SYNOD, NEURON, Parallel Neurosys, SEE*). A program for simulation at even larger scales is *BioPSE*, which models electrical field potentials in biological tissue.

### *Specialized Biochemical Packages*

Many of the packages described above can simulate intracellular processes such as diffusion of ions and second-messenger cascades (see the top half of Table 2). Other packages, designed to study metabolic or genetic networks (see the bottom half of Table 2), have additional analytical capabilities that may benefit neural researchers. For example, some (e.g., *Gepasi, Jarnac/Indigo*) are capable of metabolic control analysis. This sensitivity analysis measures the relative control exerted by each enzyme on the system's fluxes and metabolite concentrations (Wildermuth, 2000). A convenient feature of *BIOQ* allows the user to check closed-form reactions, such as the opening and closing of an ion channel, for violations of the law of conservation of energy.

Most of these biochemical modeling packages can compile a kinetic description of a reaction into differential equations. Some packages incorporate a GUI that allows the user to build a "biochemical network" using icons of molecules and reaction schemes. The equations are then generated by the program and presented for the user's inspection.

### *General Modeling Tools*

The powerful programs described in this section can potentially be used to simulate any dynamical system (Table 3). However, they are less likely to have built-in model templates relevant to a particular neurobiological system. For example, *SABER* and *SPICE* are electrical circuit simulators that have been used to simulate biological neurons (Bove et al., 1994). *MatLab* is commonly used by connectionist modelers but has no official support for compartmental neuron simulations. With the advent of model databases, this may be less of a restriction on the usefulness of general modeling tools, because individual users of a particular package may have models to share (see Databases for Neuroscience).

One advantage of these general tools is their analytical power. For instance, *MatLab* has many functions for analyzing time series data such as spike trains. *XXP-AUT* and *CONTENT* are specialized for analyzing dynamical phenomena, such as nullclines, singularity points, bifurcations, and steady states (Ermentrout, 2002; see Phase-Plane Analysis of Neural Nets). Currently, perhaps the best compromise is to analyze models built in more specialized packages with these general tools. Ready examples of this type of synergy between programs are *GENESIS* and the biochemical simulator *Jarnac/Indigo*, which can export their output in *MatLab* format.

## Increasing Cooperation among Modelers

Some of the most exciting developments in neurosimulation technology will allow modelers to compare and modify models, verify one another's simulations, and extend models with their own tools. We examine two of these enabling technologies below (see also Databases for Neuroscience).

### *Brokering Agents*

One way to coordinate the actions of multiple simulation packages is through software called a brokering agent. For example, a model can be built by using a biophysically detailed neuron model from one simulator, an integrate-and-fire network from a different simulator, and a number of individualized Java or C++ components for visualization or analysis. Each component runs independently, receiving input from the broker and sending back its output.

A brokering agent can also support the distribution of a single model onto multiple processors without the need to modify the model description. This last point is crucial, as some parallel simulation tools (such as *GENESIS*) require the model itself to be a parallel program, which is not a trivial modification. This "transparent parallelism" is possible if the model is specified as a number of entities that communicate using discrete events, a strategy that is employed to some extent by many neurosimulators.

Three brokering agents are currently under development for use in neural simulation. *Bio/Spice* (http://www.darpa.mil/ipto/research/biocomp/index.html) and the *Systems Biology Workbench* (http://www.cds.caltech.edu/erato/the_project.html) interface between biochemical simulators. *NEOSIM* (http://www.neosim.org/) is designed to work at the level of neuronal networks. An existing example of the possibilities for a brokering agent, *ISYS*, provides interfaces between genomic databases (Siepel et al., 2001).

### *Open-Source Development*

Another approach to collaborative modeling is taken by five cooperating laboratories in producing *NEST/SYNOD* (Diesmann and Gewaltig, in press). In an open-source project, registered users can modify the software. A centralized server automatically updates the software and distributes the latest version to users. The large number of reviewers ensures that bugs will be found and repaired quickly. This is unlike most neurosimulators, for which a single laboratory controls the development of the software, albeit with suggestions from users, and individual users are responsible for their own updates. It remains to be seen whether the open-source approach will spread to other neurosimulator packages.

## Discussion

Understanding the brain requires an enormous amount of data about its individual components and their interactions. Because of the sheer volume of data and the nonlinear nature of the interactions, it becomes impossible to understand the system without computational modeling.

No single monolithic simulation package can fulfill all of the diverse requirements of individual neuroscientists doing quantitative simulations. At the same time, developers are challenged to encourage collaboration by increasing interoperability among the many neurosimulators and by building tools to manage the ever-increasing number of models and simulations. As these challenges are met, models that span levels of neural organization, ranging from genetic regulatory networks to large-scale brain structures, will become possible.

# NMDA Receptors: Synaptic, Cellular, and Network Models

*Michel Baudry, Jean-Marie Bouteiller, Jim-Shih Liaw, and Theodore W. Berger*

## Introduction

NMDA receptors are subtypes of receptors for the excitatory neurotransmitter, glutamate, that are selectively activated by the agonist *N*-methyl-D-aspartate (NMDA), a glutamate analog. They are involved in diverse physiological as well as pathological processes such as visual perception, motor pattern generation, learning and memory, and epilepsy- or stroke-induced neuronal damage (Dingledine et al., 1999).

NMDA receptors have three unique properties that distinguish them from other ligand-gated channels (channels activated by molecules that bind to them). First, they mediate a relatively "slow" excitatory postsynaptic potential (EPSP). Second, their activation requires not only the binding of an agonist (a molecule that mimics the effect of the endogenous neurotransmitter), but also the depolarization of the postsynaptic membrane to remove the voltage-dependent blockade of the channel by $Mg^{2+}$ ions. Thus, NMDA receptors act as coincidence-detectors of presynaptic and postsynaptic activity. Third, NMDA receptors are 10 times more permeable to $Ca^{2+}$ ions than to $Na^{+}$ or $K^{+}$. They often are colocalized with other receptor channels that conduct "fast" EPSPs (e.g., the $\alpha$-amino-3-hydroxy-5-methyl-4-isoxazole proprionic acid, or AMPA, receptor). The interactions between the slow NMDA-mediated and fast AMPA-mediated currents provide the basis for a range of interesting dynamic properties, which contribute to a diversity of neuronal processes.

NMDA receptors have attracted a lot of interest in neuroscience because of their role in learning and memory. Their properties of coincidence detectors make them an ideal molecular device for producing Hebbian synapses, that is, synapses whose strength is modified depending on the correlation of presynaptic and postsynaptic activity. Furthermore, the influx of $Ca^{2+}$ ions through the NMDA receptor channel triggers cascades of molecular processes that lead to various forms of synaptic plasticity, including short-term potentiation, long-term potentiation, and long-term depression (Malenka and Nicoll, 1999), as well as to pathological processes, including neuronal death. As a result, they have been a subject of intense investigation by both experimentalists interested in understanding the features of the protein that result in its functional properties and theorists/modelers attempting to incorporate NMDA receptors into models of synapses, neurons, or circuitries. We will briefly review here data related to the biological characteristics of NMDA receptors and to models that have been used to describe their function in isolated membrane patches, in neurons, and in complex circuits.

## Biological Characteristics of NMDA Receptors

Cloning techniques have provided evidence for the existence of a multiplicity of NMDA receptor subunits conferring distinct properties for the NMDA receptors (see Cull-Candy, Brickley, and Farrant, 2001, for a review). The NR1 subunits is required in combination with at least one member of the NR2 family (four distinct genes), and NR1/NR2 complexes may also co-assemble with a member of the NR3 family (two genes). NMDA receptor activation requires not only the presence of glutamate, but also the presence of another amino acid, glycine, which therefore has been called a co-agonist and binds to NR1 subunits, while glutamate binds to NR2 subunits. A number of other binding sites for $Mg^{++}$, $Zn^{++}$, and polyamines are also present on the subunits, and their occupation modifies receptor properties. It is generally assumed that the NMDA receptors are multimeric entities (i.e., composed of several subunits), possibly pentameric proteins by analogy with the acetylcholine nicotinic receptor. Moreover, as different combinations of receptor subunits produce receptors with different physiological and pharmacological properties, it is likely that several functional classes of NMDA receptors exist in adult neurons, and a major challenge remains to determine their cellular distributions and the mechanisms regulating subunit expression and receptor assembly and turnover.

A major avenue of research over the last five years has focused on the mechanisms underlying NMDA receptor targeting and anchoring in postsynaptic sites. Thus a very large complex of proteins, including receptor molecules, PSD-95, cytoskeletal proteins, and associated protein kinases has been shown to be localized in postsynaptic densities and to play critical roles in mediating multiple effects of NMDA receptor activation (Kennedy, 1998).

## Kinetic Models of NMDA Receptors

The behavior of a receptor can be described by the kinetic scheme of its transition between various discrete states representing the occupancy of the different binding sites and the functional states of the channel (a simple example is $A + R \leftrightarrow AR \leftrightarrow AR^*$, where A, R, AR, and AR* represent agonist, receptor, and receptor-agonist complex in closed state and open state, respectively; additional desensitized states of the receptors correspond to receptor occupied by agonists but with closed channels). Several kinetic models of the NMDA receptors have been developed to study various aspects of the nature of the receptor and the dynamics of its behavior.

### *Glycine Binding*

Glycine is a necessary co-agonist of the receptor, and various models of NMDA receptors have been developed to study the number of glycine binding sites and the interaction between glutamate and glycine on the receptors. Recordings in outside-out patches from cultured hippocampal neurons were used to measure the rate constants for agonist binding, open/close transitions, and desensitization of the NMDA receptor. The measured rate constants were used in models assuming one, two, or three agonist binding sites. For both glutamate and glycine binding, a two-site model provided a superior fit for the time course of NMDA channel activation. Desensitization was also studied in excised outside-out patches and was interpreted as an interaction between the glutamate and the glycine site such that glycine binding produced a decreased affinity of glutamate for its binding site (Lester, Tong, and Jahr, 1993). Note that binding experiments also suggest a strong positive allosteric effect between glutamate and glycine binding (Marvizon and Baudry, 1993).

### *Number of States of the NMDA Receptor*

Jahr and Stevens (1990) developed a model of NMDA receptor-channel kinetics to address the issue of the number of states of the receptor. They assumed that the NMDA receptor exists in three states: closed (C), open (O), and blocked (B). The kinetic behavior of the NMDA receptor-channel was characterized by four experimentally measured quantities: open time ($T_o$), interruption time ($T_i$), number of interruptions ($N$), and burst length ($T_b$). The predictions made by the model failed to match several key experimental data, and these shortcomings suggested an extension to include a second blocked state in addition to the $Mg^{2+}$ block. The four-state model could describe NMDA receptor behavior in all conditions except the low-amplitude, second-exponential component in $T_o$, which occurred in low $Mg^{2+}$ concentrations and positive voltage. A theory based on the four-state model postulates that the interruptions could be the result of a voltage-dependent conformational change, which could be facilitated by the binding of Mg ions to some sites on the NMDA receptor.

## NMDA Receptors in Models of Neurons

NMDA receptor models have been incorporated in several models of synapses/neurons developed to answer questions related to short-term as well as long-term synaptic plasticity and to mechanisms of synaptic integration. As was mentioned in the introduction, a major focus is on the role of the voltage-dependent $Mg^{2+}$ blockade, which gives rise to the property of coincidence detection and $Ca^{2+}$ influx through the NMDA receptor, in initiating the molecular events leading to changes in synaptic strength. Furthermore, the interplay between the slow NMDA-mediated and fast AMPA-mediated currents leads to important features in the timing of synaptic inputs required to induce long-term potentiation (LTP)

### *Short-Term Synaptic Plasticity*

Pongrácz et al. (1992) used a compartmental model to study short-term changes in excitability of a hippocampal pyramidal neuron. The pyramidal neuron was represented by five compartments for the apical and basal dendrites, one compartment for the soma, and a layer representing extracellular $K^+$ concentration. The model included intrinsic membrane conductances and excitatory (NMDA and AMPA) and inhibitory ($GABA_A$ and $GABA_B$) synaptic conductances distributed in the apical dendrite compartment. The voltage dependency of NMDA receptors (due to the $Mg^{2+}$ blockade of the channel) resulted in a weak conductance by single stimulation, but the conductance increased with increasing number and intensity of repeated stimulation. The model suggested that such cumulative activation of NMDA-mediated synaptic conductances contributed to the frequency-dependent EPSP potentiation, a form of short-term plasticity, of hippocampal neurons.

## Long-Term Synaptic Plasticity

Holmes and Levy (1990) developed a compartmental model of a granule cell from the dentate gyrus to study the role of $Ca^{2+}$ and the subsequent biochemical events involved in triggering LTP. In particular, they were interested in understanding the mechanisms amplifying the calcium signal and the relative timing of presynaptic and postsynaptic activation. An 11-compartment model was constructed to represent a spine and a small patch of the neighboring dendrite. Calcium dynamics, including $Ca^{2+}$ influx, buffering, pumping, and diffusion were computed over this domain. One glutamate binding site and the voltage-dependent $Mg^{2+}$ block were included in the NMDA receptor kinetics. The amplitude of the peak intracellular-free $Ca^{2+}$ concentration was regarded as the critical parameter for the induction of LTP at a particular synapse. When few synapses were activated, $Ca^{2+}$ influx was small, even with high input frequency. When a large number of synapses were activated simultaneously, a steep rise in $Ca^{2+}$ influx was seen with increasing frequency due to the voltage dependency of the NMDA-mediated conductance. However, total $Ca^{2+}$ influx never increased by more than fourfold, which is too small an amount to account for the selective induction of LTP. The threefold to fourfold increase could be amplified 20- to 30-fold by transient saturation of the fast $Ca^{2+}$ buffering system. When a weak input was paired with a strong one, the largest increase in peak $[Ca^{2+}]_i$ was seen in cases in which the weak stimulation preceded the strong input by 1–8 ms, because of the slow rate constant of NMDA receptor kinetics. De Schutter and Bower (1993) extended this model to evaluate the effect of $Ca^{2+}$ permeability of the NMDA receptor channel. Maximum amplification of $[Ca^{2+}]_i$ was obtained at permeability close to values reported in the literature and decreased significantly when permeability was reduced by more than 50%. Furthermore, simulations showed that $[Ca^{2+}]_i$ was up to 80% higher at distal spines than at proximal ones.

### *Synaptic Integration*

In addition to synaptic plasticity, NMDA receptors are also involved in the integration of spatiotemporal patterns of inputs by a neuron. Fox and Daw (1992) developed an electrical model of a neuron in area 17 of the visual cortex to study neuronal responses to visual stimuli. The model was composed of two compartments: a somatic component and a dendritic compartment with NMDA and AMPA receptors. The model showed that instead of switching on only at a higher level of contrast, the NMDA receptor-mediated conductance contributed to the response to visual stimuli in a graded fashion, all the way from near threshold to saturation. This property of the NMDA receptor could not be accounted for solely by its voltage dependency. In addition, the higher affinity (binding rate) of NMDA receptors for glutamate, in comparison to the non-NMDA receptor, was involved.

A compartmental model was developed to study the integrative behavior of a complex dendritic tree with particular focus on the role of NMDA receptors in the generation of neuronal responses (Mel, 1993). An anatomically characterized cortical pyramidal cell was represented by a model consisting of 903 electrically coupled compartments. A glutamatergic synapse was placed on the distal end of a spine containing both AMPA and NMDA receptors. The major finding from the simulation of the model was that when the NMDA receptors constituted a large portion of the synapse, the neuron responded preferentially to spatially clustered, rather than randomly distributed activated synapses. This was due to the voltage dependency of the NMDA receptors that were more effective when activated in group than individually. As a result of activity-dependent synaptic modifications, synapses on a dendritic tree were organized in such a way that stimuli that activated a similar set of synapses as those activated by patterns presented during the learning period had a higher probability of eliciting a neuronal response. Therefore, manipulating the spatial ordering of afferent activation of a dendritic tree provides a biological strategy for storing and classifying patterned information.

### *Metaplasticity*

Considerable attention has been devoted to understanding mechanisms that could account for changes in rate of learning, a phenomenon referred to as metaplasticity. Several models of neurons or of networks of neurons have introduced various parameters to incorporate metaplasticity. The most popular model is the so-called modification threshold or sliding rule introduced by Bienenstock, Cooper, and Munro (1982). In their model of synaptic plasticity, activity-dependent changes in NMDA receptors could account for such a rule.

## NMDA Receptors in Models of Neuronal Circuits

The role of NMDA receptors in neuronal networks has been studied in various systems. In this section, we briefly review their roles in generating evoked field potentials, oscillatory or epileptiform activity in neuronal networks, in working memory and learning of temporal sequences. In all these cases, the interactions between excitatory and inhibitory synapses shape the dynamics of the neural network.

### *NMDA Receptors and Evoked Field Potentials*

A recent compartment model of a hippocampal network comprising pyramidal neurons, inhibitory interneurons, and feedback and feed-forward inhibition explored the contribution of NMDA receptor-mediated synaptic currents to evoked field potentials (Wang et al., in press). As predicted from the kinetics of the receptors, the NMDA receptors contribute significantly to the late phase of the evoked potentials, and their influence becomes more important with repeated stimulation as in paired-pulse or burst of stimulation. This effect is illustrated in Figure 1, which clearly indicates that NMDA receptors contribute significantly to burst-evoked synaptic depolarization. Likewise, compartment model simulation indicated that the amplitude of NMDA receptor-mediated calcium signals is greatly increased with increased frequency of stimulation. Furthermore, several experimental and model studies have now shown that the presence of NMDA receptors at synapses could account for low-pass temporal frequency tuning in several sensory pathways (Krukowski and Miller, 2001).

### *Role of NMDA Receptors in Oscillators*

A network of interneurons conformed to experimentally identified cell types was constructed to simulate the spinal locomotor pattern generation in lamprey (Trävén et al., 1993). Excitatory synapses displayed both NMDA and AMPA receptors, while the inhibitory synaptic transmission was glycinergic and mediated by chloride ions. The NMDA receptor current was modeled as a product of channel conductance, the difference of the membrane potential and the equilibrium potential and a state variable, which accounted for the voltage-dependent $Mg^{2+}$ block of the channel. Oscillatory bursts could be evoked in a postsynaptic cell driven by NMDA receptor-mediated synaptic currents, but the presynaptic neuron had little effect on oscillation frequency. The presynaptic control of oscillation frequency increased when AMPA receptors were added. A continuous range of network burst rate could be produced by the NMDA and AMPA receptor-mediated conductances. The simulations suggested that spinal locomotor network could be modulated by controlling the balance between NMDA and AMPA receptor-mediated synaptic input. The NMDA receptor-containing synapses mainly served to stabilize the rhythmic motor output, whereas the AMPA receptor-containing synapses provided direct phasic control of the burst pattern.

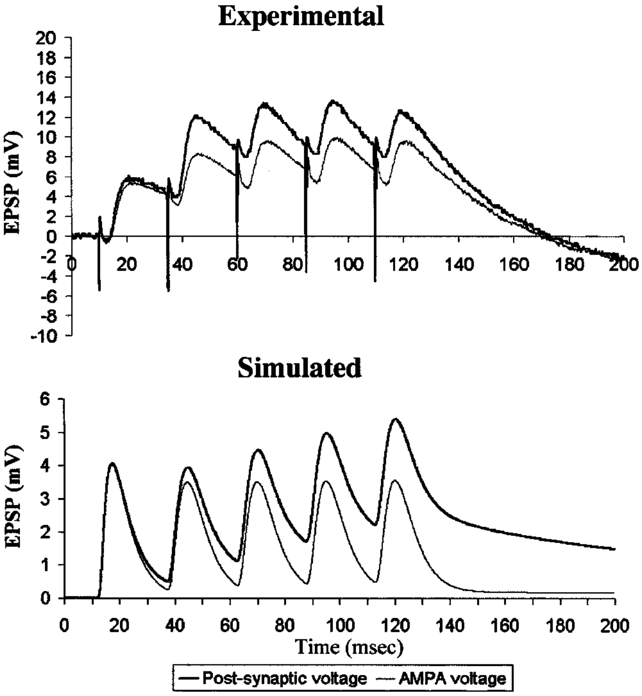

**Figure 1.** Contribution of NMDA receptors to postsynaptic depolarization elicited by a train of five pulses (40 Hz) in field CA1 (*Top*) and in a simulated computational model (*Bottom*). In both cases, the top trace represents total depolarization, and the bottom trace represents depolarization in the presence of the NMDA receptor blocker, APV.

### *NMDA Receptors and Epileptiform Activity*

Traub, Miles, and Jefferys (1993) developed a computer model of hippocampal CA3 region consisting of pyramidal neurons and inhibitory interneurons. Each pyramidal neuron was composed of 19 compartments with six voltage-dependent ionic conductances. Each pyramidal neuron was randomly connected to 20 other pyramidal neurons via excitatory (NMDA and AMPA) receptors and to 20 interneurons via inhibitory ($GABA_A$ and $GABA_B$) receptors. The computation of NMDA receptor-mediated current involved a scaling factor, a synaptic conductance term with a slow decay time constant, and a term representing the voltage-dependent $Mg^{2+}$ blockade. The simulation suggested the following conditions for the occurrence of population oscillations: (1) The strength of excitatory synapses falls within a limited range, (2) the after-hyperpolarization conductance is significantly reduced, (3) the inhibitory postsynaptic potentials are blocked, and (4) the apical dendrites of the pyramidal neurons are depolarized. The NMDA receptor conductance was not necessary for the population oscillation. The model generated synchronized population bursts that resemble experimental data obtained from hippocampal slices perfused with a $GABA_A$ receptor blocker and predicted that dendritic calcium spikes occurred during each secondary burst generated by the AMPA receptor current. However, with sufficiently high NMDA receptor conductance, synchronized bursts could occur in the absence of AMPA receptor current.

### *NMDA Receptors and Memory*

Experimental evidence has strongly implicated NMDA receptors in various forms of learning and memory. Although it is generally assumed that this is a consequence of the role of NMDA receptors in activity-dependent changes in synaptic transmission in various networks, the specific roles of NMDA receptors in memory has also been more formally evaluated in various simulations of network activity and dynamics. In particular, several groups have shown that the properties of NMDA receptors are well suited for learning of sequences of information. This is particular true for networks exhibiting both theta and gamma activities, allowing recall of stored sequence by presentation of the initial element of the sequence (Jensen and Lisman, 1996).

Another interesting role of NMDA receptors has been recently proposed to account for the persistent activity in prefrontal cortex, which is assumed to be the basis for working memory (Compte et al., 2000). In this case, stable and persistent activity could be observed when recurrent synaptic excitation was mediated principally by NMDA receptor-mediated currents.

## Discussion

This review of the various models of NMDA receptors at the synaptic, cellular, and network levels illustrates that the three unique properties of these receptors (i.e., slow conductance, voltage and transmitter dependency, and calcium permeability) provide the basis for their involvement in a large variety of fundamental dynamic properties of synaptic transmission, including not only short-term and long-term plasticity at individual synapses, but also complex network properties such as synaptic integration, motor pattern generation, and epileptiform activity.

The review also indicates the usefulness of this approach to investigate the contribution of different characteristics of the receptors at the functional level. In particular, the recent suggestion that metaplasticity could be accounted for by changes in NMDA receptor subunit composition and function needs to be emphasized. A number of issues still remain unresolved, in part because of the limited knowledge concerning the exact number of binding sites for the various effectors of the receptors, the mechanisms underlying desensitization, and the anatomical distribution of the different types of receptors. Interestingly, developmental switches in the subunit composition of NMDA receptors have been shown to dramatically alter network properties and information processing in these networks. Therefore, as the understanding of the characteristics and properties of NMDA receptors continue to be resolved in greater details, new models will need to be generated to capture these properties and to evaluate their contributions to the computational properties of individual neurons as well as to complex circuitries.

# NSL Neural Simulation Language

*Alfredo Weitzenfeld*

## Introduction

Neural simulation plays an essential role in understanding the brain. While many neural simulators exist today (see Neurosimulation: Tools and Resources for a listing of the most important ones), design considerations can be quite different. For example, systems supporting very detailed neural elements can simulate only a few neurons at a time (see NEURON Simulation Environment and GENESIS Simulation System), while systems supporting coarser elements can usually simulate larger neural populations. In this article, we describe the Neural Simulation Language (NSL) (Weitzenfeld, Arbib, and Alexander, 2002), an *object-oriented* system (Wegner, 1990) primarily designed to support simulation of large neural networks. The system addresses the needs of a wide range of users, from novice users requiring friendly user interfaces to advanced users requiring advanced programming and integration to other systems. Two versions of the system exist today, one in Java (Gosling et al., 2000) and the other in C++ (Stroustrup, 2000). Both of these can run on a wide range of computer platforms, making the system quite independent from the actual computing environment.

## Modularity in Neural Systems

A particular aspect that distinguishes NSL from comparable simulators is its special focus on *modularity*, a well-known software development strategy in dealing with large and complex systems. As neural models become large and complex, they become hard to manage. Moreover, modularization of biological neural networks is further motivated by taking into consideration the way we analyze the brain as a set of different brain regions, as seen by the example shown in Figure 1.

The general methodology for understanding a complex neural system involves two basic approaches. One is to focus on some particular brain region or module and carry out studies of that region in detail. The other is to step back and look at higher levels of organization in which the details of particular modules are hidden. Full understanding comes as we cycle back and forth between different levels of detail in analyzing different subsystems, sometimes simulating modules in isolation, at other times designing computer experiments that help us follow the dynamics of the interactions between the various modules.

## Modeling in NSL

There are two ways to describe a model in NSL: (1) by direct programming in NSLM, the NSL (compiled) modeling language, and (2) by using the Schematic Capture System (SCS), a visual programming interface to NSLM supporting the description of module assemblages. In general, NSL supports the two levels of modeling, *modules* and *neural networks*, as described next.

### *Modules*

Modules in NSL are hierarchical structures organized in a tree fashion having a root module, the *model*, and multiple levels of *module assemblages*. Modules may be implemented in different ways and independently from each other in a top-down and a bottom-up fashion, an important benefit from modular design. In particular, *neural* modules are implemented with neural networks, corresponding to leaves on a tree. In general, the external interface to a module is described by a set of unidirectional input and output *data ports*, representing module entry or exit points, where data are sent or received, usually in the form of numerical values with varying dimension, that is, a single scalar, a one-dimensional array of values (*vector*), a two-dimensional array (*matrix*), or higher ones. To communicate, modules require interconnections among ports belonging to different modules. The following is sample NSLM code describing module assemblages:

```
nslModel Model ()
{
  private StimulusModule stimulus ();
  private MainModule main ();
  private OutputModule output ();
  public void makeConn () {
    nslConnect (stimulus.sout, main.in);
    nslConnect (stimulus.sout, output.sin);
    nslConnect (main.out, output.oin);
  }
}
```

The description is analogous to a class specification in object-oriented programming. The attribute section describes a three-module assemblage consisting of a “stimulus,” “main,” and “output” modules, while the *makeConn* method specifies module interconnections using the *nslConnect* statement (see Weitzenfeld et al., 2002, for a more extensive description of all NSLM commands.) This sample NSLM code could be automatically generated from SCS as well. Figure 2 shows sample schematics for a module assemblage within a higher-level module.

### *Neural Networks*

Modules representing brain regions can be anatomically or physiologically divided to obtain *neural modules*, modules described by

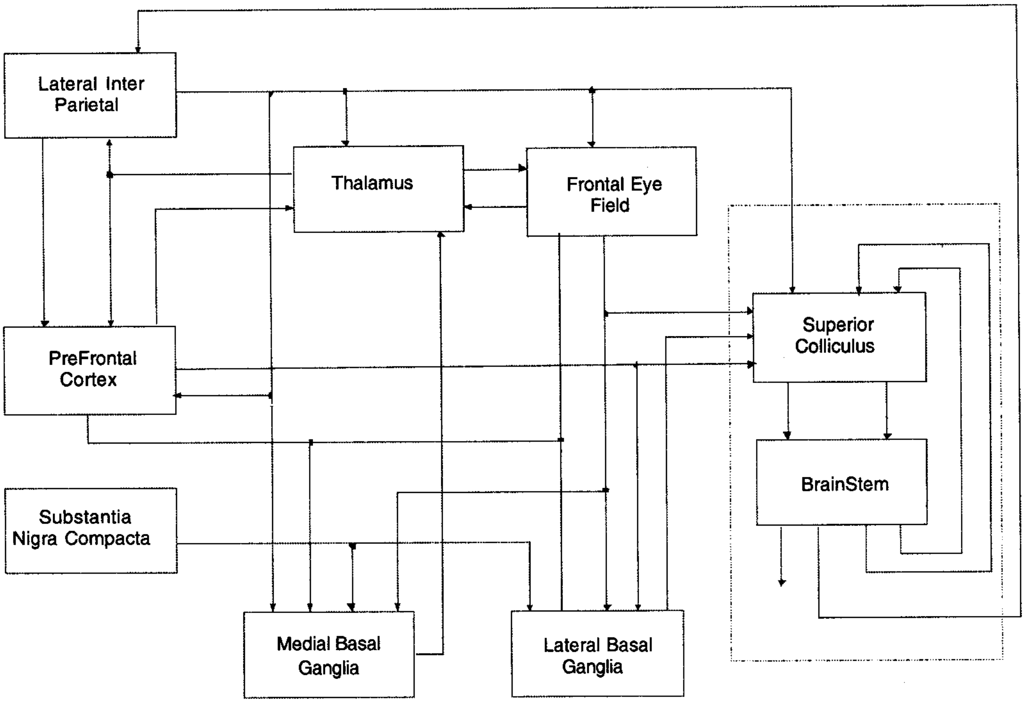

**Figure 1.** The smaller outlined diagram shows a basic model for control of eye movements consisting of a superior colliculus {XE “Superior Colliculus”} (sc) and brainstem {XE “Brainstem”} modules, each representing a single brain region, responsible for generation of saccades (see Collicular Visuomotor Transformations for Gaze Control). As an example of the benefits of modularization, the SC and Brainstem modules can be embedded into the much larger and far more complex model of interacting brain regions, such as the Crowley-Arbib model of Basal Ganglia (Crowley, Oztop, and Mármol, 2002).

neural arrays. To model a complete neural network, it is necessary to describe (1) the particular neuron model, that is, the desired neural level of detail, (2) the neurons making up the network, (3) the set of interconnections among neurons, and (4) network parameters, such as inputs and connection weights. Without disregarding the importance of other neural models, we focus here on the *leaky integrator* (Arbib, 1989) neuron model, a single-compartment neuron having one output and many inputs. The internal state of the neuron is described by a single scalar quantity, its membrane potential *mp*, which depends on the neuron's inputs and past history. The output is described by another single scalar quantity, its firing rate *mf*, and may serve as input to multiple neurons, including itself. As the input to a neuron varies, the membrane potential and firing rate vary as well.

In NSL, two numerical structures (**NslDouble0** data type) are required to represent such a neuron, one corresponding to the membrane potential and the other one to its firing rate:

```
private NslDouble0 mf ();
private NslDouble0 mp ();
```

In many cases, we may want the value of *mf* to be communicated to other modules. If such is the case, the declaration for *mf* should be modified from a private variable to a public output port (note the *Dout* keyword):

```
public NslDoutDouble0 mf();
```

The *membrane potential* for *mp* is described by a first-order differential equation with dependence on its previous history and input $S_m$:

$$\tau_m \frac{dmp(t)}{dt} = f(s_m, mp, t)$$

Variable $\tau_m$ represents the time constant, while the choice of $f$ defines the particular neural model utilized. The *leaky integrator* model is described by $f(s_m, mp, t) = -mp(t) + s_m(t)$, or

$$\tau_m \frac{dmp(t)}{dt} = -mp(t) + s_m(t)$$

In addition to the membrane potential and firing rate descriptions, we also need to specify the input to the neuron, $s_m$, internal to the module or obtained from another module. In the latter case, input $s_m$ would be specified as an input port (note the "Din" keyword):

```
public NslDinDouble0 sm();
```

where *sm* holds a weighted spatial summation of all input to the corresponding neuron.

While neural networks are continuous in their nature, their simulated state is approximated by discrete-time computations. For this reason, we must specify an integration or approximation method to generate as faithfully as possible the corresponding neural state. The dynamics for *mp* are described by the following statement:

```
mp = nslDiff (mp, tau, −mp+sm);
```

Function *nslDiff* defines a first-degree differential equation equal to "$-mp+sm$" as described by the leaky integrator model. Different methods can be used to approximate the differential equation, such as Euler and Runge-Kutta. The choice of method may affect both the computation time and its precision. The specific method to use is chosen during simulation and not as part of the model architecture.

The firing rate *mf*, the output of the neuron, is obtained by applying a *threshold*, typically a *ramp, step, saturation,* or *sigmoidal* function, to the neuron's membrane potential:

$$mf(t) = \sigma(mp(t))$$

where $\sigma$ is usually a nonlinear function.

For example, if $\sigma$ is set to a *step* threshold function, the equation for the firing rate *mf* would be described by

```
mf = nslStep (mp);
```

where *nslStep* is the corresponding NSL *step* threshold function.

The previous definition specifies a single neuron without any interconnections. An actual neural network is made of a number of interconnected neurons in which the output of one neuron serves as input to the others. In the leaky integrator neural model, interconnections are very simple structures. On the other hand, *synapses*, the links among neurons, are—in biological systems—complex electrochemical systems and may be modeled in exquisite detail. However, many models have succeeded with a very simple synaptic model in which each synapse carries a connection weight that describes how neurons affect each other. The most common formula for the input *sv* to a neuron *v* is given by

$$sv_j = \sum_{i=0}^{n-1} w_{ji}uf_i$$

where $uf_i$ is the firing of neuron $u_i$ whose output is connected to the *j*th input line of neuron $v_j$ and $w_{ji}$ is the weight for that link, as shown in Figure 3 (*up* and *vp* are analogous to *mp*, while *uf* and *vf* are analogous to *mf* ).

Expanding the summation, input to neuron $v_j$ (identified by its corresponding membrane potential $vp_j$) is given by $sv_j$, which is defined as

$$sv_j = w_{j0}uf_0 + w_{j1}uf_1 + w_{j2}uf_2 + \cdots + w_{jn-1}uf_{n-1}$$

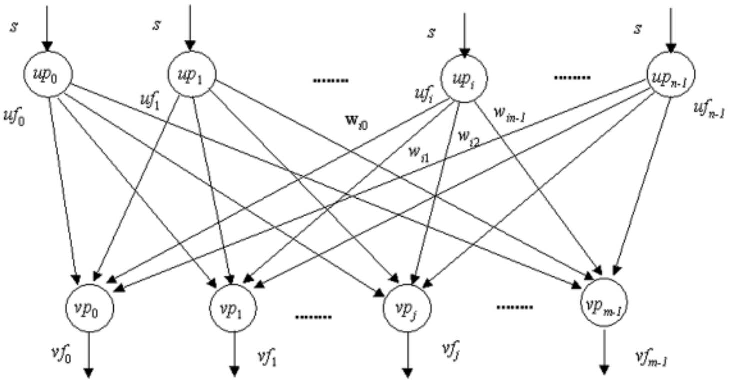

**Figure 3.** The diagram shows a sample two-layer fully connected neural organization (see Backpropagation: General Principles for an example of networks using such architectures). Each neuron is described by a single compartment represented by a value *up* or *vp*, its membrane potential, and a value *uf* or *vf*, to its firing, the output from the neuron. Input to the first neural layer is represented by *s*. Additionally, weights *w* have been added to the different connections.

While module interconnections are specified in NSL via a *nslConnect* method call, doing this with neurons would in general be prohibitively expensive, considering that there may be thousands or millions of neurons and even more connections in a single neural network. Instead, we use mathematical expressions similar to those used for their representation. For example, the input to neuron $v_j$, represented by *svj*, would be the sum for all outputs of neuron *ufi* multiplied (using the * operator) by connection weight *wji*, correspondingly, as shown next:

```
svj = wj0*ufo + wj1*uf1 + wj2*uf2 + · · · ;
```

Note that there exist *m* such equations in the network. We could describe each membrane potential and firing rate individually, or else we could make all $u_i$ and $v_j$ neuron vector structures. The first approach would be very long, inefficient, and prone to typing errors; therefore, we present the second approach, using *neuron arrays* and *connection masks* representing spatial arrangements among homogeneous neurons and their connections, respectively. We consider $uf_i$ the output from a single neuron in an array of neurons and $sv_j$ the input to a single neuron in another array of neurons.

If mask $w_{jk}$ (for $-d \leq k \leq d$) represents the synaptic weights from the $uf_{j+k}$ (for $-d \leq k \leq d$) elements to $v_j$, for every *j*, we then have

$$sv_j = \sum_{k=-d}^{d} w_{jk} uf_{j+k}$$

where the same mask *w* is applied to the output of each neuron $uf_{i+k}$ to obtain input $sv_j$. In NSL, the *convolution* operation is described by a single symbol '@':

```
sv = w@uf;
```

This kind of representation results in great conciseness, an important concern in working with large numbers of interconnected neurons. Note that this is possible as long as connections are regular. Otherwise, single neurons would still need to be connected separately, one by one. This also suggests that the operation is best defined when the number of *v* and *u* neurons matches, although a nonmatching number of units can be processed by using a more complex notation.

## Simulation in NSL

Simulation involves interactively specifying aspects of the model that tend to change, in particular parameter values, input patterns, simulation control, and visualization. It is important not only to design a good model, but also to design good graphical interfaces, both input and output. In terms of input, NSL offers a number of approaches: (1) by interactively writing code in NSLS, the NSL (interpreted) scripting language, (2) by loading NSLS scripts stored in files, and (3) by designing custom input interfaces. In terms of output, NSL enables the user to specify various forms of graphical and textual output, including temporal and spatial 2D and 3D graphics (see Weitzenfeld et al., 2002, for input and output visualization examples as well as more extensive description of NSLS commands).

## Discussion

In this article we have overviewed modeling and simulation using NSL, a system primarily designed to simulate modular neural systems, both biological and artificial (see Backpropagation: General Principles for an example of artificial neural networks). The underlying NSL computational model is based on the Abstract Schema Language (ASL) (Weitzenfeld, 1993) inspired by the work on Schema Theory (q.v.), on actors (Agha, 1986), and more generally on object-based concurrent programming (Yonezawa and Tokoro, 1987).

There are a number of issues worth discussing from our experience with NSL. While user interactivity plays an essential role while creating and testing new neural models, as model becomes more stable, simulation efficiency becomes a primary concern. This is a very important issue if we consider that neural network execution can consume extensive amounts of processing time, possibly hours or even days depending on the size and architecture of the network. For example, we have processed in NSL "simple" biological network, such as the retina model (see Retina) involving 10,000 neurons, consuming just a few seconds. On the other hand, a more complex network such as the one described in Figure 1 could take several minutes if implemented by "faithful" neural components. The general solution to this problem is to use parallelism and distributed computing facilities in speeding up computation. While a number of neural systems have been ported to supercomputers, we are currently developing a distributed simulation environment to run on networks of low-cost computers (Weitzenfeld, Peguero, and Gutiérrez, 2000). In general, the client-server distributed architecture has become quite pervasive, thanks to the Internet.

A web-based simulation interface (Alexander, Arbib, and Weitzenfeld, 1999) brings additional possibilities to the process of neural modeling. For example, users could be offered shared model repositories in creating new models or in addressing experimental data linked to it. These two thrusts are part of a project known as Brain Models on the Web (BMW), a model repository in which model assumptions, empirical data, and simulation results are stored (see Databases for Neuroscience).

An important issue arising from the sharing of module libraries is how to reuse portions of different models in creating new ones. An important consideration is to provide a general module interconnection specification to be followed by all modelers. This specification should deal with issues such as "edges" in the block diagrams as the one shown in Figure 1, where module interconnections and the corresponding ports are designed to deal only with primitive data without any temporal considerations. Additionally, the specification could address the relationship to the particular experimental protocol on which the model is based. These aspects need to be defined and then specified as a "meta-level" that will separate the internal module characteristics from the external ones.

Another consideration is the extensibility the system. Since not all users use similar simulation systems, it is important to offer interoperability of data and model descriptions to be shared by multiple simulation systems and applications in general. Additionally, integration with simulated or real-time Reactive Robotic Systems (q.v.) is of particular interest, in particular Biologically Inspired Robotics (q.v.), as exemplified by a number of NSL-based neural architectures developed to control mobile robots (Fagg et al., 1992; Weitzenfeld, 2000). Since many approaches exist today to mobile robotics, it is an interesting challenge to design new architectures integrating nonneural and neural-based approaches (Arkin et al., 2000).

# Object Recognition

*Bosco S. Tjan*

## Introduction

Visual object recognition is a classification task that assigns a behaviorally relevant label to a region of an image. It is one of the most important functions carried out by the human visual system. Understanding how it is achieved is almost as great a task as understanding visual processing in its entirety (Marr, 1982; Ullman, 1997; Rolls and Deco, 2002). Object recognition is a special case of Pattern Recognition (q.v.) in which the pattern to be classified is a two-dimensional (2D) projection of a three-dimensional (3D) structure. The 3D structure in question can be a single object (e.g., a car), an arrangement of objects (a convoy of cars), or even a space surrounding the observer (the interior of a car). For the same object, the assigned label depends on the task. A car may be recognized as "an obstacle" (along with garbage cans, lampposts) when one tries to maneuver through parked cars or "an approaching hazard" when one tries to cross the street. The level of classification also varies. An object can be recognized at what cognitive psychologists call the *basic* level (e.g., "a car"), a coarser *superordinate* level ("a vehicle"), or a finer *subordinate* level ("VW Beetle"). In general, object recognition is a mapping, $\mathbf{G}:\{x\} \rightarrow \{c\}$, from a set of input images $\{x\}$ to a set of task-dependent class labels $\{c\}$. Ideally, the mapping should be achieved by selecting the class label $c \in \{c\}$ that *best* explains the image in a probabilistic sense (i.e., by maximizing the posterior probability $\Pr(c|x)$; see Bayesian Networks). The challenge lies in the fact that the 2D image of a 3D structure changes dramatically under different *imaging conditions*: variations in lighting, position of the observer, presence or absence of other objects in the foreground and background, etc. A theory of object recognition must therefore explain (1) how a system may retain constancy in object classification in spite of large image variability, and (2) how such a system may learn and generalize. Among all the varying imaging parameters, the one that has received most attention is *viewpoint*, i.e., viewing position and direction of the observer relative to an object.

In this article, we review a number of computational theories of object recognition. The review, which is neither exhaustive nor comprehensive, is meant to show a broad range of the approaches. Space limitations prevent us from discussing the psychological validity of each approach—a difficult issue that is hotly debated. We emphasize computational theories over their neurological implementations, relying on other articles in this *Handbook* to bridge the two (see Object Recognition, Neurophysiology; Object Structure, Visual Processing). Our discussion of the computational theories of object recognition leads to a language of decision complexity, which we will use to characterize the trade-offs chosen by each theory. We will argue that a general-purpose object recognition system, such as the human brain, must be able to represent an object in multiple ways, and we outline a computational framework for such a system.

## Matching: A Core Operation

Object recognition is about matching an input *image* (2D array of luminance and chromaticity values) to a stored *representation* of an object. A very rudimentary form of object recognition is *template matching* performed at (or near) the image level, in which an input image is matched pixel to pixel to a set of stored images. The input image may be preprocessed to reduce the variability in luminance, size, 2D position, and/or image-plate rotation. A degree of mismatch is computed with some knowledge about the noise processes in image acquisition and preprocessing. For example, the commonly used mean-square error, or L2-norm, between an image and a stored template is appropriate if the imaging noise is an identically and independently distributed Gaussian in pixel value. A match is found when the degree of mismatch is less than some threshold.

The obvious advantage of image-level template matching is that little preprocessing is required, and few assumptions about the utility and detectability of certain image features are needed to transform the input image into a template. On the other hand, small variations in imaging conditions, such as changes in viewpoint or illumination direction, can produce a large mismatch between an input image and a restored template. As a result, image-level template matching methods are of little use for general-purpose object recognition.

On the other hand, it is not difficult to see that template matching is at the core of every object recognition theory. Superficially, the final decision stage that matches a processed input to a stored representation of an object is a template matcher operating at the level of the representation. A more fundamental role of template matching can be seen as follows. Let $v_c(\mathbf{g})$ be a view of object $c$ in some representation, where $\mathbf{g}$ is a vector of imaging parameters (i.e., viewpoint, illumination, occlusion, etc.). The posterior probability, $\Pr(c|x)$, of object $c$ being present in the image $x$ can be expressed in terms of all the possible views of $c$ by integrating over the generic variable $\mathbf{g}$. With Bayes's rule, we have:

$$\Pr(c|x) = \int_{\mathbf{g}} p(v_c(\mathbf{g})|x)d\mathbf{g} = \int_{\mathbf{g}} \frac{p(x|v_c(\mathbf{g}))p(v_c(\mathbf{g}))}{p(x)}\, d\mathbf{g} \qquad (1)$$

where $p(v_c(\mathbf{g}))$ is prior probability density of a view, $p(x|v_c(\mathbf{g}))$ is the likelihood of $v_c(\mathbf{g})$ being the cause of the input image $x$, and $p(x)$ is the probability density of seeing the input image $x$, which, for our purposes, is simply a normalization constant independent of $c$ and $\mathbf{g}$. The decision rule that is most accurate on average is to select $c$ that maximizes $\Pr(c|x)$. That is,

$$\arg\max_c \Pr(c|x) = \arg\max_c \int_{\mathbf{g}} p(x|v_c(\mathbf{g}))p(v_c(\mathbf{g}))d\mathbf{g} \qquad (2)$$

If the view $v_c(\mathbf{g})$ is represented as an $N$-pixel image, the likelihood function $p(x|v_c(\mathbf{g}))$ is simply the probability density function describing the imaging noise. For example, if the imaging noise is an identically and independently distributed Gaussian pixel noise, then $p(x|v_c(\mathbf{g})) = 1/(\sigma\sqrt{2\pi})^N \exp(-\|x - v_c(\mathbf{g})\|^2/2\sigma^2)$. The L2-norm term $\|x - v_c(\mathbf{g})\|^2$ in the exponent represents image-level template matching. In other words, object constancy could in theory be achieved with image-level template matching, provided one has the space and time to store and compare the input image against all views of all objects of interest (or according to Tjan and Legge [1998], a large but finite set of random views would suffice). Moreover, the decision rule of Equation 2 evaluated at the image level, with unlimited memory for object views, achieves the theoretical maximum in average accuracy.

## Theories of Object Recognition

Theoretical ideals notwithstanding, if object constancy is to be achieved practically, a visual system must explore regularities in the mapping between an input image and the intended output label. This is often done in two steps. First, photometric and geometric regularities inherent in the image-formation process are explored by extracting image features that remain constant (or nearly so) with respect to changes in imaging conditions. The extracted features then form a *representation* of the input. Second, this representation of the input is compared to the stored representations of different objects to identify a match. This decision process explores the statistical regularities inherent in the mapping between the representation (as opposed to the input image) and the output label. Theories of object recognition differ in their respective emphases on the representation or decision step. In their succinct discussion of the computational theories of object recognition, Trucco and Verri (1998) mentioned two general approaches to object recognition. If a system constructs a representation that does not vary (i.e., is *invariant*) with respect to imaging parameters but is sufficiently discriminating to tell one object from another, then the decision step will be relatively trivial. This type of approach is referred to as being *invariant based*. However, finding features that are both invariant and discriminatory is often difficult. The alternative is to rely less on an invariant representation and more on statistical inference to implicitly capture the regularities between the stimuli and the output labels. Because such an approach often makes object decisions using a representation closely resembling the input image, it is termed *appearance based*. A third type of approach, which does not fit neatly into either category described by Trucco and Verri, is to store a 3D model for each object. Recognition proceeds by trying to align a 3D model to match the input image. We will refer to this type of approach as *model based*.

## Invariant-Based Object Recognition

For an invariant-based object recognition system, the primary objective of visual processing is to extract and construct features that are constant relative to imaging conditions. For example, the presence of an *edge* often signals a discontinuity in surface orientation, mostly independent of lighting conditions. Hence, edge detection and contour formation are often proposed as the first steps of visual processing. The position, orientation, length, and curvature of a contour, however, vary with respect to an observer's viewpoint. Quantization is sometimes used to gain an additional degree of invariance. Within sensory acuity, many edges appear straight. Classifying the curvature of an edge as "straight" or "curved" makes the (qualitative) curvature of an edge invariant to viewpoint. Quantization represents a trade-off between discriminability and invariance. For example, a circle could not be discriminated from an ellipse if edges were classified solely as either straight or curved.

Another important means to attain invariance is to form compound features from elementary ones. For example, if there exist four identifiable points, $\boldsymbol{P}_1, \ldots, \boldsymbol{P}_4$, on a straight edge (perhaps due to surface markings), then the *cross ratio*, defined as $(|\boldsymbol{P}_1 - \boldsymbol{P}_2| \cdot |\boldsymbol{P}_3 - \boldsymbol{P}_4|)/(|\boldsymbol{P}_1 - \boldsymbol{P}_3| \cdot |\boldsymbol{P}_2 - \boldsymbol{P}_4|)$, is a quantity invariant to viewpoint under perspective projection (Duda and Hart, 1973). The cross-ratio of four collinear points can therefore be treated as a discriminating "feature" invariant to viewpoint. Other invariants based on configurations of points, lines, and conics have been proposed for the purpose of object recognition (Mundy and Zisserman, 1992). Like feature quantization, discriminability in object shape is often reduced when object identification relies on invariant features. For example, if shapes are represented by cross-ratios alone or any invariant derived from them, objects that are an affine (linear) transformation away from one another will be indistinguishable. In particular, a cube would be indistinguishable from a rectangular box or a parallelepiped.

Human observers are unaware of most of the geometric invariants, such as cross-ratios. However, a few spatial arrangements of features, such as collinearity of edges, parallelism, closure, or symmetry, are perceptually conspicuous. It has been proposed that such feature arrangements are ecologically significant, useful for segmenting an object from a cluttered environment. Lowe (1987) demonstrated an object recognition system that relies on perceptual organization of features to achieve invariant object recognition in a cluttered scene. Specifically, line segments were hypothesized to belong to the same object if they could be grouped based on proximity, parallelism, or collinearity.

Another well-known example of achieving invariance by feature grouping is the recognition by components theory (RBC; Beiderman, 1987). Beiderman argued that some 50 elementary 3D volumes (called *geons*) could be uniquely identified from their 2D images over a range of viewpoints by expressing edge configurations in terms of their qualitative (quantized) properties: straight versus curve, parallel versus converging, and type of intersection ("fork," "arrow," "L," or "T"). General-purpose object recognition proceeded by first identifying the geons then the spatial relationships between the geons. Spatial relationships were also identified in quantized terms, such as "on," "next-to," "left-of," etc. In short, RBC proposes that an object is represented by the qualitative spatial relationship between its parts, and the parts are represented as geons.

In general, an invariant-based object recognition theory proposes to construct, through stages of feature extraction, combination, and quantization, a set of higher-order features that are largely unaffected by imaging conditions. The final set of invariant features is then compared to those stored in memory as object models. Recognition results when a reasonably good match is found between the invariant representation of the input and that of a known object.

## Model-Based Object Recognition

Instead of combining features or quantizing feature attributes to achieve invariance, a visual system can factor out image variability by making explicit use of the 3D structure of an object. Lowe (1987) and later Huttenlocher and Ullman (1990) proposed the alignment method for object recognition, in which a small number (three or more) of identifiable features (parallel line segments, corners, junction types) were first hypothesized to be in correspondence with the compatible features of a stored 3D object model. The hypothesized correspondence was used to compute an orientation of the object (called a *pose*) that could bring the 3D model features into alignment with the corresponding 2D image features. The validity of the proposed object model was determined by the degree of match between the rest of the image and the projection of the model onto the image using the computed pose.

Common to most model-based approaches is an explicitly 3D representation of the objects, which allows the appearance of an object to be determined from any viewpoint, thus achieving invariance. Acquiring such a representation, however, can be challenging, especially if the 3D representation is to be derived from 2D inputs. Fortunately, an object's 3D structure is implicitly captured in its 2D images. Techniques have since been developed to exploit the three-dimensionality using image-to-image operations, bypassing the need to explicitly construct or store any 3D object model. Such techniques are often referred to as being appearance based.

### *Appearance-Based Object Recognition*

The most basic (and least plausible) form of appearance-based object recognition is the image-level template matching described earlier. It typifies one prominent feature of the appearance-based object recognition theories, namely, that decisions are made based on representations that closely resemble the raw input image. This is in sharp contrast to the invariant-based approach, which relies on higher-order features designed to be invariant to imaging conditions. Making object decisions near the image level relieves the system from depending on the complicated and often noisy feature extraction and construction processes, which results in higher tolerance to input noise and better discrimination. In addition, operations needed for learning new objects (model acquisition) are usually more robust and straightforward. The obvious challenge, however, is to achieve a reasonable level of viewpoint invariance for the technique to be useful.

An *N*-pixel image view $\mathbf{v}_c(\mathbf{g})$ can be expressed as a vector of *N* pixel values. This vector denotes a point in the *image space*. Over all the continuously varying imaging parameters (e.g., viewpoint, illumination), the set of points $\mathbf{v}_c(\cdot)$ form an *object manifold* embedded in the image space, which implicitly captures the 3D structure of the object. The process of object recognition in the image space can be thought of as determining which object manifold $\mathbf{v}_c(\cdot)$ is the "closest to" the input image. Because the input is a single point in the image space, but a manifold is a set of points, the distance between the two can take many forms. Equation 2 expresses one such form, which maximizes the average recognition accuracy. A brute-force implementation of Equation 2, however, would require storing too many images and would take too long to compute to be practical. Most of the appearance-based theories try to approximate Equation 2 by exploiting various regularities of the object manifolds, in order to significantly reduce storage and computation requirements.

An object manifold $\mathbf{v}_c(\cdot)$ can be arbitrarily complex and not necessarily smooth, even if the imaging parameters vary smoothly. There exist conditions, however, where the object manifold has a simple analytic form with parameters that can be determined from a sparse set of images. For example, if the only allowable variations in imaging conditions are the direction and intensity of illumination, then the object manifold will be piecewise linear (ignoring cast shadow). This means that images of the same object over a range of illumination changes can be synthesized by linearly combining three known images. Moreover, recent analysis has shown that the entire object manifold under illumination changes is "flat," residing close to a nine-dimensional subspace embedded in the image space of a few million dimensions. A practical appearance-based recognition system needs to store only nine images per object to achieve invariance over lighting variations (Basri and Jacobs, 2001; Lee, Ho, and Kriegman, 2001).

Another important case is when the image $\mathbf{v}_c(\mathbf{g})$ is not a vector of luminance values but a list of 2D coordinates of feature points. Furthermore, it is assumed that the correspondence between feature points across different views has been established. Object manifolds in this *correspondence space* (as opposed to the image space) are piecewise linear, if the viewing distance is large compared to object size. Ullman and Basri (1991) explored this property and pointed out that the views of an object over a range of viewpoints could be synthesized by linearly combining the coordinates of corresponding features between two views, thus avoiding the need for storing a large number of views. Other means of correspondence-space view interpolation, such as one using RADIAL BASIS FUNCTION NETWORKS (q.v.) (Poggio and Edelman, 1990), have also shown promise.

If the analytical form of an object manifold is not known, as is often the case, a visual system can still exploit the regularity of the manifold implicitly. For example, it could (1) use an inexact matching operation, (2) reduce the dimensionality of the manifolds, or (3) increase the distance between manifolds by mapping them to an even higher-dimensional space.

Von der Malsburg and colleagues (Lades et al., 1993) adapted Dynamic Link Architecture (q.v.) to perform elastic graph matching for object recognition. An object from a given viewpoint was represented by a grid of sparsely sampled image features, each being a vector (called a "jet") representing the local spatial frequency spectrum. To match an input image, the grid was allowed to deform mildly in search of the best-matched feature points. Recognition can be invariant over a modest range of viewpoints because a small change in viewpoint tends to displace feature points without significantly altering their local spatial frequency spectrum.

The set of images an appearance-based system can possibly store for a given object is usually a very sparse sample of the object manifold. Therefore, it is often advantageous to reduce the dimensionality of the object manifold to make the stored images more representative. The eigenspace method (Murase and Nayar, 1995; see Principal Component Analysis and Independent Component Analysis) is a principled way of achieving this. The idea is to express a set of $n$ known images of an object in terms of a weighted sum of their principal components $\mathbf{e}_1 \ldots \mathbf{e}_{\mathrm{n}}$. This mounts to a coordinate transformation from the image space (of pixel values) to an eigenspace via rigid rotation. If the principal components are arranged in descending order of their associated eigenvalues, then the weighted sum of the first $k$ principal components ($k < n$) is the "best" $k$-dimensional approximation of the image set, in the sense of having the minimum mean-square error. That is, if $\mathbf{v}_c(\mathbf{g})$ is an image of the object $c$ in some imaging condition $\mathbf{g}$, then

$$\begin{aligned}\mathbf{v}_c(\mathbf{g}) &= w_1\mathbf{e}_1 + w_2\mathbf{e}_2 + \cdots + w_k\mathbf{e}_k + \cdots + w_n\mathbf{e}_n \\ &\approx w_1\mathbf{e}_1 + w_2\mathbf{e}_2 + \cdots + w_k\mathbf{e}_k = [\mathbf{e}_1, \ldots, \mathbf{e}_k]^*\mathbf{w}_c(\mathbf{g}) \quad (3)\end{aligned}$$

where $\mathbf{w}_c(\mathbf{g}) = [w_1, w_2, \ldots, w_k]^{\mathrm{T}}$. In practice, $k$ can often be much smaller than $n$. This means that an image $\mathbf{v}_c(\mathbf{g})$ in a high-dimensional image space can be approximated with a $k$-dimensional weight vector $\mathbf{w}_c(\mathbf{g})$ in an eigenspace. Furthermore, the only images that need to be stored are the first $k$ eigenvectors $\mathbf{e}_1, \ldots, \mathbf{e}_n$, which jointly define the eigenspace.

The eigenspace method seeks to reduce the dimensionality of an object manifold. Some recent appearance-based theories, however, take exactly the opposite approach, realizing that if the manifolds of different objects can be made far apart from each other, there will be no need to represent the manifolds in any detail. A simple hyperplane (a plane in a high-dimensional space) will be sufficient to partition the decision space into regions, with each containing at most one object manifold. Support Vector Machines (q.v.), for example, first map a set of known images to a high-dimensional *feature* space by passing them through a nonlinear transformation $\psi$. The dimensionality of this feature space can be arbitrarily high, making it possible for a hyperplane to separate one object's manifold from another. For each object, a support vector machine finds the *optimal* hyperplane in the feature space by maximizing the distance between the hyperplane and the object manifolds it tries to separate. Because such a hyperplane is fully determined by the points on the object manifolds that are closest to it, only those points, which are simply images, need to be stored. These images that determined the optimal hyperplanes are called *support vectors*. Conceptually, object recognition proceeds by first mapping an input image to a point in the feature space via $\psi$, and then deciding on which sides of the hyperplanes the input resides. Mathematically, this two-step process is equivalent to comparing the input image with the set of stored images (support vectors) using an *inner product kernel* function $K$, which relates to the nonlinear feature map $\psi$ as $K(\mathbf{v}, \mathbf{v}_s) = \psi(\mathbf{v})^{\mathrm{T}}\psi(\mathbf{v}_s)$. The inner product kernel $K(\mathbf{v}, \mathbf{v}_s)$ returns a scalar and can be thought of as a generalized similarity measure in the feature space between the unknown input image $\mathbf{v}$ and a set of stored image $\mathbf{v}_s$.

Two key features of an appearance-based theory distinguish it from the invariant-based approach. First, the stored representation of an object is often very close to the images of the object and does not possess a high degree of invariance. Second, invariant object decisions are achieved with some distance measure between the unknown input image and a sizable set of image-like representations that jointly define an object.

## Decision Complexity and Representations

Each theory reviewed in the preceding section proposes one "final" representation used for object recognition. The theories differ in the amount of details the final representation retains. There is generally a trade-off between invariance (with an abstract representation) and discriminability (with an image-specific representation).

Regardless of the approach, an object recognition system has to decide which object manifold an input image belongs to. The decision task is easy if the object manifolds are (1) simple *and* (2) far apart. Historically, most object recognition theories, especially the invariant-based ones, have pursued the first factor. If successful, such an approach would have produced a general-purpose object representation that is appropriate regardless of the task or objects involved. However, if the manifolds for different objects intertwine, an attempt to reduce the manifolds' dimensionality can also make them indistinguishable from one another. Furthermore, the ever-present noise in the input can perturb the transformation processes required to map the input image to its final representation, leading to misidentification.

We refer to the extent to which object manifolds intertwine in the decision space as the *decision complexity*. Decision complexity is a function of the recognition task and the *set* of objects to be recognized. The decision complexity of telling two chickens apart is clearly different from that of recognizing a chicken from a fish. Tjan and Legge (1998) used a random sampling method to estimate the decision complexity in the image space for different sets of objects. Specifically, they measured the number of unprocessed raw images that an *ideal observer* operating according to Equation 2 would need to store in order to fully represent a set of objects. They found that decision complexity in the image space varied over two orders of magnitude across different types of objects and was highly dependent on what other objects were involved in the task. This result matches qualitatively to humans' varying difficulty in achieving viewpoint-invariant recognition across object sets.

In a practical object recognition system, the mapping between the image space and the decision space is highly nonlinear. Hence, decision complexity in the image space does not necessarily dictate decision complexity in the decision space. Intuition and practical experiences, however, suggest that the two are coupled. How intertwined the object manifolds are in the image space limits the minimum decision complexity one can practically attain in a decision space, after the noise in the input and visual processing has been accounted for. The wide range of image-space decision complexities observed by Tjan and Legge therefore implies that a general-purpose object recognition system cannot rely on a single form of representation for a wide range of tasks and objects.

## Adaptive Selection of Representations

The idea that the human visual system may use multiple forms of representations is uncontroversial, but details are lacking. Specifically, what are the representations used by the human visual system, and how does the system decide which representation to use for a particular task? We make two observations (Tjan, 2001). First, to obtain a representation with a high degree of invariance, a series of processing stages are needed for feature extraction and the construction of higher-order features. This hierarchical processing architecture is common to most invariant- or model-based theories and is consistent with neurological findings about the visual system (Rolls and Deco, 2002). The intermediate output of each processing stage is in fact a representation at a particular level of abstraction. Thus, in the process of forming a representation with high degree of invariance, we obtain as "byproducts" a series of intermediate representations, each making a different trade-off between discriminability and invariance, each suitable for a recognition task of a different decision complexity. Second, if object decisions are made by the optimal strategy of maximizing posterior probabilities (i.e., Equation 2), or are approximately so, the magnitude of posterior probability $\Pr(c|x)$ of the best choice can serve as a confidence measure regarding the decision (because posterior probabilities sum to one). The confidence of a decision can be low if (1) the representation is not detailed enough to make the discrimination, or (2) the representation is too detailed to attain a sufficient level of invariance for recognizing a novel input. Such a confidence measure can therefore be used to determine on-the-fly which level of representation is most appropriate for a given task.

Tjan (2001) proposed a simple architecture for object recognition that adaptively selects the most appropriate level of representation for a given task and objects. The architecture consists of a single visual processing pathway, loosely modular. Decision sites with local memory are attached to the processing modules along this pathway. Object-identity decision is made independently and in parallel at every decision site. The response latency of a site decreases with the maximum posterior probability evaluated at the site, but increases with the site's effective memory size. The first-arriving response from any site is taken to be the system's response. Simulation results showed that, although the intermediate representations were generic, the effective representation revealed behaviorally by the system appeared to be specific to the object category and task. The system showed an efficient trade-off between speed and accuracy, indicating that the object decisions were made at the appropriate level of abstraction.

## Discussion

A great number of object recognition theories have been proposed in the past 30 years. While not all of them are biologically feasible, each provides important insight into the range of possible computations and representations for recognizing objects. Each theory makes a particular trade-off between discriminability and invariance. A system designed to discriminate similar objects is generally more sensitive to imaging conditions and requires a larger memory footprint to represent the objects than a system designed to discriminate highly dissimilar objects. Our analysis of decision complexity shows that it is unlikely for a single form of representation to be suitable for all kinds of object recognition tasks a human or other visual animals encounter each day. A key ingredient in a comprehensive brain theory for object recognition is therefore a computational framework that allows on-demand selection or adaptation of representations based on the task. To this end, we proposed a simple confidence-driven horse-racing scheme (a sort of first past the post, temporal winner-take-all scheme) for self-selecting the most appropriate level of abstraction, given a finite set of available representations along a visual processing pathway. Simulation results suggested that the framework is consistent with known behavioral and neurological data. We believe this framework is sufficiently simple and concrete for it to be biologically viable.

## Introduction

As viewing distance, viewing angle, or lighting conditions change, so too does the image of an object that we see. Despite the seemingly endless variety of images that objects can project, the human visual system is able to rapidly and reliably identify those objects. How humans achieve this feat of recognition has long been a source of debate. Researchers have still not agreed on even the most fundamental questions of how objects are represented in cortex. This article provides a brief overview of some theoretical approaches in the context of mainly neurophysiological evidence. It also considers the related question of objects within a physical context, that is, the analysis of visual scenes. Scene analysis is relevant to the question of object recognition because scenes are initially recognized at a holistic, object-like level, providing a context or "gist" that itself influences the speed and accuracy of recognition of the constituent objects (Rensink, 2000). A precise characterization of gist remains elusive, but it may well include information such as global color patterns, spatial frequency content, correlational structure, or anything that is useful for categorizing or recognizing the scene.

To provide an anatomical framework for this chapter it is instructive to review the major functional divisions of visual cortex. Visual processing begins at the back of neocortex, in the occipital lobe. From there, information flows down into the temporal lobe, forming the ventral stream, and up into the parietal lobe, forming the dorsal stream (Figure 1). On the basis of neuropsychological and single-cell recording data, theorists have proposed a functional division between these streams. The dorsal stream is considered to process deciding "where" an object is and the ventral stream "what" an object is (Ungerleider and Haxby, 1994). In this article we mainly focus on the "what" stream, since it is seen as the center of object recognition, but an integrated model of scene perception will almost certainly require a broader approach encompassing all four lobes.

## The Ventral Stream

The path from primary visual cortex to the inferior temporal lobe (IT) passes through as many as ten neural areas before reaching the last wholly visual areas (Figure 1). Early recordings of the temporal lobe indicated neurons selective for faces, and from later recordings workers were able to verify that these cells could not be excited by simple visual stimuli or as part of an emotional response to seeing a particular face (Rolls, 1992; Logothetis and Sheinberg, 1996).

One striking feature of the response properties of neurons in the IT is that the farther down the ventral stream one looks, the more specialized and selective the neurons become. Of special interest to the field of object recognition was the discovery that along with increasing selectivity, many neurons become tolerant to shifts in stimulus position; changes in viewing angle, size/depth, or illumination; or the spatial frequencies present in the image (Rolls, 1992).

A great deal of this work originally had to do with neurons selective for faces, but although face cells account for as much as 20% of neurons in some regions of the IT and STS, they account for only about 5% of all cells present in IT cortex. In the early 1990s, Tanaka and his colleagues (Tanaka et al., 1991) showed that many of the remaining neurons are selective for complex combinations of features, including a basic shape with bounded light and shaded or colored bounded regions, and that these neurons also demonstrate useful invariance properties. This work has dispelled the idea of a special stream designed specifically for face recognition.

Recent work has focused on the issue of how the cellular response properties of temporal lobe neurons change over time. Several studies have shown that repeated exposure to a particular object class results in changes in the number of neurons selective for that stimulus (e.g., Rolls, 1992; Miyashita, 1993; Logothetis and Sheinberg, 1996). In humans, we should not be surprised to learn that a car enthusiast has neurons tuned to the appearance of a yellow VW Beetle, or that a lepidopterist has neurons tuned to an Orange Tip butterfly.

## The Dorsal Stream

Abstracting an object's form from its precise location, size, or orientation is clearly important for tasks such as recognition and categorization. However, there are plenty of situations in which an object's location and orientation are important, not least when we want to interact with that object by picking it up or manipulating it. The processing of location and orientation appears to be the major concern of neurons in the parietal lobe. These neurons form part of the dorsal stream. In humans, damage to the parietal lobe severely affects the localization of objects within a scene, leading to disorders such as visual neglect, and it appears that the dorsal stream is intrinsically linked to the control of visual attention and eye movements (Ungerleider and Haxby, 1994).

Of course, many tasks require the interaction of the two types of information, both where and what an object is. Our lepidopterist would like to be able to net a Tortoiseshell fluttering among Red Admirals. This raises an as yet unanswered question, namely, how these types of information interact and where various representations are held. It turns out that there are plenty of routes that information could take between the temporal and parietal lobes, including a direct route, via the occipital lobe or the frontal lobe. It has been shown, for example, that regions AIT and CIT of IT (see Figure 1) connect to the frontal lobe, and CIT and PIT connect to the parietal lobe (Webster, Bachevalier, and Ungerleider, 1994). One aim of any modeling work must be to investigate the possible siginificance of these connections.

## A Processing Hierarchy

One of the striking features of the ventral stream is its hierarchical structure. Neurons in the regions of the temporal lobe furthest from the retina can be thought of as sitting on top of a processing pyramid (Figure 2). Receptive field size grows steadily larger the farther up this pyramid one looks, and the response times of neurons also rise systematically (Rolls, 1992).

One possible explanation for the presence of such a hierarchy is that the visual system is gradually building representations of ever-increasing complexity to produce neurons that respond to combinations of inputs, themselves forming the effective stimuli for later neurons. By responding to local combinations of neurons co-active in the previous layer, arbitrary spatial arrangements of the same features should fail to activate the same neuron. This should then reduce the chance of finding the trigger features supporting recognition in random arrangements of the features, an issue often referred to as the "feature-binding problem." Some of the most selective and view-invariant responses belong to cells in the superior temporal areas. These neurons appear to pool the outputs of view-selective AIT cells. One explanation of how the STPa neurons know which AIT neurons to group together is discussed in the next section.

**Figure 2.** Schematic of convergence in the ventral processing stream. The steady growth in receptive field size suggests that neurons in one layer of the hierarchy receive input from a select group of neurons in the preceding layer. The time taken for the effects of seeing a new visual stimulus increases systematically through the hierarchy, supporting the notion of a strictly layered structure.

Neuroanatomists tell us that there are at least as many connections running back as there are running forward in the ventral stream, and this is important when one comes to devise models. The precise use of these connections remains unclear. Some theorists have argued that they are used in recall, and it is true that the act of remembering visual events causes activity to spread into primary visual areas. They may also control visual attention. Certainly attending to specific regions of the visual environment has been shown to facilitate the processing of signals in topographically matched regions of visual cortex, which may well be due to selectively raising the activity (or lowering the activation thresholds) of neurons along the processing hierarchy. One important role that the connections almost certainly do play is in relaying "top-down" influences on recognition, due to expectations or selective attention, perhaps prompted by the gist of a scene. Such influences include contextual priors, which in this case are functions that govern the likelihood of seeing a particular object in a particular context. Our lepidopterist will implicitly change these priors with habitat, improving the chances of correctly distinguishing a Caper White in the rocky bush of South Australia from a Cabbage White on the meadows of southern England.

Some have argued that the backward-projecting connections, apart from their role in relaying attentional mechanisms, play an integral role in normal visual processing. Some have gone so far as to suggest that each neural region forms a recurrent attractor network, each connected through the cortex, up to and including the temporal lobe. Although such models may be needed to deal with confusing or low-quality images, there is good evidence that timing constraints prohibit such a model from acting during the rapid recognition of everyday, familiar objects (Thorpe, Fize, and Marlot, 1996).

## Encoding Objects in the Temporal Lobe

Despite the apparent selectivity of temporal lobe neurons, it is important to realize that they are not "grandmother cells" selective for a single entity (such as your grandmother) in the manner proposed in early theories of object representation. On the contrary, many of the cells reported in the literature responded to several examples of objects within their particular object category. Evidence is emerging that object encoding is achieved via small ensembles of firing cells that efficiently and robustly code for individual objects.

Under a distributed scheme, many hundreds or thousands of neurons, each selective for its specific feature, would act together to represent an object. Although many of these features represent only small regions of an object, others appear to represent an object's outline, or some other global but general property. In addition, the neural representation of these features is more sophisticated than a simple template, since they may exhibit invariance to scale and size, something typical of temporal lobe neurons.

Implementing representation in a distributed code brings with it several advantages. First, the representations are robust to cell damage: since hundreds or thousands of neurons react to the presence of a single object, the death of one neuron within the ensemble will not adversely affect recognition accuracy or speed. Second, a distributed representation provides immediate recognition generalization to novel stimuli: a new object can be represented distinctly from all other stimuli by using a unique combination of the many well-established feature-selective neurons already present. In so doing, each neuron brings knowledge of how its feature changes in appearance with changes in viewpoint. The numerous beneficial, emergent properties of a distributed representation have long been realized by neural network theorists (see Population Codes).

In addition to the general encoding and topological organization of IT cortex, work has also been carried out to establish what functional organization might be present. Some researchers have made moves to describe the functional organization of IT. Cells were tested and their key stimulating features characterized, revealing a columnar structure in which groups of neurons appear to respond to similar though subtly different collections of features. Neighboring columns seem to have less in common. This work in part replicates the findings of other researchers who have described localized "clusters" or "patches" of face cells (see Rolls, 1992), and the findings have been taken by some as evidence for local excitatory and more diverse inhibitory connections within the processing layers, akin to those used in competitive networks (see Wallis and Bülthoff, 1999; Riesenhuber and Poggio, 2000).

## Models of Object Representation and Recognition

A huge number of systems for object recognition have been proposed over the years. Some were inspired by the desire to build intelligent machines, others by the desire to describe human recognition processes. This section summarizes some of the popular models and their relevance, or otherwise, to human object recognition. Extensive reference lists can be found in review articles on the topic by Wallis and Bülthoff (1999) and Riesenhuber and Poggio (2000).

One family of models, which owes its heritage to artificial intelligence research in the 1970s, sees the need to extract cues to three-dimensional (3D) structure. Using texture gradients, linear perspective, structure from motion, and so on, models in this family seek to transform the retinal image into a full-fledged internal 3D model capable of rotation, scaling, and translation and therefore matching to a store of known objects. Various means for achieving this reconstruction have been proposed, although perhaps the most preeminent is the geon theory of Biedermann and its associated network model, called JIM (see OBJECT STRUCTURE, VISUAL PROCESSING). Unfortunately, although there are plenty of neurons sensitive to cues such as terminated edges or complex forms of motion, neurophysiologists have yet to find evidence for large quantities of the types of neural analyzers that this type of models would predict, and even less evidence for the set of 36 3D volumetric building blocks that Biederman's theory claims are combined to represent all objects. What is more, there is only limited evidence for the neural synchronization mechanism that it uses to bind elements of activated geons, and there is no evidence of neurons purely selective for the spatial relationships of parts, such as "left of," "above," and so on. Nonetheless, some form of structural representation must surely exist, particularly in defining object categories for distinguishing a quadruped from a biped, or a telephone from an elephant. The JIM model is one of the very few models focused on human object recognition that provides a principled means of extracting and representing structure.

As an alternative to this type of bottom-up object reconstruction, a number of approaches to object recognition have considered the possibility of matching the incoming image to a large collection of 2D images or whole 3D objects. This process takes a number of different forms. In some models the image of the object is normalized for size and location and then simply matched pixel by pixel to a stored set of images. Of course, simple 3D transformations such as depth rotation lead to nontrivial changes in the 2D projected image. To compensate for this, some models have employed local distortions of the incoming image in the matching process. Others have presupposed an ability to extract 3D anchor points in the image that allow stored 3D representations to be rotated and scaled in 3D before the matching process begins. In practice, most of these models work well on predefined sets of objects and small changes in appearance, but they are prone to errors if the incoming image changes considerably. Models that employ local distortion or rotation algorithms are more robust, but this robustness comes at a cost. The models are slow and become slower the more objects are stored in the internal library. The simplest form of 2D template matching is at least fast, and if the process proceeds in parallel, it can scale extremely well as the number of objects increases. However, where all of these models fall down is in explaining our ability to categorize and generalize recognition of new objects to changes in viewing direction.

A possible solution to this final problem is based on a further alternative model for how objects are represented and recognized. This approach once again suggests that objects are stored as images or multiple views (Bülthoff and Edelman, 1992). However, rather than being stored as a single template, each view is represented as a collection of small picture elements, each tolerant to small view changes (Wallis and Bülthoff, 1999; Riesenhuber and Poggio, 2000). Such a system immediately reaps the benefits of a distributed encoding system in terms of robustness and transformation generalization for novel objects; it also accords with the types of neural response properties known to exist in the ventral stream.

In practice, many systems base recognition on a combination of pictorial features. Some have simply attempted to look across the entire image for telltale features, irrespective of relative position, as evidence for the presence of one object rather than another. Of course, models that throw away spatial information in this way run into the problem of "recognizing" random rearrangements of the features triggering recognition. This is not the case for real neurons responsive to faces, which often reduce their response to faces in which the features appear jumbled up (Rolls, 1992; Logothetis and Sheinberg, 1996). Nor is it true for cells responsive to more abstract features (Tanaka et al., 1991); indeed, this is an example of the feature-binding problem. As described earlier in this article, one solution to this problem is to combine features gradually over a series of stages, achieving translation invariance step by step. This has inspired many theorists to take this approach in object recognition. One of the first to construct a truly hierarchical model was Fukushima (1980). His neocognitron is an elegant example of how piecewise combinations of features can lead to comprehensive translation and scale invariance while at the same time retaining object specificity, thereby avoiding one form of the feature-binding problem. Fukushima's ideas accord well both with elements of the known neurophysiology of the ventral stream and a view-based scheme of object representation, and has inspired a whole series of models (see Wallis and Rolls, 1997; Riesenhuber and Poggio, 2000). The Riesenhuber and Poggio paper also describes their development of Fukushima's model and how it predicts the use of a nonlinear weighting mechanism on the inputs to neurons of each layer. Wallis and Rolls describe their own model, which is once again hierarchical and convergent but simpler in structure. Despite its simplicity, it has been shown to be able to learn invariant representations of objects without recourse to nonlocal learning mechanisms, supervised learning, specialist neural populations, or specific, prescribed connectivity. An important omission from such models is any explicit representation of object structure. As mentioned earlier, structure may well be important for higher levels of categorization, for distinguishing broad categories such as insects from mammals. Image-based approaches, on the other hand, are probably of more importance for within-category discrimination, such as discriminating a Peacock butterfly from a Meadow Brown. For more on this and related issues, see OBJECT RECOGNITION.

Another aspect that the hierarchical feedforward models lack is an account of the effects of top-down information due to expectation or selective attention. As such they really only deal with recognition within the high-acuity center of the visual field and would require some other mechanism for locating and fixating objects. One hierarchical model that does consider this has been described by Olhausen, Anderson, and van Essen (1993). It selects targets by controlling the breadth and number of pathways present in the model's hierarchy. Recognition is achieved using a classical object-matching algorithm, which suffers from the disadvantages noted earlier, but the model does provide insight into a possible mechanism for object selection, and with it an additional solution to the problem of translation and scale invariance.

## Temporal Order

Although it is possible to conceive of the ventral stream building features to represent individual views of objects, the question still remains as to how neurons learn to treat their preferred feature as the same, irrespective of size or location. Indeed, ultimately, one would like to understand how neurons learn to recognize objects as they undergo nontrivial transformations, perhaps due to changes in viewing direction or lighting.

One solution to this problem is to assume that each neuron receives some external information as to the identity of a particular stimulus. Of course, this simply begs the question of where this information originates in the first place. To describe a potential solution, it is worth reflecting on what clues our environment gives us about how to associate the stream of images that we see in everyday life. Recently, several theorists have argued that our natural environment provides a temporal cue to object identity. This cue emerges from the simple fact that we often study objects for extended periods. This then provides us with a simple heuristic for deciding how to associate novel images of objects with stored object representations. Since objects are often seen over extended periods, any unrecognized view coming straight after a recognized one is most probably of the same object. This heuristic will work as long as accidental associations from one object to another are random and associations from one view of an object to another are experienced regularly. There is every reason to suppose that this is actually what will happen under normal viewing conditions, and that by approaching an object, watching it move, or rotating it in our hand we will receive a consistent associative signal capable of bringing all of the views of the object together.

It was Miyashita (1993) who discovered that many neurons within IT cortex had developed selectivity for small sets of fractal images that he had been using in a short-term memory task. Although this task did not explicitly require the overall test sequence to be remembered, Miyashita noted that these neurons consistently responded well to single images that neighbored one another in the test sequence. For example, one neuron might respond preferentially to images 5, 6, and 7, whereas another neuron responded to images 37, 38, and 39. The fact that the images were generated randomly meant that there was no particular reason—on the grounds of spatial similarity—why these images should have become associated together by a single neuron. Instead, the results indicate the importance of temporal order in controlling the learning of neural selectivity. Recent studies of human recognition learning have found evidence for such a mechanism as well (Wallis and Bülthoff, 2001). Taken together, the two sources of evidence provide important preliminary support for the temporal association hypothesis (Wallis and Bülthoff, 1999). Several network models have made successful use of the temporal cue to view association, and it forms the core of learning in the model described by Wallis and Rolls (1997).

## Discussion

This article has reviewed much of the current thinking on object recognition. In particular, it has proposed the presence of a distributed, view-based representation in which objects are recognized on the basis of multiple, 2D feature-selective neurons. Specialist cells appear to play a role in associating such feature combinations into certain nontrivial image transformations, coding for a certain percentage of all stimuli in a largely view-invariant manner. The article has also pointed to evidence that a convergent hierarchy is used to build invariant representations over several stages, and that at each stage lateral competitive processes are at work between the neurons.

We have argued that temporal association could act as a cue for associating views of objects. If such a mechanism exists, it could only work in the ventral stream, since it would *not* be appropriate in the dorsal visual system, where motion and location are processed (Ungerleider and Haxby, 1994). Indeed, the importance of using temporal association in invariant object recognition, and the importance of not making such associations in the part of the visual system involved in processing motion and location, might be a fundamental reason for keeping these two processing streams apart.

We have touched on the analysis of visual scenes both within and beyond the ventral stream. Although much has been said about the roles of the parietal and temporal lobes, relatively little has been said about the frontal lobe. We do know that it acts as a temporary or working memory store, and that neurons within the frontal lobe are responsive to combinations of both where and what an object is. It may well turn out that the frontal lobe acts as a running store of objects currently being represented within a scene (Rensink, 2000). A challenge for models in the future will be to integrate the frontal lobe into the overall picture of scene analysis.

## A Functional Characterization of Structure Processing

A computational-level analysis of the processes dealing with object and scene structure requires that we first identify the common functional characteristics of structure-related behavioral tasks. In other problems in high-level vision, effective functional characterization typically led to advances in the computational understanding, and to better modeling, of the relevant aspects of the human visual system. In the study of visual motion, for example, realization of the central role of the correspondence problem constituted just such an advance. Likewise, object recognition tasks, such as identification or categorization, have at their core a common operation, namely, the matching of the stimulus against a stored memory trace.

For the structure-processing tasks, a good candidate for the signature common characteristic is the *restriction of the spatial scope* of at least some of the operations involved to some fraction of the visual extent of the object or scene under consideration. In other words, a task should qualify for the label "structural" only if it calls for a separate treatment of some *fragment(s)* of the stimulus (and not merely of the whole). Here are a few examples of behavioral tasks that qualify as structural according to this criterion:

- *Given two objects, or an object and a class prototype, identify their corresponding regions.* The correspondence here may be based on local shape similarity (find the eyes of a face in a Cubist painting), or on similar role played by the regions in the global structure (find the eyes in a smiley icon).
- *Given an object and an action, identify a region in the object toward which the action can be directed.* Similarities between objects vis à vis this task are defined functionally (as in the parallel that can be drawn between the handle of a pan and a door handle: both afford grasping).
- *Given an object, describe its structure.* This explicitly structural task arises in the context of trying to make sense of an unfamiliar object (as in perceiving a hot-air balloon, upon seeing it for the first time, as a pear-like shape over a box-like one).

The characterization of structure processing in terms of scope-restricted spatial analysis mechanisms has two immediate implications. Consider, on the one hand, the *appearance-based* computational approaches to recognition and categorization, according to which objects are represented by collections of entire, spatially unanalyzed views. Because of the holistic nature of the representations they rely on, these approaches are seen to be incapable, in principle, of supporting structure processing (Hummel, 2000). On the other hand, the "classical" *structural decomposition* approaches (Biederman, 1987) have the opposite tendency: the recursive symbolic structure they impose on objects seems too rigid and too elaborate, compared to the basic principle of spatial analysis proposed above, which requires merely that the spatial scope of each of its operators be limited to a fragment of the visual scene.

## Object Form Processing in Computer Vision

Until recently, the attainment of classical structural descriptions has been widely considered to be the ultimate goal of object form processing in computer vision. The specific notion that the structural descriptions are to be expressed in terms of volumetric parts, popularized by Marr (1982), was subsequently adopted by Biederman (1987), who developed it into a (psychological) theory of recognition by components (RBC). In Biederman's formulation, the representation is explicitly *compositional*: it consists of symbols that stand for generic parts (called "geons"); the symbols are drawn from a small repertoire and are bound together by categorical symbolically coded relations (such as "above" or "to the left of"). RBC's compositional nature is explicit in a sense stressed by Fodor and McLaughlin (1990): a classical structural description of an entire object necessarily contains *tokenings* of its (stipulated) constituent parts, in the same sense that a sentence considered as a concatenation of some words necessarily contains each and every of its words in their original, unchanged format (see COMPOSITIONALITY IN NEURAL SYSTEMS).

By virtue of their compositionality, the classical structural descriptions meet the two main challenges in the processing of structure: productivity and systematicity. A visual system is productive if it is open-ended, that is, if it can deal effectively with a potentially infinite set of objects. A visual representation is systematic if a well-defined change in the spatial configuration of the object, such as swapping top and bottom parts, causes a principled change in the representation, such as the interchange of the representations of top and bottom parts. Compositionality, however, has its cost. The requirement that object parts be "crisp" and relations syntactically compositional is a principle that may be appealing (by analogy with an intuitive view of the language faculty that it embodies), but is difficult to adhere to in practice. Indeed, in computer vision, a panel of experts deemed the structural analysis of raw images (as opposed to the analysis of symbolically specified line drawings of Biederman's examples) to be unpromising: "the principal problems with this approach seem to be the difficulty in extracting sufficiently good line drawings, and the idealized nature of the geon representation" (Dickinson et al., 1997, p. 284).

Both of these problems can be effectively neutralized by giving up the classical compositional representation of shape by a fixed alphabet of crisp "all-or-none" explicitly tokened primitives (such as geons) in favor of a fuzzy, superpositional coarse-coding by an open-ended set of image fragments. This alternative approach has met with considerable success in computer vision. For example, the system described by Nelson and Selinger (1998) starts by detecting contour segments, then determines whether their relative arrangement approximates that of a model object. Because none of the individual segment shapes or locations is critical to the successful description of the entire shape, this method does not suffer from the brittleness associated with the classical structural description models of recognition. Moreover, the tolerance for moderate variation in the segment shape and location data allows it to categorize novel members of familiar object classes (Nelson and Selinger, 1998).

In a similar fashion, the method of Burl, Weber, and Perona (1998) combines "local photometry" (shape primitives that are approximate templates for small snippets of images) with "global geometry" (the probabilistic quantification of spatial relations between pairs or triplets of primitives). In general, such methods use snippets of images taken from objects to be recognized to represent these objects; recognition is declared if at least some of the fragments are reliably detected, and if the spatial relations among these fragments conform to the stored description of the target. In all of these methods, the interplay of loosely defined local shape ("what") and approximate location ("where") information leads to robust algorithms supporting both recognition and categorization. These same methods may also lead to the development of an effective alternative to the classical structural description approach to object form, provided that they can be extended to support hierarchical treatment of shape details across spatial scales.

## Mechanisms Implicated in Structure Processing in Primate Vision

In theoretical neuroscience, ideas advanced to explain structure processing by the primate visual system can be roughly divided into two groups, following the distinction made in the preceding discussion between the classical crisp part-based compositional methods and the fuzzy fragment-based *what* + *where* approach. The two kinds of theories invoke distinct neural mechanisms to explain the manner in which object constituents (whether explicitly tokened crisp parts or fuzzy superimposed fragments) are (1) represented individually and (2) bound together to form the whole.

Consider the classical theories built around the syntactic compositionality idea (Biederman, 1987). First, these theories require that "crisply" defined geon-like parts and categorical relations be explicitly represented on the neural level. Although no evidence seems to exist for the neural embodiment of geons as such, there are reports that cells in the inferotemporal (IT) cortex exhibit a higher sensitivity to "nonaccidental" visual features than to "metric" properties of the stimuli; nonaccidental features such as curvature sign or parallelism of contours are used to define geons, because of their diagnosticity and invariance to viewpoint changes. Second, the classical theories hold that symbols representing the parts are bound into the proper structure dynamically, by the synchronous firing of the neurons that code each symbol. Thus, a mechanism capable of supporting dynamic binding must be available; it is possible that this function is fulfilled by the synchronous or phase-locked firing of cortical neurons (see SYNCHRONIZATION, BINDING, AND EXPECTANCY), although the status of this phenomenon in primates has been disputed.

The alternative theory, proposed by Edelman and Intrator (2000), calls for an open-ended set of fuzzy fragments instead of geons. The role of fragment detectors may be fulfilled by those neurons in the IT cortex that respond selectively to some particular views of an object or to a specific shape irrespective of view (Logothetis and Sheinberg, 1996). This very kind of shape-selective response may also constitute the neural basis of *binding by retinotopy*, an idea based on the observation (Edelman, 1994) that the visual field itself can serve as the frame encoding the relative positions of object fragments, simply because each such fragment is already localized within that frame when it is detected. The binding by retinotopy is possible if the receptive field of each cell is confined to some relatively limited portion of the entire visual field (as per the definition of the signature characteristic of structural processing proposed in the Introduction). Neurons with such response properties have been found in the IT cortex (Op de Beeck and Vogels, 2000) and in the prefrontal cortex, where they were called *what* + *where* cells (Rao, Rainer, and Miller, 1997).

## Neuromorphic Models of Visual Structure Processing

We now proceed to outline two implemented models of structure representation in primate vision. The first of these, JIM.3 (Hummel, 2001), exemplifies the classical compositional approach, and the second, Chorus of Fragments, or CoF (Edelman and Intrator, 2000), the alternative one just discussed.

The JIM.3 model is structured as an eight-layer network (Figure 1). The first three layers extract local features: contours, vertices and axes of symmetry, and surface properties. Surfaces are represented in terms of five categorical properties: (1) elliptical or not; (2) possessing parallel, expanding, convex, or concave axes of symmetry; (3) possessing a curved or a straight major axis; (4) truncated or pointed; and (5) planar or curved in 3D. Units coding these local features group themselves into representations of geons by synchrony of firing. These representations are then routed by the units of layer 4 to two distinct destinations in layer 5. The first of these is a population of units coding for geons and spatial relations that are independent or "disembodied" in the sense that each of them may have originated from any location within the image. Within this population, the emergence of a representation of the object's structure requires dynamic binding, which the model stipulates to be carried out under attentional guidance and to take a relatively long time (a few hundred milliseconds).

The second destination of the outgoing connections of layer 4 is a population of geon units arranged in the form of a retinotopic map. Here, the relations between the geons are coded implicitly, by virtue of each representation unit residing in the proper location within the map, which reflects the location of the corresponding geon in the image. In contrast to the attention-controlled stream, this one can operate much faster, and is postulated to be able to form a structural representation in a few tens of milliseconds. This speed and automaticity have a price: because of the fixed spatial structure imposed by the retinotopic map, the representation this stream supports is more sensitive to object transformations such as rotation in depth and reflection (Hummel, 2001).

The other implemented model we outline here, the Chorus of Fragments (CoF) model, exemplifies the coarse-coded fragment-based approach to the representation of structure (Edelman and Intrator, 2000, 2001). It simulates cells with *what* + *where* receptive fields to represent object fragments and uses attentional *gain fields*, such as those found in area V4 (Connor et al., 1997), to decouple the representation of object structure from its location in the visual field (the gain field of a neuron refers to those locations where the presence of a secondary stimulus modulates the cell's response to the primary stimulus shown within the classical receptive field; in this case, the modulation is exerted by shifting the focus of attention).

Unlike JIM.3, the CoF system operates directly on gray-level images, preprocessed by a front end that is a rough simulation of the primary visual cortex. The system illustrated in Figure 2 contains two *what* + *where* units, one (labeled "above center") responsible for the top fragment of the object (as extracted by an appropriately configured Gaussian gain field), and the other (labeled "below center") responsible for the bottom fragment. The units are trained jointly for three-way discrimination, for translation tolerance, and for autoassociation. Figure 3 shows the performance of a CoF system charged with learning to reuse fragments of the members of the training set (three bipartite objects composed of numeral shapes) in interpreting novel composite objects. The gain field mechanism allowed it to respond largely systematically to the learned fragments shown in novel locations, both absolute and relative.

The CoF model offers a unified framework for understanding the functional significance of *what* + *where* receptive fields and of attentional gain modulation. It extends the previous use of gain fields in the modeling of translation invariance, and highlights a parallel between *what* + *where* cells and probabilistic fragment-based approaches to structure representation in computer vision, such as that of Burl et al. (1998). The representational framework it embodies is both productive and effectively systematic. It is capable, as a matter of principle, of recognizing such objects that are related through a rearrangement of "middle-scale" fragments, without the need for dynamic binding, and without being taught those fragments individually. When coupled with statistical inference methods such as the Minimum Description Length principle, this model may be capable of unsupervised learning of useful fragments, an issue that is currently under investigation (Edelman and Intrator, 2001). Further testing is also needed to determine whether or not the CoF model can be scaled up to learn larger collections

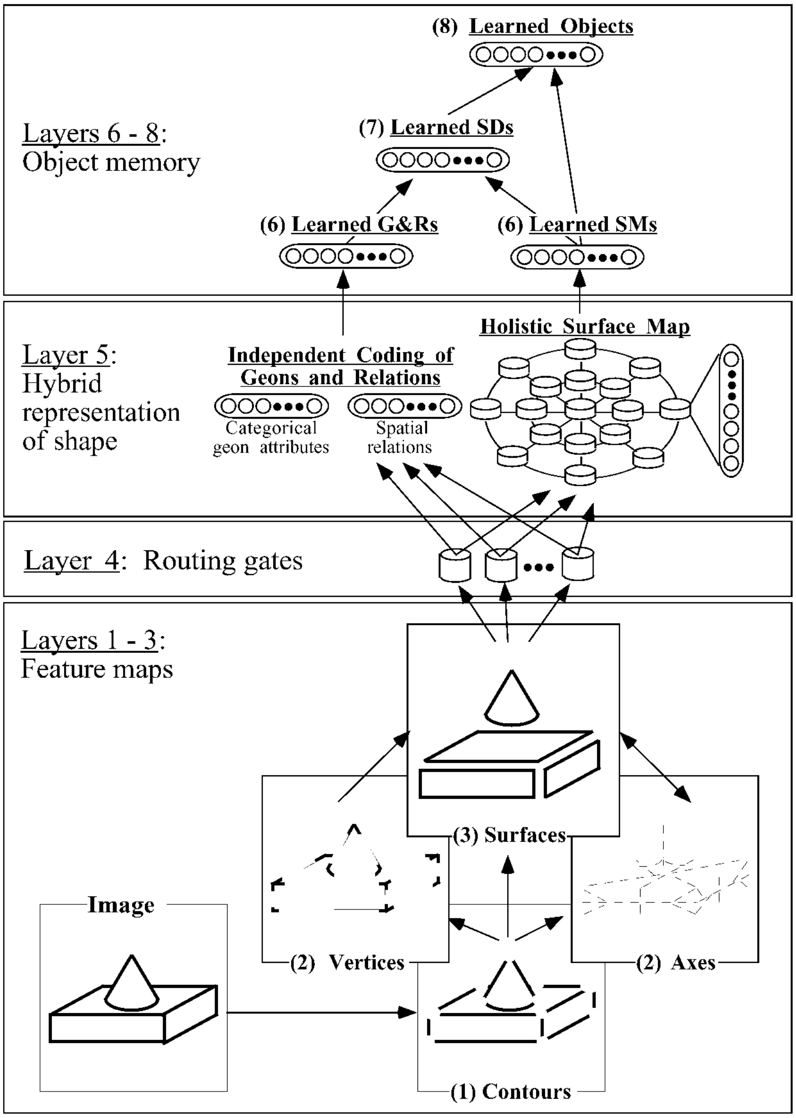

**Figure 1.** The architecture of the JIM.3 model (Hummel, 2001). The model had been trained on a single view (actually, a line drawing) of each of 20 objects—hammer, scissors, and so on—as well as on some "nonsense" objects. It was then tested on translated, scaled, reflected, and rotated (in the image plane) versions of the same images. The model exhibited a pattern of results consistent with a range of psychophysical data obtained from human subjects (Hummel, 2001). Specifically, the categorization performance was invariant with respect to translation and scaling, and was reduced by rotation. Moreover, because of the dual nature of the binding process in JIM.3—dynamic and static/retinotopic—the model behaved differently when given attended and unattended objects: reflected images primed each other in the former case, but not in the latter case. (Figure courtesy of J. E. Hummel.)

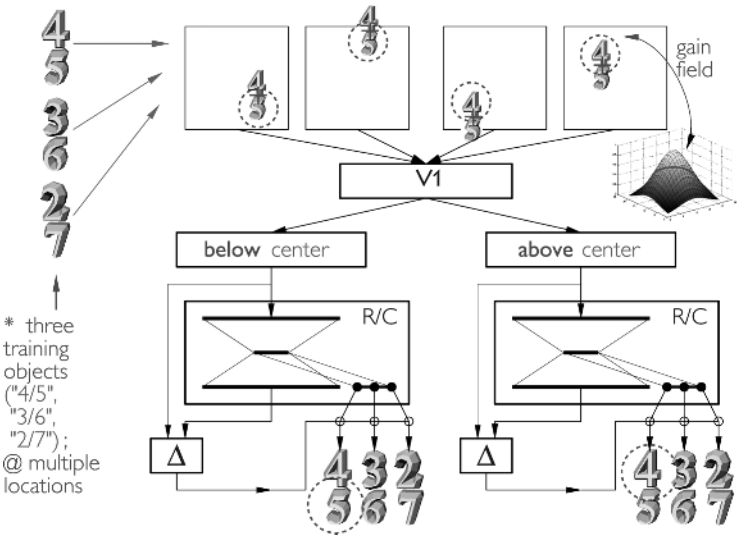

**Figure 2.** The CoF model, trained on three composite objects (numerals 4 over 5, 3 over 6, and 2 over 7). The model consists of two *what* + *where* units, responsible for the top and the bottom fragments of the stimulus, respectively. Gain fields (boxes labeled "below center" and "above center") steer each input fragment to the appropriate unit. The learning mechanism (R/C, for Reconstruction and Classification) can be implemented either as a multilayer perceptron or as a radial basis function network. The reconstruction error (Δ) modulates the classification outputs and helps the system learn binding (a coactivation pattern over units of the preceding stage will have a small reconstruction error only if both its *what* and *where* aspects are correct).

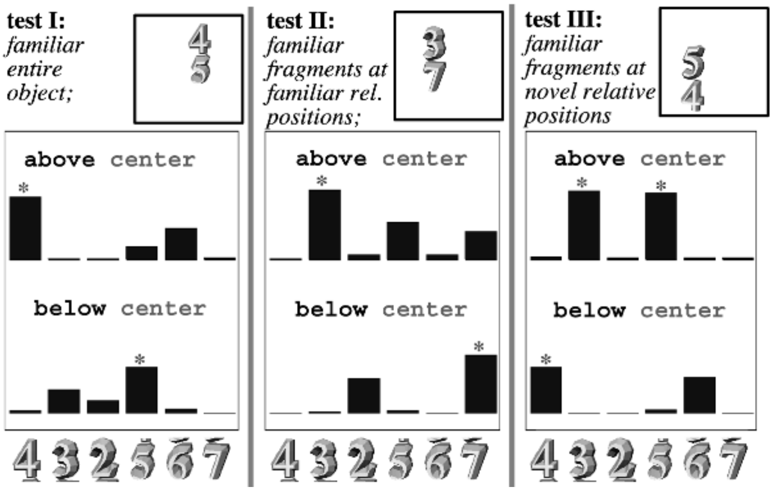

**Figure 3.** The response of the CoF model to a familiar composite object at a novel location (test I) and to novel compositions of fragments of familiar objects (tests II and III). In the test scenario, each unit ("above" and "below") must be fed each of the two input fragments ("above" and "below"); hence the 12 bars in the plots of the model's output.

of objects, and to represent finer structure, under realistic transformations such as rotation in depth.

## Conclusions

For decades, the prevalent "classical" theory of visual structure processing has been rooted in the perceived computational need for the structure of an object to be "made explicit" to enable its recognition (Marr, 1982), and by the apparent uniqueness of the compositional solution to the problems of productivity and systematicity (Fodor and McLaughlin, 1990).

The first of these two issues is made moot by recent advances in computer vision, which indicate that neither recognition nor categorization requires a prior derivation of a classical structural description. Moreover, making structure explicit may not be a good idea, either from a philosophical viewpoint or from a practical one. On the philosophical level, it embodies a gratuitous ontological commitment to the existence of object parts, which are presumed to be waiting for detection by the visual system; on the practical level, reliable detection of such parts has proved to be an elusive goal. The second issue, focusing on productivity and systematicity of structure processing, is also being transformed at present by claims that a system can be productive and systematic without relying on representations that are compositional in the classical sense (Edelman and Intrator, 2000).

The alternative stance on these issues, discussed in the preceding sections, holds that structure can be represented by a coarse code based on image fragments that are bound together by retinotopy. This notion is supported by the success of computer vision methods (such as "local photometry, global geometry"), by data from neurophysiological studies in primates (such as the discovery of *what + where* cells), and by psychological findings and metatheoretical considerations not mentioned in this article (Edelman and Intrator, 2000). In the field of neuromorphic modeling, these developments have brought about a curious convergence between an approach initially grounded in classical structural description theory (Hummel, 2001) and that derived from a holistic view of object representation (Edelman and Intrator, 2001). In this rapidly changing field, the theoretical and factual aspects of structure processing (but, we believe, not the metatheoretical ones) are likely to require reconsideration on a regular basis.

# Ocular Dominance and Orientation Columns

*Kenneth D. Miller*

## Introduction

The classic example of activity-dependent neural development is the formation of ocular dominance columns in the cat or monkey primary visual cortex (reviewed in Miller and Stryker, 1990; Crair et al., 2001; Katz and Crowley, 2002). The primary visual cortex (V1) receives signals from the lateral geniculate nucleus of the thalamus (LGN), which in turn receives input from the retinas of the two eyes (Figure 1).

To describe ocular dominance columns, several terms must be defined. First, the *receptive field* of a cortical cell refers to the area on the retina in which appropriate light stimulation evokes a response in the cell, and also to the pattern of light stimulation that evokes such a response. Second, a *column* is defined as follows. V1 extends many millimeters in each of two "horizontal" dimensions. Receptive field positions vary continuously along these dimensions, forming a *retinotopic* map, a continuous map of the visual world. In the third, "vertical" dimension, the cortex is about 2 mm in depth, and consists of six layers. Receptive field positions do not significantly vary through this depth. Such organization, in which cortical properties are invariant through the vertical depth of cortex but vary horizontally, is called *columnar* organization and is a basic feature of cerebral cortex. Finally, *ocular dominance*, or eye preference, describes the degree to which a cortical cell's responses are better driven by stimulation of one eye or the other. Like retinotopy, ocular dominance has a columnar organization: alternating stripes or patches of cortex are dominated throughout the cortical depth by a single eye, and are known as *ocular dominance columns*.

The anatomical basis for ODCs is the segregated pattern of termination of the LGN inputs to V1 (Figures 1 and 2*A*). Inputs serving a single eye terminate in alternating stripes or patches of cortex. This segregation arises early in development. Although the exact time at which ocular dominance columns emerge is currently controversial (compare Crair et al., 2001, with Katz and Crowley, 2002, noting that 2 weeks of age in cat corresponds developmentally to about 5 weeks of age in ferret), it is clear that they begin to form at least a week before the beginning of the critical period. The *critical period* is the time during which the structure of the ocular dominance columns is susceptible to alteration by altered patterns of visual experience. For example, closure of one eye during the critical period will cause that eye's patches to shrink and the open eye's patches to expand.

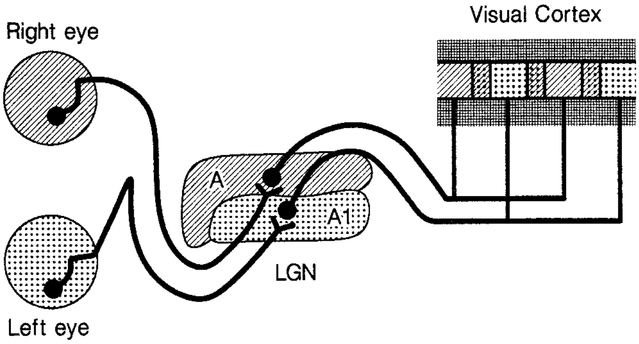

**Figure 1.** Schematic of the mature visual system. Retinal ganglion cells from the two eyes project to separate layers of the lateral geniculate nucleus (LGN). Neurons from these two layers project to separate patches or stripes within visual cortex (V1). Binocular regions (receiving input from both eyes) are depicted at the borders between the eye-specific patches. (From Miller, K. D., Keller, J. B., and Stryker, M. P., Ocular column dominance development: Analysis and simulation, *Science*, 245:605–615. © 1989 by the AAAS. Reprinted with permission.)

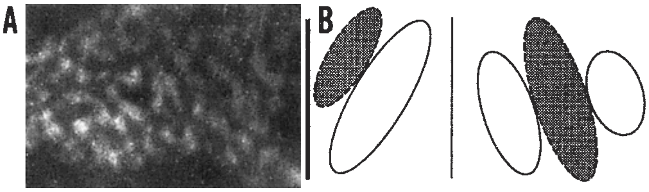

**Figure 2.** *A*, Ocular dominance columns from cat V1. A horizontal cut through the LGN-recipient layer of V1 is shown. Terminals serving a single eye are labeled white. Dark regions at edges are out of plane containing LGN terminals. Region shown is 5.3 × 7.9 mm. (Photograph courtesy of Dr. Y. Hata.) *B*, Two examples of simple cell-receptive fields (RFs). Regions of the visual field from which a simple cell receives ON-center (white) or OFF-center (dark) input are shown. Note: Ocular dominance columns (*A*) represent an alternation, across cortex, in the type of input (left or right eye) received by different cortical cells, while a simple cell RF (*B*) represents an alternation across visual space in the type of input (ON- or OFF-center) received by a *single* cortical cell.

A longstanding hypothesis is that the formation of ocular dominance columns results from an activity-instructed competition between the geniculate terminals serving the two eyes. Under this hypothesis, the signal indicating that different terminals represent the same eye is the correlation in their neural activities (reviewed in Weliky, 2000). These correlations exist because of both spontaneous activity, which is locally correlated within each retina, and visually induced activity, which correlates the activities of retinotopically nearby neurons within each eye and, to a lesser extent, between the eyes. An attractive feature of this hypothesis is that it suggests that the same mechanisms underlie both the formation of ocular dominance columns and their subsequent susceptibility to alteration by visual experience. However, one must then explain why ocular dominance columns begin forming *before* the beginning of the critical period, that is, at a time when alterations in visual experience do not influence ocular dominance column development. A possible explanation (Crair et al., 2001) is that before the critical period, the loop between cortex and LGN may dominate over the retinal input in determining LGN activities (see Weliky, 2000), so that alterations in retinal activity would have minimal effect on activity-instructed development of connections from LGN to cortex. Alternatively, it has been proposed that the initial formation of ocular dominance columns may be guided by molecular cues in cortex that label the regions appropriate for each eye's innervation (no such molecules have yet been found), and that activity only comes to play an instructive role in ocular dominance column development at the onset of the critical period (Katz and Crowley, 2002). In this article, we shall consider models of ocular dominance column formation under the first scenario, in which the initial formation of ocular dominance columns is instructed by activity.

At least during the critical period, the process guiding the segregation of ocular dominance columns is *competitive*—the two eyes compete for cortical territory based on their patterns of activity (reviewed in Miller and Stryker, 1990). If one eye is caused to have less activity than the other during the critical period, the more active eye takes over most of the cortical territory; but the eye with reduced activity suffers no loss of projection strength in retinotopic regions in which it lacks competition from the other eye. Thus, the fate of one eye's projection is not determined solely by its own activity, but rather by its activity *relative* to that of the opposite eye.

Orientation columns are another striking feature of visual cortical organization. Most V1 cells are orientation selective, responding selectively to light/dark edges over a narrow range of orientations. The preferred orientation of cortical cells varies regularly and periodically across the horizontal dimension of cortex, and is invariant in the vertical dimension. The initial development of orientation selectivity often begins before eye opening and is unaffected by whether the eyes are open or closed, but depends on normal spontaneous patterns of neural activity, while the later maturation of orientation selectivity depends on vision (reviewed in Miller, Erwin, and Kayser, 1999). The dependence of orientation selectivity on vision begins at about the same time that the critical period for ocular dominance plasticity begins, suggesting that a single set of changes renders both systems vulnerable to visual experience.

The inputs from LGN to V1 serving each eye are of two types: ON-center and OFF-center. Both kinds of cells have circularly symmetric receptive fields that are relatively insensitive to stimulus orientation, and respond to contrast rather than uniform luminance. ON-center cells respond to light against a dark background, or to light onset; OFF-center cells respond to dark against a light background, or to light offset. In the cat, the orientation-selective V1 cells that receive the bulk of LGN input are *simple cells*: cells with receptive fields consisting of alternating oriented subregions that receive exclusively ON-center or exclusively OFF-center input (Figure 2*B*). One theory for the development of orientation selectivity is that, like ocular dominance, it develops through a competition between two input populations: in this case, a competition between the ON-center and the OFF-center inputs (Miller, 1994).

## Correlation-Based Models

To understand ocular dominance and orientation column formation, two processes must be understood:

1. The development of *receptive field structure*: Under what conditions do receptive fields become monocular (drivable only by a single eye) or orientation selective?
2. The development of *periodic cortical maps* of receptive field properties: What leads ocular dominance or preferred orientation to vary periodically across the horizontal dimensions of cortex, and what determines the periodic length scales of these maps?

Typically, the problem is simplified by consideration of a two-dimensional model cortex, ignoring the third dimension, in which properties such as ocular dominance and orientation are invariant.

One approach to addressing these problems is to begin with a hypothesized mechanism of synaptic plasticity and to study the outcome of cortical development under such a mechanism. Most commonly, theorists have considered a Hebbian synapse (see HEBBIAN SYNAPTIC PLASTICITY): a synapse whose strength is increased when pre- and postsynaptic firing are correlated, and possibly decreased when they are anticorrelated. Other mechanisms can lead to similar dynamics, in which synaptic plasticity depends on the correlations among the activities of competing inputs. We refer to models based on such mechanisms as correlation-based models.

### *Von der Malsburg's Model of V1 Development*

Von der Malsburg (1973; von der Malsburg and Willshaw, 1976) first formulated a correlation-based model for the development of visual cortical receptive fields and maps. His model had two basic elements. First, synapses of LGN inputs onto cortical neurons were modified by a Hebbian rule that is *competitive*, so that some synapses were strengthened only at the expense of others. He enforced the competition by holding constant the total strength of synapses converging on each cortical cell (conservation rule). Second, cortical cells tended to be activated in *clusters*, due to intrinsic cortical connectivity, e.g., short-range horizontal excitatory connections and longer-range horizontal inhibitory connections.

The conservation rule leads to competition among the inputs to a single target cell. Inputs that tend to be coactivated—that is, that have correlated activities—are mutually reinforcing, working together to activate the postsynaptic cells and thus to strengthen their own synapses. Different patterns that are mutually un- or anticorrelated compete, since strengthening of some synapses means weakening of others. Cortical cells eventually develop receptive fields responsive to a correlated pattern of inputs.

The clustered cortical activity patterns lead to competition between different groups of cortical cells. Each input pattern comes to be associated with a cortical cluster of activity. Overlapping cortical clusters contain many coactivated cortical cells, and thus become responsive to overlapping, correlated input patterns. Adjacent, nonoverlapping clusters contain many anticorrelated cortical cells, and thus become responsive to un- or anticorrelated input patterns. Thus, over distances on the scale of an activity cluster, cortical cells will have similar response properties, while on the scale of the distance between nonoverlapping clusters, cortical cells will prefer un- or anticorrelated input patterns. This combination of local continuity and larger-scale heterogeneity leads to continuous, periodic cortical maps of receptive field properties.

In computer simulations, this model was applied to the development of orientation columns (von der Malsburg, 1973) and ocular dominance columns (von der Malsburg and Willshaw, 1976). For orientation columns, inputs were activated in oriented patterns, each pattern consisting of a stripe of inputs through a common center position. Individual cortical cells then developed selective responses corresponding to one such oriented pattern, with nearby cortical cells preferring nearby orientations. For ocular dominance columns, inputs were activated in monocular patterns consisting of a localized set of inputs from a single eye. Individual cortical cells came to be driven exclusively by a single eye, and clusters of cortical cells came to be driven by the same eye. The final cortical pattern consisted of alternating stripes of cortical cells preferring a single eye, with the width of a stripe approximately set by the diameter of an intrinsic cluster of cortical activity.

In summary, a competitive Hebbian rule leads individual receptive fields to become selective for a correlated pattern of inputs. Combined with the idea that the cortex is activated in intrinsic clusters, this suggests an origin for cortical maps: coactivated cells in a cortical cluster tend to become selective for similar, coactivated patterns of inputs. These basic ideas are used in most subsequent models.

### *Mathematical Formulation*

A typical correlation-based model is mathematically formulated as follows (von der Malsburg, 1973; Linsker, 1986; Miller and Stryker, 1990). Let $x, y, \ldots$ represent retinotopic positions in V1, and let $\alpha, \beta, \ldots$ represent retinotopic positions in the LGN. Let $S^{\mu}(x, \alpha)$ be the synaptic strength of the connection from $\alpha$ to $x$ of the LGN projection of type $\mu$, where $\mu$ may signify left eye, right eye, ON-center, OFF-center, etc. Let $B(x, y)$ represent the synaptic strength and sign of connection from the cortical cell at $y$ to that at $x$. For simplicity, $B(x, y)$ is assumed to take different signs for a fixed $y$ as $x$ varies, but alternatively, separate excitatory-projecting and inhibitory-projecting cortical neurons may be used. Let $a(x)$ and $a^{\mu}(\alpha)$ represent the activity of a cortical or LGN cell, respectively.

The activity $a(x)$ of a cortical neuron is assumed to depend on a linear combination of its inputs:

$$a(x) = f_1\left(\sum_{\mu,\alpha} S^{\mu}(x, \alpha)a^{\mu}(\alpha) + \sum_{y} B(x, y)a(y)\right) \qquad (1)$$

Here, $f_1$ is some monotonic function such as a sigmoid or linear threshold.

A Hebbian rule for the change in feedforward synapses can be expressed

$$\Delta S^{\mu}(x, \alpha) = A^{\mu}(x, \alpha)f_2[a(x)]f_3[a^{\mu}(\alpha)] \qquad (2)$$

Here, $A(x, \alpha)$ is an "arbor function," expressing the number of synapses of each type from $\alpha$ to $x$; a minimal form is $A(x, \alpha) = 1$ if there is a connection from $\alpha$ to $x$, $A(x, \alpha) = 0$ otherwise. A typical form for the functions $f_2$ and $f_3$ is $f(a) = (a - \langle a \rangle)$, where $\langle a \rangle$ indicates an average of $a$ over input patterns. This yields a *covariance rule*: synaptic change depends on the covariance of postsynaptic and presynaptic activity.

Next, the Hebbian rule must be made *competitive*. This can be accomplished by conserving total synaptic strength over the postsynaptic cell (von der Malsburg, 1973), which in turn may be done either subtractively or multiplicatively (Miller and MacKay, 1994). The corresponding equations are

$$\frac{d}{dt} S^{\mu}(x, \alpha) = \Delta S^{\mu}(x, \alpha) - \varepsilon(x)A(x, \alpha) \quad \text{(Subtractive)} \qquad (3)$$

$$\frac{d}{dt} S^{\mu}(x, \alpha) = \Delta S^{\mu}(x, \alpha) - \gamma(x)S^{\mu}(x, \alpha) \quad \text{(Multiplicative)} \qquad (4)$$

where $\varepsilon(x) = [\Sigma_{\kappa,\alpha}\Delta S^{\kappa}(x, \alpha)]/[\Sigma_{\kappa,\alpha}A(x, \alpha)]$, and $\gamma(x) = [\Sigma_{\kappa,\alpha}\Delta S^{\kappa}(x, \alpha)]/[\Sigma_{\kappa,\alpha}S^{\kappa}(x, \alpha)]$. Either form of constraint ensures that $\Sigma_{\mu,\alpha}(d/dt)S^{\mu}(x, \alpha) = 0$. Alternative approaches have been developed that lead Hebbian rules to be competitive (Miller and MacKay, 1994; Song, Miller, and Abbott, 2000).

Finally, synaptic weights may be limited to a finite range, $s_{\min}A(x, \alpha) \leq S^{\mu}(x, \alpha) \leq s_{\max}A(x, \alpha)$. Typically, $s_{\min} = 0$ and $s_{\max}$ is some positive constant.

## Semilinear Models

In semilinear models, the $f$s in Equations 1 and 2 are chosen to be linear. Then, after substituting for $a(x)$ from Equation 1 and averaging over input patterns (assuming that all inputs have identical mean activity and that changes in synaptic weights are negligibly small over the averaging time), Equation 2 becomes

$$\begin{aligned}\Delta S^{\mu}(x, \alpha) = \lambda A(x, \alpha) \sum_{y,\beta,\kappa} I(x - y)[C^{\mu\kappa}(\alpha - \beta) - k_2] \\ \times S^{\kappa}(y, \beta) + k_1 A(x, \alpha) \qquad (5)\end{aligned}$$

Here, $I(x - y)$ is an element of the intracortical interaction matrix $\mathbf{I} \equiv (\mathbf{1} - \mathbf{B})^{-1} = \mathbf{1} + \mathbf{B} + \mathbf{B}^2 + \cdots$, where the matrix $\mathbf{B}$ is defined in Equation 1. This summarizes intracortical synaptic influences, including contributions via 0, 1, 2, . . . synapses. The sum over $\kappa$ is a sum over input types. The covariance matrix $C^{\mu\kappa}(\alpha - \beta) = \langle(a^{\mu}(\alpha) - \bar{a})(a^{\kappa}(\beta) - \bar{a})\rangle$ expresses the covariation of input activities. The factors $\lambda$, $k_1$, and $k_2$ are constants. Translation invariance has been assumed in both cortex and LGN.

When there are two competing input populations, Equation 5 can be further simplified by transforming to sum and difference variables: $S^S \equiv S^1 + S^2$, $S^D \equiv S_1 - S_2$. Assuming equivalence of the two populations (so that $C^{11} = C^{22}$, $C^{12} = C^{21}$), Equation 5 becomes

$$\begin{aligned}\Delta S^{S}(x, \alpha) = \lambda A(x, \alpha) \sum_{y,\beta} I(x - y)[C^{S}(\alpha - \beta) - 2k_2] \\ \times S^{S}(y, \beta) + 2k_1 A(x, \alpha) \qquad (6)\end{aligned}$$

$$\Delta S^{D}(x, \alpha) = \lambda A(x, \alpha) \sum_{y,\beta} I(x - y)C^{D}(\alpha - \beta)S^{D}(y, \beta) \qquad (7)$$

Here, $C^S \equiv C^{11} + C^{12}$, $C^D \equiv C^{11} - C^{12}$. A similar transformation to one sum and three difference coordinates can be made in the case of four competing input populations, such as ON and OFF inputs from left and right eyes (Erwin and Miller, 1998).

## How Semilinear Models Behave

Linear equations like Equations 6 and 7 can be understood by finding the eigenvectors or "modes" of the operators on the right side of the equation. The eigenvectors are the synaptic weight patterns that grow independently and exponentially, each at its own rate. The fastest-growing eigenvectors typically dominate development and determine basic features of the final pattern, although the final pattern ultimately is stabilized by nonlinearities such as the limits on the range of synaptic weights or the nonlinearity involved in multiplicative renormalization (Equation 4).

I will focus on the behavior of Equation 7 for $S^D$. $S^D$ describes the difference in the strength of two competing input populations. Thus, it is the key variable describing the development of ocular dominance segregation, or development under an ON-center/OFF-center competition. It also is sensible to imagine that $S^D$ is initially small, and that the dynamics do not intrinsically favor either of the competing input types; under these assumptions, the initial development of $S^D$ will be described by linear equations, giving some justification for studying linear equations for the development of $S^D$.

Equation 7 can be simply solved in the case of full connectivity from the LGN to the cortex, when $A(x, \alpha) \equiv 1$ for all $x$ and $\alpha$. Then modes of $S^D(x, \alpha)$ of the form $e^{ikx}e^{il\alpha}$ grow exponentially and independently, with rate proportional to $\tilde{I}(k)\tilde{C}^D(l)$, where $\tilde{I}$ and $\tilde{C}^D$ denote the Fourier transforms of $I$ and $C^D$, respectively. The wave number $k$ determines the wavelength $2\pi/|k|$ of an oscillation of $S^D$ across cortical cells, while the wave number $l$ determines the wavelength $2\pi/|l|$ of an oscillation of $S^D$ across geniculate cells. The fastest-growing modes, which will dominate early development, are determined by the $k$ and $l$ that maximize $\tilde{I}(k)$ and $\tilde{C}^D(l)$, respectively. The peak of a function's Fourier transform corresponds to the cosine wave that best matches the function, and thus represents the "principal oscillation" in the function.

To understand these modes (Figure 3), consider first the set of inputs received by a single cortical cell, that is, the shape of the mode for a fixed cortical position $x$. This can be regarded as the "receptive field" of the cortical cell. Each receptive field oscillates with wave number $l$. This oscillation, of $S^D \equiv S^1 - S^2$, is an oscillation between receptive field subregions dominated by $S^1$ inputs and subregions dominated by $S^2$ inputs. Thus, in ocular dominance competition, monocular cells (cells whose entire receptive fields are dominated by a single eye) are formed only by modes with $l = 0$ (no oscillation). Monocular cells thus dominate development if the peak of the Fourier transform of the $C^D$ governing left/right competition is at $l = 0$, which occurs if this $C^D(\alpha)$ is a nonnegative, monotonically decreasing function of $|\alpha|$ such as a Gaussian. Now instead consider an ON/OFF competition: $S^1$ and

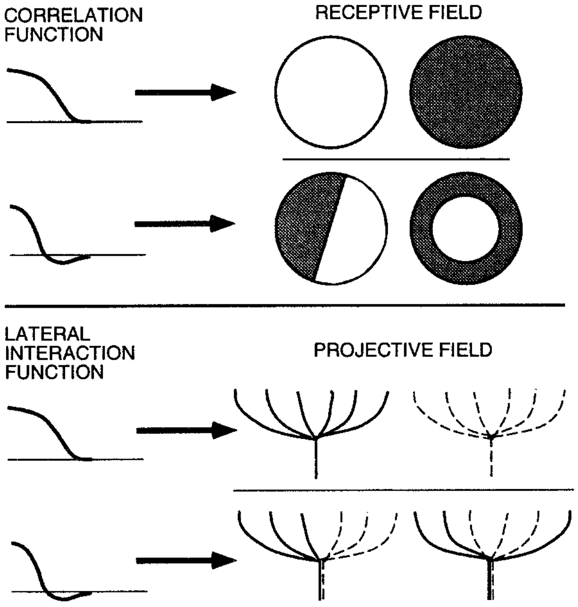

**Figure 3.** Schematic of the outcome of semilinear correlation-based development. *Top*, The correlation function ($C^D$) determines the structure of receptive fields (RFs). White RF subregions indicate positive values of $S^D$; dark subregions indicate negative values. If $C^D$ oscillates, there is a corresponding oscillation in the type of input received by individual cortical cells, as in simple cell RFs. Alternative RF structures could form, as shown, but oriented simple-cell-like outcomes predominate for reasonable parameters (Miller, 1994). When $C^D$ does not oscillate, individual cortical cells receive only a single type of input, as in ocular dominance segregation. *Bottom*, The intracortical interactions ($I$) similarly determine the structure of projective fields. Here, solid lines indicate positive values of $S^D$, dotted lines indicate negative values.

$S^2$ represent ON- and OFF-center inputs from a single eye. Then the receptive fields of modes with non-zero $l$ resemble simple cells: they receive predominantly ON-center and predominantly OFF-center inputs from successive, alternating subregions of the visual world. Thus, simple cells can form if the $C^D$ governing ON/OFF competition has its peak at a non-zero $l$, which occurs if this $C^D(\alpha)$ oscillates from positive to negative with increasing $|\alpha|$.

Now consider the arborizations or "projective fields" projecting from a single geniculate point, that is, the shape of the mode for a fixed geniculate position $\alpha$. These oscillate with wave number $k$. In ocular dominance competition, this means that left- and right-eye cells from $\alpha$ project to alternating patches of cortex. When monocular cells form ($l = 0$), these alternating patches of cortex are the ocular dominance columns: alternating patches of cortex receiving exclusively left-eye or exclusively right-eye input, respectively. Thus, the width of ocular dominance columns—the wavelength of alternation between right-eye-dominated and left-eye-dominated cortical cells—is determined by the peak of the Fourier transform of the intracortical interaction function $I$. In ON/OFF competition, with $l \neq 0$, the identity of the cortical cells receiving the ON-center or OFF-center part of the projection varies as $\alpha$ varies, so individual cortical cells receive both ON- and OFF-center input, but from distinct subregions of the receptive field.

In summary, there is an oscillation across receptive fields, with wave number $l$ determined by the peak of $\tilde{C}^D$, and an oscillation across arbors, with wave number $k$ determined by the peak of $\tilde{I}$ (Figure 3). These two oscillations are "knit together" to determine the overall pattern of synaptic connectivity. The receptive field oscillation, which matches the receptive field to the correlations, is the quantitative generalization of von der Malsburg's finding that individual receptive fields become selective for a correlated pattern of inputs. Similarly, the arbor oscillation matches projective fields to the intracortical interactions, and thus to the patterns of cortical activity clusters. This quantitatively generalizes the relationship between activity clusters and maps. Note that the factor $e^{ikx}$ can be regarded as inducing a phase shift, for varying $x$, in the structure of receptive fields. Thus, cortical cells that are nearby on the scale of the arbor oscillation have similar receptive fields, while cells ½ wavelength apart have opposite receptive fields.

The competitive, renormalizing terms (Equations 3 and 4) do not substantially alter this picture, except that multiplicative renormalization can suppress ocular dominance development in some circumstances (Miller and MacKay, 1994). These results hold also for localized connectivity (finite arbors), and thus generally characterize the behavior of semilinear models (Miller and Stryker, 1990). The major difference in the case of localized connectivity is that, if $k$ or $l$ corresponds to a wavelength larger than the diameter of connectivity from or to a single cell, then it is equivalent to $k = 0$ or $l = 0$, respectively.

## *Understanding Ocular Dominance and Orientation Columns with Semilinear Models*

This understanding of semilinear models leads to simple models for the development of ocular dominance columns (Miller and Stryker, 1990), orientation columns (Miller, 1994), and their codevelopment (Erwin and Miller, 1998), as follows.

Monocular cells develop through a competition of left- and right-eye inputs in a regime in which $\tilde{C}^D(l)$ is peaked at $l = 0$. The wavelength of ocular dominance column alternation is then determined by the peak of $\tilde{I}(k)$.

Orientation-selective simple cells develop through a competition of ON-center and OFF-center inputs in a regime in which $\tilde{C}^D(l)$ is peaked at $l \neq 0$. The mean wavelength of alternation of ON-center and OFF-center subregions in the simple cells' receptive fields is determined by the peak of $\tilde{C}^D(l)$. This wavelength corresponds to a cell's preferred spatial frequency under stimulation by sinusoidal luminance gratings. In individual modes, all cortical cells have the same preferred orientation, but their spatial phase varies periodically with cortical position. The mixing of such modes of all orientations, along with the saturating nonlinearities limiting the sizes of individual synaptic weights, leads to a periodic variation of preferred orientation across cortex.

For ocular dominance and orientation selectivity to codevelop, the two eyes must be sufficiently uncorrelated to allow ocular dominance segregation, but sufficiently correlated that preferred orientations match in the two eyes on binocular cells and that the map of preferred orientations is continuous across ocular dominance boundaries. The requirements for this to occur turn out to be simple generalizations of the above two requirements, plus an additional requirement that between-eye correlations be specific for center type (e.g., between-eye ON-ON and ON-OFF correlations should be distinct, in a manner that varies over a receptive field diameter).

This model of ocular dominance column formation is similar to that of von der Malsburg (von der Malsburg and Willshaw, 1976). The latter model assumed anticorrelation between the two eyes; this assumption was required because of the use of multiplicative renormalization (Equation 4). With subtractive renormalization (Equation 3), ocular dominance column formation can occur even with partial correlation of the two eyes (Miller and MacKay, 1994).

The model of orientation-selective cell development is quite different from that of von der Malsburg (1973). Von der Malsburg postulated that oriented input patterns lead to the development of orientation-selective cells. The ON/OFF model instead postulates that ON/OFF competition results in oriented receptive fields in the absence of oriented input patterns; the circular symmetry of the input patterns is spontaneously broken. This symmetry-breaking potential of Hebbian development was first discovered by Linsker (1986). In all of these models, the continuity and periodic alternation of preferred orientation is due to the intracortical connectivity.

The models can be compared to experiment most simply by measuring activity correlations in the LGN, such as to determine whether the ON/OFF $C^D$ has the predicted oscillation or whether the between-eye correlations have the predicted structure. Progress toward such tests is reviewed in Weliky (2000).

### *Related Semilinear Models*

Linsker (1986) proposed a model that was highly influential in two respects. First, he pointed out the potential of Hebbian rules to spontaneously break symmetry, yielding orientation-selective cells given approximately circularly symmetric input patterns. Second, he demonstrated that Hebbian rules could lead to segregation *within* receptive fields, so that a cell would come receive purely excitatory or purely inhibitory input in alternating subregions of the receptive field. Two factors underlay the results. One factor was that oscillations in a correlation function can induce oscillations in a receptive field, as described earlier. The other factor was a constraint in the model fixing the percentage of positive or negative synapses received by a cell; this constraint forced an alternation of positive and negative subregions even when the correlation function did not oscillate.

Tanaka has independently formulated models of ocular dominance (Tanaka, 1991) and orientation columns (Miyashita and Tanaka, 1992) that are similar to those described above. The major difference is that in his regime, each cortical cell comes to receive only a single LGN input. (The reason is that he works in a regime in which, on each postsynaptic cell, (1) total synaptic weight is conserved, (2) the only stable outcome is if all or all-but-one synapses are saturated at either the lower or upper bounds on synaptic weights [this is also true for linear rules with subtractive weight normalization—see Miller and MacKay, 1994—although Tanaka's rule is slightly different], and (3) there is a lower bound on synaptic weights at zero, but no upper bound. The result is that the only stable configuration is one in which one synapse acquires all of the conserved weight, and all of the other synapses are forced to the lower bound at zero.) Tanaka defines cortical receptive fields as the convolution of the input arrangement with the intracortical interaction function. This definition means that a cortical cell's receptive field is due to its single input from the LGN, plus its input from all other cortical cells within reach of the intracortical interaction function. Thus, orientation selectivity in this model arises from the breaking of circular symmetry in the pattern of inputs to different cortical cells rather than to individual cortical cells.

## The Problem of Map Structure

The models described to this point account well for basic features of primary visual cortex, including the structure of individual receptive fields and local continuity across cortex of receptive field properties. However, certain details of real orientation maps are not replicated by these models (reviewed in Erwin, Obermayer, and Schulten, 1995; Swindale, 1996). One reason may be the simplicity of the model of cortex: the real cortex has three dimensions rather than two, has cell-specific connectivity rather than connectivity that depends only on distance, and has plastic rather than fixed intracortical connections. Another reason is that the details of map structure inherently involve nonlinearities, by which the fastest-growing modes interact and compete, whereas the semilinear framework primarily focuses on early pattern formation, in which the fastest-growing modes emerge and mix randomly without interacting.

Some simple models that focus on map development rather than on receptive field development and that use reduced, feature-based representations of the input yield maps that strikingly match the structures observed in monkey visual cortex (Erwin et al., 1995; Swindale, 1996). One such model uses the self-organizing feature map (SOFM) of Kohonen (see SELF-ORGANIZING FEATURE MAPS). In the SOFM, only a single cluster of cortical cells is activated in response to a given input pattern. This is an abstraction of the idea that the cortex responds in localized activity clusters. In addition, an abstract representation of the input is used. Correlation-based models are "high-dimensional" models: the vector of input weights received by a cell has hundreds or thousands of dimensions, one for each input cell. The SOFM model of visual cortex is instead a "low-dimensional" or "feature-based" model: the vector of input weights received by a cell has only five dimensions, representing features of the visual input (two dimensions represent retinotopic position and one each represent ocular dominance, orientation selectivity, and preferred orientation). Assumptions are made as to the relative "size" of, or variance of the input ensemble along, each dimension. There is no obvious biological interpretation for this comparison between dimensions. Under certain such assumptions, Hebbian learning in the feature space leads to maps of orientation and ocular dominance that are, in detail, remarkably like those seen in macaque monkeys (Erwin et al., 1995; Swindale, 1996). (SOFMs with high-dimensional input representations have also been studied, but it is not clear whether they are any better at capturing map structure than other high-dimensional models.)

The SOFM and other feature-based models, such as those based on the "elastic net" algorithm (Erwin et al., 1995; Swindale, 1996), lead to locally continuous mappings in which a constant distance across the cortex corresponds to a roughly constant distance in the reduced "input space." This means that, when one input feature is changing rapidly across cortex, the others are changing slowly. Thus, the models predict that orientation changes rapidly where ocular dominance changes slowly, and vice versa. This feature may be key to replicating the details of macaque maps. However, recent results suggest that this relationship may not hold between retinotopy and orientation in cat visual cortex (Das and Gilbert, 1997).

A possibly related approach to map organization supposes that the structure of maps is determined by evolutionary pressure to minimize the wire length of neuronal connections (Chklovskii and Koulakov, 2000; Koulakov and Chklovskii, 2001). Assuming a certain "connectivity function," specifying probabilistically which cells should connect to which, a feature map that allows such connectivity to be achieved with minimal wire length is computed. For certain forms of the connectivity function, orientation maps are obtained with pinwheels—point singularities around which preferred orientation rotates by 180 degrees—much as in real maps (Koulakov and Chklovskii, 2001). The model predicts that the ocular dominance map should go from a stripe-like structure to a patch-like structure when one eye contributes less than 40% of the total innervation, and just such a transition at about the appropriate point is seen in monkey visual cortex (Chklovskii and Koulakov, 2000).

Another approach to studying map development is based on very general assumptions as to symmetries of the map-formation process. It was shown that any of a large class of developmental models of orientation selectivity that obey a few basic symmetries and that produce a periodic map of preferred orientation with period $\lambda$ should produce an initial density of pinwheels of at least $\pi$ per $\lambda^2$ (Wolf and Geisel, 1998). Comparison with actual maps showed a range of densities from 2 to 4, suggesting that if real maps develop by a self-organizing process, those with densities less than $\pi$ must undergo reorganization involving pinwheel annihilation during early development. It will be exciting if such pinwheel annihilation should be observed, although it is possible that such annihilation might occur only before maps become visible with current methods.

## Open Questions

Among the many open questions in the field are these: How can biologically interpretable developmental models replicate the details of cortical maps? How might more realistic models of Hebbian learning and of competition (e.g., Song et al., 2000) modify the basic insights into development obtained by studying simple semilinear models? How will these insights, which apply to development of feedforward connections, be modified by considering codevelopment of feedforward and intracortical synaptic innervations? (See Song and Abbott, 2001, and Kayser and Miller, 2002.) How will they be modified by developing models that learn on temporal as well as spatial correlations? The simple models have yielded real insights, but the field now seems prepared to enter more complex terrain.

# Olfactory Bulb

*Andrew P. Davison and Gordon M. Shepherd*

## Introduction

The olfactory bulb is the second stage in the olfactory pathway. It receives input from the sensory neurons in the olfactory epithelium and sends its outputs to the olfactory cortex, among other brain regions. The bulb is of special interest to neural modelers. It was one the first regions of the brain for which compartmental models of neurons were constructed, which led to some of the first computational models of functional microcircuits. The aim of this article is to give an overview of (1) olfactory bulb cells and circuits, (2) current ideas about the computational functions of the bulb, and (3) modeling studies to investigate these functions. Together with the article on the Olfactory Cortex (q.v.), this material provides an introduction to the nature of information processing in the olfactory system.

## Cells and Circuits

### Olfactory Sensory Input

The first stage in the vertebrate olfactory pathway is the detection of odor molecules by olfactory sensory neurons (OSNs). Odor molecules bind to olfactory receptor proteins (ORs), leading to the generation of receptor potentials, which are converted into action potentials. There are genes for several hundred to more than a thousand ORs in mammalian genomes. Each OSN expresses only one of these proteins. The axons of OSNs project to the olfactory bulb, where they form synapses with the dendrites of olfactory bulb neurons in spherical regions of neuropil called glomeruli. There are 1,000–2,000 glomeruli in a rodent olfactory bulb. The subset of OSNs expressing the same OR type all project their axons to the same glomeruli, generally one on the medial side and one on the lateral side of the bulb. Furthermore, since it appears that each glomerulus receives axons from only a single type of receptor neuron, there is a one-to-one mapping between a glomerulus and an OR type.

An odor molecule typically binds to many ORs, with varying affinities, and therefore activates many glomeruli to different degrees. Since the olfactory bulb is a laminar structure, there is a mapping from 1,000-dimensional odor space (one dimension per OR) to two-dimensional neural space.

### *The Basic Circuit of the Olfactory Bulb*

There are two distinct levels of synaptic interactions in the olfactory bulb, the glomerular layer and the external plexiform layer (EPL) (Figure 1). These layers can be regarded as levels of input processing and output control, respectively.

Within the glomeruli, OSN axons make excitatory synapses onto the distal dendritic tuft of mitral, tufted, and periglomerular (PG) cells. Mitral and tufted (M/T) cells make excitatory dendrodendritic synapses onto PG cells. PG cells make inhibitory dendrodendritic synapses onto M/T cells and probably onto other PG cells. PG cells also send axons to neighboring glomeruli, where they form inhibitory synapses onto M/T cell dendrites.

The secondary dendrites of M/T cells extend long distances laterally in the EPL, up to half of the circumference of the bulb for mitral cells. There is evidence that action potentials can propagate from the soma to the very tips of these dendrites. M/T secondary dendrites make reciprocal, dendrodendritic synapses with granule cells, which are anaxonal interneurons. These reciprocal synapses consist of an excitatory synapse from M/T cells onto granule cell spines paired with an inhibitory synapse from the spine onto the M/T cell dendrite.

The effects of the dendrodendritic synapses are strongly affected by the intrinsic properties of the cells, particularly the granule cells. First, the synapses are onto spines, so a small current can produce a large local membrane depolarization. Second, the granule cell dendrites contain an A-type potassium current, which prevents short-duration synaptic inputs from producing an action potential. Granule cell action potentials may not be required for recurrent inhibition of the M/T cells; glutamate released by the M/T cell depolarizes the granule cell spine sufficiently to produce GABA release, which then inhibits the M/T cell. In mitral cells, subthreshold membrane potential oscillations may interact with postsynaptic potentials to gate the times at which action potentials occur.

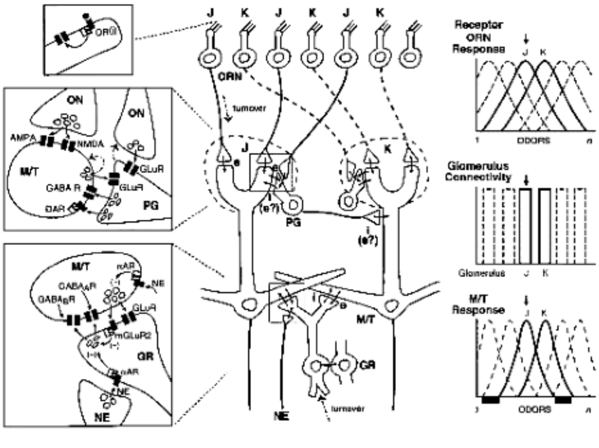

**Figure 1.** Basic circuit for the olfactory bulb. Abbreviations (left, molecular components): OR, olfactory receptor; ON, olfactory nerve; AMPA, 2-amino-5-phosphonovaleric acid; NMDA, *N*-methyl-D-aspartate; M/T, mitral/tufted cell; PG, periglomerular cell; GluR, ionotropic glutamate receptor; GABA R, $\gamma$-aminobutyric acid receptor; DAR, dopamine receptor; NE, norepinephrine; $\alpha$AR, $\alpha$-adrenoreceptor; mGluR2, metobotropic glutamate receptor; GR, granule cell. Middle (synaptic circuit): ORN, olfactory receptor neuron; J, K, ORN subsets; e, excitatory; i, inhibitory. Right (structure-function relations) top: overlapping response spectra of ORNs to a range of odors ($1 - n$); middle: connectivity of subsets to individual glomeruli; bottom: response spectra of M/T cells show less overlap because of lateral inhibition (black bars below abscissa).

M/T cells exhibit autoexcitation due to diffusion of synaptically released glutamate to extrasynaptic ionotropic and metabotropic receptors on both primary and secondary dendrites. This can lead to very prolonged responses to excitatory input. M/T cells do not make chemical synapses with other M/T cells. However, several studies have recently demonstrated functional excitatory connections between mitral cells, probably due again to glutamate spillover to extrasynaptic receptors. M/T cells give off collaterals in the granule cell layer.

Mitral cells send axons to several basolateral brain regions, including the piriform cortex (primary OLFACTORY CORTEX) and the amygdala. The projections of tufted cells are more limited. Centrifugal inputs from several brain areas include cholinergic, serotonergic, and noradrenergic pathways. These inputs mostly terminate on granule and PG cells to influence neuronal excitability and neurotransmitter release. They are critical in setting the behavioral state of the whole system.

## Compartmental Models of Olfactory Bulb Neurons

Wilfrid Rall introduced the compartmental method for computational modeling of neurons in 1964 (see PERSPECTIVE ON NEURON MODEL COMPLEXITY). Motoneurons in the spinal cord and mitral and granule cells in the olfactory bulb (Rall and Shepherd, 1968) were the first neurons to be modeled using this approach. Both active and passive dendritic properties were explored in these models. These studies have been extended by compartmental models in which the distribution of active properties in the dendritic trees has been assessed by systematic parameter searches (Bhalla and Bower, 1993). A limitation of earlier studies is that the physiological data were obtained from single-point recordings in the soma, so distal parts of the neurons (e.g., the mitral cell primary dendrite tuft) are much less well constrained than the soma and proximal parts.

Recently, more tightly constrained models have been made possible by experimental data obtained from single- and dual-patch recordings from the soma and from distal sites on the primary dendrite. These studies have shown that full action potentials are generated throughout the primary dendrite, supported by an even distribution of fast Na and K conductances. The M/T cell primary dendrite supports the backpropagation of action potentials from the soma to the tuft. Under conditions of moderate to strong ON input and/or somatic inhibition, action potentials can be initiated in the tuft and propagate in the forward direction to the soma.

These properties have been closely simulated by a tightly constrained compartmental model of the mitral cell (Shen et al., 1999). The results provide one of the best models, in a vertebrate central neuron, of the shifting sites of action potential initiation dependent on the integration of excitatory and inhibitory synaptic inputs with active membrane properties. They support a wide range of studies giving evidence of the importance of active properties of distal dendrites in neuronal function. This gives added emphasis to the importance of the contributions of distal dendrites to the basic circuits for different brain regions, which need to be incorporated into neural networks in order to fully capture the mechanisms used by the real nervous system.

Compartmental models of granule cells have shown that high-input-resistance spines and low levels of activity favor reciprocal over lateral inhibition; conversely, lower-input-resistance spines and high levels of activity favor lateral inhibition (Antón, Granger, and Lynch, 1993), and that with entirely passive membrane in a morphologically detailed model, "the degree of spread of synaptic potentials can define functionally related subsets of spines within the dendritic tree . . . that can mediate discrete localized inhibition onto subsets of mitral or tufted cell secondary dendrites" (Woolf, Shepherd, and Greer, 1991).

## The Computational Functions of the Olfactory Bulb

As the first stage of synaptic processing in the olfactory pathway, the olfactory bulb carries out several key functions.

### *Glomeruli Contribute to Odor Detection*

A mechanism that has long been recognized for supporting odor detection is the tremendous convergence of OSNs onto glomeruli. In mammals, the convergence ratio is of the order 10,000:1. As noted earlier, it is believed from axon-labeling studies that all of the OSNs expressing a given OR converge onto one or two common target glomeruli. Thus, at the lowest concentrations, when only the highest-affinity receptor type is activated, all odor responses are concentrated on a single pair of glomeruli.

### *Spatial Maps Mediate Odor Recognition*

A given odor activates a particular set of OR types. The set of activated ORs is mapped onto a two-dimensional pattern of activated glomeruli. These patterns have been visualized by a large number of imaging techniques (see Xu, Greer, and Shepherd, 2000, for a review). The responses to different odor stimuli have also been characterized. These studies have shown that odor molecules that are structurally similar activate glomeruli that are near one another, and the patterns of activation for different odorants generally overlap considerably. There is thus increasing support for the hypothesis that odor recognition is based on patterns characteristic for given odors.

### *Odor Maps Encode Odor Concentration*

Odor mapping methods show that increasing odor concentration recruits increasing numbers of activated glomeruli, as the higher concentrations cause binding of additional ORs with lower affinities in OSNs projecting to other glomeruli (see Xu et al., 2000). Thus, odor concentration appears to be encoded at least in part by the number of activated glomeruli, and probably also by the intensity of their activation. Modeling studies have suggested that odor intensity could additionally be encoded by the number of M/T cells within a glomerulus that are firing (Antón, Lynch, and Granger, 1991). Experimentally, there is a gradient of decreasing excitability from tufted to mitral cells, so that increasing odor intensity will recruit additional neurons to fire. An argument against this hypothesis is the observation that M/T cells have different projection patterns and so are not a single population for the purpose of transmitting information to cortex.

### *Temporal Structure Encodes Odor Concentration*

Time may also be used as a dimension for encoding stimulus intensity. First, the temporal firing pattern of M/T cells changes as odor concentration is increased. Second, time delays may be used to encode odor intensity. White et al. (1998) developed a network model of the olfactory bulb that receives input from an array of fiber-optic chemodetectors constituting an artificial nose. The network functions as a delay line neural network in which odor identity is encoded by spatial pattern and odor intensity by response delay. This network outperforms standard feedforward neural networks in discriminating odors when limited training sets are used. This work represents an important practical application of neural networks in the olfactory system for artificial chemosensing systems, with applications in industry and for detecting narcotics and hidden explosives.

### *Lateral Inhibition Mediates Odor Discrimination*

A critical function of olfactory bulb circuits is to contribute to the neural basis for discrimination between different odors. As we have seen, the responses to different odors are carried in some 2,000 parallel glomerular pathways. Discrimination between odors requires circuits that can compare the patterns of responses across the pathways and extract the differences.

A key operation for mediating odor discrimination is reducing the overlap between the representations of different odors. Strongly activated mitral cells suppress the activity of more weakly activated mitral cells by lateral inhibition, mediated through the dendrodendritic synapses with granule and periglomerular cells. This sharpens the tuning curves of mitral cells connected to a given glomerulus. This is equivalent to reducing the overlap between the affinity spectra (the molecular receptive ranges) of the individual glomeruli. This was demonstrated experimentally by Yokoi, Mori, and Nakanishi (1995), who found that affinity spectra for a series of aldehydes were broadened by blocking lateral inhibition, presumably mediated through granule cells.

The distinction between the roles of granule and PG cells in mediating lateral inhibition has been investigated in an olfactory bulb model developed by Linster and Hasselmo (1997): PG cell activity affects the number of active mitral cells, while granule cell activity determines the response intensity of active mitral cells. Both granule and PG cell activities may be controlled by centrifugal inputs. The result of the two levels of lateral inhibition is to make the odor representation more sparse.

A complementary mechanism for reducing overlap is to add temporal structure to the responses (i.e., two odors may activate the same ensembles of cells, but at different times) by way of the lateral interactions. Adding time as an extra dimension gives more space in which to separate out odors. Experimentally, the response patterns of mitral cells have complex temporal structures. Laurent et al. (2001) have introduced a dynamical systems model of the olfactory bulb/antennal lobe in which the state of the system, represented by the instantaneous firing rates of the projection neurons, follows a heteroclinic orbit in phase space. Orbits starting from nearby starting points (representing similar odorants) diverge rapidly, thus allowing easier discrimination between them. Experimentally, they provide evidence in zebrafish that an initially "clustered" representation becomes declustered with time.

### *Temporal Correlations May Contribute to Odor Discrimination*

It has been suggested that one function of the bulb is to introduce temporal correlations, such as spike synchronization, between the signals from different receptors responding to the same odor (Laurent et al., 2001). If the olfactory cortex has cells that are tuned as "coincidence detectors," this could increase the salience of mitral cells that are synchronized relative to unsynchronized cells. Gamma-frequency, odor-induced oscillations in local field potential (LFP) recordings have been reported in the olfactory bulbs of vertebrates and in the antennal lobes of insects. These oscillations are thought to reflect the rhythmical, synchronous firing of populations of neurons. In insects and rabbits, the spiking of individual neurons is phase-locked to the LFP, and spiking in simultaneously recorded pairs of neurons is often closely synchronized. Oscillations with different (sometimes harmonically related) frequencies may be elicited in different regions of the olfactory bulb. In insects, different subpopulations of neurons may be synchronized with the global oscillation at different periods during the response (see Laurent et al., 2001). In honeybees, oscillatory synchronization has been shown to have functional relevance: pharmacologically induced desynchronization impairs the ability to discriminate between similar odorants but has no effect on discrimination of dissimilar odorants (see Laurent et al., 2001).

### *Synaptic Modification Produces a Transformation of Odor Space*

Not all synapses are equal in strength. Therefore, the firing of some cells will have a larger influence on bulb output than others. The strength of synapses may be changed by mechanisms of synaptic plasticity during learning experiences. For example, recordings of mitral cell activity in the olfactory bulb of sheep before and after giving birth showed that before parturition, the majority of cells responded preferentially to food odors, and after parturition, the majority responded preferentially to lamb odors (Kendrick, Lévy, and Keverne, 1992). Accompanying this change in preference were increases in neurotransmitter release in the bulb. It appears, therefore, that a function of the bulb is to produce a mapping between the input, physical/chemical odor space and the output, neural odor space, such that behaviorally important odors cover a larger region of output space, enhancing the ability of the system to discriminate between similar odors. Odors with less behavioral significance would be mapped to a reduced region of output space. Changes in synaptic strengths can alter this mapping. In the case of the sheep, synaptic changes in the bulb increased the representation of lamb odors in output space at the expense of the extent of output space representing food odors.

## Realistic Network Models

Several models have been developed that attempt to reproduce the anatomy and physiology of real cells and synapses and the connectivity of the real olfactory bulb network without any a priori idea of how the network should behave.

White et al. (1992) have investigated how responses of olfactory bulb neurons to electrical or odor stimulation may be shaped by microcircuit interactions in the salamander olfactory bulb. The total number of cells in the model is 1,000-fold fewer than found in the real system, but the ratios between the populations are maintained. Mitral cells are modeled with three compartments (soma and two dendritic tufts) using standard cable equations. Granule and PG cells are represented by single compartments. Presynaptic spikes and/or subthreshold increases in membrane potential trigger postsynaptic conductance changes. In simulations, each of the major types of response seen in electrophysiological recordings of salamander cells is reproduced by varying the spatial pattern of activity applied to the receptor cells (Figure 2).

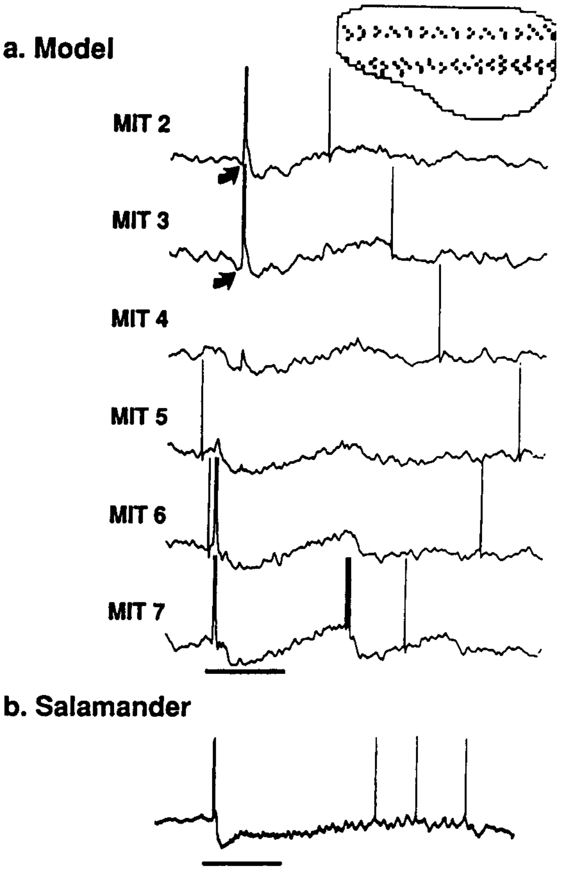

**Figure 2.** Odor stimulation of modeled mitral (MIT) cell responses (MIT 2–7) (*A*) compared with experimental recordings (*B*). Note the pattern of excited receptor cells in the receptor sheet in the inset at top. Arrows in *A* indicate a brief hyperpolarization that is also seen in experimental recordings. (From White, J., Hamilton, K. A., Neff, S. R., and Kauer, J. S., 1990, Emergent properties of odor information coding in a representational model of the salamander olfactory bulb, *J. Neurosci.*, 12:1772–1780. Reprinted with permission.)

Davison, Feng, and Brown (2003) simulated a network of 100 mitral cells and 15,000 granule cells using simplified versions of the models of Bhalla and Bower (1993) and realistic synaptic conductances. This model network displayed properties of center-surround inhibition that are consistent with the experimental findings of Yokoi et al. (1995) (Figures 3*A–D*). The model also displayed synchronization between mitral cells in response to odor inputs, as seen in the rabbit olfactory bulb and similar to the synchronization seen in the insect antennal lobe (Figure 3*E*). Weakly activated mitral cells fire less frequently than, but always synchronously with, strongly activated cells. Nearby cells synchronize more readily than widely separated ones. These findings also demonstrate the central role of the dendrodendritic synapses in generating both the spatial and the temporal properties of the network behavior.

Bazhenov et al. (2001) have developed a realistic model of the locust antennal lobe based on single-compartment cell models with ionic currents chosen to generate realistic firing profiles. The model reproduces the phenomena of transient oscillatory synchronization and slow temporal patterning seen in experimental recordings. The fast excitatory/inhibitory connections between local neurons (LNs) and projection neurons (PNs) were found to be necessary for network oscillations, while inhibitory connections between LNs were needed to make the synchronization transient. Adding slow inhibitory synapses from LNs to PNs was sufficient to produce the slow temporal patterns.

## Discussion

The olfactory bulb has a simple structure that has made it attractive for analysis of microcircuit organization and models of neural circuits. For brain theorists, its organization offers examples of information processing without impulses and of output functions of dendrites, which has forced new concepts of the neuron as a complex computational unit. It provides unique opportunities for correlating

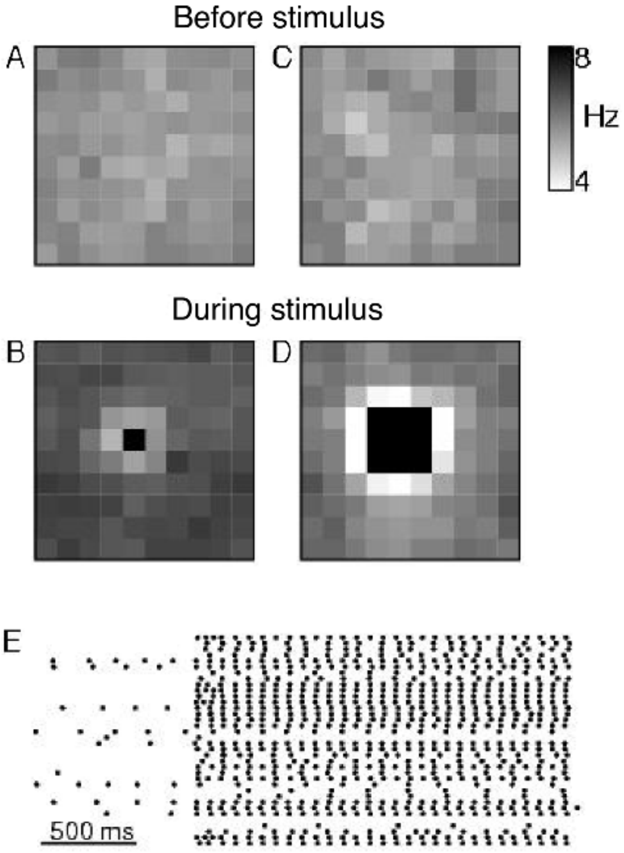

**Figure 3.** Lateral inhition and stimulus-induced synchronization in an olfactory bulb model. (*A–D*), 10 × 10 array of mitral cells with uniform background activity. The gray-scale value of each square represents the mean firing rate, averaged over 2 s of simulation. Firing rates above 8 Hz are represented by black. Firing rates below 4 Hz are represented by white. *A* and *C*, The background firing rate, before stimulus onset. *B*, Stimulation of a single mitral cell. The firing rates of neighboring cells are depressed by about 1.5 Hz relative to the bulk of the mitral cell population. *D*, Stimulation of a 3 × 3 block of mitral cells. The firing rates of cells neighboring this block are depressed by about 3 Hz relative to the bulk of the population. *E*, Raster plot for a 6 × 6 array of mitral cells. Each dot represents an action potential. Each line is a different mitral cell. The cells are unsynchronized prior to stimulus onset. The stimulus increases the degree of synchronization in the network. (From Davison, A. membrane and cellular properties with network functions, thus pointing the way toward a deeper understanding of the neural basis of network functions. The main challenge for the future is to understand how the spatial and temporal aspects of the olfactory responses interact in olfactory information processing.

# Olfactory Cortex

*Christiane Linster, Michael E. Hasselmo, Matthew A. Wilson, and Gordon M. Shepherd*

## Introduction

The olfactory cortex has traditionally played an important role in theoretical studies of cortical function. It is the earliest cortical region to differentiate in the evolution of the vertebrate forebrain. It is the only region within the forebrain to receive direct sensory input. The olfactory input processed by the cortex dominates the behavior of most vertebrate species. Thus, the role of the olfactory cortex is critical for the evolution of much of vertebrate behavior. Finally, the olfactory cortex has the simplest organization among the main types of cerebral cortex. These features have suggested that the olfactory cortex may serve as a model for understanding basic principles underlying cortical organization.

The olfactory pathway begins with the olfactory receptor neurons in the nose, which project their axons to the olfactory bulb. The function of the Olfactory Bulb (q.v.) is to perform the initial stages of sensory processing of the olfactory signals before sending this information to the olfactory cortex. The olfactory cortex is defined as the region of the cerebral cortex that receives direct connectons from the olfactory bulb (Figure 1). It is subdivided into several areas that share a basic organization but are distinct in terms of details of cell types, lamination, and sites of output to the rest of the brain. The main area involved in olfactory perception is the piriform (also called prepiriform) cortex (Figure 1), which projects to the mediodorsal thalamus, which in turn projects to the frontal neocortex. This is often regarded as the main olfactory cortex, and is the subject of this article.

## Evolutionary Significance of the Olfactory Cortex

For brain theorists interested in principles of cortical organization, the early appearance of the olfactory cortex in phylogeny deserves attention. The cerebral cortex first appears in vertebrate evolution in fishes as a simple structure composed of three layers: a superficial layer containing incoming nerve fibers, dendrites of intrinsic and output neurons, and scattered cell bodies of interneurons; a layer of the large cell bodies of output neurons; and a deep layer of interspersed input and output fibers, and scattered cell bodies of interneurons. This is the classical three-layered cortex. The cortex on the ventrolateral surface that receives direct olfactory input from the olfactory bulb is termed *paleocortex*, which is the olfactory cortex as described above. On the medial surface is another part related to the septum, termed *archicortex*; this is the anlage of the hippocampus in higher vertebrates. On the dorsal surface is the so-called dorsal cortex, generally believed to be the anlage of neocortex.

During phylogeny, the paleocortex and archicortex develop in extent and complexity but retain their three-layered character. Neocortex, however, emerges in mammals as a five- to six-layered structure. It is controversial among evolutionary neurobiologists whether the dorsal cortex can in fact be considered an early representation of neocortex or whether it is more properly considered an anlage, i.e., a predecessor of true neocortex. In reptiles, such as turtles, this dorsal cortex has become sufficiently differentiated to serve as the visual cortex for visual input relayed from the thalamus. Whether this can be regarded as a true "primary" visual cortex, homologous to primary visual cortex in the mammal, or whether it is only a primitive anlage of primary visual cortex is a matter for debate.

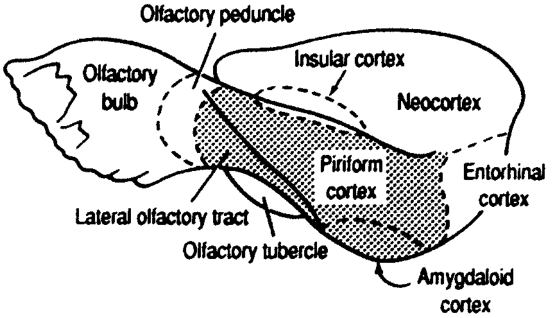

**Figure 1.** The relation of the olfactory cortex to the main components of the olfactory pathway. (From Haberly, L. B., 1990, Olfactory cortex, in *The Synaptic Organization of the Brain* (G. M. Shepherd, Ed.), New York: Oxford University Press. Reprinted with permission.)

With the rise of modern studies of synaptic organization, it was hypothesized that comparisons between brain cortical regions in phylogeny should focus less on the numbers of layers and more on the particular types of circuits that are present and the functions that they mediate (Shepherd, 1998). We will therefore identify the main types of circuits that are present in the olfactory cortex. We will then describe compartmental and network models, and discuss the insights gained from these models into olfactory processing and their relevance for understanding general properties of cortical networks.

## Basic Circuit for Olfactory Cortex

The concept of a basic or "canonical" circuit is of critical importance for computational neuroscience and brain theory. The basic circuit combines the results of anatomical, physiological, neurochemical, and computational studies into a consensus representation of the main circuits in a particular region (Shepherd, 1998). This objective is facilitated by the extent to which the region in question has distinct layers, clearly differentiated cell types, and readily characterizable inputs. Of all cortical regions, the olfactory cortex best satisfies these criteria.

Our current understanding of the olfactory cortex basic circuit has arisen from a series of anatomical, physiological, and pharmacological studies. The current consensus model is summarized in Figure 2. The main features of the basic circuit include the following.

The primary sensory input (through the lateral olfactory tract from the olfactory bulb) makes its synapses on the most distal parts of the apical dendrites of the pyramidal neurons. This continues the pattern present in the earlier stages of the olfactory pathway, in which primary sensory input is delivered to the most distal parts of the dendrites of the sensory neurons, and their axons in turn make synapses on the most distal dendrites of their targets, the mitral/tufted cells of the olfactory bulb. Thus, distal dendrites, rather than being sites for weak background modulation of neuronal activity, are the preferred sites for rapid transmission of specific sensory transmission from neuron to neuron in this pathway. This fact is critically important for brain theorists and neural modelers, because it means that the specific properties of distal dendrites must be included in network models in order to represent the mechanisms of processing. The properties of dendrites are discussed in Perspective on Neuron Model Complexity.

The distal inputs in olfactory cortex are made exclusively onto dendritic spines of the apical dendrites. These are very small branches, only a micron or so in length and 0.1–0.2 $\mu$m in diameter, terminating in a head (1–2 $\mu$m across) that receives an excitatory synapse. Spines are of considerable current interest as sites for activity-dependent mechanisms, such as long-term potentiation (LTP), that may underlie learning (reviewed in Shepherd, 1998). Both the afferent excitatory inputs and the recurrent excitatory inputs are made to spines, and both show properties of LTP.

The intrinsic cortical circuits for processing information consist of inhibitory and excitatory local circuits. The inhibitory circuits are of two types: those for feedforward inhibition and those for feedback (lateral) inhibition, as indicated in Figure 2. A given interneuron may be involved exclusively in one of these types, or it may be a node for convergence and integration of both types. The excitatory circuits provide not only for the excitation of the inhibitory interneurons in the feedback (lateral) pathway, but also for direct recurrent excitation of other pyramidal neurons. These intrinsic excitatory and inhibitory inputs are made to different regions

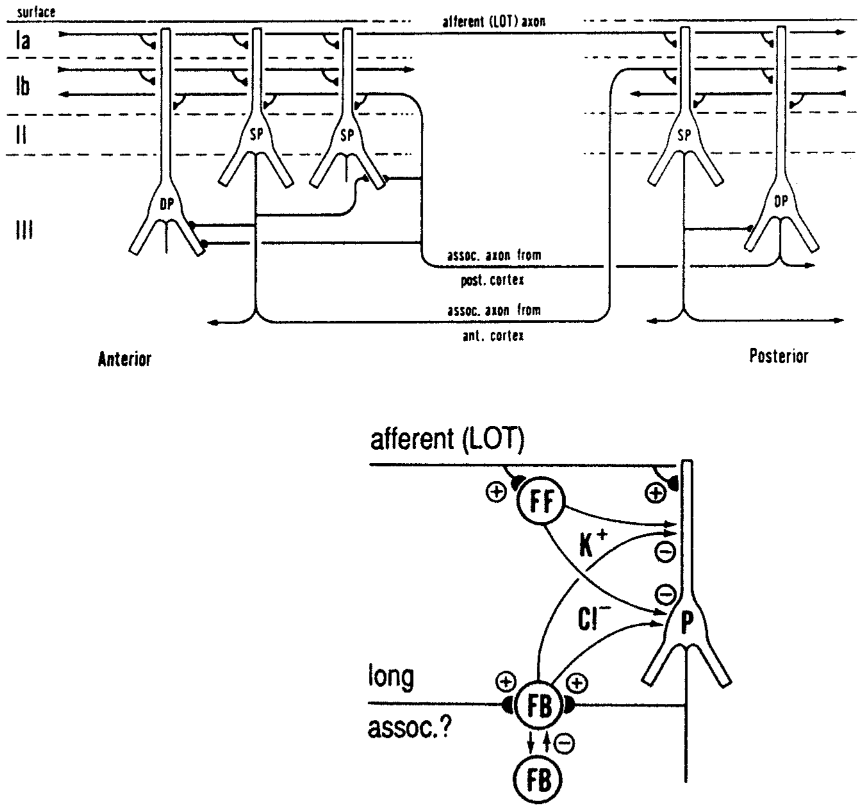

**Figure 2.** The basic circuit of the olfactory cortex. FF, feedforward; FB, feedback; P, pyramidal neurons, superficial (S) and deep (D). (From Haberly, L. B., 1990, Olfactory cortex, in *The Synaptic Organization of the Brain* (G. M. Shepherd, Ed.), New York: Oxford University Press. Reprinted with permission.)

and levels of the apical and basal dendritic trees of the pyramidal neurons. Thus, in the case of apical dendrites, these inputs can gate the transfer of the specific sensory responses in the distal dendrites to the soma.

The essential elements of the olfactory cortex basic circuit can thus be summarized as follows: (1) pyramidal output neurons, with apical and basal dendritic fields; (2) differentiation of pyramidal neurons into subtypes in sublayers; (3) reception of excitatory inputs by dendritic spines; (4) different modes of input driving: direct excitation, feedforward inhibition; (5) intrinsic recurrent axon collaterals for feedback and lateral inhibition; (6) intrinsic recurrent axon collaterals for feedback and lateral excitation; and (7) lamination of inputs to the dendritic trees of pyramidal neurons. Taken together, these constitute a unique set of circuit elements that not only is characteristic of olfactory cortex but also is shared with the other type of three-layered cortex, the dentate-hippocampal complex. Furthermore, these elements are also embedded in most regions of neocortex, where they are further elaborated into additional layers, additional subtypes of neurons and internal circuits, and additional types of inputs and outputs (see Shepherd, 1998).

## Network Models of Olfactory Cortex

The first suggestion that olfactory cortex could serve as a simple model for learning and memory in cortical networks was made by Lewis Haberly. In a landmark paper (Haberly, 1985), he described the features of the olfactory cortex outlined above, and pointed out that this organization, distributed in a broad sheet, would subserve the functions of a cortex with content-addressable memory. The critical features were the widespread distribution of inputs by the input fibers and the presence of recurrent excitation, providing for a wealth of combinatorial possibilities for activation and reactivation of the cortical circuits. He further pointed out the possible similarities between processing of the olfactory input by olfactory cortex and processing of complex visual stimuli in the face area of the neocortex.

These suggestions stimulated studies by several laboratories that have established the olfactory cortex as an attractive subject for network models of cortical functions. We will summarize briefly some of the main studies to date.

Ambros-Ingerson, Granger, and Lynch (1990) drew on the basic olfactory circuit to discuss the principles of a model of piriform (olfactory) cortex that would function as an associative memory network having the ability to identify conjunctions of odor components that constitute complex odors. The role of piriform cortex in olfactory memory was contrasted with the role of the hippocampus in maintaining or enabling the establishment of long-term olfactory associations. A reduced model of the basic olfactory circuit was described that incorporated properties of LTP and that implements a "combinatorial memory system." In this model, during learning, novel combinations of stimulus features result in unique representations. Complex stimuli composed of previously experienced odor components produce a response that is biased toward the existing representations within the cortex. It was proposed that piriform cortex could be regarded as a model for a general cortical memory representational system of this type.

In pursuing this model, Ambros-Ingerson et al. (1990) obtained results that led to a proposal that interactions between the olfactory bulb and olfactory cortex, with synaptic modification in the input pathway, could result in a form of hierarchical clustering that could serve to construct perceptual hierarchies used for storage and recognition of complex olfactory stimuli. This was a departure from earlier models, which had explored the role of intrinsic excitatory connections in associative memory functions. In this model, the olfactory cortex selectively inhibits previously active olfactory bulbar neurons. The response to subsequent odor presentations leads to responses that reflect the differences between stimuli. While experimental work reported a tendency for cortical response generalization following the presentation of a number of similar stimuli, supporting the type of clustering predicted by this model, this intriguing hypothesis awaits further experimental testing.

Building on the work of Haberly and his collaborators, Wilson and Bower (1992) used the piriform cortex to approach the investigation of cortical function on two fronts. First, compartmental models of pyramidal neurons based on anatomical and physiological data, as reviewed above, were used to simulate intracellular potentials, extracellular field potentials, and ensemble impulse activity as recorded experimentally in response to orthodromic volleys in the lateral olfactory tract. Second, this network model, constrained by physiological response properties, was used for simulations that attempted to demonstrate computational properties that would underlie its functions as an associative memory. The results of this study showed the ability to store and retrieve patterned impulse information in a network that displayed the physiological responses and temporal dynamics of the real cortex, using only a local Hebbian-type rule for modification of intrinsic excitatory synaptic interactions (Figure 3).

An interesting aspect of these simulations was the suggestion of a role for oscillatory phenomena, such as the prominent gamma range (30–100 Hz) extracellular oscillations. It was proposed that these oscillations coordinate computational processes that directly underlie the associative memory function of piriform cortex (Wilson and Bower, 1992). Oscillatory phenomena have become one of the chief subjects of interest among workers pursuing models of piriform cortex.

Based on this model, Liljenstrom (1991) drew on the work of Hopfield to develop further a model that used simplified sigmoidal output units. The local circuits for feedforward and feedback inhibition, together with the excitatory interactions between pyramidal neurons, were critically important for the input-output dynamics. The model demonstrated simultaneous slow theta and rapid gamma oscillations characteristic of olfactory cortex. It reproduced the experimental effects of acetycholine, both on the modulation of these oscillations by selectively increasing excitability and suppressing intrinsic synaptic transmission and on associative memory functions (reviewed in Hasselmo and Linster, 1999).

Hasselmo developed both simplified network models and compartmental network simulations to investigate learning mechanisms (see Hasselmo and Linster, 1999). These models explored the effects of selective modification of both input and intrinsic excitatory connections. Associative memory performance was enhanced by the combination of suppression of intrinsic fiber transmission and increased excitability during learning, as seen with cholinergic modulation. The model could also exhibit effective associative memory properties under these conditions. This work represents a synthesis of abstraction and physiological detail in modeling of cortical function. It was proposed that this model could represent a basic unit for learning and memory in cortical circuits. This model has helped to guide subsequent experimental studies on the suppressive modulatory actions of cholinergic inputs and intepret their implications for the associative memory functions of the network (see Linster and Hasselmo, 2001, for review). Based on this modeling, several behavioral experiments on cholinergic modulation from Hasselmo's group have shown that cholinergic modulation is indeed involved in the processing and learning of overlapping olfactory stimuli (Linster and Hasselmo, 2001). This group has also proposed a possible role for the neuromodulator noradrenaline (NA) in signal-to-noise enhancement in piriform cortex; in that study, data on noradrenergic suppression of synaptic transmission in piriform cortex slices were combined with a model of odor processing in piriform cortex.

This illustrates a noteworthy aspect of olfactory cortical models: their close application to guiding and interpreting experimental

studies of olfactory cortex. Cattarelli and her colleagues (Litaudon, Datiche, and Cattarelli, 1997) have also used this approach to identify different functional regions within the olfactory cortex.

Nonlinear and chaotic properties of olfactory cortex were studied by Freeman (1987), who showed that a simple cortical model could display the chaotic properties of EEG rhythms; he proposed that a feedback gain parameter Q sets the level of arousal of the cortex. It is this factor that appears to be sensitive to the modulatory actions of acetycholine, as described above. Simulated actions of acetycholine on this parameter in the simplified olfactory cortical model produce point attractor, limit cycle attractor, and strange chaotic or nonchaotic attractor behavior (Liljenstrom, 1991). Recently, several theoretical papers have shown that the neural dynamics observed in olfactory cortex can be modeled to encode odor stimuli in spatiotemporal activity patterns (corresponding to limit cycles) (Li and Hertz, 2000) that resemble those described experimentally (Freeman, 1987) in the olfactory bulb.

An important development in studies of olfactory cortical networks is the realization that their operations are closely interrelated with those of the olfactory bulb, so that they function as an integrated system. An analogy with thalamocortical systems may be made in this regard. This has been recognized in both experimental and computational approaches. Fukai (1996) analyzed the importance of mutual feedback interactions between the olfactory bulb and cortex in a model that represented both structures as chained oscillators. The models incorporated the backprojection from cortical units to the bulbar oscillators in particular ways. Both structures exhibited rapid and robust synchronous oscillations in the presence of odorant stimuli, while they showed either nonoscillatory states or propagating waves in the absence of stimuli, depending on the values of model parameters. Feedback interactions between the two structures were shown to enhance the establishment of large-scale synchrony. The results suggest, in agreement with experimental data, that the modulation of neural activity through centrifugal inputs may play an important role at the early stage of cortical information processing.

A second example of combined olfactory bulb–olfactory cortex networks is the model of Li and Hertz (2000). They postulated that olfactory bulb to olfactory cortex transmission encodes recognition of an odor, while feedback from cortex to bulb generates odor segmentation by producing adaptation that is odor specific. As discussed in Olfactory Bulb (q.v.), this allows the system to recognize a subsequent novel odor. Independently, Wilson (2000) has provided experimental evidence in single-unit recordings from olfactory cortex that cell responses do habituate to a given odor, that this habituation is associated with a decrease in amplitude of excitatory postsynaptic potentials (EPSPs) from the olfactory bulb, and that this habituation is odor specific. Other examples of analysis of the distributed system that includes olfactory bulb and olfactory cortex include Chabaud et al. (1999).

Running through much of current studies, both experimental and theoretical, of odor processing is the question of the relative importance of spatial and temporal patterns in encoding the information contained in different odorous compounds. The presence of spatial patterns, forming virtual internal "odor images" within the olfactory bulb, has been demonstrated by many methods. However, these patterns are not seen in the olfactory cortex. Temporal patterns are seen in both the responses of single cells and summed EEG potentials, and a strong case has been made on both experimental and computational grounds for their role in encoding odors (see Freeman, 1987). It is important to recognize that both space and time are involved in encoding odors, at all stages of odor processing, as in the processing of other senses; construction of networks is not complete without incorporation of both aspects.

In view of the similarities in organization of the olfactory bulb of vertebrates and the antennal lobe of insects (Hildebrand and Shepherd, 1997), it is of interest to inquire into possible similarities between olfactory cortex and the next stage in the insect olfactory pathway, the mushroom bodies. Several properties that may be involved have been identified experimentally; these properties include long-lasting inhibitory potentials, synaptic plasticity, and wide interconnectivity. It has been proposed that these properties, incorporated into a network model, are well suited for decoding temporal patterns specific for given odors in the dendrites of Kenyon cells in the mushroom bodies.

The models of olfactory cortical function discussed here have been at the neuronal or circuit/network level. The behaviors at these levels depend in turn on properties at the membrane and synaptic level, and on the differential properties of cell bodies and dendrites. An initial step toward assessing these has been made by constructing compartmental models of apical dendrites and their spines and analyzing their responses to excitatory and inhibitory inputs. Basic logic operations of AND, OR, and NOT-AND were found to arise from spine interactions when active membrane properties were placed in the spines or the dendritic branch (Shepherd, Woolf, and Carnevale, 1989). These studies support the idea, discussed earlier, that distal dendrites of pyramidal neurons receive and process rapid, precise input information, rather than mediating only slow and weak background modulation. They emphasize the importance of including apical and dendritic properties in network models to represent the full complexity of cortical circuits and cortical functions.

## Summary

The organization of the olfactory cortex can be summarized by a basic circuit composed of a unique set of elements, which may be embedded and elaborated in more complicated cortical regions. Models of olfactory cortex emphasize the importance of cortical dynamics, including the interactions of intrinsic excitatory and inhibitory circuits and the role of oscillatory potentials, in generating the computations performed by the cortex. This replaces earlier interpretations of simple modulation or synchronization of activity within the cortex. In this way, the olfactory cortex, and neural networks based on it, may serve as a useful approach to the study of computations defined by cortical dynamics. It is also recognized that the olfactory cortex functions in close interaction with the olfactory bulb, forming a bulbar-cortical system, in processing odor inputs.

# Optimal Sensory Encoding

*Li Zhaoping*

## Introduction

What is optimal depends on computational tasks. Many recent works define optimality in information-theoretic terms, such as information transmission rates. This can be particularly revelant in the early stages of vision, which are mainly concerned with transmitting information indiscriminately. In this article we focus on the better-known visual system to discuss optimal sensory encoding, although encoding in other sensory systems can be addressed by similar avenues.

Consider a simplified visual input model with, say, 1,000 × 1,000 pixels arranged in a regular grid at one byte per pixel and 20 images per second. This model provides many megabytes per second of raw data. Given the information bottleneck in the long optic nerve from retina to thalamus and the limited firing rates (thus limited data capacity) of cortical neurons (see SENSORY CODING AND INFORMATION TRANSMISSION), early vision can greatly benefit from a data encoding that reduces the rate of data transmission without significant information loss. Since nearby image pixels tend to convey similar signals (e.g., luminance values) and thus carry redundant information, significant savings can be achieved by avoiding transmitting the information redundantly. If, within a particular time window, each original pixel codes one byte of information, 80% of which is redundant information shared with neighboring pixels, then one million pixels code only 200 kilobytes of nonredundant information. One way to avoid redundancy is to transform the original signal $\mathbf{S} = \{S_1, S_2, \ldots, S_N\}$ in the $N$ neurons (e.g., photoreceptors) to signals $\mathbf{O} = \{O_1, O_2, \ldots, O_M\}$ in another $M$ (more/fewer) neurons (e.g., the retinal ganglion cells or cortical neurons), such that signals in $O_i$ and $O_j$ for all $i$, $j$ are not significantly redundant. Consequently, 200 kilobytes of information in $\mathbf{S}$ could be coded by only 0.2 bytes in each neuron $O_i$ if $M = N$, which needs a much reduced firing rate. Lossless encoding means that, if needed, $\mathbf{S}$ can be reconstructed from $\mathbf{O}$. Such observations have led to the *Infomax* proposal, namely, that early vision constructs an optimal coding of input to allow maximum information transmission from retina to cortex under limited channel capacity of the optic nerve or neural activities (Attneave, 1954; Barlow, 1961; Linsker, 1990; Atick, 1992). This principle has provided many insights into the properties of the receptive fields in early vision.

## Optimal Encoding Illustrated by Stereo Vision

Consider the redundancy and encoding of stereo signals (Li and Atick, 1994a). Let $S_L$ and $S_R$ be the signals to the left and right eyes (Figure 1). They may be the average luminance in the images or the Fourier components (of a particular frequency) of the images. Assume that they have zero mean (for simplicity) and equal variance (or signal power) $\langle S_L^2 \rangle = \langle S_R^2 \rangle$ ($\langle .. \rangle$ denotes average over the input ensemble). The redundancy is seen in the correlation matrix:

$$R^S \equiv \begin{pmatrix} \langle S_L^2 \rangle & \langle S_L S_R \rangle \\ \langle S_R S_L \rangle & \langle S_R^2 \rangle \end{pmatrix} = \langle S_L^2 \rangle \begin{pmatrix} 1 & r \\ r & 1 \end{pmatrix}$$

where $0 \leq r \leq 1$ is the correlation coefficient between $S_L$ and $S_R$. The value of $r$ is high, $r \to 1$, for mean luminance signals $S_{L,R}$, but low, $r \to 0$, if $S_{L,R}$ are a high spatial frequency Fourier component of the respective images. A simplifying assumption is that $\mathbf{S}$ are Gaussian signals, which are defined to have a probability distribution $P(\mathbf{S}) \propto exp(-\Sigma_{ij} S_i S_j (R^S)^{-1}_{ij}/2))$. An encoding

$$O_+ = S_+ \equiv (S_L + S_R)/\sqrt{2}, \quad O_- = S_- \equiv (S_L - S_R)/\sqrt{2}$$

gives zero correlation $\langle O_+ O_- \rangle$ in $\mathbf{O}$, leaving output probability $P(\mathbf{O}) = \Pi_i P(O_i)$ factorized, as is easily verified. The transform $\mathbf{S} \to \mathbf{O}$ is linear, which approximates the cell response properties in the retina and, to a less degree, in primary visual cortex. The cell coding $O_+$ is a binocular cell, owing to the binocular summation of inputs, while the cell coding $O_-$ is monocular or ocularly opponent. Note that $S_\pm$ are the eigenvectors of the correlation matrix $R^S$, or the principal components of the signals, and their signal power $\langle S_\pm^2 \rangle = (1 \pm r) \langle S_L^2 \rangle$ is the corresponding

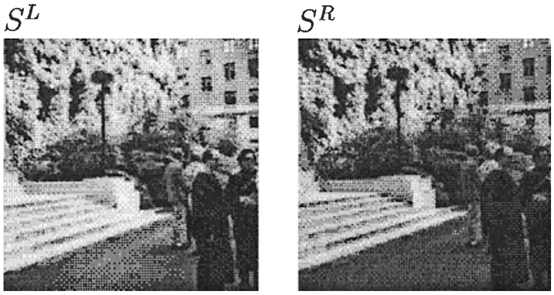

**Figure 1.** A stereo pair input to the two eyes.

eigenvalues. In reality, input noise **N** is added on **S**, and the coding transform introduces additional noise $\mathbf{N}_o$; hence, $O_\pm = [(S_L + N_L) \pm (S_R + N_R)]/\sqrt{2} + N_{o,\pm}$, giving effective output noise $N_\pm = (N_L \pm N_R)/\sqrt{2} + N_{o,\pm}$. For simplicity, the noise terms are assumed to be independent of each other and of the signals. Let $\langle N^2 \rangle \equiv \langle N_L^2 \rangle = \langle N_R^2 \rangle$, and $\langle N_o^2 \rangle \equiv \langle N_{o,+}^2 \rangle = \langle N_{o,-}^2 \rangle$. Input $S_{L,R} + N_{L,R}$ has

$$I_{L,R} = \frac{1}{2} \log_2 \frac{\langle S_{L,R}^2 \rangle + \langle N^2 \rangle}{\langle N^2 \rangle}$$

bits of (mutual) information about $S_{L,R}$, since, for Gaussian signals and noise, the information amount is (½)$\log_2$ (signal-to-noise), whereas $O_\pm$ has

$$I_\pm = \frac{1}{2} \log_2 \frac{\langle O_\pm^2 \rangle}{\langle N_\pm^2 \rangle} = \frac{1}{2} \log_2 \frac{\langle S_\pm^2 \rangle + \langle N^2 \rangle + \langle N_o^2 \rangle}{\langle N^2 \rangle + \langle N_o^2 \rangle}$$

bits of information about $S_{L,R}$ or $S_\pm$. Note that the redundancy between $S_L$ and $S_R$ causes higher or lower signal powers $\langle O_+^2 \rangle$ or $\langle O_-^2 \rangle$ in $O_+$ or $O_-$, respectively, leading to a higher or lower information rate $I_+$ or $I_-$. As an initial choice, define cost as the total signal power, although there can be many other cost considerations (discussed later). Since $I_\pm = (½)\log_2(\langle O^2_\pm \rangle) +$ constant $=$ (½)$\log_2$ (cost) $+$ constant, we note that the gain in information per unit cost ($\Delta I/\Delta$ cost) is smaller in the $O_+$ than in the $O_-$ channel. This motivates a reduction (increment) of costs in the $O_+(O_-)$ channels by introducing the gains $V_\pm$, such that $O_\pm = V_\pm[(S_L + N_L) \pm (S_R + N_R)]/\sqrt{2} + N_{o,\pm}$, at the expense (benefit) of the information transmitted:

$$I_\pm = \frac{1}{2} \log_2 \frac{V_\pm^2(\langle S_\pm^2 \rangle + \langle N^2 \rangle) + \langle N_o^2 \rangle}{V_\pm^2 \langle N^2 \rangle + \langle N_o^2 \rangle} \tag{1}$$

Hence, the optimal encoding, balancing the cost and information extraction, is to find the gains $V_\pm$ to minimize

$$\begin{aligned} E(V_\pm) &\equiv \sum_a (\langle O_a^2 \rangle) - \lambda \sum_a (I_a) \\ &= \text{cost } -\lambda \cdot \text{Information} \end{aligned} \tag{2}$$

where $\lambda$ is the Lagrange multiplier whose value determines the balance. The optimal gains can be obtained by $\partial E/\partial V_\pm = 0$ to give

$$\begin{aligned} V_\pm^2 \propto \text{Max}\Bigg\{ \Bigg[ &\frac{1}{2} \frac{\langle S_\pm^2 \rangle}{\langle S_\pm^2 \rangle + \langle N^2 \rangle} \\ &\times \left(1 + \sqrt{1 + \frac{4\lambda}{\log 2 \langle N_o^2 \rangle} \frac{\langle N^2 \rangle}{\langle S_\pm^2 \rangle}}\right) - 1 \Bigg], 0 \Bigg\} \end{aligned} \tag{3}$$

In the zero noise limit, when $(\langle S_\pm^2 \rangle / \langle N^2 \rangle) \gg 1$, $V_\pm^2 \propto \langle S_\pm^2 \rangle^{-1}$. As expected, this suppresses the stronger ocular summation signal $S_+$ and amplifies the weaker ocular contrast signal $S_-$, in order to save the cost, since the cost increases linearly with $V_\pm^2$, but the extracted information increases only logarithmically with $V_\pm^2$. Hence, for instance, when the coding noise $\mathbf{N}_o$ is negligible (i.e., $(\langle N_o^2 \rangle / V_\pm^2 \langle N^2 \rangle) \ll 1$), output **O** and the original input **S** + **N** contain about the same amount of information about the true signal **S**, but **O** consumes much less power with $V_+ \ll V_- < 1$, when $r \sim 1$. This gain $V_\pm \propto \langle S_\pm^2 \rangle^{-1/2}$ also equalizes output power $\langle O_+^2 \rangle \approx \langle O_-^2 \rangle$, since $\langle O_\pm^2 \rangle = V_\pm^2 \langle S_\pm^2 \rangle +$ noise power, making the output correlation matrix $R^o$ (with elements $R_{ab}^o = \langle O_a O_b \rangle$) proportional to an identity matrix (since $\langle O_+ O_- \rangle = 0$). Such a transform **S** → **O**, which leaves output channels decorrelated and equally powered, is called *whitening*. Any rotation **O** → **UO** via a rotation or unitary transform $\mathbf{U}(\mathbf{U}\mathbf{U}^\mathbf{T} = 1)$, by angle $\theta$ in the two-dimensional space **O**, multiplexes the channels $O_+$ and $O_-$ to give two alternative channels

$$\begin{pmatrix} O_1 \\ O_2 \end{pmatrix} = \begin{pmatrix} \cos(\theta) & \sin(\theta) \\ -\sin(\theta) & \cos(\theta) \end{pmatrix} \begin{pmatrix} O_+ \\ O_- \end{pmatrix} = \begin{pmatrix} \cos(\theta)O_+ + \sin(\theta)O_- \\ -\sin(\theta)O_+ + \cos(\theta)O_- \end{pmatrix}$$

which are also decorrelated ($\langle O_1 O_2 \rangle = 0$). Furthermore, note from Equations 2 and 1 that cost $= \text{Tr}(R^o)$ and Information $=$ (½) log (det $R^o$)/(det $R^N$), where $R^N$ is the correlation matrix of the noises in the output channel and Tr(.) and det(.) denote the trace and determinant of a matrix. Since both the trace and the determinant are invariant to unitary transforms (rotations), the optimized objective function $E =$ (cost $-\lambda$ Information) is invariant to this rotation $O_\pm \rightarrow O_{1,2}$. Hence, both encoding schemes $S_{L,R} \rightarrow O_\pm$ and $S_{L,R} \rightarrow O_{1,2}$, with the former a special case of the latter, are equally optimal in making the output decorrelated (nonredundant), in extracting information about $S_{L,R}$, and in saving the coding cost $\Sigma_a \langle (O_a)^2 \rangle$. Since

$$\begin{pmatrix} O_1 \\ O_2 \end{pmatrix} = \begin{pmatrix} S_L(\cos(\theta)V_+ + \sin(\theta)V_-) + S_R(\cos(\theta)V_+ - \sin(\theta)V_-) \\ S_L(-\sin(\theta)V_+ + \cos(\theta)V_-) + S_R(-\sin(\theta)V_+ - \cos(\theta)V_-) \end{pmatrix}$$

in general $O_1$ and $O_2$ prefer different eyes. In particular, $\theta = -45°$ gives $O_{1,2} \propto S_L(V_+ \mp V_-) + S_R(V_+ \pm V_-)$. The visual cortex indeed has neurons of a whole spectrum of ocularities.

## Variations of Optimal Encodings

It is now apparent that infomax coding as defined in Equation 2 is related to whitening, decorrelation, principal component analysis, and *factorial codes*, defined as when probabilities of signals factorize $P(\mathbf{O}) = \Pi_a P(O_a)$. Among the many other relatives of optimal codings are *minimum entropy* or *minimum description length*, since minimizing $\langle O_1^2 \rangle + \langle O_2^2 \rangle$ reduces the total output entropy $H(O_1) + H(O_2)$ ($H$(.) stands for entropy) for Gaussian signals $O_a$; *independent component analysis*, since principal components are independent components for Gaussian signals; *redundancy reduction*, since the well-known inequality $\Sigma_a H(O_a) > H(\mathbf{O})$ means that minimizing $\Sigma_a H(O_a)$ reduces the redundancy, intuitively defined as $\Sigma_a H(O_a)/H(\mathbf{O}) - 1 \geq 0$ (equal to zero when there is no redundancy), between output channels; *sparse coding*, since it is defined as lowering the coding bits $H(O_a)$ for all channels $a$; *maximum entropy code*, since $H(\mathbf{O})$ is maximized given $\Sigma_a H(O_a)$ when redundancy is removed; *predictive codes*, since the code effectively predicts or explains away $S_R$ from $S_L$ to achieve minimum $\Sigma_a \langle O_a^2 \rangle$ for given $I(\mathbf{O}; \mathbf{S})$ (information in **O** about **S**); and *minimum predictability codes* or *least mutual information* between output channels, since $\Sigma_a H(O_a) = H(\mathbf{O})$ means zero mutual information between output channels $O_a$ and $O_b$. All of these variations of "optimal encoding" often mean approximately or exactly the same (Nadal and Parga, 1997), depending on their precise definitions and the statistics of the signals concerned, and should not be thought of as independent coding principles.

## Optimal Visual Encoding in Space, Time, Color, and Scale

In general, for simple linear encoding of approximately Gaussian signals **S**, a recipe for optimal coding is visualized in Figure 2. Given input signal **S** with noise **N**, the encoding transform **K** and additional coding noise $\mathbf{N_o}$ gives output signal $\mathbf{O} = \mathbf{K}(\mathbf{S} + \mathbf{N}) + \mathbf{N_o}$. The optimal transform **K** is dictated by the input statistics characterized by the correlation matrix $R^S$. The first step is principal component analysis, transforming $\{S_a\}$ via a matrix $\mathbf{K_o}$ to the principal components $\{S_k\}$, i.e., $S = K_o\mathbf{S}$. The powers of the components $S$ are the eigenvalues of $R^S$. Next, the optimal gain $V_k$ to $S_k$ is determined by $S_k$'s signal-to-noise ratio via Equation 3. A particular optimal coding transform is $\mathbf{K} = \mathbf{V}\mathbf{K}_o$, where **V** is a diag-

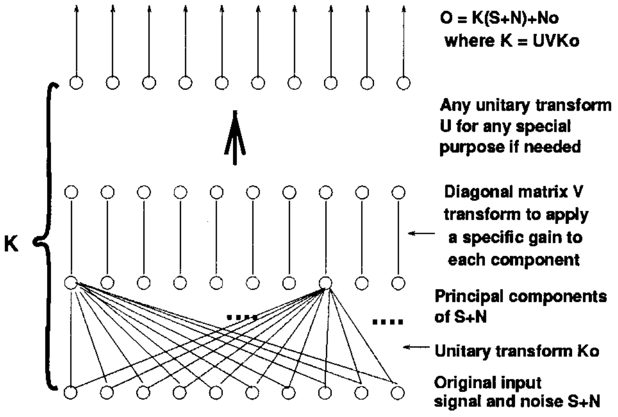

**Figure 2.** A schematic of the steps to obtain infomax (linear) code for Gaussian signals.

onal matrix with diagonal elements equal to the optimal gains $V_k$ or $V(k)$. The resulting $\mathbf{O}$ have decorrelated components and retain the maximum information about $\mathbf{S}$ given output cost $\Sigma_a\langle O_a^2\rangle$. Furthermore, any transform in the class $\mathbf{K} = \mathbf{UVK}_o$, where $\mathbf{U}$ is any unitary transformation (rotation, $\mathbf{UU}^T = 1$), is equally optimal, since it leaves the outputs $\mathbf{O}$ with the same information extraction and cost, and, in the zero noise limit, the same decorrelation. The conceptual steps above correspond mathematically to finding the (degenerate) solution $\mathbf{K}$ of $\partial E/\partial\mathbf{K} = 0$, where $E(\mathbf{K}) = \text{cost} - \lambda$ Information.

In spatial coding (Atick, 1992), the signal at visual location $x$ is $S_x$. Since the signal correlation is translation invariant, i.e., $\langle S_x S_{x'}\rangle$ is a function of only $x - x'$, the principal components are Fourier modes, and $K_o$ is the Fourier transform $K_o^{kx} \sim e^{-ikx}$ such that $S_x \rightarrow S_k \sim \Sigma_x K_o^{kx} S_x \sim \Sigma_x e^{-ikx} S_x$. Field (1987) measured the power spectrum as $\langle S_k^2\rangle \sim 1/k^2$ with Fourier frequency $k$. Assuming white noise power $\langle N^2\rangle$, the high signal-to-noise ratio $S^2/N^2$ in the low-$k$ region leads to the gain $V_k$ or $V(k) \propto k$ that increases with $k$. However, for high $k$, where $S^2/N^2$ is low, $V(k)$ quickly decays with increasing $k$ to zero, according to Equation 3, in order not to amplify noise. This gives a bandpass $V(k)$ as a function of $k$ (Figure 3). If $\mathbf{U}$ is the inverse Fourier transform $U^{x'k} \sim e^{ikx'}$, then the whole transform $\mathbf{K} = \mathbf{UVK}_o$ transforms signal $S_x$ to activities $O_{x'}$ of a neuron with a receptive field at location $x'$ as a bandpass filter, i.e., $O_{x'} \sim \Sigma_k V(k) \Sigma_x e^{ik(x'-x)} S_x$ + noise. This is roughly what retinal output (ganglion) cells do, achieving a center-surround transform on the input image and emphasizing the intermediate-frequency band where the signal-to-noise ratio is of order 1. Function $V(k)$ is the well-known contrast sensitivity function. When the visual environment dims down, reducing the overall signal-to-noise ratio $\langle S_k^2\rangle/\langle N^2\rangle$ in all frequencies, say from $(\langle S_k^2\rangle/\langle N^2\rangle) \sim 100/k^2$ to $(\langle S_k^2\rangle/\langle N^2\rangle) \sim 1/k^2$, the bandpass region should shift toward lower frequencies, effectively making $V(k)$ a low pass. This explains the dark adaptation of the retinal ganglion cells' receptive fields, from a center-surround contrast-enhancing (bandpass) filter to a Gaussian-like smoothing (low-pass) filter, to integrate signals and smooth out noise.

Encoding in time is analogous to encoding in space. Image statistics in time (Dong and Atick, 1995) determine the temporal frequency sensitivities $V(\omega)$ (of frequency $\omega$) of the optimal temporal filter. Given a sustained input $S(t)$ over time $t$, the output $O(t)$ may be more sustained or transient depending on whether the filter is more low pass or band pass. By an appropriate choice of the rotation transform $\mathbf{U}$ (Dong and Atick, 1995; Li, 1996), the temporal filter can be made causal, i.e., the output $\mathbf{O}$ depends only on input $\mathbf{S}$ of the past but not the future.

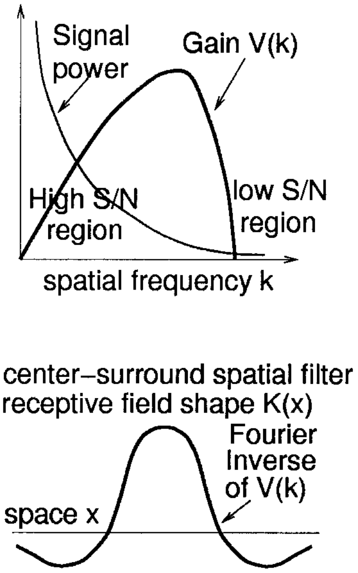

**Figure 3.** The contrast gain $V(k)$ as a function of spatial frequency $k$, determined from the signal-to-noise ratio (S/N) of the inputs (S + N) at that frequency. The corresponding spatial filter $K(x)$ is the Fourier inverse of $V(k)$, adopted by the retinal ganglion cells on the photoreceptor inputs.

Visual color encoding (Atick, 1992) is analogous to stereo encoding. The inputs are three-dimensional (3D), $S_r$, $S_g$, and $S_b$, for red, green, and blue signals. The principal components include a strong luminance channel, a weighted summation of the cone inputs, and two weaker chrominance channels, one roughly red-green opponency and another yellow-blue opponency. Optimal encoding then involves appropriate gains to these channels and additional multiplexing of them as needed. Physiologically, color and space codings are coupled, resulting, for instance, in the red-center, green-surround receptive fields (Figure 4) of the retinal ganglion cells. This can be understood in a simplified two-cone system, red and green. The high signal-to-noise luminance channel ($S_r + S_g$) needs a center-surround or bandpass spatial filter, while the low signal-to-noise chromatic channel ($S_r - S_g$) needs a smoothing or low-pass filter. The multiplexing of these two channels, a rotational operation $\mathbf{U}$ in the 2D color space, leads to addition or subtraction

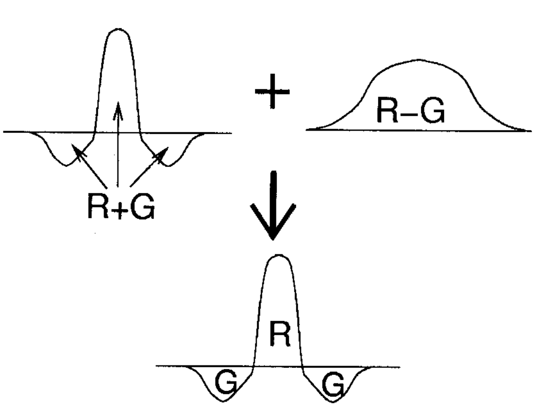

**Figure 4.** Multiplexing the center-surround achromatic (R + G) filter with the chromatic (R − G) Gaussian-like filter gives a red-center, green-surround double (in space and in color) opponency receptive field observed in retina.

of these two filters. The results are the red-center, green-surround or green-center, red-surround receptive fields. In the retina and/or primary visual cortex, codings in space, time, color, and stereo are all coupled together (Atick, 1992; Li and Atick, 1994a,b; Li, 1996).

## Multiscale Encoding in the Primary Visual Cortex

Primary visual cortex receives retinal outputs via the lateral geniculate nucleus. Its receptive fields are orientation selective in the shape of small bars or edges. Different receptive fields have different orientations and different sizes (or tuned to different spatial frequency bands), in a multiscale fashion such that receptive fields of different sizes are roughly scaled versions of each other, also called wavelet coding. These receptive fields can be seen as components of another optimal code by a particular choice of the rotation (unitary) matrix $\mathbf{U}$ in the coding transform $\mathbf{K} = \mathbf{UVK}_o$. Retinal receptive fields are given when $\mathbf{U} = \mathbf{K}_o{}^{-1}$, and are theoretically the same for all retinal ganglion cells except for a spatial translation. Another optimal code, apparently not adopted anywhere in our visual system, is when $\mathbf{U} = \mathbb{I}$, an identity matrix. The receptive fields would be infinitely large, and each would be unique and a particular principal component (Fourier component) with a particular gain. The $\mathbf{U}$ transform for the multiscale coding is when $\mathbf{U}$ is somewhere in between the two extremes $\mathbf{U} = \mathbf{K}_o{}^{-1}$ and $\mathbf{U} = \mathbb{I}$. To construct a cortical receptive field, $\mathbf{U}$ multiplexes the principal components (Fourier waves) within a finite frequency range $\mathbf{k} \in (\mathbf{k}_1, \mathbf{k}_2)$ such that the resulting receptive field is responsive only to a restricted range of orientations and spatial frequencies $\mathbf{k}$. The code can be viewed as an intermediate between the Fourier wave code, where each receptive field is infinitely large and responds to only one frequency and orientation, and the retinal code, where each receptive field is small and responsive to all frequencies $k$ and all orientations. Different cortical units cover different ranges of frequencies to give a complete sampling (Li and Atick, 1994b).

It has been argued (reviewed by Simoncelli and Olshausen, 2001) that the multiscale code, which should be as good as the retinal code if the visual inputs assume Gaussian statistics, is actually better in light of the actual non-Gaussian nature of the signals. Oriented receptive fields have been argued to capture the nontrivial third-order statistics, in particular the third-order correlation $\langle S_a S_b S_c \rangle$ between signals from three image pixels $a$, $b$, and $c$, that are not accounted for by Gaussian statistics. Previous works (Simoncelli and Olshausen, 2001) argued that the cortical orientation-selective reflective fields match the orientation features in inputs, and that the neurons are inactive unless those matches happen. The code is thus argued to be a sparser code, since the activities of different cells are supposedly less correlated (see SPARSE CODING IN THE PPRIMATE CORTEX). Why doesn't retina adopt this code? One reason could be that the cortical representation is in addition overcomplete, i.e., the number $M$ of cortical units (output units $O_a$) is orders of magnitude larger than the number $N$ of the retinal units (input units $S_a$). The overcompleteness has been argued to improve sparseness, though at the expense of the neural proliferation, because cells tuned to different image features cannot be active together. However, it should be noted that if cortical activities $\mathbf{O}$ depend linearly on visual input $\mathbf{S}$, the $\mathbf{O}$ units are necessarily (mathematically) dependent on, or correlated with, each other in an overcomplete representation where $M > N$ (Li, 1996). Cortical response $\mathbf{O}$ depends on visual input $\mathbf{S}$ nonlinearly, by rectification, thresholding, saturation, and normalization, etc. (Simoncelli and Olshausen, 2001). The observed nonlinearity is unlikely to be sufficient to achieve decorrelation. However, the nonlinearity and the overcomplete representation are more likely to serve nontrivial cognitive computations (Li, 2002) beyond the traditional coding considerations.

## Discussion

It is clear that maximizing information transmission alone is not enough to specify optimal codes. One may prefer one code or another when considering other costs and benefits (see, e.g., Levy and Baxter, 1996). The retinal code has the advantage of small and identical receptive field shapes that involve shorter neural wiring and easier specifications. It also has stronger correlation between output signals than the Fourier wave codes outside the zero noise limit (both codes should have zero second-order correlation in zero noise limit), making it easier for error correction purposes. Its translation invariance also allows an object translated laterally to induce the same pattern of neural activities except for a change in the responding neurons. When this invariance is extended to objects moving in depth (when images of objects change sizes), the cortical multiscale code is preferred. In this case many different receptive fields are scaled and/or translated versions of each other, leading to translation invariance within a scale and scale invariance between scales (Simoncelli et al., 1992).

More significant are optimality measures not based on information measures. For example, to give a best estimation $\hat{S}$ of input $S$ from $O = K(S + N) + N_o$, the optimal coding transform $K$ to minimize the estimation error $\langle (S - \hat{S})^2 \rangle$ given output power $\langle O^2 \rangle$ certainly does not satisfy infomax. Another example is afforded by the two classes of the retina ganglion cells. Whereas the infomax principle explains well the receptive fields of the more numerous class of retinal ganglion cells, the P cells in monkeys or X cells in cats, another class of ganglion cells, M cells in monkeys or Y cells in cats, have receptive fields that are relatively larger, color unselective, and tuned to higher temporal frequencies. These M cells do not extract the maximum information possible (infomax) about input $S$, but can serve to extract the information as fast as possible (Li, 1992), i.e., the temporal outputs ($O(t = -\infty), \ldots O(t - 1), O(t)$) should contain some information about $S(t' \leq t)$ with a shortest possible delay $t - t'$. This observation should have significant implications for how P and M pathways should interact at later stages of processing.

Information theory provides excellent means to *quantify the amount* of information to design optimal coding for *information transmission*. Cognitive functions often require a selection of the *quality or modality* of information, which is beyond information theory. Information theory is more likely to find application in the early stages of sensory processing, before information is selected or discriminated for any specific cognitive task, when general purpose information transmission is the main concern. This explains the success of information theory in the retina and partly in the primary visual cortex, to the extent that there is quantitative agreement with experimental results and to the extent that information theory has predictive power for new data (Dong and Atick, 1995; Chen and Li, 1998). Optimal sensory coding in later stages of sensory pathways is expected to depend on cognitive tasks beyond simple information transmission, and should require applications of alternative theories in future research.

# Optimality Theory in Linguistics

*Kie Zuraw*

## Introduction

Prince and Smolensky (1993) introduced Optimality Theory (OT) as a framework for linguistic analysis. Kager (1999) gives an entry-level introduction to OT, McCarthy (2001) surveys advanced topics, and the Rutgers Optimality Archive (http://ruccs.rutgers.edu/roa.html) contains hundreds of OT papers. Within phonology, OT has largely supplanted rule-based frameworks. OT has also been applied to syntax and semantics, although not as widely; Legendre, Grimshaw, and Vikner (2001) provide an overview of current work in OT syntax.

Rule-based frameworks account for linguistic patterns through the sequential application of transformations to lexical entries. Variation between two pronunciations of the English plural suffix—[s] in *cats* but [z] in *dogs*—is explained by a rule that devoices the suffix after voiceless consonants (like [t]). The input *cat* + /*z*/, assembled from entries in the speaker's mental dictionary, is transformed by rule into the output *cat[s]*. In OT, the output is instead chosen through competition with other candidates: a constraint requiring adjacent consonants to match in voicing favors *cat[s]* over *cat[z]*.

Generation of utterances in OT involves two functions, *Gen* and *Eval*. *Gen* takes an input and returns a (possibly infinite) set of output candidates. Some candidates might be identical to the input, others modified somewhat, others unrecognizable. *Eval* chooses the candidate that best satisfies a set of ranked constraints; this optimal candidate becomes the output.

The constraints of *Eval* are of two types. *Markedness* constraints enforce well-formedness of the output itself, prohibiting structures that are difficult to produce or comprehend, such as consonant clusters or phrases without overt heads. *Faithfulness* constraints enforce similarity between input and output, for example, requiring all input consonants to appear in the output, or all morphosyntactic features in the input to be overtly realized in the output. Markedness and faithfulness constraints can conflict, so the constraints' ranking, which differs from language to language, determines the outcome. One language might eliminate consonant clusters by deleting consonants, despite the resulting faithfulness violations; another might retain all input consonants, violating the markedness constraint.

In standard OT, constraints are strictly ranked and violable. *Strict ranking* means that a candidate violating a high-ranked constraint cannot redeem itself by satisfying lower-ranked constraints (constraints are not numerically weighted, and lower-ranked constraints cannot gang up on a higher-ranked constraint). *Violability* means that the optimal candidate need not satisfy all constraints. *Eval* can be viewed as choosing the subset of candidates that best satisfy the top-ranked constraint, then, of this subset, selecting the sub-subset that best satisfies the second-ranked constraint, and so on. Another way of describing *Eval* is that a candidate *i* is optimal if and only if, for any constraint that prefers another candidate *j* to *i*, there is a higher-ranked constraint that prefers *i* to *j*.

The *tableau* (a standard expositional device in OT) in Figure 1 illustrates output selection for the input /*ilp*/ in a hypothetical mini-language. Each of the four output candidates is flawed: *c*, the most faithful, has a consonant cluster, violating the markedness constraint *CC, as indicated by the asterisk at the intersection of *CC's column and *c*'s row. Candidate *b* has deleted a segment, and *a* has inserted a segment; these candidates violate the faithfulness constraints Don'tDelete and Don'tInsert, respectively (phonologists' Max and Dep). Candidate *d* has inserted a segment without breaking up the consonant cluster, violating both Don'tInsert and *CC.

*CC is the highest-ranked constraint (ranking is indicated by left-to-right ordering of the constraints' columns; we can also write

| | /ilp/ | *CC | Don't Delete | Don't Insert |
|---|---|---|---|---|
| *a* | ☞ [ilip] | | | * |
| *b* | [il] | | *! | |
| *c* | [ilp] | *! | | |
| *d* | [ilpi] | *! | | * |

**Figure 1.** Optimality Theory tableau.

*CC ≫ Don'tDelete ≫ Don'tInsert). *Eval* first eliminates *c* and *d* from the competition (an exclamation point represents elimination) because they alone violate *CC. The shading in the cells to the right represents the irrelevance of *c*'s and *d*'s performance on any lower-ranked constraints. *Eval* next eliminates *b*, because it violates Don'tDelete. The remaining candidate, *a*, is optimal, as indicated by the pointing finger. In this language, an input string /ilp/ is pronounced [ilip]; in another language the constraint ranking, and thus the output, might be different. There are rankings that would choose *a* or *b* as the optimal candidate. Candidate *d*, however, is *harmonically bounded* by *a*, and by *c*: its violations are a proper superset of both *a*'s and *c*'s. Therefore, *d* cannot be the optimal candidate under any ranking of just these three constraints, although it could be optimal with a larger constraint set.

Wilson (2001) proposes an alternative formulation of *Eval* in which markedness constraints are "targeted": they compare only candidates that are maximally perceptually similar and impose only pairwise preferences on candidates. For each constraint, starting with the highest ranked, *Eval* adds any new pairwise preferences that do not contradict those imposed by higher-ranked constraints, and constructs the transitive closure.

## OT in Linguistic Theory

This section reviews why OT has been so widely adopted, and its advantages and disadvantages (see McCarthy, 2001).

OT was developed as a response to a "conceptual crisis at the center of phonological thought" (Prince and Smolensky, 1993, p. 1) concerning the role of output constraints. In a 1970 *Linguistic Inquiry* article, Charles Kisseberth identified a "conspiracy" in Yawelmani: rules of vowel insertion and deletion conspire to place every consonant adjacent to a vowel. Kisseberth proposed introducing constraints (such as *CCC, forbidding three-consonant clusters) to block or trigger rules, which could then be simplified and made more similar across languages. Output constraints were increasingly exploited in the literature, but many aspects of their use were unclear. How should a constraint be designated to block or trigger a rule? What if output constraints conflicted? How could nonabsolute preferences be expressed? For example, Yawelmani allows the sequences C*i*CC and CC*i*C, but underlying CCC is repaired to C*i*CC. Therefore, in addition to the constraint *CCC and the rule of *i*-insertion, there must be a constraint preferring C*i*CC over CC*i*C. But this second constraint is violable, because CC*i*C sequences do occur. OT addressed these problems by eliminating rules entirely in favor of constraints, and specifying how constraints interact.

One advantage of OT over rule-based theories is that it predicts the emergence of the unmarked (TETU): a markedness constraint that is frequently violated in a language may still affect outputs. The constraint favoring C*i*CC over CC*i*C in Yawelmani, for example, is not surface-true (CC*i*C sequences do occur, because high-ranking faithfulness constraints preserve them), but when *CCC forces a vowel to be inserted, C*i*CC is preferred over CC*i*C. A major contribution of OT has been to focus attention on TETU, of which many new cases have been found.

Another advantage of OT is its straightforward account of what McCarthy calls "homogeneity of target/heterogeneity of process." A rule specifies the structure to which it applies (the target) and the operation to be performed on that structure (process). It has long been observed, however, that rules applying different processes to the same target tend to occur, both across languages and within the same language. A rule-based theory has no explanation for why a structure should be a recurring target. In OT, however, the explanation is straightforward: there is a markedness constraint against the target, but whether and how the target is repaired depends on interaction with other constraints. In Figure 1, for example, permuting the constraint ranking yields three minilanguages: one that allows CC clusters, one that eliminates them by vowel insertion, and one that eliminates them by consonant deletion. The set of predicted languages that results from permuting the ranking of a group of constraints is its *factorial typology*. A proposed set of interacting constraints is considered viable only if its factorial typology matches the typology of observed languages—that is, it predicts all existent and no nonexistent patterns.

In some cases, OT's prediction of heterogeneity of process may be overly exuberant. For example, all else being equal, languages that resolve intervocalic CC clusters by deletion delete the first consonant, not the second. Wilson's targeted constraints close this gap and others in the factorial typology: with targeted constraints, deleting the second consonant cannot be optimal under any constraint ranking.

OT is at a disadvantage in dealing with opacity. In a rule-based framework, opacity occurs when a later rule either eliminates the structure that caused an earlier rule to apply (obscuring why the earlier rule applied) or creates a structure that would have caused an earlier rule to apply (obscuring why the earlier rule failed to apply). Standard OT, however, is unable to capture most opacity. Several additional proposals have therefore been made, including harmonic serialism, turbid output representations, output-output faithfulness, sympathy, targeted constraints, and constraint conjunction (see McCarthy, 2001, chap. 3, for a survey). The computability consequences of these proposals, in learning and/or generation, remain to be established.

## Computability of OT

### *Generation*

In rule-based frameworks, generation—mapping input to output, the speaker's task—is straightforward. Each rule identifies target structures in a representation, makes the required change, and passes the result to the next rule. In OT, generation presents a computational challenge, because the candidate set may be infinite (in phonology, it is always infinite, because insertions are unlimited). In that case, *Eval* cannot proceed in the obvious way, by first going through all candidates and totaling violations of the highest-ranked constraint, because that first step would never end.

Eisner (1997), building on earlier work by Mark Ellison, proposes a simple way of dealing with the infinite candidate set. At every point in his generation algorithm, the candidate set is represented as a finite-state automaton (FSA), rather than as a list. This is possible if the candidates and constraints are expressed in Eisner's Primitive Optimality Theory (OTP) formalism.

The winning candidate in OTP can be defined recursively. *Repns* is an FSA that accepts all syntactically well-formed OTP representations of input-output mappings. *Input* is an FSA that accepts mappings from the given input to any output. Intersecting *Repns* and *Input* produces an FSA, $S_0$, that accepts well-formed mappings from the given input. $S_0$ is the initial candidate set.

Further, define an FSA $C_i$ for each of the $n$ constraints in the hierarchy, where $C_1$ corresponds to the highest-ranked constraint. Each $C_i$ accepts any mapping, but the arcs that a mapping traverses when it violates Constraint*i* are weighted. $C_1$ is intersected with $S_0$ to produce an FSA that accepts $S_0$, but with the arcs corresponding to violations of Constraint1 weighted. Dijkstra's Best Paths algorithm, which finds the least-weighted path(s) through an FSA, is then applied to $C_1 \cap S_0$ to yield an FSA ($S_1$) that accepts the representations in $S_0$ that minimally violate Constraint1—i.e., the set of candidates left after Constraint1 has applied. Repeating this procedure for all $n$ constraints, the winning candidate (or set of candidates, if there are not enough constraints to select a unique winner) is $S_n$.

### Comprehension

Comprehension—the listener's task—has been little addressed for standard OT, although Eisner (2000) proposes an algorithm for comprehension under "directional constraint evaluation." A comprehension algorithm would yield, for a given output form, the (possibly infinite) set of inputs that would map to that output under the given grammar. The problem is not trivial: the input may contain a markedness violation not found in the output just in case the constraint ranking is such that the violation would have been repaired by a higher-ranking faithfulness constraint, and the result of the repair would be the observed output.

### Learning

Learning—the child's task—includes (at least) two subtasks: building a lexicon and determining the constraint ranking of the target language. If the constraint set is not universal, the learner must also determine what the constraints of her language are; see Boersma (1998) for a model of learning articulatory and acoustic constraints, and Albright and Hayes (1999) for an algorithm that learns morphophonological constraints.

Little work exists on the learnability of the lexicon. Prince and Smolensky (1993) propose "lexicon optimization": where possible, learners construct lexical representations that are identical to the surface representations they hear. When the learner encounters alternations, such as the different pronunciations of the English plural suffix, she must construct a single lexical representation. Curtin (2001) presents evidence that children's early lexical representations are phonetically detailed and do not strip out redundancies; this suggests that lexical consolidation of different pronunciations of the same morpheme occurs relatively late in learning, perhaps after most of the constraint ranking is established.

The problem of establishing a constraint ranking has been addressed more thoroughly. Tesar and Smolensky's (2000) Constraint Demotion Algorithm and its variants rank a set of constraints given a set of outputs. The algorithm compares an observed output (presumed to come from a mature speaker) to any candidate erroneously rated as optimal under the learner's current constraint ranking. In order to make the observed output optimal, for every constraint *B* that prefers the spurious output, some higher-ranked constraint *A* must prefer the observed output. If this is not already the case, the learner demotes *B* below *A*. The learner must know the input form in order to evaluate faithfulness constraints; in a more realistic model, some interleaving of input-learning and ranking-learning would be necessary. Variants of the algorithm accommodate the common proposal that the learner ranks markedness above faithfulness unless she encounters evidence to the contrary.

The Constraint Demotion Algorithm finds a ranking consistent with the learning data, if one exists. The algorithm has not been successfully generalized to learn variable grammars (discussed below), however, and is not robust to occasional errors in the learning data.

## Probabilistic and Variable OT

Intraspeaker variation is common in language: a speaker may produce an utterance differently on different occasions. For example, American English speakers optionally produce [nt] as a nasalized flap (so that "winter" sounds similar to "winner"). The desire to capture variability in OT has led to proposals of variable constraint ranking.

Anttila (1997) proposes that a "stratified" constraint ranking is equivalent to all the linear rankings that are consistent with it, and the predicted frequency of a variant is the proportion of linear rankings that generate it. Suppose a language has the stratified ranking $A \gg \{B, C, D\}$ (i.e., *B*, *C*, and *D* are freely ranked, but below *A*), and a candidate *a* is optimal only under $A \gg B \gg C \gg D$ and $A \gg B \gg D \gg C$. The stratified ranking collapses six linear rankings, two of which produce *a*, so *a* should be observed 33% of the time. In a corpus study of Finnish genitive plurals, Anttila found a good match between predicted and observed frequencies of variants. No learning algorithm has been proposed, however, for grammars with free rankings.

Boersma (1998) proposes stochastic constraint ranking—ranking that is neither absolutely fixed nor absolutely free, but probabilistic. Each constraint in an individual's grammar has a ranking value in arbitrary units. For every utterance, the speaker generates effective values for each constraint by randomly perturbing each ranking value slightly. Each constraint is thus associated with a probability density function centered on its ranking value. Figure 2 illustrates a minigrammar in which constraint $C_1$ is nearly always top ranked, and $C_4$ is nearly always bottom ranked, but $C_2$ and $C_3$ are variably ranked, with a preference for the ranking $C_2 \gg C_3$.

Stochastic constraint ranking captures fine-grained frequencies. In an Anttilian grammar with three variably ranked constraints, a variant can occur only 0%, 33%, 67%, or 100% of the time, depending on which rankings produce that variant. In a Boersmian grammar with the same three constraints, the variant can occur at any frequency, depending on the ranking values of the constraints. Boersma and Hayes (2001) suggest some cases of very infrequent variants that would be difficult to capture in an Anttilian model, although firm data remain to be gathered.

An advantage of Boersma's model is its learnability. Boersma's Gradual Learning Algorithm can learn stochastic grammars from variable learning data (if the learning data are not variable, the ranking values learned are so far apart that the ranking is effectively fixed). In each learning trial of the algorithm, the learner compares its production to an adult target form. If there is a mismatch, the learner increments the ranking values of all constraints that prefer the learner's incorrect form, and decrements the ranking values of all constraints that prefer the adult form. The algorithm is robust to errors in the learning data; if an erroneous learning datum nudges a constraint in the wrong direction, subsequent data push it back. The Gradual Learning Algorithm can also model the course of acquisition. Curtin (2001) shows how, for the acquisition of prosody, the Gradual Learning Algorithm successfully models variability in children's productions, stage-like progression, and the order in which markedness constraints are demoted.

The Gradual Learning Algorithm can learn rates of variation because conflicting variants exert opposite influences on ranking values. The more frequent variant occurs in more learning trials, so the relevant constraints' ranking values are separated to the degree that the variants differ in frequency. The algorithm is also able to learn rates of lexical variation (situations in which each word's pronunciation is stable, but certain words display a phonological phenomenon and others do not), as shown in Zuraw (2000). In Zuraw's model, the resulting grammar has high-ranking faithfulness constraints that ensure the correct pronunciation of existing words, with lexical variation encoded in low-ranked constraints that come into play in the production and comprehension of new words.

## Discussion

OT was partly inspired by neural networks. The ideas of optimization, parallel evaluation, competition, and soft, conflicting constraints are familiar. Prince and Smolensky (1997) discuss the implementation of OT in a neural network. Constraints are implemented as connection weights, and the network implements a Lya-

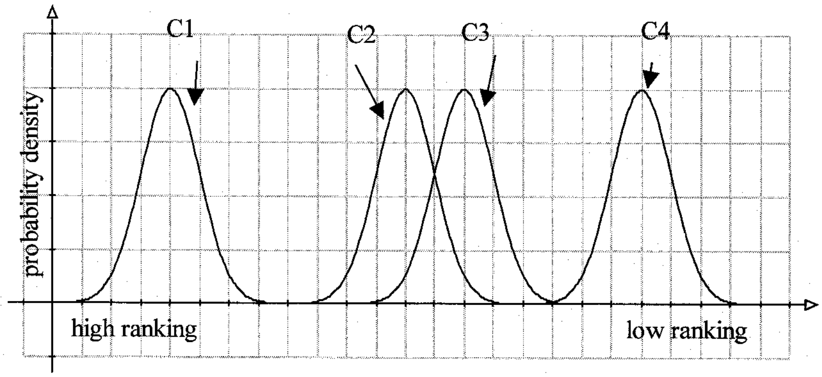

**Figure 2.** Stochastic constraint ranking.

punov function that maximizes "harmony" ($\Sigma_{ij}\, a_i w_{ij} a_j$: the sum, for all pairs $i$, $j$ of neurons, of the product of the neurons' activations and their connection weight). Hierarchically structured representations (e.g., consonants and vowels grouped into syllables) can be represented as matrices of neurons, where each matrix is the tensor product of a vector for a linguistic unit and a vector for its position in the hierarchy. Implementing strict domination (rather than the usual numerical weighting) of constraints remains unsolved, however, so translation between OT grammars and neural networks is not in general possible.

# Optimization, Neural

*Carsten Peterson and Bo Söderberg*

## Introduction

Many combinatorial optimization problems require a more or less exhaustive search to achieve exact solutions, with the computational effort growing exponentially or worse with system size. Hence, for large problems, the quest for an exact solution has to be abandoned. Instead, various kinds of heuristic methods have been developed that yield reasonably good approximate solutions.

Artificial neural network (ANN) methods in general fall within this category. Particularly interesting in the context of optimization are *recurrent network* methods based on *deterministic annealing*. In contrast to most other methods, these are not based on a direct exploration of the given discrete state space; instead, they utilize an interpolating continuous (analogue) space, allowing for shortcuts to good solutions. Key concepts here are the *mean-field* (MF) approximation (Hopfield and Tank, 1985; Peterson and Söderberg, 1989) and *annealing*.

Although early versions were confined to problems encodable with a quadratic energy in terms of a set of binary variables, in the past decade the method has been extended to deal with more general problem types in terms of both variable types and energy functions, and has evolved to a general-purpose heuristic for combinatorial optimization. An appealing feature is that the basic MF dynamics is directly implementable in VLSI (see Analog VLSI Implementations of Neural Networks), facilitating hardware implementations.

## Recurrent Networks

Recurrent networks appear in the context of associative memories (Hopfield, 1982) and difficult optimization problems (Hopfield and Tank, 1985; Peterson and Söderberg, 1989). Such networks resemble statistical models of magnetic systems ("spin glasses"), with an atomic spin state (up or down) seen as analogous to the "firing" state of a neuron (on or off). This similarity has been the source of much inspiration for neural network studies.

The archetype of a recurrent network is the Hopfield model (Hopfield, 1982), which is based on an energy function of the form

$$E(s) = -\tfrac{1}{2} \sum_{ij} w_{ij} s_i s_j \tag{1}$$

in terms of binary variables (or Ising spins, as used in magnetic models), $s_i = \pm 1$ (in some contexts, equivalent 0,1 spins are preferred), with symmetric weights $w_{ij}$. Owing to the identity $s_i^2 = 1$, diagonal components $w_{ii}$ are redundant and can be assumed to vanish.

With an appropriate choice of weights determined by a set of stored patterns, the latter appear as local minima, satisfying

$$s_i = \operatorname{sgn}\left(\sum_j w_{ij} s_j\right) \tag{2}$$

With a simple asynchronous dynamics based on iterating Equation 2, this system turns into a recurrent ANN, having the local minima as stationary points. In effect, this model serves as an associative memory (see Computing with Attractors).

### *Update Modes*

Note the importance of *asynchronous* update (in random order or sequentially), in which case $E(s)$ is a Lyapunov function and cannot increase. This guarantees the convergence toward a fixed point defining a local energy minimum.

Attempting to iterate Equation 2 in *synchrony* would not necessarily yield convergence to a local minimum. The system could wind up in a two-cycle instead, with a subset of the spins flipping signs on every update.

This behavior can be understood by viewing two consecutive synchronous updates of the $N$ spins as a single sequential update of a system of $2N$ spins, $\{x_i, y_i\}$, where first the $x$ are updated based on $y$ (as $x_i = \operatorname{sgn} \Sigma_j w_{ij} y_j$), and then the $y$ are updated based on the new $x$. The corresponding energy $\hat{E}(x, y) = -\Sigma_{ij} x_i w_{ij} y_j$ is a Lyapunov function, and the extended system must converge to a fixed point $(x^*, y^*)$. If $x^*$ and $y^*$ are equal, they define a fixed point $s^*$ (a local energy minimum) of the original system; otherwise a two-cycle results with $s$ alternating between $x^*$ and $y^*$. If $x^*$ and $y^*$ are maximally different ($x^* = -y^*$), they define two equivalent local *maxima* of $E$. Other, mixed cases can be seen as saddle points.

Consider also the related problem of minimizing $-E$ (i.e., maximizing $E$), obtained by flipping all signs in $w$. In terms of $x$, $y$, the corresponding update equations differ from the original only by replacing, say, $y$ by $-y$. Thus, there is a one-to-one correspondence between sequences of states for $s$ obtained for $-E$ and for $E$: one is obtained from the other by flipping the signs of every second state. This shows that with synchronous update, the system cannot really tell the difference between minimizing and maximizing $E$.

The undesirable behavior of synchronous update can be avoided by introducing stabilizing *self-couplings* in the form of positive diagonal elements large enough to make $w$ a positive-definite matrix (and $E(s)$ a concave function); this, however, has the negative side effect of adding a multitude of stationary states that are not local minima.

Below the sequential update mode without self-couplings will be assumed where not otherwise stated.

## Optimization with Recurrent Networks

Many types of optimization problems can be encoded in terms of a Hopfield model, with the energy function adapted to a specific problem by a dedicated choice of weights, such that global minima of $E(s)$ correspond to solutions. For simple problems, the recurrent network dynamics of iterating Equation 2 can be used to find a solution. For more difficult problems, however, the system will most likely get trapped in a nonoptimal local minimum close to the starting point, which is not desired. A more refined approach is needed to reach the global minimum, or at least a low-lying local minimum.

### *Stochastic Methods*

A possible strategy is to employ a stochastic algorithm that allows for uphill moves, such as simulated annealing (SA) (see Simulated Annealing and Boltzmann Machines). In this approach, a stochastic neighborhood search method is used in an attempt to generate a sequence of configurations distributed according to a Boltzmann distribution, $P(s) \propto e^{-E(s)/T}$, where $T$ is an artificial temperature representing the noise level of the system, which is slowly decreased (annealing). With a very slow annealing rate, the system can avoid getting stuck in a local minimum, and produce a global minimum as $T \to 0$. Such a procedure can be very CPU-consuming, however.

### *The Mean-Field Equations*

An alternative is given by MF annealing, where the stochastic SA method is approximated by a deterministic dynamics based on the MF approximation, defined as follows for a system of Ising spins.

The true Boltzmann distribution $P(s)$ is approximated by the direct product of single-spin distributions, $\Pi_i p_i(s_i)$. Such a factorized distribution is characterized by the absence of correlations between the spins and is completely determined by the single-spin averages $v_i \equiv \langle s_i \rangle = p_i(1) - p_i(-1) \in [-1, 1]$. The parameters $v_i$ are variationally determined so as to minimize the *free energy*,

$$F(v) = E(v) - TS(v) \tag{3}$$

where $E(v) \equiv \langle E(s) \rangle \equiv -(\tfrac{1}{2}) \Sigma_{i \neq j} w_{ij} v_i v_j$ is the average energy, while $S(v) \equiv -(\tfrac{1}{2}) \Sigma_i [(1 + v_i) \log(1 + v_i) + (1 - v_i) \log(1 - v_i)]$ is the entropy associated with the approximating distribution. Minimization of $F$ with respect to $v_i$ directly yields the *MF equations*,

$$v_i = \tanh(u_i/T), \text{ with} \tag{4}$$

$$u_i \equiv -\frac{\partial E(v)}{\partial v_i} \equiv \sum_j w_{ij} v_j \tag{5}$$

The analog *MF variables* $v_i$ take values in the interval $[-1, 1]$, interpolating between the discrete spin states $\pm 1$, which is natural since they approximate the thermal spin averages $\langle s_i \rangle_T$.

### *Analog Network*

The MF equations (Equation 4) can be solved by asynchronous iteration, analogously to the discrete Equation 2. The only difference is the replacement of the sharp step function $\operatorname{sgn}(u_i)$ by a smooth sigmoid $\tanh(u_i/T)$, with an adjustable parameter $1/T$ controlling the gain: high $T$ corresponds to very smooth sigmoids, while in the low-$T$ limit the stepfunction of Equation 2 is recovered.

Most of the discussion on update modes in the context of Equation 2 also applies to the MF dynamics; thus, with asynchronous updating, the free energy $F(v)$ of Equation 3 defines a Lyapunov function guaranteeing the convergence to a fixed point defined by a local minimum of $F$.

### *Mean-Field Annealing*

In MF (or deterministic) annealing, the fixed-$T$ MF dynamics is slowly modified by lowering an initially high $T$, using, for example, a geometric annealing schedule.

For the quadratic Hopfield energy, the dynamics then will exhibit a behavior with two phases. At large temperatures, the system relaxes to a trivial fixed point $v^o$, with $v_i^o = 0$. As the temperature sinks below a critical value $T_c$, $v^o$ becomes unstable and nontrivial fixed points emerge; as $T \rightarrow 0$ these are pushed toward discrete ($\pm 1$) values, representing a specific decision made as to the solution of the problem in question.

The position of the bifurcation point $T_c$ can be determined by linearizing Equation 4 around $v^o$, that is, replacing the sigmoid function (tanh) by its argument. With sequential updating without self-couplings, this yields a smooth tangent bifurcation at a temperature given by the largest positive eigenvalue of $w$ (Peterson and Söderberg, 1989) (see also Dynamics and Bifurcation in Neural Nets).

For an energy without the exact symmetry under $v \rightarrow -v$, as results, for example, from adding a linear energy term, a distinct bifurcation might be absent; then the high-$T$ fixed point is only approximately zero, with the MF variables evolving continuously from smaller to larger values over a finite $T$ interval. This is not a problem: a suitable initial $T$ can still be estimated. Alternatively, an auxiliary spin variable can be introduced and multiplied by the linear term to restore symmetry.

Deterministic annealing yields a more efficient method for finding low-lying energy minima than setting $T = 0$ from the start (i.e., iterating Equation 2). Tracking a local minimum as $T$ is lowered can guide the system to better low-$T$ minima (see Statistical Mechanics of Neural Networks).

### *The Graph Bisection Problem*

As an example application illustrating the abstract discussions heretofore presented, we will use graph bisection (GB). A graph with an even number $N$ of nodes is to be divided into two halves of $N/2$ nodes each, such that the cut-size (the number of connections between the halves) is minimal (Figure 1*A*). The encoding is particularly transparent here because of the binary nature of the problem: with each node $i$ a binary spin $s_i$ is associated, to be assigned a value $\pm 1$ representing whether the node will wind up in the left or right partition of Figure 1*A*. The graph is given in terms of a symmetric connection matrix $J$, such that an element $J_{ij}$ equals 1 if vertices $i$, $j$ are connected, and 0 if not (or if $i = j$). With this notation, the product $J_{ij}s_is_j$ is non-zero only for a connected pair of nodes $i$, $j$, yielding 1 if they are put in the same partition and $-1$ if not. Thus, the cut-size is proportional to $-(\frac{1}{2})\Sigma_{ij}J_{ij}s_is_j$ plus an unimportant constant.

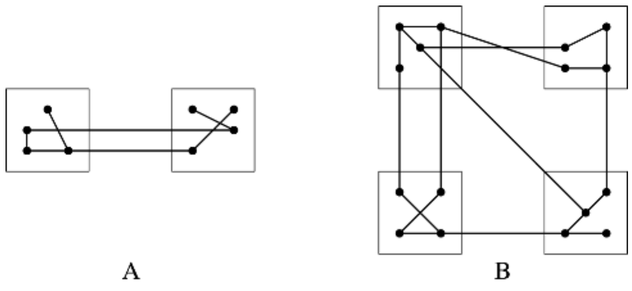

**Figure 1.** *A*, A graph bisection problem. *B*, A $K = 4$ graph partition problem.

In addition, one needs to take into account the global constraint of equal partition of the nodes, requiring $\Sigma_i s_i = 0$. This can be done by adding to the energy function a term that penalizes an illegitimate partition. A term proportional to $(\Sigma s_i)^2$ will do the trick.

Discarding the constant diagonal part $\Sigma_i s_i^2 = N$, we obtain a Hopfield energy function, Equation 1, with $w_{ij} = J_{ij} - \alpha(1 - \delta_{ij})$:

$$E = -\frac{1}{2}\sum_{ij} J_{ij}s_is_j + \frac{\alpha}{2}\left(\left(\sum_i s_i\right)^2 - \sum_i s_i^2\right) \qquad (6)$$

where the constraint coefficient $\alpha$ sets the relative strength of the penalty term.

Equation 6 has a structure common in combinatorial optimization problems: $E$ = Cost + Global constraint. The origin of the difficulty inherent in this kind of problem is very transparent here: the conflict associated with minimizing the two competing terms makes the system frustrated, which often leads to the appearance of many local minima.

For large random GB problems, MF annealing yields a distinctively better performance than simple iteration of Equation 2.

## Recurrent Potts Networks

For GB and many other optimization problems, an encoding in terms of binary elementary variables is natural. However, there are many problems where the natural elementary decisions are of the type one-of-$K$ with $K > 2$.

Early attempts to approach such problems with recurrent network methods were based on *neuron multiplexing* (Hopfield and Tank, 1985), where for each elementary $K$-fold decision, a set of $K$ binary 0/1 neurons was used, with a *syntax* constraint requiring that precisely one of them be on (i.e., equal to 1) implemented in a soft way with a penalty term. In the original work on the traveling salesman problem, as well as in subsequent investigations on the graph partition problem (Peterson and Söderberg, 1989), this approach did not yield high-quality solutions in a parameter-robust way.

A more efficient encoding is based on $K$-state *Potts spins* with the syntax constraint built in. This confines the dynamics to the relevant parts of solution space and leads to a drastically improved performance.

### *MF Annealing with Potts Spins*

A $K$-state Potts spin is a variable that has $K$ possible values (states). For our purposes, the best representation is in terms of a $K$-dimensional vector $\mathbf{s} = (s_1, s_2, \ldots, s_K)$, with the $a$th state given by the $a$th principal unit vector, defined by $s_a = 1$, $s_b = 0$ for $b \neq a$. These vectors point to the corners of a regular $K$-simplex (see Figure 2 for the case of $K = 3$). They are all normalized and mutually orthogonal, and fulfill in addition the syntax constraint $\Sigma_a s_a = 1$.

The MF equations for a system of Potts spins $\mathbf{s}_i$ with a given energy function $E(\mathbf{s})$ in multilinear form ($\partial^2 E/\partial s_{ia}\partial s_{ib} = 0$) are derived in analogy to the Ising case: Approximate the Boltzmann distribution with a factorized Ansatz, $P(\mathbf{s}) = \Pi_i p_i(\mathbf{s}_i)$, parameterized by the single-spin averages $\mathbf{v}_i \equiv \langle \mathbf{s}_i \rangle$. These are determined so as to minimize an associated free energy,

$$F(\mathbf{v}) = \langle E(\mathbf{s}) \rangle - TS(\mathbf{v}) = E(\mathbf{v}) - TS(\mathbf{v}) \qquad (7)$$

where the last equality follows from multilinearity; the entropy $S$ is given by $-\Sigma_{ia}v_{ia}\log(v_{ia})$. A local minimum of $F$ satisfies the MF equations

$$v_{ia} = \frac{e^{u_{ia}/T}}{\sum_b e^{u_{ib}/T}} \qquad (8)$$

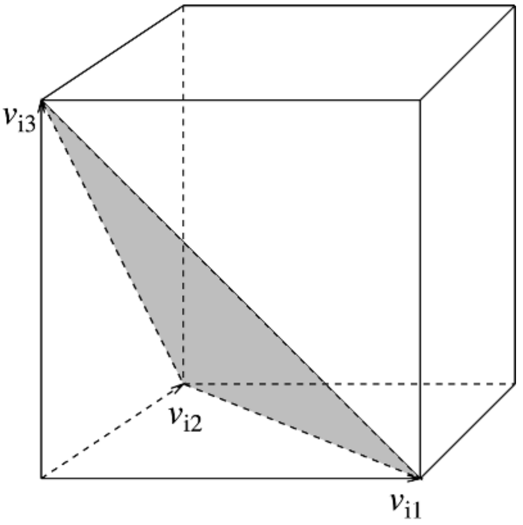

**Figure 2.** The cubic solution space corresponding to the neuron multiplexing encoding for $K = 3$, interpolating between the eight allowed spin states at the corners of the cube. With a Potts encoding, the solution space is restricted to the shaded triangle, interpolating between the three allowed Potts spin states at its corners.

with

$$v_{ia} \equiv -\frac{\partial E(\mathbf{v})}{\partial v_{ia}} \tag{9}$$

These result in *Potts MF neurons* $\mathbf{v}_i$, approximating the thermal average of $\mathbf{s}_i$, and satisfying $v_{ia} \geq 0$, $\Sigma_a v_{ia} = 1$ (for $K = 3$ the shaded region in Figure 2). A component $v_{ia}$ represents a probability for the $i$th spin to be in state $a$. For $K = 2$ one recovers the formalism of the Ising case (with $v_i = v_{i1} - v_{i2} \in [-1, 1]$). As $T \to 0$, each MF neuron $\mathbf{v}_i$ is forced to approach a sharp spin state, defined by the index of the largest component of $\mathbf{u}_i$ in Equation 8 (see also WINNER-TAKE-ALL NETWORKS).

Asynchronous iteration of the Potts MF equations in combination with annealing yields a deterministic annealing approach for Potts systems. As for an Ising system, a suitable initial temperature can be obtained, for example by means of a linear stability analysis.

### The Graph Partition Problem

An illustration is given by $K$-fold *graph partition* (GP): The $N$ nodes of a graph, defined by a symmetric connection matrix $J_{ij} = 0, 1$, $i \neq j = 1, \ldots, N$, are to be grouped in $K$ subsets of $N/K$ nodes each, with a minimal cut-size (i.e., the number of connections between distinct subsets; see Figure 1*B*).

GP is naturally encoded with Potts spins, as follows. With each node $i = 1, \ldots, N$, a $K$-state Potts spin, $\mathbf{s}_i = (s_{i1}, \ldots, s_{iK})$, is associated, where a single nonvanishing component $s_{ia} = 1$ is to be chosen to represent the choice of subset $a$ for node $i$. A suitable quadratic energy function (cf. Equation 6) is

$$E(\mathbf{s}) = -\frac{1}{2}\sum_{i,j=1}^{N} J_{ij}\mathbf{s}_i \cdot \mathbf{s}_j + \frac{\alpha}{2}\left(\left(\sum_{i=1}^{N} \mathbf{s}_i\right)^2 - \sum_{i=1}^{N} \mathbf{s}_i^2\right) \tag{10}$$

where the first term is a cost term (cut-size), while the second is a penalty term with a minimum when the nodes are equally partitioned into the $K$ subsets. Note that the diagonal contributions are subtracted in the second term to secure multilinearity.

Writing $E$ as $-(\frac{1}{2})\Sigma_{ij} w_{ij}\mathbf{s}_i \cdot \mathbf{s}_j$, we have for the input $\mathbf{u}_i = \Sigma_j w_{ij}\mathbf{v}_i$, in analogy to Equation 5.

## Refinements and Generalizations

In this section, we discuss modifications and extensions of MF annealing, as well as complications that may arise in optimization applications and that require special care in one way or another.

### Continuous-Time Methods

An alternative method for solving, say, the Ising MF equations (Equations 4 and 5) is to use a continuous-time formalism, based on $\dot{u}_i = -u_i + \Sigma_j w_{ij} v_j$, with $v_j \equiv \tanh(u_j/T)$. Indeed, such a formulation was used in the original work of Hopfield and Tank (1985). It is easily generalized to the Potts case. In both cases such a dynamics can also be directly implemented in VLSI.

A continuous-time formalism facilitates an alternative method for implementing a global constraint, such as $\Sigma_i s_i = 0$ in GB, with a linear term $\lambda \Sigma_i s_i$, where $\lambda$ is a *Lagrange multiplier* to be dynamically adjusted such that a balanced stationary state results. Such methods are discussed in Platt and Barr (1988).

A naive discretization of the continuous-time system with a unit time step results in synchronous updating of Equation 4, with problems like an absent Lyapunov function and two-cycle behavior. However, with a small enough time step $\varepsilon \ll 1$, a stabilized discrete-time approach results, corresponding to synchronous updating of the inputs $u$ according to $u_i = (1 - \varepsilon)u_i + \varepsilon \Sigma_j w_{ij} v_j$, defining a parallelizable alternative to the standard asynchronous discrete-time dynamics. For a sequential software implementation, however, the latter is far more efficient.

### Nonquadratic Energy Functions

With a quadratic Potts energy $E(\mathbf{s})$, self-couplings can be avoided and multilinearity secured by removing all diagonal terms, $s_{ia}s_{ib} \to \delta_{ab}s_{ia}$; such a procedure can be generalized to any polynomial $E$. Although in principle any energy function of a finite number $N$ of spins can be rewritten as a polynomial of at most degree $N$, this may be difficult in practice for large $N$ with an energy in nonquadratic form.

An efficient and general alternative method for disarming self-couplings in a Potts system with a given generic energy function $E$ is to simply replace the derivative in Equation 9 for the input by a difference:

$$u_{ia} = -\frac{1}{T}\left(E(\mathbf{v})|_{\mathbf{v}_i = \mathbf{e}_a} - E(\mathbf{v})|_{\mathbf{v}_i = 0}\right) \tag{11}$$

where $\mathbf{e}_a$ is a unit vector in the $a$-direction. Whenever $E$ is multilinear, Equations 9 and 11 are equivalent.

### Inequality Constraints

In the optimization problems mentioned above, the constraints considered were all of the *equality* type, $g(s) = 0$, that could be implemented with quadratic penalty terms $\propto g(s)^2$. However, in many optimization problems, especially those of the resource allocation type, one has to deal with *inequalities*. An inequality constraint, $g(s) \leq 0$, can be implemented with a penalty term proportional to, e.g.,

$$\Phi(g) = g\Theta(g) \tag{12}$$

with $\Theta$ the Heaviside step function: $\Theta(x) = 1$ if $x > 0$ and 0 otherwise. Of course, such a nonpolynomial term in the energy requires the use of Equation 11.

Inequality constraints appear, for example, in the *knapsack problem*, where one has a set of $N$ items $i$, with associated utilities $c_i$ and loads $a_{ki}$. The goal is to fill a "knapsack" with a subset of the items such that their total utility is maximized, subject to a set of

$M$ load constraints. In terms of binary spins $s_i \in \{1, 0\}$, representing whether or not item $i$ goes into the knapsack, the total utility can be expressed as

$$U = \sum_{i=1}^{N} c_i s_i \tag{13}$$

and the load constraints as

$$\sum_{i=1}^{N} a_{ki} s_i \leq b_k, \quad k = 1, \ldots, M \tag{14}$$

where $b_k > 0$ define load capacities, which can be seen as representing distinct limiting aspects of the knapsack (its height, width, etc.).

In Ohlsson, Peterson, and Söderberg (1993), a set of difficult random knapsack problems were successfully approached with an MF annealing method based on the energy function

$$E = -\sum_{i=1}^{N} c_i s_i + \alpha \sum_{k=1}^{M} \Phi\left(\sum_{i=1}^{N} a_{ki} s_i - b_k\right) \tag{15}$$

### *Scheduling and Constraint Satisfaction*

Scheduling problems have a natural formulation in terms of Potts spins and can be approached with Potts MF annealing. A pure scheduling problem can have the following simple structure: For a given set of events, a time slot and a location are to be chosen, each from a set of allowed possibilities, such that no clashes occur. Such a problem consists entirely in fulfilling a set of basic no-clash constraints, $g = 0$, each of which can be handled with a nonnegative penalty term, e.g., $\propto g^2$, that will vanish for a legal schedule.

In realistic scheduling applications, there often exist additional preferences within the set of legal schedules that lead to the appearance also of *cost terms*. A set of real-world scheduling problems was successfully dealt with in Gislén, Peterson, and Söderberg (1992), using a straightforward MF Potts formalism.

Pure scheduling is a special type of *constraint satisfaction* problem (CSP) where the entire object is to satisfy a set of constraints. Such problems have been much studied in computer science. *INN* is a modified MF annealing approach dedicated to CSP, where a particular kind of nonpolynomial penalty term is used, based on an information-theoretic analysis. In Jönsson and Söderberg (2001), INN was applied to a set of difficult $K$-SAT problems and shown to outperform a conventional MF annealing approach based on polynomial penalty terms.

For constrained optimization, a *hybrid approach* might be advantageous, using a conventional polynomial energy term for the cost part and nonpolynomial INN-type penalty terms for the constraints.

### *Routing Problems*

Many network routing problems can be conveniently handled using a Potts MF approach. The basic idea can be illustrated with a simple shortest-path problem: Given a network of $N$ nodes connected by arcs of given lengths, find the shortest path between nodes $a$ and $b$, i.e., the shortest sequence of arcs leading from $a$ to $b$.

This problem can be solved in polynomial time using, e.g., the Bellman-Ford (BF) algorithm (Bellman, 1958), where every node $i$ estimates its distance $D_{ib}$ to $b$, minimized with respect to the choice of a continuation node $j$ among its neighbors (nodes directly connected to $i$ via an arc of length $d_{ij}$):

$$D_{ib} = \min_j (d_{ij} + D_{jb}), \quad i \neq b \tag{16}$$

while $D_{bb} = 0$. Iteration of Equation 16 gives convergence in less than $N$ steps, and $D_{ab}$ can be read off.

Also, more complex routing problems, such as ones with several competing routing requests, can be formulated in terms of optimal neighbor choices that can be encoded by a set of Potts spins. The resulting system can then be handled with a Potts MF annealing algorithm. An appealing feature of such an approach is the *locality* inherited from BF: all information required for the neighbor choice is local to the node and its neighbors.

In Häkkinen et al. (1998) a set of complex routing problems in finite-capacity networks was approached in this manner, aided by a *propagator* formalism for monitoring global topological aspects of the fuzzy MF routes.

### *Mutual Assignment Problems*

In certain classes of problems, one seeks an optimal one-to-one assignment between the elements in two sets of equal size $N$. Such an assignment can be encoded with a doubly stochastic 0/1-matrix $s$,

$$s_{ij} \in \{0, 1\}, \quad i, j = 1, \ldots, N \tag{17}$$

$$\sum_j s_{ij} = 1 \tag{18}$$

$$\sum_i s_{ij} = 1 \tag{19}$$

such that $s_{ij} = 1$ represents the mutual assignment of element $i$ in the first set with element $j$ in the other.

An example is the traveling salesman problem, where the goal is to minimize the total length of a closed tour connecting a set of $N$ cities with given pairwise distances. This can be seen as finding an optimal mutual assignment between cities and positions in the tour.

In an early approach Hopfield and Tank (1985) to the traveling salesman problem, each component of $s$ was considered an independent binary 0/1 spin, and the row and column sum constraints on $s$ were softly implemented by means of penalty terms. In a refined MF annealing approach (Peterson and Söderberg, 1989), each row of $s$ was taken as a separate Potts spin, while penalty terms were used for the column sum constraints (*row-Potts*; the opposite, *column-Potts*, is of course also possible), yielding a noticeable increase in performance.

Ideally, however, one would prefer a dedicated MF method for mutual assignments. Such an approach can indeed be devised, by using a single Potts spin with $N!$ components, one for each possible assignment. A problem with this approach is the inevitably nonpolynomial time consumption for large $N$, which makes it infeasible for large problems.

For large mutual assignment problems, the best recurrent network method around appears to be *Softassign* (Yuille and Kosowski, 1994; Rangarajan, Gold, and Mjolsness, 1996), where both row and column sum constraints are formally implemented in an exact manner by means of Lagrange multipliers, yielding a formalism that can be seen as a synthesis between the row- and column-Potts MF approaches, although not strictly derived from a proper MF formalism. Softassign requires synchronous updating, in contrast to the row-Potts approach, where one row at a time can be updated; this yields instability problems that have to be remedied, such as with positive self-couplings. At low temperatures, it also suffers an inevitable slowing down of the row and column normalization procedure.

### *Hybrid Approaches*

A large class of optimization problems can be viewed as *parametric assignment* problems, containing elements of both discrete assignment and parametric fitting to given data, e.g., by using templates with a known structure. Then the assignment part can be encoded in terms of Potts neurons while the template part can be formulated in terms of a set of continuous adjustable parameters.

Also, certain pure assignment problems with a well-defined geometric structure can be cast in this form; a nice example is the *elastic net* algorithm (Durbin and Willshaw, 1987; Simic, 1990; Yuille, 1990) for planar traveling salesman problem, where a closed curve is allowed to move and deform elastically in the plane, with each city choosing a nearby point on the curve by means of an analog Potts MF neuron. As $T \to 0$, each chosen point is attracted to the respective city, while the remaining points on the curve are adjusting to form straight segments in between.

## Discussion

For a large class of combinatorial optimization problems, a straightforward MF annealing approach can be used, based on an encoding in terms of Ising or Potts spins, with the following basic steps:

- Map the problem onto a recurrent network by a suitable encoding of solution space (in terms of a set of binary or Potts spins) and an appropriate choice of energy function, and derive the associated MF equations.
- Compute a suitable starting temperature (e.g., by means of a linear stability analysis of the asynchronous MF dynamics).
- Solve the MF equations iteratively while slowly lowering $T$.
- When the system has settled, the solutions are checked with respect to constraint satisfaction, if applicable. If needed, one may perform a simple corrective postprocessing or rerun the system (possibly with modified constraint coefficients).

This very general approach has been numerically explored for many different problem types, resulting in the following general picture. The MF annealing method, without excessive fine-tuning, consistently performs roughly in parity with dedicated problem-specific heuristics, designed to perform well for a particular problem class. Convergence is consistently achieved after a modest number (typically 50–100) of iterations, independently of problem size.

Modified variants of this method have been defined for specific problem types, such as INN for pure constraint satisfaction problems and Softassign for mutual assignment problems. For parametric assignment problems and for certain low-dimensional geometrical assignment problems such as the planar traveling salesman problem, hybrid methods can be used in which Potts MF neurons are combined with conventional analog parameters.

# Optimization Principles in Motor Control

*Tamar Flash, Neville Hogan, and Magnus J. E. Richardson*

## Introduction

Optimization theory has become an important research tool in our attempts to discover organizing principles that guide the generation of goal-directed motor behavior. It provides a convenient way to formulate a coarse-grained model of the underlying neural computation, without requiring specific details of the way those computations are carried out. Generally speaking, this application of optimization theory consists of defining an objective function that quantifies what is to be regarded as optimum (i.e., best) performance and then applying the tools of variational calculus to identify the specific behavior that achieves that optimum. This forces us to make explicit, quantitative hypotheses about the goals of motor actions and allows us to articulate how those goals relate to observable behavior. Not all motor behaviors are necessarily optimal, but attempts to identify optimization principles can be useful for developing a taxonomy of motor behavior and gaining insight into the neural processes that produce motor behavior.

### *Ill-Posed Problems in Motor Behavior*

Many optimization-based models in the literature have been developed to address the "excess degrees-of-freedom" problem. How does the motor system select the behavior it uses from the infinite number of possibilities open to it? In mathematical parlance, this is an "ill-posed" problem in the sense that many solutions are possible. For example, most limb segments are moved by a larger number of muscles than appear to be necessary. To reach for a cup of coffee, the hand may move along many different paths. The same figural form (e.g., the letter *Z* or an ellipse) may be drawn using a wide variety of time profiles for the pen's position. The central question is how the nervous system chooses values for the large number of parameters that can be controlled. One appealing possibility is that the nervous system has evolved to select solutions that maximize the organism's fitness, i.e., that are optimal in some sense. More specifically, the hypothesis is that in performing a motor task, the brain produces coordinated actions that minimize some measure of performance (such as effort, smoothness, etc.). In this article we review several studies in which the validity of such ideas was examined in the context of planar upper limb movements. Similar ideas have been explored in the context of other effector systems and motor actions, such as whole body posture, gait, and various sporting activities, but they will not be considered here. The interested reader is referred to Winters and Crago (2000) for further information.

## Arm Trajectory Formation

Our first topic is the kinematic aspects of movement. *Kinematics* refers to the time course of limb position, velocity, etc., while *dynamics* refers to variables such as forces and torques. In principle, even a single-degree-of-freedom movement (e.g., elbow rotation) can be performed in many different ways. Thus, while the hand path is constrained to follow a circular arc, its speed along the path may follow many different time profiles. One way to gain insight into the processes responsible for the selection of specific limb trajectories is to experimentally observe human movements. Patterns or invariances in the observed behavior suggest hypotheses about the way these movements are organized. Optimization theory provides a mathematical tool for concisely formulating and testing these hypotheses. The key step is the identification of an *objective function* that defines a measure of performance by assigning a cost to each member of the class of possible behaviors under study (e.g., arm trajectories). One member of this class (e.g., one trajectory) will then be selected to maximize or minimize that function. How the objective function is defined determines what aspects of the motor behavior are considered important.

### *Kinematic Versus Dynamic Objective Functions*

In this article we will consider two different types of objective functions that have been proposed (out of the multitude of possibilities) as they reflect two major competing theories of how motor computations are organized. The first type of objective function is based solely on kinematic variables (e.g., limb position and its time derivatives). If a kinematic objective function can be found that leads to optimal trajectories that accurately reproduce the patterns of observed behavior, it implies that the brain ignores nonkinematic factors in selecting and producing that behavior. This would be consistent with a theory that, to produce movement, neural computations are organized hierarchically and executed by proceeding from the abstract (i.e., move to that light over there) to the particular (i.e., activate that set of motor neurons in this manner). The most compelling evidence supporting this idea is the observation that similar kinematic patterns are observed even when widely different musculoskeletal systems are involved in producing motor behavior. One's signature on paper is equally as recognizable and distinctive as one's signature on a blackboard, despite the enormous differences in the mechanics and physiology of the body parts used to produce it. Nevertheless, a troubling aspect of this theory is that it seems to imply that, at least at the higher levels of the postulated hierarchy, the brain does not take into account *any* dynamic considerations, such as the energy required, the loads on the limb segments, or the force and fatigue limitations of its peripheral neuromuscular system.

To circumvent this problem within the framework of optimization theory, a second type of objective function may be formulated based on dynamic variables (e.g., joint torques, muscle forces, etc., and their time derivatives). If a dynamic objective function can be found that leads to optimal trajectories that accurately reproduce the patterns of observed behavior, it implies that the brain considers dynamic factors in selecting and producing that behavior. It is also consistent with a theory that neural computations to produce movement are executed in parallel, taking all relevant factors (e.g., dynamics as well as kinematics) into account simultaneously.

### *Single-Joint Movements*

As has been frequently observed, single-joint movements are characterized by single-peaked, bell-shaped speed profiles. This finding and the tendency of natural movements to be characteristically smooth and graceful led Hogan (1984) to suggest that motor coordination can be mathematically modeled by postulating that voluntary movements are made, at least in the absence of any other overriding concerns, to be as smooth as possible. For mathematical convenience (there are many other plausible measures of smoothness), maximizing smoothness was expressed as minimizing mean-squared average jerk, the third time derivative of position. In the single-joint case,

$$C = \int_{t_0}^{t_f} \left(\frac{d^3\theta}{dt^3}\right)^2 dt \qquad (1)$$

where $\theta(t)$ is the joint angle, and $t_0$ and $t_f$ are the initial and final movement times, respectively. Using variational calculus, the unique time history of joint positions that minimizes this performance measure may be derived analytically. It is described by the following quintic polynomial in time:

$$\theta(t) = c_0 + c_1 t + c_2 t^2 + c_3 t^3 + c_4 t^4 + c_5 t^5 \qquad (2)$$

where $c_i$, $i = 0, \ldots, 5$ are unspecified coefficients whose values are determined by the conditions at the beginning and end of the movement (boundary conditions). Originally, Hogan (1984) analyzed movements that start and end at rest and therefore assumed zero initial and final velocities and accelerations. Consequently, the predicted trajectories were characterized by symmetric bell-shaped speed profiles. For movements of different amplitudes and durations, the ratio of peak speed to average speed was invariant at 1.88. For a repetitive sequence of movements, speed profiles were again symmetric and this ratio was again invariant, but with a value of 1.57. These predictions appear to be in good agreement with observation. A constant ratio of peak speed to average speed has been reported by several researchers, with values between 1.60 and 1.90, depending on the conditions of measurement. However, a distinctive feature of these minimum-jerk movements is their symmetric speed profile, and that is not always observed experimentally. For example, when enhanced accuracy of target acquisition is demanded, an asymmetric speed profile is typically observed, with the peak speed occurring earlier in the movement. This indicates that the simple minimum-jerk theory may need to be modified. One possible way to account for this asymmetry is by adding (to the objective function) a term to minimize hand-to-target error integrated across the movement. An alternative is to modify the boundary conditions.

Another alternative is to use a dynamic objective function. This requires formulation of a model of neuromuscular and skeletal mechanics to relate dynamic variables (e.g., forces) to kinematics. Hasan (1986) proposed a minimum-effort theory of single-joint movement generation based on a model that described neuromuscular behavior as equivalent to a "spring-like" element driving the limb toward a neurally defined "equilibrium position," determined by simultaneous activation of agonist and antagonist muscle groups. Minimization of effort was expressed as follows:

$$C = \int_{t_0}^{t_f} \left( \sigma(t) \left( \frac{d\beta}{dt} \right)^2 \right) dt \tag{3}$$

where $\sigma$ is the joint stiffness (describing the rate of change of the restoring force generated by the "spring-like" element with its displacement from equilibrium) and $d\beta/dt$ is the time derivative of the equilibrium position. Thus, for single-joint movements, optimization theories using both kinematic and dynamic objective functions have been applied with success. A more telling test of these theories is found in multijoint movements.

## Multijoint Movements and the Question of Coordinates

The kinematics of multijoint arm movements may be represented in a number of different ways, e.g., as a series of hand positions, joint angles, or muscle lengths. Each of these may be considered as alternative "coordinate frames" for describing the movement. The neural computations underlying multijoint arm movements may make use of any one (or even several) of these representations. Experimental observations of unconstrained human reaching movements are characterized by approximately straight hand paths and symmetric bell-shaped speed profiles that remain nearly invariant despite changes in movement direction, speed, and starting position. Because these features are evident only in the motions of the hand, and not in the movements of individual limb segments, it was proposed that the neural computations underlying movement production take place in terms of hand motion through extracorporeal space and not in terms of joint rotations.

Flash and Hogan (1985) showed that the maximum-smoothness theory reproduced all of these features, provided the objective function was expressed in terms of the Cartesian coordinates of the hand as follows:

$$C = \int_{t_0}^{t_f} \left( \left( \frac{d^3x}{dt^3} \right)^2 + \left( \frac{d^3y}{dt^3} \right)^2 \right) dt \tag{4}$$

where $x(t)$, $y(t)$ describe the hand position coordinates and $t_f$ is the movement duration.

Minimizing this objective function yielded analytic expressions for the hand trajectories. For unrestrained point-to-point movements starting and ending at rest, the model predictions agreed closely with experimental data and successfully accounted for the invariance of hand trajectories under translation, rotation, amplitude and speed scaling.

In more complex curved movements, patterns were again evident in hand kinematics, but not in joint kinematics. When subjects were instructed to generate curved or obstacle-avoidance movements, although the hand paths appeared smooth, movement curvature was not uniform; the trajectories displayed two or more curvature maxima. The hand speed profiles also had two or more maxima, and the minima between adjacent peaks temporally corresponded to the peaks in curvature.

To describe curved and obstacle-avoidance movements, the maximum-smoothness model was extended by assuming that a small number of points along the path through which the hand should pass are specified (Flash and Hogan, 1985). The time of passage through those "via" points and the hand velocity at that time were not specified a priori but were predicted by the model. For the simplest case of one via point between the initial and final positions, the theory yielded explicit mathematical expressions for the hand motion (Flash and Hogan, 1985) that reproduced all the features of the experimental observations: distinct maxima in the speed profile with a minimum between them which coincided temporally with a curvature maximum; trajectory shape invariant under translation, rotation, amplitude, and time scaling; and nearly equal durations of movement from the initial position to the via point, and from the via point to the final position. The latter observation was referred to as the *isochrony principle* (Viviani and Terzuolo, 1982), or the phenomenon that movement durations of large and small segments of a trajectory are roughly equal.

### *Minimum Torque Change Models*

In contrast to the maximum-smoothness model, Uno, Kawato, and Suzuki (1989) postulated that movement selection optimizes the rate of change of actuator efforts, e.g., joint torques. Although minimizing jerk and minimizing the rate of change of joint torques appear conceptually similar (in a single-joint system with predominantly inertial dynamics they are proportional to one another), there are important differences. First, the objective function is based on dynamic variables: the rate of change of torque. Therefore, the predicted motion depends sensitively on the modeled dynamic behavior of the musculoskeletal system. Second, the objective function was formulated in terms of joint torques rather than functions of the hand's coordinates, as is the case for minimum jerk. This implies that motor computations are based on a joint-space representation of behavior. Although (as outlined above) kinematic patterns are most evident in hand motions in extracorporeal space, approaches based on either joint or muscle spaces have the advantage that they can generate solutions to important aspects of the ill-posed motor control problems, such as kinematic redundancy (the apparent excess degrees of freedom) or actuator redundancy (the apparent excess of muscles). The maximum-smoothness model expressed in hand coordinates does not address these issues.

Initially, Uno et al. (1989) reported that the performance of the minimum torque change model surpassed that of the maximum-smoothness model. It appeared to account for the small but systematic curvature seen in point-to-point movements, and also for the larger curvature seen in movements that pass from the side to the front of the body. However, an independent study (Flash, 1990) and a later reappraisal co-authored by some of the original proponents of the minimum torque change model (Nakano et al., 1999) invalidated these conclusions: it was shown that a combination of too large an inertia and too small a viscosity contingently led to predictions compatible with experimental results.

However, in Nakano et al. (1999), a variant of the minimum torque change model, the minimum *commanded* torque change model, was introduced. In this model the commanded torque includes non-zero viscous terms that arise from biochemical and mechanical reaction processes within the muscles, and in this way both the muscles and the link dynamics are considered as controlled objects. Using more realistic, measured physical parameters, this second model was again able to reproduce the experimentally verified effects of curvature.

### *Motor Adaptation Studies*

The most critical comparison of these two models arises from their fundamental differences. According to kinematically based optimization models, neural computations specify intended motions independently of movement dynamics or external load conditions. In contrast, dynamically based optimization models imply that external loads profoundly influence intended motions. For example, according to the minimum torque change models, movements in the presence of elastic loads should be more curved than unloaded movements, whereas the maximum-smoothness model predicts no effect.

Investigating motor adaptation to elastic loads, Uno et al. (1989) concluded that the behavior in the presence of the load was different from the unloaded case. Completely different results, however, were obtained in another study in which static elastic loads were unexpectedly introduced during human reaching toward visual targets (Flash and Gurevich, 1997). In the first few trials following load application, movements were found to be misdirected and to miss the target, but after a small number of practice trials (five to seven), the loaded movements tended to follow straight hand paths with symmetric velocity profiles. In another study (Shadmehr and Mussa-Ivaldi, 1994), velocity-dependent force fields were used to perturb the motion, and the perturbed trajectories performed in the presence of the new force fields were again found to converge toward the ones seen in the unloaded case. In a third related study, Wolpert, Ghahramani, and Jordan (1995) used altered visual feedback conditions that caused an increase in the perceived curvature of aiming movements. This led to significant corrective adaptation of the movements actually produced: the hand movements became curved, thereby reducing the visually perceived curvature. These results support the notion that arm trajectories follow a kinematic plan formulated in extrinsic visual space, independent of movement dynamics or external force conditions. They are incompatible with the assumptions of dynamically based optimization models formulated in terms of intrinsic coordinates.

Furthermore, it should be noted that small deviations from straight-line movements do not necessarily imply planning in joint coordinates. Such phenomena are compatible with planning in kinematic space, but with perturbations due to the dynamics of the arm and neuronally controlled muscles at the implementation stage (Flash, 1990). Conclusions with respect to the sensorimotor mapping that associate desired trajectories to motor commands were drawn based on motor adaptation studies. Shadmehr and Mussa-Ivaldi (1994) have analyzed the aftereffects observed when, after training in one region of the work space, subjects were asked to perform reaching movements at a nearby space. The patterns of aftereffects suggested that generalization from learning was in terms of intrinsic joint-based coordinates.

## Relation to Physiology

The kinematic and dynamic objective functions discussed above are based on measures of smoothness in different coordinate frames. Both of these models have in common that they are *phenomenological* approaches. The controller (nervous system) and plant (arm) are treated as a *black box*, with the input the experimental task and the output the goal-fulfilling movement. The success (or otherwise) of phenomenological theories in fitting experiment affords insight into which variables the central nervous system (CNS) might consider important in the movement planning process. Results have been presented above that support the idea that the high-level planning processes in the CNS might be in the coordinates of the hand's position.

The fact that movements are smooth, whether in hand or joint coordinates, has been interpreted as compatible with increasing the predictability of the trajectory or reducing the amount of information needed to internally represent motion plans (Hogan, 1984; Flash and Hogan, 1985). Smoothness maximization and the superposition of elemental movements to generate more complicated arm trajectories are also closely related to regularization-based approaches to learning from examples. Those approaches view learning as equivalent to identifying a function from sparse and noisy data. The trade-off between accurate data reproduction and "well-behavedness" of the mapping is achieved by maximizing the smoothness of the function.

Work has also been done on how the CNS might implement an optimization procedure such as minimum jerk. For example, it has been shown that a minimum-jerk movement planner can be directly implemented by a radial basis function (RBF) network. Another implementation scheme was described by Hoff and Arbib (1992), who showed how the minimum-jerk principle could be converted into a real-time controller in which delays and noise effects could explain a number of experimental observations beyond the fitting of simple point-to-point trajectories. However, looking for neural circuits that can reproduce explicitly the calculations inherent in the phenomenological theories of minimum jerk and minimum torque might be a too literal interpretation of the success of such theories in reproducing experiment. The kinematic and psychophysical observations reported to date do not sufficiently constrain the possible movement-generating algorithms to distinguish the finer details of neural implementation. Nevertheless, these phenomenological theories serve as background, coarse-grained descriptors to which deeper, more biologically detailed theories must conform.

Recently, some effort has been made in grounding the optimization approach to motor control in a neurobiological context. It was noted that biological systems are corrupted by noise, the variance of which increases with the size of the signal (Harris and Wolpert, 1998). Hence, any preplanned movement is likely to be off-target when the motor program is run through the noisy neuromuscular system. As each goal-directed movement has some characteristic level of error, this suggests a natural optimization criterion: the CNS chooses movements that minimize the final error in the achievement of the motor task.

Harris and Wolpert (1998) analyzed the predictions of this hypothesis in the context of saccadic eye movements. The error in the final eye position was functionally minimized with respect to the control signal (using a linear model of the plant). It was found that small final error was achieved by low-bandwidth neuronal signals, corresponding to the smooth velocity profiles seen experimentally. This approach was also extended to arm movements in the particular case of two-joint motions in the plane (Harris and Wolpert, 1998). A large range of experimental results were successfully reproduced, including the small curvature seen in point-to-point movements. Furthermore, it was claimed that the predicted trajectory of the hand was, to a large degree, independent of the specifics of the model of the plant: the controlling neuronal signal adapts to produce similar output.

The role of noise in the coordination of movement has been further examined in the context of *optimal feedback control* (Todorov and Jordan, 2001). It was noted that the variability and redundancy inherent in, for example, the control of the human arm are often treated as problems to be overcome in the planning process. In their work on optimal feedback control, Todorov and Jordan showed that increased accuracy in the goal-specific parameters of movement can be obtained by allowing the variance to increase in the redundant variables. In fact, their model does not enforce a desired trajectory but corrects only those deviations that interfere with the task, a principle of *minimum intervention*. Despite this minimal formulation, experimentally observed features such as simplifying rules, control parameters, and synergies emerge as epiphenomena of the control process. The theory is supported by a number of exemplary experimental results and provides a satisfying interpretation of the role of variability and the so-called degrees-of-freedom problem.

## Motion Planning for Three-Dimensional Movements

For completeness, we briefly mention recent work on motion in three dimensions (i.e., not confined to a plane). Compared with the success of optimization techniques in two dimensions, the use of cost function analysis is still in the investigative phase for this more general class of motion. It is known that point-to-point motions in three dimensions are considerably more curved than in the plane. Nevertheless, there has been some success in predicting this more complex behavior using the techniques of the optimization approach. Hypothesized cost functions have included minimum kinetic energy (Soechting et al., 1995), in which it was also shown that a simple Donder's law rule that expresses a kinematic constraint on eye orientation does not apply to arm motions. Other models that incorporate a description of muscle dynamics and hypothesize the minimization of a metabolic energy cost or consider the effect of final posture of the arm have also been developed, representing attempts to deal with the acute degrees-of-freedom problem found in three-dimensional movements.

## Discussion

One of the exciting challenges of brain theory is the need to deal with reality at the level of whole, functioning systems. Traditionally, scientific endeavor has advanced our state of knowledge by delving into finer and finer details of isolated pieces of reality—the essence of the reductionist approach. However, because of the limited amount known of these fine details and the difficulties involved in studying complex systems of many neurons, this bottom-up approach is severely limited in its ability to describe systemwide behavior: large-scale, strongly interacting systems exhibit characteristics that emerge primarily from interactions among their parts. To understand them, a top-down approach is far more effective, beginning at a coarse-grained macroscopic level and proceeding to finer levels of detail as their structure is discerned. Optimization theory provides a powerful set of mathematical tools that lend themselves well to a top-down approach to studying the brain. As we have reviewed in this article, optimization theory facilitates a rigorous approach, based on macroscopic observations of psychophysical behavior, to some fundamental and far-reaching questions about the structure of neural computations.

# Orientation Selectivity

*Robert Shapley, David McLaughlin, and Michael Shelley*

## Introduction

The detection of edge information from within a visual scene is an essential component of visual processing. This processing is believed to be initiated in the primary visual cortex, where individual neurons are known to act as feature detectors of the orientation of edges within the visual scene. Individual neurons can have an *orientation preference* (which states that neuron's preferred orientation of the angle of edges) and an *orientation selectivity* (which measures the neuron's sensitivity as a detector of orientation).

This article considers mechanisms of orientation selectivity in the visual cortex. In V1 there is a transformation to orientation-tuned elements (Hubel and Wiesel, 1962). Along the visual pathway prior to V1, in the retina and lateral geniculate nucleus (LGN) of the thalamus, there is weak or no orientation selectivity in single cells. It has been thought from the time of its discovery that orientation selectivity, as an emergent property in visual cortex, must be an important clue to how the cortex works and why it is built the way it is. Much has been learned about the basic principles of cortical neurophysiology through intense investigations of orientation selectivity.

## Models of Orientation Selectivity

### Feedforward Models

There are two schools of thought about the explanation for cortical orientation selectivity: feedforward filtering, on the one hand, and strong excitatory corticocortical feedback on the other. The models of the latter, with sufficiently strong excitatory feedback, possess "attractor states" that are intrinsic to the nonlinear cortical dynamics.

Our view, based on experimental results and also on our own modeling, is somewhere in the middle; perhaps a good label for our view of the cause of orientation selectivity in V1 would be *recurrent network filtering*. However, the first view proposed his-

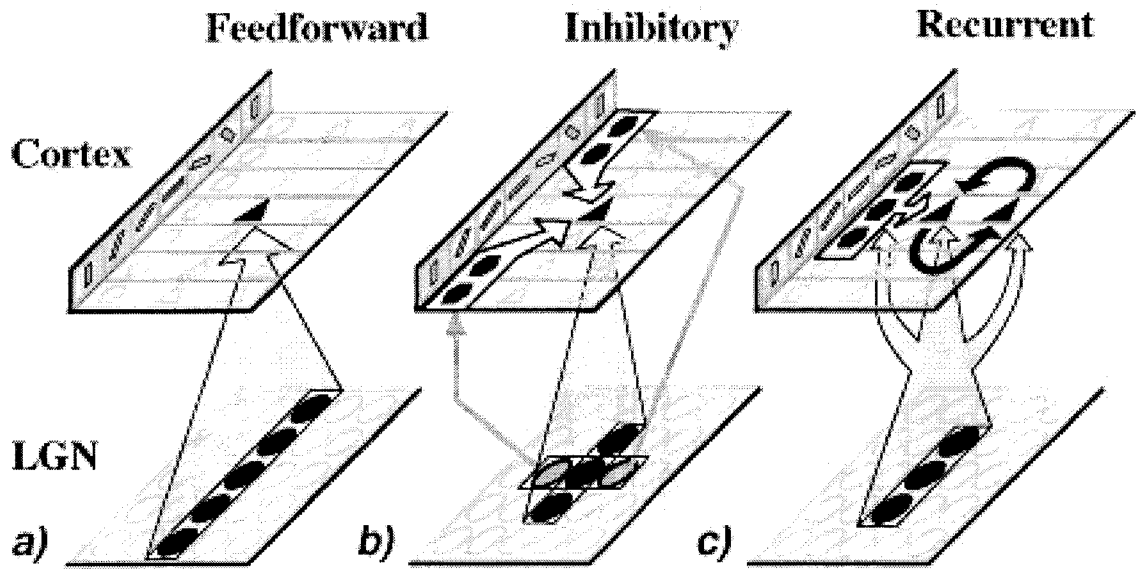

**Figure 1.** Sketch of different models for cortical orientation selectivity. At the cortical level, hexagonal shapes stand for inhibitory neurons and triangular shapes stand for excitatory neurons. The LGN cells are depicted as the circular shapes at the LGN level in the models. *A*, Feedforward. All cortical cells receive input from a row of LGN cells aligned in space. *B*, In inhibitory models, there is inhibitory input from orientation-tuned cortical neurons, indicated by the outlined white arrows. *C*, Recurrent excitatory and inhibitory feedback models have both corticocortical inhibition (white arrows) and corticocortical excitation (black arrows) impinging on all cortical cells. These corticocortical interactions are supposed to greatly sharpen a broadly tuned input from LGN (indicated by the shorter row of aligned LGN cells). (From Somers, D. C., Nelson, S. B., and Sur, M., 1995, An emergent model of orientation selectivity in cat visual cortical simple cells, *J. Neurosci.*, 15:5448–5465. Reprinted with permission.)

torically and the first one discussed here is the feedforward view, which descended from the pioneering work of Hubel and Wiesel (1962). From the time of its publication, Hubel and Wiesel's feedforward model has been a dominant idea in this field. Figure 1, from Somers, Nelson, and Sur (1995), compares and contrasts the feedforward model in panel *A* with cortical interaction models in panels *B* and *C*. As shown in the figure, the HW model involves the addition of signals from LGN cells that are aligned in a row along the long axis of the receptive field of the orientation-selective neuron. In the HW model, this collection of LGN cells, taken together, sets the orientation preference and selectivity of that cortical cell onto which the LGN cells converge. The experiment on the cooling of cat V1 by Ferster, Chung, and Wheat (1996) is an important result that was interpreted to mean that there is substantial orientation tuning of the collective thalamic input to a cortical neuron, consistent with the HW model. In spite of this evidence, several authors agree that the HW model predicts rather little orientation selectivity, and therefore does not account for the visual properties of V1 cells (Sompolinsky and Shapley, 1997; Troyer et al., 1998; McLaughlin et al., 2000).

The reason for the shortfall of orientation selectivity in the HW model can be stated as follows. LGN cells have a low spontaneous rate but are quite responsive to visual stimuli, so their firing rate during visual stimulation clips at zero spikes per second. Because of this rectification, LGN cells act like nonlinear excitatory subunits as inputs to their cortical targets. Since the HW model simply adds up the LGN sources, and each of these responds to every orientation, the model's summation of the clipped LGN inputs would cause it to have a non-zero response at 90° from the optimal orientation. In fact, the HW model predicts that the total number of spikes elicited by a stimulus could be the same at 90° as at 0°, although the spikes would be more spread out in time at 90° (Sompolinsky and Shapley, 1997; Troyer et al., 1998). Computational simulations of the HW model have demonstrated that this analysis is correct (Sompolinsky and Shapley, 1997; McLaughlin et al., 2000), as illustrated in Figure 2, where the orientation selectivity of an HW model is shown. But experimental observations establish that many cortical cells respond little or not at all at 90° from peak orientation, so we must conclude that the HW convergence mechanism is only part of the story of cortical orientation selectivity. In the literature on orientation selectivity, it is often stated that the nonlinearity of the neuronal spike threshold could cause major sharpening of the orientation tuning curve in the cortical cell response even if the convergent LGN input is as broad as in Figure

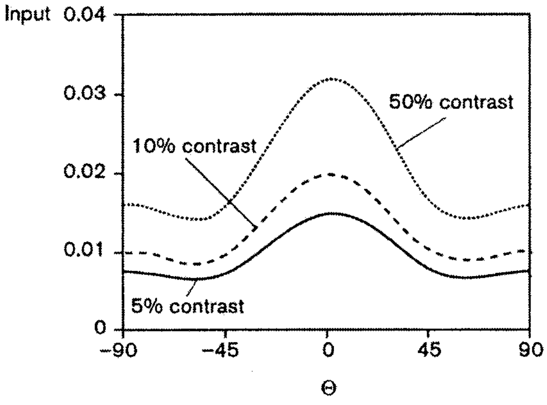

**Figure 2.** Orientation tuning of a feedforward model. Many LGN elements are assumed to converge via excitatory synapses onto single cortical cells in this model. No corticocortical excitation or inhibition modifies the feedforward excitation. Responses at three contrast levels are shown: 5% 10%, and 50% contrast. At all levels of contrast, there is a non-zero voltage generated 90° away from the preferred orientation. (After Sompolinsky and Shapley, 1997.)

2. This sharpening based on nonlinear thresholding is sometimes termed the iceberg effect. The iceberg effect is not a practical way to obtain sharpening, however. If the threshold is set so high that it causes the requisite significant sharpening, it will also diminish response magnitude a great deal, causing a loss of sensitivity. Also, thresholding works only at one stimulus contrast level. To obtain orientation tuning that does not broaden a great deal at high contrast, one needs another kind of mechanism.

One may wonder why the experiments of Ferster et al. (1996) are not decisive pieces of evidence for the hypothesis that LGN convergence causes a large amount of orientation selectivity. Here is our analysis of these experiments. The cooling experiments of Ferster et al. measured the first-order temporal Fourier component (F1) in the intracellular voltage response to a drifting grating from a neuron in a cooled cortex, and found it to be as tuned for orientation as in the warm cortex. But this does not account for the tuning of the mean spike rate, which is tuned as much as the F1 component of the spike rate. Also, the mean spike rate during a stimulus is the most often measured component of the neuron's response, and thus it is important to explain the tuning of this component. It is known from the work of Ferster et al. and others that the mean spike rate is an approximately linear function of mean membrane voltage (above a threshold value). So, to attempt to account for the orientation selectivity that is observed in the mean spike rate, it would have been necessary for Ferster et al. to measure also the orientation selectivity of the mean intracellular voltage response in the cooled cortex. They did not do this in the cooling experiments reported in 1996, probably for technical reasons. But suppose they had measured the DC response in the cooled cortex, and suppose the HW model does describe the LGN input to V1 neurons. Then we can predict that Ferster et al. would have found the mean (or DC) intracellular voltage response to be only weakly selective for orientation (based on the analysis of the HW model in the previous paragraph and Figure 2). Because the HW model predicts substantial membrane voltage response at 90° from peak, it cannot account for the sharp tuning of mean spike rate that is observed in experiments.

One can go further and analyze why Ferster et al. found so much orientation tuning for the F1 component. The only mechanism for orientation-selective response for an F1 response in the HW model is different spatial frequency resolution along the two axes of the elliptical receptive field. The reason is, the HW model has no inhibition; it is a purely excitatory model. Thus (if indeed the HW model applied), Ferster et al. probably observed orientation selectivity in the cooled cortex only because the spatial frequency of the grating they used was too high for the elliptical LGN array to resolve it along the long axis. However, the spatial frequency was not too high for the summed LGN input to resolve it along the minor axis. To put it another way, if orientation selectivity for the F1 Fourier component depended on feedforward LGN convergence as in the HW model, it would be very strongly dependent on spatial frequency, but in the normally functioning cortex, it is not, as reported 20 years ago by Jones and Palmer and then a few years after that by Webster and DeValois. The conclusion of all these considerations of the cooling experiment is that it is not decisive evidence for a feedforward explanation of orientation selectivity.

## *Cortical Inhibition*

One possible addendum to the HW model that increases the orientation selectivity greatly is to add inhibition, either push-pull inhibition (Troyer et al., 1998) or some other kind of inhibition that is broadly distributed in orientation (Somers et al., 1995; Ben-Yishai, Bar-Or, and Sompolinsky, 1995; McLaughlin et al., 2000). But given what is known about V1, this inhibition must come through cortical interneurons rather than directly from the thalamic afferents. Such a model is diagrammed in Figure 1, panel *B*. Experiments on intracortical inhibition in V1 have given mixed results. Initially, Adam Sillito's experiments with bicuculline suggested that intracortical inhibition might be necessary for orientation tuning. However, subsequent experiments by Sacha Nelson and colleagues at MIT, involving blocking inhibition intracellularly, have been interpreted to mean that inhibition of a single neuron is not necessary for that neuron to be orientation tuned. However, the role of intracortical inhibition has been supported by the work of A. B. Bonds and his collaborators. They have studied interactions between stimuli at different orientations, the effects of blocking activity in infragranular layers, and the effects of GABA on orientation selectivity. More recently, Ulf Eysel and his collaborators in Germany have accumulated a body of evidence in cat cortex for the important role of inhibition in causing a sharpening of orientation selectivity. Eysel and co-workers have blocked the lateral spread of cortical inhibition with local injection of inhibitory agonists that block local activity. When they do this, they often observe broadening of orientation tuning curves.

A theory of orientation tuning in cat cortex offered by Troyer et al. (1998) attempts to explain orientation tuning in terms of specific "push-pull" inhibition in which there is phase-specific inhibition superimposed on phase-specific excitation of the opposite sign. However, the main mechanism for sharpening of orientation tuning in the Troyer model is corticocortical inhibition that is broadly tuned for orientation. In the Troyer model there is moderately tuned LGN-convergent excitation from an HW mechanism, and then more broadly tuned inhibition that cancels out the wide-angle responses but leaves the tuning curve around the peak orientation relatively unchanged. Therefore, this model is one of a class of corticocortical interaction models for orientation selectivity.

More recently, we have developed a large-scale model of four hypercolumns in layer 4c$\alpha$ of macaque V1. The hypercolumn, a compact cortical region approximately 0.5 mm × 0.5 mm in area, is the unit of cortical processing. All orientations are represented in a hypercolumn, by arrays of neurons of similar orientation preference arranged as if they were spokes of a pinwheel around a central singularity, the pinwheel center. This architecture has been deduced from the results of experiments with intrinsic optical imaging by Bonhoeffer and Grinvald (1993). Our model incorporates known facts about the physiology and anatomy of V1. This model accounts for many visual properties of V1 neurons, especially orientation selectivity. Inspired by the Somers et al. (1995) and Ben-Yishai et al. (1995) models, it seeks to account for the same set of phenomena as these models but with more biological realism. One novelty in our model is that the spatial strength of connections between neurons is taken to be the spatial density of synaptic connections revealed by anatomical investigations of cortex. The model places the "footprints" of synaptic excitation and inhibition on the pinwheel latticework that is revealed by optical imaging (Bonhoeffer and Grinvald, 1993). In our model the spatial scale of corticocortical excitation exceeds that of inhibition, as indicated by cortical neuroanatomy. In its focus on the visual-functional consequences of the pinwheel organization, our model is novel and original. Our model causes significant sharpening and also diversity of orientation selectivity, and produces simple cells. The most significant difference between this model and that of Troyer et al. (1998) is that in our model (the McLaughlin model), the inhibitory conductance input to a cell is phase-insensitive (the opposite of push-pull). This happens because inhibition of a model cell is a sum from many neural sources, and it is likely that each of these sources is a cortical inhibitory cell with a fixed phase preference different from those of neighboring neurons. It is also consistent with the measured phase insensitivity of measured inhibition (Borg-Graham, Monier, and Fregnac, 1998; Anderson, Carandini, and Ferster, 2000). Anderson et al. (2000) state that their data support a push-pull, that is, phase-sensitive inhibition model. However, a close scrutiny of their data reveals that much of the measured inhibitory conductance (in response to drifting gratings) is a phase-insensitive elevation of inhibition, as predicted by the McLaughlin model (a point discussed in Wielaard et al., 2001).

### *Cortical Excitation and Attractor Models*

The idea that corticocortical excitatory feedback plays a crucial role in orientation tuning has been put forward most forcefully by theorists of brain function. Several well-known papers make the case for this corticocortical feedback. One, by Somers et al. (1995), presents an elaborate computational model for orientation tuning. Another paper in this genre is by Ben-Yishai et al. (1995), who offer an analytical model from which they make several qualitative and quantitative predictions. One of their important theoretical results is that one cannot predict contrast invariance of orientation tuning with feedforward models, but the feedback model of Ben-Yishai et al., with recurrent excitation and inhibition, does exhibit contrast invariance. Another of their results is that if recurrent feedback is strong enough, one will observe the "marginal phase" state in which V1 behaves like a set of attractors for orientation. Using a ring model that resembles the architecture of the Ben-Yishai model, Pugh et al. (2000) demonstrated that they could account for some of the important features of orientation dynamics that could not be explained by feedforward models, features such as the Mexican-hat tuning in orientation.

The attractor states of recurrent excitatory models are discussed not only by Ben-Yishai et al. (1995) but also by Tsodyks et al. (1999). Using intrinsic optical imaging of visual cortex, Tsodyks et al. found that there were patterns of spontaneous activity that resembled the patterns evoked during stimulation with oriented gratings. This provided some evidence for the idea that there were active states of cortical activity associated with orientation selectivity. The concept is that very weakly orientation-selective feedforward signals can be massively sharpened by strong recurrent excitatory feedback, causing the cortex to respond to any visual signal by relaxing into a state of activity governed by the pattern of corticocortical feedback. We believe that this theory, like the pure feedforward theory, has trouble explaining some important data, for instance, the existence of simple cells in which response waveforms follow the time course of the stimulus faithfully.

### *Bandwidth and Circular Variance*

There are different ways to measure orientation selectivity, and they can tell us about different aspects of orientation selectivity. A traditional method is to determine the half-bandwidth of the tuning curve around the peak of the tuning. This indicates the shape of the tuning curve near the peak. However, there are important questions about mechanisms that depend on the global shape of the tuning curve at all orientations. Various vector-averaging measures have been devised by different investigators. We favor the use of circular variance, a measure that is used in circular statistics. If we write the spike rate as a function of angle as $m(\theta)$, the circular variance of $m(\theta)$ is:

$$CV[m] = 1 - \left| \frac{\int m(\theta)\ \exp\ (2i\theta)d\theta}{\int m(\theta)d\theta} \right|$$

Circular variance is $1 - \{$relative modulation of $m(\theta)$ as a function of $\theta\}$. The relative modulation is the ratio of the best-fitting Fourier component of the orientation tuning curve (with period equal to 180°), divided by the average response. For a flat tuning curve, CV $= 1$. For a very highly tuned tuning curve, CV approaches 0. CV reflects wide-angle responses that the bandwidth does not. Other investigators have also used global measures for selectivity that are related to circular variance.

### *Response Dynamics*

In an attempt to provide a database to test models of orientation selectivity, Ringach, Hawken, and Shapley (1997) applied the subspace reverse correlation method. The idea was to measure the time evolution of orientation selectivity extracellularly in single V1 neurons. One main result from the use of this technique is that there is evidence for a slightly delayed inhibition or suppression in orientation selectivity's time evolution. Also, in a few neurons one observes a progressive shift of the peak orientation with time. The presence of shifter cells provides a realization of the "marginal mode" (a name for one of the attractor states referred to above) predicted by Ben-Yishai et al. (1995), and thus provides some confirmation of the attractor states of the recurrent models with strong corticocortical excitation. However, such neurons are found to be the exception, not the rule, in the reverse correlation observations. What one does observe often are highly selective cells in the output layers of the cortex in whose activity there is the following pattern: a delayed suppression at the orientation that is the peak orientation early in the response. The suppression causes it to become the least preferred orientation late in the response. Thus, in neurons with such delayed suppression, one observes a change in the preferred orientation later in the response, also. But unlike the shifter neurons, the suppressed neurons have a rather sudden flip in preferred orientation, usually by as much as 90°.

The time dependence of orientation tuning is illustrated for one macaque 4c$\alpha$ neuron in Figure 3, row *a*. This neuron, like many

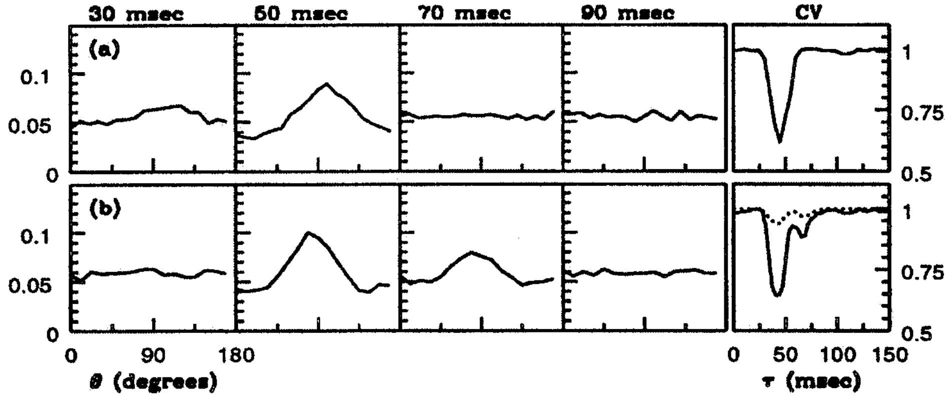

**Figure 3.** Time dependence of orientation tuning in a macaque 4c$\alpha$ neuron and in the large-scale model of McLaughlin et al. (2000). In the first four panels, $p(\theta, \tau)$ is graphed. In the fifth panel the circular variance (CV) is shown. Row *a* is for a typical 4c$\alpha$ neuron; row *b* is from the model. The dotted line in the rightmost panel of row *b* is the CV versus time for a pure feedforward model.

cells in the input layer 4c$\alpha$, does not exhibit much late suppression. Figure 3 also illustrates that a feedforward model would produce little orientation selectivity in the reverse correlation experiment. This is illustrated in the rightmost panel of row *b*, in which circular variance (CV) is drawn for the full model (solid line) and for a pure feedforward model (dotted line).

## Discussion

In our view, corticocortical inhibition is a crucial ingredient in the emergence of orientation selectivity in the visual cortex. The orientation preference of each neuron, and the orderly orientation preference map, are likely to be consequences of the pattern of feedforward convergence. However, the selectivity observed in steady-state experiments, and even more so in orientation dynamics experiments, cannot be achieved by a purely feedforward model. At present, we cannot yet evaluate the relative importance of corticocortical excitation in enhancing orientation selectivity. It may play a role for some neurons. For cortical simple cells, the results of our modeling indicate that corticocortical inhibition dominates, and that in simple cells, cortical excitation has to be relatively weak compared to the LGN excitation (see Wielaard et al., 2001). However, it is highly likely that corticocortical excitation is much more significant for the function of complex cells in V1.

# Oscillatory and Bursting Properties of Neurons

*Xiao-Jing Wang and John Rinzel*

## Introduction

*Rhythmicity* is a common feature of temporal organization in neuronal firing patterns. Historically, when recordings from *isolated* nerves became possible in the 1930s, systematic study of repetitive firing behaviors ensued. Arvanitaki (1939) and Hodgkin (1948, see citation in Rinzel and Ermentrout, 1998) identified three categories of crustacean axons by their rhythmic discharge patterns: those that fire repetitively over a wide (I) or narrow (II) range of frequencies and those whose firing hardly repeats (III). Later, Arvanitaki also pioneered the *Aplysia* preparation and discovered *bursting* oscillations, in which impulse clusters occur periodically, separated by phases of quiescence.

Since then, many other stereotypical single-neuron firing patterns, including a fascinating variety of endogeneous oscillations, have been identified (Llinás, 1988; Connors and Gutnick, 1990). One wonders anew about categorizing neuronal firing modes and the criteria on which to base such a classification. In 1952, Hodgkin and Huxley showed that many spiking properties could be explained in terms of various active ionic currents across the cell membrane. Today, many types of ion channels are known, and some particular neuronal rhythms have been linked to selected subsets of channels. However, membrane potential oscillations with apparently similar characteristics can be generated by different ionic mechanisms and by other biophysical factors, such as cable properties. In addition, a given cell type may display several different firing patterns under different neuromodulatory conditions. For these reasons, the visual appearance of particular voltage time courses and the presence of certain ionic mechanisms are insufficient bases for classification. A rational scheme should consider a cell's complete *repertoire* of dynamical modes and the nature of the transitions between modes.

Here we apply the mathematics of dynamical systems to describe precisely the dynamical modes of neuronal firing and the transformations between them. The approach was pioneered by FitzHugh (1961) with his phase space analysis of nerve membrane excitability. In this theoretical framework, membrane dynamics is described by coupled *differential equations,* e.g., à la Hodgkin and Huxley (cf. Rinzel and Ermentrout, 1998), the behavior modes by *attractors,* and the transitions between modes by *bifurcations.* The rest state is represented by a time-independent *steady state* and repetitive firing by a *limit cycle.* The transition from resting to oscillating typically occurs via either a *Hopf bifurcation* or a *homoclinic bifurcation* (Figure 1) (see, e.g., Rinzel and Ermentrout, 1998). The firing frequency versus applied current curves are qualitatively different in the two cases (minimum frequency being non-

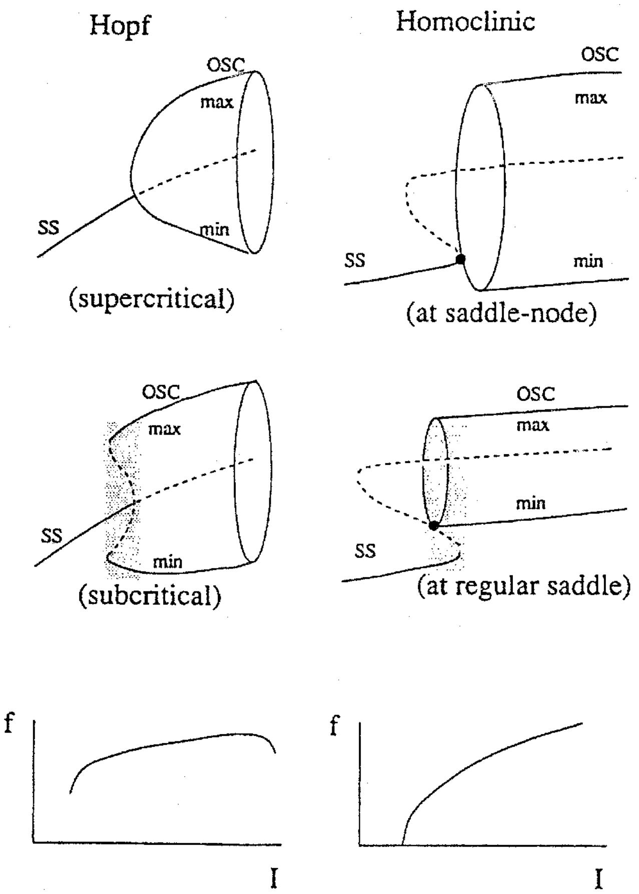

**Figure 1.** Schematic bifurcation diagrams from a steady state (SS) to an oscillatory firing state (OSC). The abscissa is a control parameter, such as the applied current intensity. The ordinate corresponds to the membrane potential, the repetitive firing state being indicated by the maximal and minimal amplitudes of the oscillatory membrane potential. The solid curve indicates stable and the dashed curve unstable. In the lowermost panels, the ordinate (f) is the frequency of repetitive firing. The left panels show *Hopf bifurcation.* At the onset of oscillation, the rhythmic amplitude is small and the frequency is finite. The bifurcation may be *supercritical,* where the new oscillatory branch is stable, or *subcritical,* where the new oscillatory branch is unstable and becomes stable at a turning point. The right panels show *homoclinic bifurcation.* It corresponds to the coalescence of an oscillatory state with an unstable steady state. This steady state can be either of saddle-node or saddle type. As this bifurcation point is approached, the amplitude of oscillation remains finite, while the rhythmic frequency tends to zero (the period diverging to infinity). In the case of a subcritical Hopf bifurcation or a normal homoclinic bifurcation, there is a range of parameter values where a steady-state attractor and an oscillatory attractor coexist (bistability, shaded region).

zero or zero, respectively) and might subserve an abstract basis for the distinction between the Arvanitaki-Hodgkin type II and type I axons. Our review generalizes this theoretical methodology to characterize various *bursting* oscillations in single neurons, elaborating on a qualitative classification scheme for bursting mechanisms proposed by Rinzel (1987).

## Neuronal Bursting: Examples

We summarize some qualitative features of observed bursting patterns and then relate these to our classification scheme. We briefly mention conductance mechanisms that are *sufficient* to produce some of these bursting oscillations. Although network synaptic interactions and dendritic cable properties influence bursting behavior, for the most part our discussion concerns an isolated, isopotential neuron. The main biophysical idea is that rhythmicity is generated by a depolarization process that is autocatalytic (positive feedback), followed by a *slower* repolarization process (negative feedback). These opposing processes may involve activation and slow inactivation of an inward ionic current, or a fast inward current and a slower outward current. Such features underlie action potential generation, and for bursting, there is at least another, *slower* negative feedback process.

The burst pattern of Figure 2*A* has a *square-wave* form, with abrupt periodic switching between rest (silent phase) and depolarized repetitive firing (active phase). Spiking here is due primarily to a *high-threshold* fast calcium current and a Hodgkin-Huxley-like potassium current. A minimal biophysical mechanism for square-wave bursting involves a calcium-activated potassium current, as originally proposed by Chay and Keizer in 1983. During the active phase, each calcium spike slightly increases $[Ca^{2+}]_i$, slowly turning on this current and eventually repolarizing the membrane to terminate the active phase. During the silent phase, the $Ca^{2+}$ channels are closed, $[Ca^{2+}]_i$ decreases, and, as the potassium conductance deactivates, the cell slowly depolarizes until threshold for the next active phase is reached. Suggested alternative mechanisms for this type of bursting include slow inactivation by $Ca^{2+}$ or by voltage of the $Ca^{2+}$ current. Here, if spikes are abolished by pharmacologically blocking the calcium current, bursting is lost.

Although the dopamine-secreting neuron (Figure 2*B*) superficially appears to be a square-wave burster, we would not classify it as such. Its underlying slow wave persists even when action potentials are blocked. It appears to be of dendritic origin, and it drives somatic spiking via electrotonic interaction.

The bursting patterns of Figure 2*C* and 2*D* exhibit brief spike bursts riding on a slow *triangular wave.* Thalamocortical relay cells (Figure 2*C*) burst at the delta wave frequency (3 Hz) of quiet sleep (Steriade, McCormick, and Sejnowski, 1993), while the 5-Hz oscillation in inferior olivary cells (Figure 2*D*) is probably involved with movement tremor (see Llinás, 1988). Remarkably, in both cases, rhythmic bursting occurs for maintained hyperpolarizing rather than depolarizing stimuli. The underlying slow wave (due to a low-threshold calcium current) is unmasked when the fast action potentials are blocked, and is sometimes seen for modest hyperpolarizing inputs, even without blocking spikes. The $Ca^{2+}$ current activates rapidly, below the voltage threshold for action potentials. Its inactivation by voltage, with a time scale like that of the triangular wave's depolarization, provides the slow negative feedback.

The *Aplysia* R15 neuron is the quintessential experimental model of an endogenous burster (Figure 2*E*). The sodium spike rate during a burst first increases and then decreases; hence there is *parabolic* bursting. Blocking these spikes reveals an underlying quasi-sinusoidal slow wave that is generated primarily by a $Ca^{2+}$ current. This current activates more slowly and at lower depolarizations than that associated with the square-wave bursting of Figure 2*A*. Its slow activation and the slower $[Ca^{2+}]_i$ that inactivates it provide the two variables for a minimal model of a parabolic burster's underlying slow oscillator (see the next section).

Parabolic burst-like features are seen in the 10-Hz oscillations of mammalian thalamic reticular neurons (Figure 2*F*) during the spindle waves of quiet sleep (Steriade et al., 1993). The oscillation depends on a low-threshold calcium current, like that of triangular bursting. In addition to this current's slow inactivation, there is likely a second slow variable to support the parabolic pattern, e.g., $[Ca^{2+}]_i$ for activating a calcium-dependent potassium current in these cells.

A quite different kind of burst pattern consists of spike clusters interspersed with epochs of small-amplitude subthreshold oscilla-

tions (Figures 2*G* and 2*H*). The envelope of fast events slowly waxes and wanes, forming an approximate spindle or ellipse; hence the term, *elliptic bursting.* Here, the inactive phase is not totally silent but often shows small oscillations. The frequency of intraburst spiking is comparable to that of the interburst subthreshold oscillations. Only recently has this bursting pattern been reported for mammalian neurons and associated with important functional roles, such as the limbic system's theta rhythm (not shown), and the gamma fast oscillations (about 40 Hz) that occur intermittently with increased alertness and focused attention (Figure 2*H*). Experimental (Llinás, Grace, and Yarom, 1991) and computational (Wang, 1993) studies indicate that the 40-Hz elliptic bursts involve a persistent $Na^+$ conductance and a specific voltage-dependent transient $K^+$ conductance.

Some oscillations (Figures 2*I* and 2*J*) depend on the electrical cable properties of neuronal dendrites and intracellular sources of regenerative ion fluxes. The bursting behavior of some pyramidal neurons (Figure 2*I*) in neocortex (Connors and Gutnick, 1990) and in the hippocampus depends on high-threshold calcium channels located on the distal dendrites, while the faster sodium spikes are generated primarily in the perisomatic region (Williams and Stuart, 1999). Computer simulations suggest that a one-compartment description is inadequate, and that electrotonically distinct compartments must be explicitly modeled and analyzed (Traub et al., 1991; Pinsky and Rinzel, 1994). Figure 2*J* displays the bursting pattern of a pituitary gonadotropin-releasing cell. Although it resembles the square-wave form of Figure 2*A*, here the underlying slow rhythm is generated by a cytoplasmatic second messenger system that leads to nonlinear, time-dependent calcium fluxes across the endoplasmic reticulum (ER) membrane and to oscillations in $[Ca^{2+}]_i$.

## Bursting Systems Analysis: Fast/Slow Phase Space Dynamics

Since different bursters may have qualitatively similar patterns, a qualitative classification should not depend on quantitative properties such as the rhythm's period or its precise biophysical bases. Our general framework involves a *geometrical* analysis of the bursting dynamics for a model's differential equations (Rinzel, 1987; Rinzel and Ermentrout, 1998; Izhikevich, 2000). The model for an isopotential neuron may be written as:

$$\frac{dX}{dt} = F(X, Y) \tag{1}$$

$$\frac{dY}{dt} = G(X, Y) \tag{2}$$

where the vectors $X$ and $Y$ represent the variables with fast and slow time scales, respectively. Typically, the membrane potential is a fast variable, so Equation 1 might be the membrane's current balance equation:

$$C_m \frac{dV}{dt} = -\sum_i I_i + I_{\text{app}}$$

The other dynamic variables include the gating variables for specific ionic channels plus relevant second-messenger variables and ionic concentrations. Here we consider only one or two slow variables $Y_k$, which might be a slow voltage-dependent gating variable or $[Ca^{2+}]_i$, or both.

The fast/slow phase space dissection method (Rinzel, 1987; Rinzel and Ermentrout, 1998; Izhikevich, 2000) exploits the presence of two disparate time scales. For simplicity, suppose there is only one slow variable, $Y$. One first treats $Y$ as a *control parameter* and considers the dynamics of Equation 1 as a function of $Y$. The fast subsystem's various behavioral states are then summarized in a bifurcation diagram, plotting response amplitude, say $V$, versus $Y$, as in Figure 1, but where $Y$ (instead of $I$) is the parameter. When the full system is considered, $Y$ evolves slowly in time according to Equation 2, slowly sweeping through a range of values, while the fast subsystem slowly tracks its stable states (*attractors*). For example, an oscillatory state of the fast subsystem corresponds to the repetitive firing of a burst's active phase. During a silent phase, the fast subsystem would be following a pseudo-steady state of hyperpolarized $V$. To complete the description, one must understand the slow dynamics from Equation 2 in order to know where on the fast subsystem's bifurcation diagram $Y$ will be increasing or decreasing. When the full system, Equations 1 and 2, is integrated and the resulting burst trajectory is projected onto the ($V$, $Y$) plane, it coincides with portions of the bifurcation diagram. Through visualization of this geometrical representation, one can make predictions about the qualitative behavior of bursting and the effects of various parameter changes.

1. *Square-wave bursting.* The prototypical fast/slow phase plane (Figure 3*A*) was originally developed for the Chay-Keizer model of $\beta$-cell bursting, where $[Ca^{2+}]_i$ was the slow, negative-feedback variable. For the fast/slow dissection, one first constructs the fast subsystem's bifurcation diagram by treating $Y$ as a parameter. This yields the Z-shaped curve of steady states. The oscillatory state "surrounding" the upper branch corresponds to repetitive spiking of an active phase. It terminates by contacting the unstable middle steady-state branch, at a homoclinic bifurcation. The Z-curve's lower branch represents a stable steady state of hyperpolarization, as tracked during a burst's silent phase. In an intermediate range of $Y$ values, there is bistability of the depolarized oscillation and the hyperpolarized steady state.

Next, $Y$ is allowed to vary according to its kinetics. Bursting occurs if the slow kinetics dictate that $Y$ increases (decreases) when the fast spike-generating subsystem is in its upper (lower) state, where the voltage-dependent channels are (are not) activated. The slow $Y$ modulation induces abrupt switching between the two coexisting states and thus temporal alternation between a train of spikes and a resting phase, as seen in Figure 2*A*.

2. *Triangular bursting.* Figure 3*B* shows fast/slow phase planes associated with triangular bursting. A minimal model has one slow variable, and its fast subsystem has regimes of bistability, as in the square-wave case. Here, however, the steady-state curve has five branches, composed of *two* S-shaped portions in different $V$ ranges. These S-curves correspond to the two sets of regenerative currents active in the subthreshold voltage ranges, such as in thalamic relay or inferior olivary cells. The depolarized oscillatory state (repetitive spiking) joins the middle steady-state branch at its right knee (a saddle-node homoclinic bifurcation). Different oscillation patterns occur, depending on whether the lower S's right knee extends rightward beyond that of the upper S's right knee. If this is not the case (Figure 3*B*, left), a slow subthreshold oscillation without fast spikes may occur. The alternative case (Figure 3*B*, right) corresponds to more intense hyperpolarizing input, when triangular bursting arises (Figure 2*D*). "Triangular" refers to the gradually falling $V$ time course of the active phase, related to the middle branch's steep slope (Figure 3*B*).

3. *Parabolic bursting.* This bursting type has a smooth underlying slow subthreshold wave. Its generation requires at least two slow variables, one for positive feedback and the other for negative feedback. The minimal fast/slow phase plot has three dimensions: $V$ and the two slow variables (Figure 3*C*, originally constructed for a model of the *Aplysia* R15 neuron; see Rinzel, 1987). Steady states of the fast subsystem are now represented by a *Z-surface.* Similarly, a surface describes the fast oscillatory (repetitive spiking) attractors. These periodic solutions disappear via homoclinic bifurcation as they contact the Z-surface, precisely at its lower knee, a saddle-

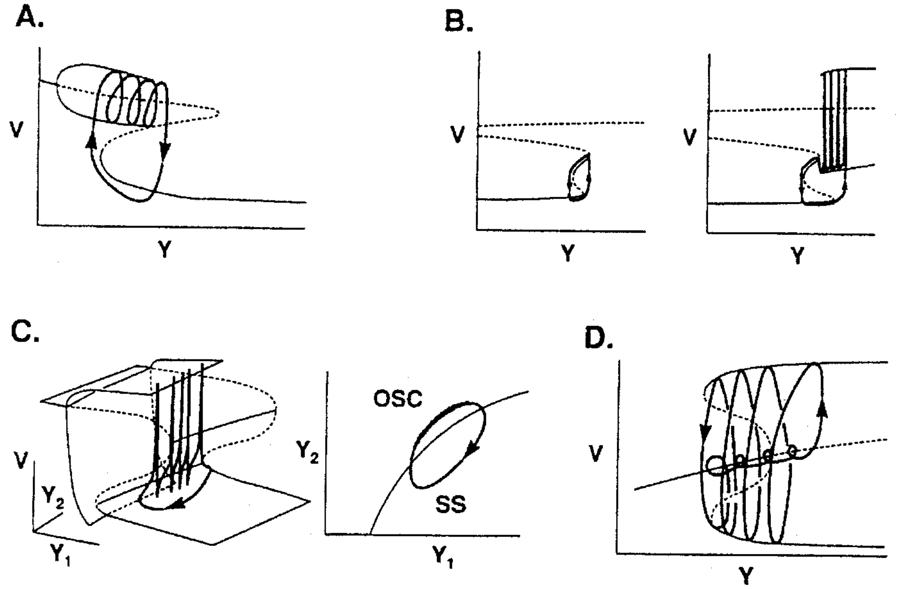

**Figure 3.** Fast- and slow-phase plot of bursting dynamics. The variable $Y$ is a slow variable (there are two slow variables, $Y_1$ and $Y_2$, in part *C*). In each case the bifurcation diagram is computed for the fast subsystem, with $Y$ treated as a parameter and plotted in terms of the membrane potential ($V$) behavior as a function of $Y$. The solid curve shows stable and the dashed curve unstable branches. The oscillatory state of repetitive firing is represented by its maximum and minimum of $V$ (cf. Figure 1). The heavy curves with arrows are bursting trajectories of the full system plotted on the ($V$, $Y$) plane or the ($V$, $Y_1$, $Y_2$) space. *A,* Square-wave bursting is based on a bistability of a steady state and a repetitive firing state in the fast subsystem and periodic switching between the two, induced by the slow-variable dynamics. *B,* Triangular bursting has a similar phase plot as in part *A,* but the fast subsystem's steady-state curve is quintic rather than cubic, with two branches of stable steady states. Depending on whether the stable repetitive firing state overlaps with the lowermost steady-state branch, oscillations of the full system may be either purely subthreshold (left panel) or bursting (right panel). For simplicity, the repetitive firing state is shown only on the right panel, not on the left panel. *C,* Parabolic bursting is generated by an oscillation in a two-variable ($Y_1$ and $Y_2$) slow subsystem (right panel) that induces smooth periodic switching between a steady state (SS) and a repetitive spiking state (OSC) (which do not overlap) of the fast subsystem. *D,* Elliptic bursting involves a subcritical Hopf bifurcation in the fast subsystem. Bursting involves slow switching between a steady state and a repetitive firing state that are bistable in the fast subsystem. The silent phase exhibits damped or growing small oscillations as its trajectory passes through the Hopf bifurcation point. (Parts *A* and *C–D* are adapted from Rinzel, 1987; Part *B* from Rush, M., and Rinzel J., 1994, *Biol. Cybern.,* 71:281–291.)

node coalescence (cf. Figure 1). Here, the fast subsystem is monostable. The slow-variable phase plane is divided into two nonoverlapping regions: one for the resting steady state and the other for the repetitive spiking regime of the fast subsystem.

Now, when the slow variables are allowed to vary, an oscillation may occur in this two-variable slow system (Figure 3*C*, right). If the slow oscillatory trajectory visits both of the fast subsystem's regimes, bursting occurs, with repetitive smooth switching between the resting and spiking states. As a burst begins and ends, its trajectory crosses a homoclinic bifurcation of the fast subsystem and spike frequency drops dramatically; hence the parabolic nature.

4. *Elliptic bursting.* A minimal model has only one slow variable (Figure 3*D*, originally constructed for a modified FitzHugh-type model; see Rinzel, 1987). The fast subsystem has bistability because of a *subcritical* Hopf bifurcation (cf. Figure 1) of periodic solutions from a monotonic steady-state curve. As in the square-wave case, during bursting the full system operates in the ($V$, $Y$) regime of bistability, repetitively switching between the steady state and the spiking state. A distinguishing feature, however, is that the "silent phase," when the fast subsystem operates near its steady state, is no longer truly silent: it can display small oscillations that damp and then grow as the trajectory slowly passes through the Hopf bifurcation point, where the steady state is a spiral-type fixed point.

5. *Complex bursting.* The theoretical study of certain bursting types (Figures 2*I* and 2*J*) is relatively recent, and mathematical understanding of their mechanisms is just emerging. For analyzing the case of Figure 2*I*, one requires a minimal model of at least two electrotonically separated compartments (Pinsky and Rinzel, 1994). Such a model can still be analyzed by the fast/slow dissection method, which shows that complex bursting of neocortical pyramidal cells can be described as the square-wave type (Kepecs and Wang, 2000). As for Figure 2*J*, one must take into account the interaction between second-messenger-mediated calcium fluxes from intracellular pools and voltage-dependent plasma membrane calcium currents.

The classification discussed here is based on various fast/slow phase plots. Although consistent with some of the wave-form phenomenology, the two may sometimes disagree. For instance, a system with the fast/slow phase plot of Figure 3*C* may burst with a slow wave that is less sinusoidal and more rectangular if one slow variable is much slower than the other. However, in contrast to a square-wave burster (Figures 2*A* and 3*A*), its slow wave may persist, even with the fast action potentials blocked.

## Discussion

We have reviewed various neuronal bursting oscillations and, by using notions and analytic tools from the mathematics of dynamical systems, we discussed how these bursting patterns might be theoretically described and classified. Our examples are minimal for these categories. Indeed, one can imagine subcategories based on differences in the fast subsystem's bifurcation diagram. In summary, bursting in a single-compartment model typically involves some slow processes that induce repetitive switching between a relatively quiescent state and an active state of repetitive spiking of a faster system. In the cases of square-wave, triangular, and elliptic bursting, one slow variable is sufficient, and the fast subsystem must be bistable. In the parabolic bursting case, the fast subsystem need not display bistability, and two slow variables are required.

The geometrical analysis by fast/slow dissection illustrates how novel and powerful theoretical approaches can emerge from fruitful interactions between neurobiology and the science of dynamical systems. Possible extensions might consider cable-like distributed systems with local burst-generating dynamics, or systems with many slow variables, or systems with complicated bifurcation diagrams, perhaps involving chaotic attractors. One can expect that dynamical systems methods, including fast/slow dissection, may also play a role in our understanding of neural networks with many synaptically coupled neurons, as long as there are disparate time scales in the system (Tabak et al., 2000).

# PAC Learning and Neural Networks

*Martin Anthony and Norman Biggs*

## Introduction

In this article, we discuss the "probably approximately correct" (PAC) learning paradigm as it applies to artificial neural networks. The PAC learning model is a probabilistic framework for the study of learning and generalization. It is useful not only for neural classification problems but also for learning problems more often associated with mainstream artificial intelligence, such as the inference of Boolean functions. In PAC theory, the notion of successful learning is formally defined using probability theory. Very roughly speaking, if a large enough sample of randomly drawn training examples is presented, then it should be likely that, after learning, the neural network will classify most other randomly drawn examples correctly. The PAC model formalizes the terms "likely" and "most." Furthermore, the learning algorithm must be expected to act quickly, since otherwise it may be of little use in practice.

There are thus two main emphases in PAC learning theory. First, there is the issue of how many training examples should be presented. Second, there is the question of whether learning can be achieved using a fast algorithm. These are known, respectively, as the *sample complexity* and *computational complexity* problems. This article provides a brief introduction to these problems. We highlight the importance of the Vapnik-Chervonenkis dimension, a combinatorial parameter that measures the expressive power of a neural network, and describe how this parameter quantifies fairly precisely the sample complexity of PAC learning. In discussing the computational complexity of PAC learning, we shall present a result that illustrates that in some cases, the problem of PAC learning is inherently intractable.

There are many variations on the basic PAC model that is the topic of this article, but there is insufficient space to explore these variations here. However, our discussion of the basic model serves as an introduction to the considerations that form the basis of recent extensions.

## PAC Learning

### Basic Definitions

In this section, we describe the basic PAC model of learning introduced by Valiant (1984). This model is applicable to neural networks with one output unit that outputs either the value 0 or 1; thus, it applies to *classification* problems. In the PAC model, it is assumed that the neural network receives a sequence of *examples* $x$, each labeled with the value $t(x)$ of the particular *target function* that is being "learned." A fundamental assumption of this model is that these examples are presented independently and at random according to some fixed (but unknown) probability distribution on the set of all examples.

We first explain how to formalize the notion of generalization. Suppose that the set of all possible examples is $X = \mathbb{R}^n$ or $X = \{0, 1\}^n$, where $n$ is the number of inputs to the network, and that the target function $t$ can be computed by the neural network in some state. A *training sample* for $t$ of length $m$ is an element $\mathbf{s}$ of $(X \times \{0, 1\})^m$, of the form

$$\mathbf{s} = ((x_1, t(x_1)), (x_2, t(x_2)), \ldots, (x_m, t(x_m)))$$

We shall denote by $S(m, t)$ the set of all training samples of length $m$ for $t$. The learning algorithm accepts the training sample $\mathbf{s}$ and alters the state of the network in some way in response to the information provided by the sample. It is desired that the function computed by the network when in the resulting state be an approximation to the target function.

### *Probability and Approximation*

If $L(\mathbf{s})$ is the function computed by the network after training sample $\mathbf{s} \in S(m, t)$ has been presented and learning algorithm $L$ has been applied, one way in which to assess the success of the learning process is to measure how close $L(\mathbf{s})$ is to $t$. Since there is assumed to be some probability distribution $P$ on the set of all examples, and since $t$ takes only the values 0 or 1, we may define the *error,* $\mathrm{er}_P(h, t)$, of a function $h$ (with respect to $t$) to be the $P$ probability that a randomly chosen example is classified incorrectly by $h$. In other words,

$$\mathrm{er}_P(h, t) = P(\{x \in X : h(x) \neq t(x)\})$$

The aim is to ensure that the error of $L(\mathbf{s})$ is "usually small." Since each of the $m$ examples in the training sample is drawn randomly and independently according to $P$, the sample vector $\mathbf{x}$ is drawn randomly from $X^m$ according to the product probability distribution $P^m$. Thus, more formally, we want it to be true that with high $P^m$ probability, the sample $\mathbf{s}$ arising from $\mathbf{x}$ is such that the function $L(\mathbf{s})$ computed after training has small error with respect to $t$. This leads us to the following formal definition of PAC learning.

The learning algorithm $L$ is a *PAC learning algorithm* for the network if *for any* given $\delta, \varepsilon > 0$ there is a sample length $m_0(\delta, \varepsilon)$ such that *for all* target functions $t$ computable by the network and *for all* probability distributions $P$ on the set of examples, we have

$$m \geq m_0(\delta, \varepsilon) \Rightarrow P^m(\{\mathbf{s} \in S(m, t) : \mathrm{er}_P(L(\mathbf{s}), t) > \varepsilon\}) < \delta$$

In other words, provided the sample has length at least $m_0(\delta, \varepsilon)$, then it is "probably" the case that after training on that sample, the function computed by the network is "approximately" correct. (We should note that the product probability distribution $P^m$ is really defined not on subsets of $S(m, t)$ but on sets of vectors $\mathbf{x} \in X^m$. However, this abuse of notation is convenient and is unambiguous: for a fixed $t$, there is a clear one-to-one correspondence between vectors $\mathbf{x} \in X^m$ and training samples $\mathbf{s} \in S(m, t)$.) Note that the probability distribution $P$ occurs twice in the definition: first in the requirement that the $P^m$ probability of a sample be small, and again in the fact that the error of $L(\mathbf{s})$ is measured with reference to $P$. The crucial feature of the definition is that we require that the sample length $m_0(\delta, \varepsilon)$ be independent of $P$ and of $t$. It is not immediately clear that this is possible, but the following informal arguments explain why it can be done. If a particular example has not been seen in a large sample $\mathbf{s}$, the chances are that this example has low probability (with respect to $P$), and therefore misclassification of that example contributes little to the error of the function $L(\mathbf{s})$. In other words, the penalty paid for misclassification of a particular example is its probability, and, very loosely speaking, the two occurrences of the probability distribution in the definition can therefore "balance" or "cancel" each other.

### *The Finite Case*

We shall show that if the network computes only a finite number of functions (for example, when the weights of a neural network are restricted to a finite set of allowed values), then there is a PAC learning algorithm for the network.

We say that the learning algorithm $L$ is *consistent* if, given any training sample $\mathbf{s} = ((x_1, t(x_1)), (x_2, t(x_2)), \ldots, (x_m, t(x_m)))$, the functions $L(\mathbf{s})$ and $t$ agree on $x_i$, for each $i$ between 1 and $m$. Such a condition seems quite natural. We should note, however, that neither the standard on-line perceptron learning algorithm nor the on-line backpropagation algorithm is, in general, consistent. But the batch versions of these algorithms, in which one repeatedly cycles through the training sample until no further changes are required, *are* consistent algorithms.

Suppose that the network is capable of computing a total of $M$ different functions, and let $t$ be any one of these. If $h$ is computable by the network and has error $\varepsilon_h \geq \varepsilon$ with respect to $t$ and $P$, then the probability (with respect to the product distribution $P^m$) that $h$ agrees with $t$ on a random sample is clearly at most $(1 - \varepsilon_h)^m$. This is at most $\exp(-\varepsilon_h m)$, using a standard approximation. Thus, since there are certainly at most $M$ such functions $h$, the probability that *some* function computable by the network has error at least $\varepsilon$ *and* is consistent with a randomly chosen sample $\mathbf{s}$ is at most $M \exp(-\varepsilon m)$. Here we have used the "union bound" (see LEARNING AND GENERALIZATION: THEORETICAL BOUNDS). For any fixed positive $\delta$, this probability is less than $\delta$, provided that

$$m \geq m_0(\delta, \varepsilon) = \frac{1}{\varepsilon} \log \left(\frac{M}{\delta}\right)$$

This bound is independent of both the distribution and the target function.

This analysis shows that if a network computes only a finite number of functions, then there is a PAC learning algorithm for the network; moreover, *any* consistent learning algorithm for the network is a PAC learning algorithm. The argument fails if the network in question computes infinitely many functions, and it is not immediately clear that PAC learning is possible in such circumstances. In the next section, we present a theory that shows that, in many such cases, it is possible.

## PAC Learning and the Vapnik-Chervonenkis Dimension

### *The Vapnik-Chervonenkis Dimension*

In this section, we show how the problem of PAC learning can be addressed by means of a combinatorial parameter known as the Vapnik-Chervonenkis dimension (henceforth called the VC-dimension) (see also VAPNIK-CHERVONENKIS DIMENSION OF NEURAL NETWORKS). Suppose $\mathcal{N}$ is a neural network that outputs 0 or 1, and suppose that $\mathcal{N}$ accepts examples from a set $X$ (for example, $X = \mathbb{R}^n$, where $n$ is the number of inputs). We say that a set $T$ of examples is *shattered* by $\mathcal{N}$ if for each of the $2^{|T|}$ possible ways of dividing $T$ into two disjoint sets $T_1$ and $T_0$, there is *some* function $f$ computable by $\mathcal{N}$ such that $f(x) = 1$ if $x \in T_1$ and $f(x) = 0$ if $x \in T_0$. In what follows, it is sometimes convenient to say that $x$ is a positive (respectively, negative) example of $f$ if $f(x) = 1$ (respectively $f(x) = 0$). The *VC-dimension* of $\mathcal{N}$, denoted $\mathrm{VCdim}(\mathcal{N})$, is defined to be the largest size of a set of examples shattered by $\mathcal{N}$. The VC-dimension may be thought of as a measure of the "expressive power" of the network, although Vapnik and Chervonenkis (1971) defined this parameter in a more general context and not specifically in the context of neural networks. It should be noted that the notion of Vapnik-Chervonenkis dimension is, in a sense, an extension to that of linear (or vector-space) dimension. Dudley (1978) proved that if $\mathcal{F}$ is a vector space of real functions defined on a set $X$ and if, for $f \in \mathcal{F}$, we define $f_+ : X \to \{0, 1\}$ by $f_+(x) = 1 \Leftrightarrow f(x) > 0$, then the VC-dimension of $\{f_+ : f \in \mathcal{F}\}$ is the linear dimension of $\mathcal{F}$.

It is instructive at this stage to determine the VC-dimension of the simplest neural network, the *simple real perceptron* $\mathcal{P}_n$ on $n$ inputs. This network consists of $n$ real-valued inputs, each of which is connected by a weighted connection to the single, linear threshold, output unit. (The weights can be any real numbers.) It is clear that, for functions computable by $\mathcal{P}_n$, the sets of positive examples and negative examples are separated by a hyperplane.

*Theorem 1.* For any positive integer $n$, let $\mathcal{P}_n$ be the simple real perceptron with $n$ inputs. Then

$$\text{VCdim } (\mathcal{P}_n) = n + 1$$

*Proof.* Let $T$ be *any* set of $n + 2$ examples. It can be shown that there is a nonempty subset $T_1$ of $T$ such that, if $T_0 = T \backslash T_1$, then $\text{conv}(T_1) \cap \text{conv}(T_0) \neq 0$, where conv($A$) denotes the convex hull of $A$. (This follows from Radon's theorem, which may be found in Grunbaum [1967], for instance.) It follows immediately that the sets $T_1$ and $T_0$ cannot be separated by a hyperplane; in other words, there can be no function $f$ computable by $\mathcal{P}_n$ such that $f(x) = 1$ if $x \in T_1$ and $f(x) = 0$ if $x \in T_0$. Therefore $T$ is not shattered and the VC-dimension of $\mathcal{P}_n$ must be at most $n + 1$. It remains to prove the reverse inequality. Let $o$ denote the origin of $\mathbb{R}^n$ and, for $1 \leq i \leq n$, let $e_i$ be the point with a 1 in the $i$th coordinate and all other coordinates 0. Then $\mathcal{P}_n$ shatters the set $T = \{o, e_1, e_2, \ldots, e_n\}$ of $n + 1$ examples. To see this, suppose that $T_1 \subseteq T$. For $i = 1, 2, \ldots, n$, let $\alpha_i$ be 1 if $e_i \in T_1$ and $-1$ otherwise, and let $\theta$ be $-1/2$ if $o \in T_1$, 1/2 otherwise. Then it is straightforward to verify that if $h$ is the function computed by the perceptron when the threshold is $\theta$ and the weights are $\alpha_1, \alpha_2, \ldots, \alpha_n$, then $h(x) = 1$ if $x \in T_1$ and $h(x) = 0$ if $x \in T_0$. Therefore, $T$ is shattered and, consequently, VCdim $(\mathcal{P}_n) \geq n + 1$. □

### Finite VC-Dimension Characterizes PAC Learning

We have observed that if $\mathcal{N}$ computes only a finite number of functions, then any consistent learning algorithm is a PAC algorithm, and a value of $m_0(\delta, \varepsilon)$ involving the number of computable functions can be determined. It turns out that, as far as PAC learning is concerned, it is not the size of the set of computable functions that is crucial but the *VC-dimension* of the network. More precisely, we have the following key result, due to Blumer et al. (1989) and Ehrenfeucht et al. (1989).

*Theorem 2.* If a neural network $\mathcal{N}$ has finite VC-dimension $d \geq 1$, then any consistent learning algorithm $L$ for $\mathcal{N}$ is a PAC learning algorithm. Moreover, there is a constant $K$ such that a sufficient sample length $m_0(\delta, \varepsilon)$ for any such algorithm is

$$K\varepsilon^{-1}(d \ln (\varepsilon^{-1}) + \ln (\delta^{-1}))$$

On the other hand, there is a constant $c$ such that for any PAC learning algorithm for $\mathcal{N}$, the sufficient sample length $m_0(\delta, \varepsilon)$ must be at least $c\varepsilon^{-1}(d + \ln (\delta^{-1}))$, for all $\varepsilon \leq 1/8$ and $\delta \leq 1/100$.

In fact, an analogue of Theorem 2 holds for general classes of $\{0, 1\}$-valued functions, and not simply those computable by neural networks.

### VC-Dimension of Neural Networks

We now discuss some results on the VC-dimensions of certain types of network. A more detailed treatment of this topic may be found in Vapnik-Chervonenkis Dimension of Neural Networks. First, we start with the feedforward linear threshold network. The first part of the following result is due to Baum and Haussler (1989) and the second part is due to Maass (1993).

*Theorem 3.* There is $K > 0$ such that, if $\mathcal{N}$ is any feedforward linear threshold network having $W$ variable weights and thresholds and $N$ threshold units, then $\text{VCdim}(\mathcal{N}) \leq KW \log N$. Furthermore, there is $c > 0$ such that some feedforward linear threshold networks having $W$ weights and $N$ threshold units have VC-dimension at least $cW \log N$; in other words, the upper bound is tight to within a constant.

Recent important work on the VC-dimension of neural networks includes that of Goldberg and Jerrum (1993) and Karpinski and MacIntyre (1995). In these papers, techniques from geometry and logic are used to study the VC-dimension of neural networks of certain types. In particular, the paper of Karpinski and MacIntyre, among other things, provides bounds on the VC-dimension of feedforward networks in which the output unit is a linear threshold and all other computational units have the standard sigmoid activation function given by $f(x) = 1/(1 + e^{-x})$. They obtain the following result.

*Theorem 4.* Suppose $\mathcal{N}$ is a feedforward network with a linear threshold unit as output unit, and with the remaining $N$ computational units having the standard sigmoid activation. If $\mathcal{N}$ has $W$ variable weights and thresholds, then

$$\text{VCdim}(\mathcal{N}) \leq (WN)^2 + 11WN \log_2 (18WN^2)$$

## The Computational Complexity of PAC Learning

### Efficiency with Respect to Accuracy, Example Size, and Sample Length

Thus far, a learning algorithm has been defined as a function that maps training samples into hypotheses. We shall now be more specific about the computational effectiveness of this function. If the process of PAC learning by an algorithm $L$ is to be of practical value, it should be possible to implement the algorithm quickly. We wish to quantify the behavior of a learning algorithm for a particular neural network architecture with respect to the size of the network. In particular, we wish to consider how the running time of the algorithm varies with the number $n$ of inputs to the network: for a learning algorithm to be efficient, this running time should increase polynomially with $n$. However, there is another important consideration in any discussion of efficiency. Until now, we have regarded the accuracy parameter $\varepsilon$ as fixed but arbitrary. It is clear that decreasing this parameter makes the learning task more difficult, and therefore the time taken to produce a probably approximately correct output should be constrained in some appropriate way as $\varepsilon$ decreases; the appropriate condition is that the running time must be polynomial in $1/\varepsilon$. Formally, we say that a learning algorithm $L$ is *efficient with respect to accuracy* $\varepsilon$, *example size* $n$ *and sample length* $m$ if its running time is polynomial in the length $m$ of the training sample and if there is a value of $m_0(\delta, \varepsilon)$ sufficient for PAC learning that is polynomial in $n$ and $\varepsilon^{-1}$.

### Hardness Results

In complexity theory, two important classes of problems, RP and NP, are defined. The class RP is the class of all problems that can be solved by "randomized" algorithms in polynomial time, while NP is the class of problems that can be solved by nondeterministic Turing machines in polynomial time. (We refer the reader to the book by Cormen, Leiserson, and Rivest, 1990.) It is conjectured, and widely believed, that these classes are not the same; more precisely, it is believed that RP is a strict subset of NP. This is known as the "RP ≠ NP" conjecture. For fixed $k$, for each $n$, let $\mathcal{P}_n^k$ be the neural network that consists of $k$ linear threshold units, each connected to all of $n$ inputs, the outputs of these threshold networks then being combined together by a hardwired AND gate. Thus, the network outputs 1 if and only if all $k$ threshold units output 1. Blum and Rivest (1988) proved (essentially) the following result. (See also Anthony and Biggs, 1992.)

*Theorem 5.* Let $\mathcal{P}_n^k$ be as described, where $k \geq 2$. If there is a PAC learning algorithm for $\mathcal{P}_n^k$ that is efficient with respect to accuracy, example size, and number of inputs, then the "RP ≠ NP" conjecture is false.

Thus, it is extremely unlikely that there is an efficient PAC learning algorithm for this surprisingly simple class of neural networks.

The point of this section has been to define what we might mean by an efficient algorithm, and to illustrate an approach (via computational complexity) to showing that certain learning problems are difficult. Therefore, we have presented a "negative" result. However, it should not be supposed that there are no positive results on efficient neural network learning. For example, there are efficient algorithms for perceptron learning, and also for more complex networks, including those in which the output of the network is a real number (and where we have to modify the definition of efficient learning from that given above, but in a fairly straightforward way). For instance, see Chapter 26 of Anthony and Bartlett (1999) for an efficient algorithm (due to Lee, Bartlett, and Williamson) for certain types of two-layer neural networks with linear threshold hidden units and a linear output unit.

## Discussion

We have considered basic PAC learning as it applies to learning in artificial neural networks. There are two distinct aspects: the length of training sample to be used and the efficiency of learning. In other words, we have the *sample complexity* problem and the *computational complexity* problem. The Vapnik-Chervonenkis dimension of a neural network determines in a fairly precise way the length of sample sufficient for PAC learning. This dimension can, in many cases, be related to the structure of the network, as in the examples presented here. Techniques from computational complexity theory can be applied to show that in a number of cases, *efficient* algorithmic PAC learning is impossible unless the NP ≠ RP conjecture is false.

There are a number of recent important extensions and generalizations of the PAC model that can be applied to artificial neural networks. For example, much attention has focused on PAC-type models of learning for networks in which the output is a real number rather than simply 0 or 1. The paper by Haussler (1992) was an important part of this development, and much work has subsequently been carried out on extending the PAC model to regression and to classification by real-output neural networks. This involves generalized notions of VC-dimension. There is insufficient space here to do these recent developments justice, but the reader can consult the book by Anthony and Bartlett (1999) for details.

# Pain Networks

*Marshall Devor*

## Introduction

Pain is an unpleasant sensory and emotional experience that arises in a conscious brain, typically in response to noxious stimuli. There is a growing consensus that the classical conception of how the pain system works is incomplete, notably for its failure to adequately account for sensory abnormalities seen in patients with chronic pain. For example, people with nerve injury often report bizarre symptoms such as electric shock-like paroxysms, or severe burning pain in skin that is numb to the touch. In this article, I outline a new synthesis, now emerging, that builds on the old scheme by addressing both normal and pathophysiological pain processes. There are many unsolved problems that could benefit from computational analysis but very little computational work has been done on pain to date.

## The Pain System: Normal Functioning

### *Stimulus-Response Variability*

The pain system encodes information on the intensity, location, and dynamics of strong, tissue-threatening stimuli. This sensory-discriminative function is shared with all sensory systems. Where pain differs is in the degree to which emotional-motivational and cognitive-evaluative variables can modulate the basic sensory message. The sight of blood may frighten you, but fright doesn't make red look like blue. In contrast, emotional and cognitive factors can render strong noxious stimuli painless. Consider, for example, the wounded soldier pulling his unconscious buddy out of the line of fire, or the placebo effect, in which belief that an inert pill contains analgesic ingredients is often enough to relieve pain. Even under everyday conditions, shifts of attention and expectation cause normal, rational people to display wide variability in pain sensation. For this reason, pain professionals usually avoid speaking of pain stimuli (or pain receptors), preferring instead *noxious stimuli* (or *nociceptors*). A noxious stimulus may evoke more or less pain, depending on context; the degree of pain felt depends as much on system variables as it does on the stimulus itself (Wall, 1999).

### *Stimulus Encoding by Sensory Receptor Endings*

The first step in sensory signaling is to encode the quality and location of the stimulus. This is done with spatial arrays of sensory receptor endings, each responsive to a specific type of stimulus at a specific location. Sensory receptors are the ends of axons of primary somatosensory neurons (primary afferents), the cell bodies of which are located near the spine (but not in the spinal cord), in the dorsal root ganglia (DRGs, Figure 1*B*). Each DRG neuron has a peripheral axon that travels in a nerve and terminates in a sensory transducer ending in skin, muscle, viscera, etc., and a central axon that travels in a dorsal root and ends synaptically in the spinal cord and/or the brainstem. The cell body itself is offset from the main

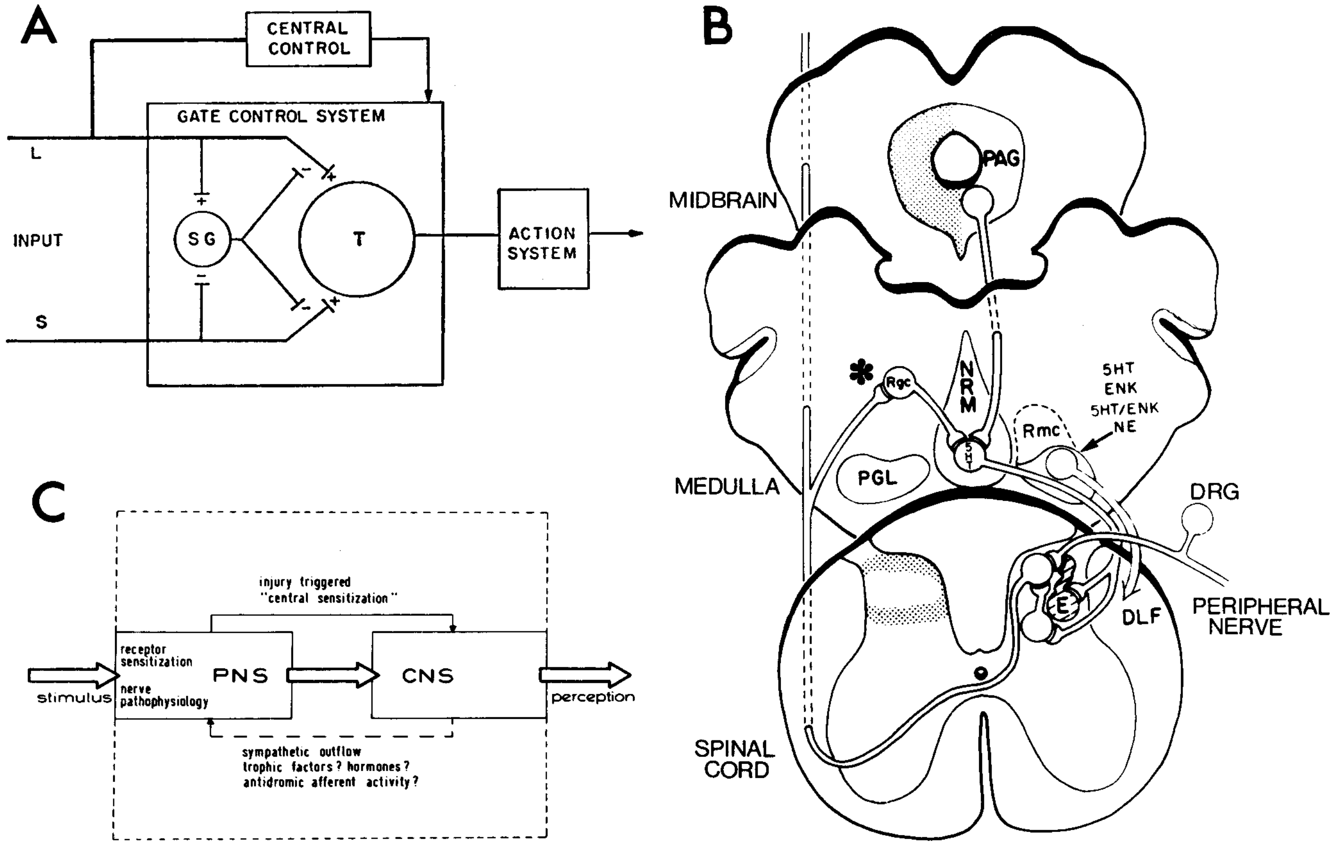

**Figure 1.** Three circuits for the modulation of pain signals. *A*, The original gate control system of Melzack and Wall (1965). Input from low-threshold (L) afferents and nociceptors (S) activates WDR transmission neurons (T) in the dorsal horn of the spinal cord. The former, but not the latter, activate substantia gelatinosa (SG) interneurons, which presynaptically inhibit the nociceptive input. Central control is also noted. *B*, Subsequently discovered details of the central control system (Fields and Basbaum, 1999). Activity in the midbrain PAG, relayed through specific medullary nuclei, including the nucleus raphe magnus (NRM) and the reticular magnocellular nucleus (Rmc), evokes synaptic inhibition on ascending pain-signaling neurons in the spinal cord partly via enkephalinergic (E) spinal interneurons. The descending axons of the NRM and Rmc, which use as neurotransmitters 5-hydroxytryptamine (5-HT), enkephalin (ENK), and/or norepinephrine (NE), travel in the dorsolateral funiculus (DLF). A collateral branch of the ascending WDR pain-signaling neurons (T) contributes to descending inhibition via nucleus reticularis gigantocellularis (Rgc, asterisk) in a negative feedback loop. *C*, Pain amplification mechanisms associated with tissue and nerve damage. The pain signal is modulated in the PNS and CNS by the local processes noted, and by a combination of feedback and feedforward. (From Devor, M., and Seltzer, Z., 1999, Pathophysiology of damaged nerves in relation to chronic pain, in *Textbook of Pain*, 4th ed. [P. D. Wall and R. Melzack, Eds.], London: Churchill Livingstone, pp. 129–164.)

axon by a small stem. Nerve impulses run from the receptor ending, past the DRG, and on into the CNS without pause. Curiously, the cell is specially designed so that spikes will invade it. Given that there are no synapses in the DRG, why has nature gone to the trouble of arranging for this spike invasion?

Somatosensory afferents are modality specific. Some, *low-threshold mechanoreceptors* (LTMs), respond to gentle touch and vibration. Others, *nociceptors*, respond only to strong stimuli. Some nociceptors respond to a particular submodality, e.g., mechanical (pinch) or thermal (hot, cold), but most encode the combined intensity of strong mechanical, thermal, and irritant chemical stimuli. These *polymodal nociceptors* pose the dilemma of how we distinguish a pinprick from a bee sting. Some nociceptors do not respond to any stimuli at all unless they have been sensitized by tissue inflammation (*silent nociceptors*). LTMs mostly have heavily myelinated, fast-conducting A$\beta$ axons. Nociceptors have slow-conducting axons either with thin myelin (A$\delta$ fibers) or with no myelin (C-fibers).

Within each modality, firing frequency encodes stimulus strength. LTMs, for example, respond to increasing pressure by accelerating their firing rate. LTMs also respond to noxious pinch. But since their firing rate saturates below the noxious range, they do not encode the intensity of noxious stimuli. Direct electrical microstimulation of LTM axons evokes a sensation of touch or pressure, but it does not (normally) evoke pain even at very high frequency (Vallbo et al., 1979). *Normally*, pain is felt only when activity is recruited in nociceptors; when stimulus strength approaches the noxious range, encoding is handed off from LTMs to nociceptors. I stress "normally" because there are system states where activity in LTMs does evoke pain (discussed in the next section).

### Central Convergence

The spatial information inherent in the arrays of sensory receptor endings—in the skin, for example—is preserved by topographic (*somatotopic*) mapping of primary afferent axons onto the spinal cord, and thence onto all subsequent waystations up to the cortex. The coding of sensory quality is more complicated.

Extrapolating from the specificity of primary afferents, many investigators concluded in the past (and some still believe) that each somatosensory modality, including pain, remains separate and pathway-specific all the way to consciousness. This idea, the classical specificity theory of pain, should have been shaken by the discovery that most neurons in the spinal cord that receive synaptic input from nociceptors also receive low-threshold input; they are modality-convergent *wide dynamic range* (WDR) neurons. Indeed, some combine low-threshold and nociceptive skin input with proprioceptive and/or visceral input and hence are *multireceptive* neurons. Specificity theory was saved by the discovery of a small population of neurons in the most superficial part of the spinal dorsal horn that are (normally) nociceptive selective. But if these alone signal pain, what of the large majority of spinal WDR neurons that have convergent nociceptor input?

In fact, there is now abundant evidence that activity in WDR neurons can evoke pain sensation. But with the modality multiplexing of WDR neurons, how are the specific touch and pain sensations that we feel decoded? A number of schemes have been advanced. For example, the comparator model holds that activity in WDR neurons is interpreted as pain only if nociceptive-selective neurons are also active. Another proposal posits that stimulus quality is coded in discharge patterning. The most likely scheme, however, is that spike frequency is the key parameter. Touch is felt when WDR neurons fire slowly; pain is felt when they fire rapidly. Since each WDR neuron has its own encoding function (firing rate as a function of stimulus strength), increasingly strong stimuli progressively recruit WDR neurons with sequentially overlapping encoding functions. In this model, any given stimulus would produce a unique aggregate of neuronal activity when viewed across the entire population of neurons that map a particular patch of skin. Somatosensation is a symphony.

### Ascending Pathways and Cephalic Representation

Textbook representations of ascending somatosensory pathways typically show two compact routes, the spinothalamic (anterolateral column) system for pain and temperature, and the dorsal column-medial lemniscus system for touch and vibration, each relaying through nuclei of the ventrobasal thalamus and ending mapwise in the somatosensory cortex. This vision, virtuous for being easy to teach and learn, corresponds to the ideology of specificity theory. It is also fundamentally misleading. Although some axons of the anterolateral column system reach the thalamus directly, most branch extensively, dropping terminals en route in numerous spinal, medullary, pontine, and mesencephalic structures. There are also massive projections to the cerebellum, and directly or indirectly to widespread areas of the limbic forebrain. In other words, much of the brain receives direct or nearly direct synaptic input from spinal cord WDR neurons. Ascending pain pathways are also dynamic. For example, cutting the anterolateral column usually relieves pain felt below the cut, but the pain usually returns within a few months. Any successful pain theory must take these facts into account.

## Modulation and Gate Control

### Peripheral Nervous System Sensitization

Sensory modulation is obvious from everyday experience. In sunburned skin, for example, gentle warming is painful. This primary hyperalgesia apparently results from peripheral sensitization, the fact that tissue inflammation can increase the gain (sensitivity) of the transduction process in nociceptive endings in skin, muscle, joints, and so forth, rendering them responsive to previously innocuous stimuli. Much of modern pain research is devoted to working out the molecular details of peripheral sensitization (Levine and Reichling, 1999; Woolf and Salter, 2000). Tissue inflammation is usually self-limiting, and hence the resulting pain is acute or subacute. Sustained inflammation, such as in rheumatoid arthritis, causes chronic pain. Most simple over-the-counter analgesics work by reducing peripheral sensitization. However, recent evidence suggests that these drugs may also have a significant CNS action.

### Modulation in the CNS

Although peripheral sensitization yields pain in response to normally nonpainful stimuli (*allodynia*), it does not violate the spirit of the specificity theory in the sense that the signaling lines for the various modalities remain specific and independent. In 1965 Melzack and Wall presented the first real challenge to the specificity theory with their famous gate control theory of pain (Figure 1*A*). This theory began with the radical idea that pain is signaled primarily by populations of convergent WDR neurons, and added that the convergence itself is dynamic and modulated in an ongoing fashion by afferent input from the periphery, and by descending control from the brain. For example, input along low-threshold A$\beta$ afferents inhibits the response of WDR neurons to simultaneously arriving nociceptive input, "closing a gate on pain." This explains the relief obtained from gently rubbing tender skin. Central control was also a key feature of the original gate control model (Figure 1*A*), but the details emerged only later (Fields and Basbaum, 1999). Although ideas about the circuitry of spinal gating/modulation have changed over the years, the fundamental concept has been vindicated by a great richness of CNS modulatory processes that form the basis of the new synthesis.

### *Descending Inhibition*

The midbrain periaqueductal gray matter (PAG in Figure 1*B*) is a nodal point for a descending inhibitory control circuit through which the brain gates ascending nociceptive information. Electrical stimulation of the PAG, or microinjection of opiates (e.g., morphine), activates nuclei in the medulla that contain cells rich in the neurotransmitters serotonin (5-HT; e.g., NRM in Figure 1*B*) and norepinephrine (NE). These cell groups in turn give rise to a compact bundle of axons that descend in the dorsolateral part of the spinal cord (DLF in Figure 1*B*). Activity in these descending axons inhibits the response of dorsal horn WDR neurons to noxious input, while responses to innocuous input are largely unaffected. Activation of this midbrain-medullospinal inhibitory circuit by morphine or by endogenous morphine-like neurotransmitters (enkephalin, endorphin) appears to be largely responsible for the antinociception obtained from opiates. Moreover, there is accumulating evidence that this system is also responsible for the stress-induced analgesia shown by the heroic soldier noted earlier, and for the placebo effect (Benedetti, Arduino, and Amanzio, 1999). We are talking about the neurology of belief and anticipation.

### *Central Sensitization*

Spinal gating involves excitation and not just inhibition. For example, I noted the fact that inflammation may sensitize nociceptor endings, yielding primary hyperalgesia. However, tenderness around such injuries often spreads to a much larger area of surrounding skin where there is no inflammation and no nociceptor sensitization. There has long been evidence that such “secondary hyperalgesia” is due to impulses entering the CNS along LTM A$\beta$ touch afferents. This idea of A$\beta$ pain was strongly resisted, as it violates the most fundamental dogma of specificity theory, namely, that pain can only be evoked by A$\beta$ and C nociceptors. However, in recent years the evidence has become increasingly compelling.

It turns out that a momentary noxious input is enough to trigger a system state, called *central sensitization*, in which A$\delta$ touch input transiently elicits pain (Raja et al., 1999; Woolf and Salter, 2000). Moreover, this state can be maintained indefinitely so long as a persistent source of nociceptive input is present (Gracely, Lynch, and Bennett, 1992). Central sensitization is particularly important as an amplifier in touch/brush-evoked pain (in contrast to thermal-evoked pain). It now appears that most of the tenderness we feel after everyday bumps and scrapes is due to A$\beta$ touch afferents. A working model of central sensitization is given in Figure 2 (see legend).

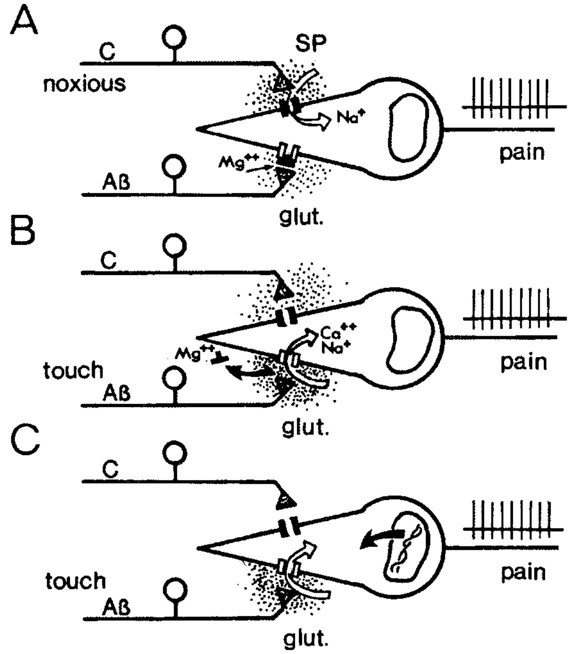

**Figure 2.** A proposed central sensitization mechanism for triggering touch-evoked pain (Woolf and Salter, 2000). *A*, Normally, activity in peripheral C-nociceptors activates spinal WDR neurons by means of excitatory amino acid and peptide neurotransmitters, probably including substance P (SP). This triggers an ascending pain signal. Touch input, carried along low-threshold A$\beta$ afferents, evokes release of the neurotransmitter glutamate (glut). However, this drives the WDR neurons minimally because the NMDA-type (*N*-methyl *d*-aspartate) glutamate receptors on the postsynaptic dendrites are blocked at normal membrane potentials by $Mg^{2+}$ ions. *B*, Intense noxious C-input produces prolonged (tens of seconds) SP-evoked depolarization. This displaces the $Mg^{2+}$ block, enabling the NMDA receptors. Now, glutamate released from A$\beta$ touch afferents can strongly activate the WDR neurons and hence evoke pain and tenderness. $Ca^{2+}$ entering the WDR neurons through the enabled NMDA receptor channels may trigger phosphorylation of the channels, due to activation of a $Ca^{2+}$-dependent protein kinase (PKA), sustaining the touch-evoked pain state for hours. *C*, More speculatively, a change in gene expression triggered by tissue or nerve injury could prolong the central sensitization state indefinitely.

## Neuropathic Pain

The strongest impetus for revising classical ideas about pain came from observations of chronic pain in patients, particularly the bizarre and intractable pain associated with damage to peripheral nerves, dorsal roots, and the CNS. Such *neuropathic pain* is paradoxical in the sense that when a sensory conduction channel is compromised, sensation is expected to be reduced, not augmented. Perhaps the most striking example is phantom limb pain in amputees, but neuropathic pain also includes such common conditions as limb pain in diabetics (diabetic neuropathy), postherpetic neuralgia (shingles), sciatica, and many instances of cancer pain.

### *Nerve Pathophysiology/Ectopia*

The key to understanding neuropathic pain is the realization that nerves do not behave like copper telephone cables. When an axon is cut across, or stripped of its myelin, the neuron reacts with pathophysiological changes that may render it intrinsically resonant (Amir et al., 2002) and electrically hyperexcitable (Figure 3). The result is ongoing and stimulus-evoked firing that originates at abnormal (ectopic) sites, notably in the region of injury and/or the sensory cell body in the DRG. Other pathophysiological processes, such as nonsynaptic neuron-to-neuron coupling, may augment the ectopia (Devor and Seltzer, 1999)

Ectopic hyperexcitability appears to result primarily from injury-provoked remodeling of membrane electrical properties in the axon and/or sensory cell body, due to changes in gene expression and vectorial trafficking of expressed proteins (Devor and Seltzer, 1999; Waxman et al., 1999). Early simulations of the process indicated the potential importance of $Na^+$ channel accumulation (Figure 3*C*), but ultimately, excitability is due to the complex integrated action on numerous channel types and subtypes (Amir et al. 2002). Ectopic firing in injured afferents contributes to pain in two ways. First, it injects an abnormal afferent impulse barrage into the CNS. Second, it may trigger and maintain central sensitization. In the sensitized state, A$\beta$ touch input from the skin, and also A$\beta$ activity from ectopic sources, is felt as pain (tenderness to touch and spontaneous pain).

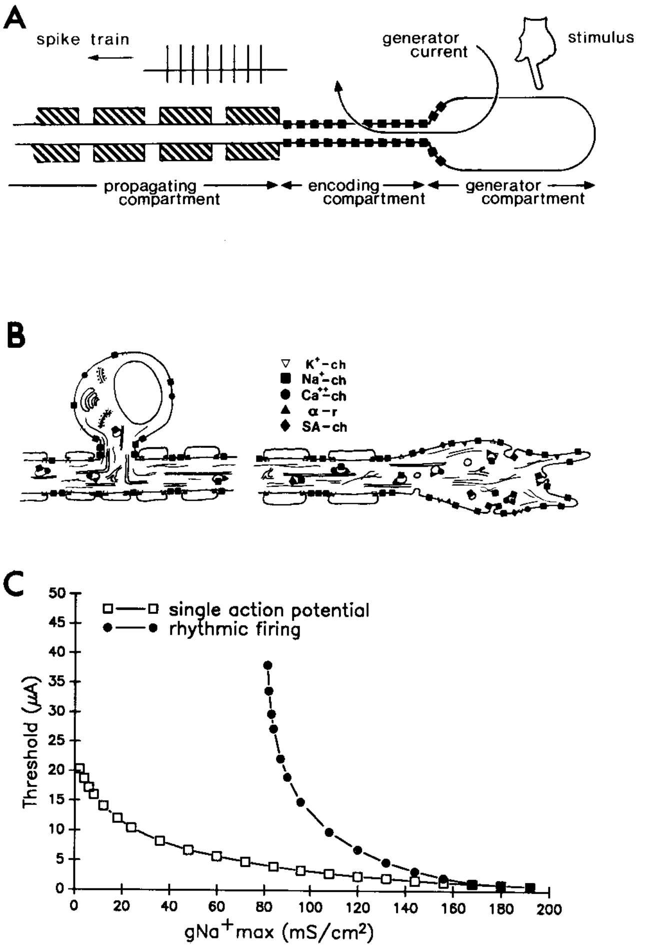

**Figure 3.** Stimulus transduction and encoding at normal sensory endings, and ectopic electrogenesis at sites of nerve injury, depends on the precise regulation of membrane electrical properties in the cell body and at the axon end. *A*, Applied stimuli create a generator current that is encoded into a spike train in a patch of membrane rich in $Na^+$ channels (black squares in encoding compartment). *B*, The membrane channels (-ch), receptors (-r), and other proteins responsible for electrogenesis are synthesized in the cell body and transported down the axon. These include $K^+$, $Na^+$, and $Ca^{2+}$ ion channels, $\alpha$-adrenoreceptors ($\alpha$-r), and mechanosensitive stretch-activated (SA) channels, among others. In the presence of nerve injury, channels and receptors accumulate in the membrane of the cut axon end and sprouts (right), rendering them hyperexcitable and a source of ectopia and neuropathic pain. *C*, Numerical simulation demonstrating that the accumulation of voltage-sensitive $Na^+$ channels ($gNa^+max$) sharply reduces the threshold for rhythmic firing, but has less of an effect on the threshold for evoking individual nerve impulses. (From Devor, M., and Seltzer, Z., 1999, Pathophysiology of damaged nerves in relation to chronic pain, in *Textbook of Pain*, 4th ed. [P. D. Wall and R. Melzack, Eds.], London: Churchill Livingstone, pp. 129–164.)

## Where Is Pain?

I opened this article by characterizing pain as an unpleasant percept aroused in a conscious brain by noxious stimuli. So far I have referred to the signal acquisition apparatus of the pain system, and to neural pathways that transmit and modulate nociceptive signals. But where does the experience of pain actually occur?

First, it is safe to exclude the PNS and spinal cord, on the grounds that quadriplegics experience pain, including pain referred to anesthetic parts of the body (phantom body pain). Surprisingly, the somatosensory cortex also appears nonessential, despite the fact that cortical neurons in a number of different regions respond to noxious stimuli (Peyron, Laurent, and Garcia-Larrea, 2000). For example, while lesions in the occipital cortex produce blindness, even extensive damage to the postcentral gyrus and other cortical projections does not preclude pain sensation, even in parts of the body whose cortical representation has been destroyed. More important, cortical seizure activity, and direct electrical stimulation of the somatosensory cortex, rarely evoke pain.

A part of the anterior cingulate gyrus has been implicated recently in pain perception on the grounds that the magnitude of activations there correlates with felt pain rather than with stimulus intensity when the pain percept is manipulated by hypnosis and distraction (Rainville et al., 1997). However, this correlation may simply reflect the operation of descending spinal modulatory pathways (Figure 1*B*) and hence attentional modulation of the ascending nociceptive signal. A final candidate is the collection of brainstem and subcortical forebrain regions that receive and modulate nociceptive signals (Devor and Zalkind, 2001). Few would argue that pain behavior, both withdrawal reflexes and more complex escape responses, may be organized subcortically. But can perception occur outside of the cortex? Might pain experience have arisen early in vertebrate evolution, in parallel with pain behavior and before cortical domination of the brain?

## Perspective

Pain, particularly persistent pain, remains a medical health problem of the first order: witness the prominence of alternative approaches to treating pain, built largely on the therapeutic failures of conventional medicine. It is also a remarkable basic science challenge. Situated at the interface of body and mind, only a few synapses intervene between the biophysics of stimulus transduction and the magic of conscious perception (Devor and Zalkind, 2001).

At each level of analysis there are problems that could be fruitfully approached using computational methods. For example, in the periphery, the fine diameter of C-fiber endings precludes direct electrophysiological measurement. Testable hypotheses concerning the ionic mechanisms of transduction, encoding, sensitization (e.g., during inflammation), and ectopia could be provided by theoretical analysis. At the level of spinal processing are issues such as the modes of convergence that go into synthesizing natural receptive fields, the problem of how WDR neurons encode specific sensations, and mechanisms of functional plasticity (e.g., gate control and central sensitization). Finally, theoretical analysis might provide insights into the higher-level functions that control descending pain inhibition and ultimately pain experience. In the visual pathway, the extraction of meaning (Is it a passing cloud or a rhinoceros charging?) requires a massive analytical apparatus. In the pain system, meaning is much closer at hand.

# Past Tense Learning

*Amit Almor*

## Introduction

The English past tense, a seemingly simple linguistic phenomenon that has come to epitomize the latest round in the centuries-old debate between rationalists and empiricists, exemplifies the processes that more generally handle the formation of words and their structure. These processes have been traditionally studied by the linguistics field of "morphology," which has assumed a level of representation that is based on the smallest meaning-bearing linguistic units, called *morphemes*. The main goal of linguistic morphology has been to systematically identify morphemes and describe the principles that govern the way they are used to form words (see Spencer and Zwicky, 1998, for current issues in linguistic morphology). Morphemic representation lies in between the phonological level, where the basic representations consist of individual sounds (phonemes), and whole words. Some morphemes are identical to whole words. For example, each of the words *base* and *ball* consists of one morpheme (/base/ and /ball/, respectively), and the word *baseball* consists of these two morphemes combined. Not all morphemes are words, however; the word *dislike* consists of the non-word morpheme /dis/ and the word morpheme /like/, and the word *liked* consists of the stem morpheme /like/ and the non-word past tense morpheme /ed/. The relation between meaning and word form is not always transparent. One reason is that the meaning of some morphemes can only be traced etymologically. For example, the meaning of *-mit* in *permit, submit*, and *remit* is not transparent to modern day English speakers but can be traced back to the Latin suffix *mittêre* (roughly meaning, "to let go"). Moreover, even when the meanings of the component morphemes are known and can be ascertained (as in */break//fast/*, i.e., the meal that breaks the fast) it is not clear that these meanings are transparent and accessible enough to affect actual word use. Finally, even when the meanings of the component morphemes are transparent and readily accessible, the meaning of the resulting compound is not consistently entailed. Although there is much regularity in how the meanings of morphemes are related to word meanings (e.g., *housedog* is a kind of dog and a *doghouse* is a kind of house) there are many exceptions. *Hotdog* is not a kind of dog, *sweetbread* is not a kind of bread, and *hammerhead* is not a kind of head. Thus, although the relation between word form, word meaning, and morphemes seems to encompass much regularity, it is not trivial and cannot be easily captured by simple combinatorial rules.

This may be differentially true for different kinds of morphological processes. Most morphological theories distinguish between inflectional and derivational processes. Inflectional processes generally involve elements of word structure that are related to grammar, such as markings for tense, number, gender, and case. Languages vary in the extent to which this grammatical information is morphologically encoded. In Hebrew, verbs are marked for tense, number, gender, and argument structure, resulting in a complex and highly regular verbal inflectional system. In English, verbs are only marked for tense and number, and in Mandarin Chinese, verbs are marked for neither tense nor number. Inflectional processes apply in accordance with sentence structure (in English, the subject noun of a sentence has to agree in number with the verb; a failure to do so results in ungrammaticality) and do not alter the core meaning or grammatical class of the inflected stem. Inflectional processes can be viewed as generating classes of systematically related word forms from a basic stem/root form via a small set of morphological operations. Inflectional processes are also highly productive in the sense that they apply to all the words in the language with new words "automatically" receiving a so-called regular "default" treatment. For example, all verbs in English are marked for tense and new verbs generally receive the regular *-ed* past tense suffix (e.g., *faxed, emailed*).

In contrast, derivational processes are more open ended and involve the creation of new words from other words and morphemes, often resulting in changes in grammatical category. For example, in English, the suffix *-ly* can be used to form adverbs from adjectives: *glad-gladly, poor-poorly*, etc. Derivational processes do not apply across the board (e.g., the suffix *-ly* cannot be added to adjectives such as *tall, old, young*).

Historically, the more regular nature of inflectional processes suggested that the relation between morphemes, meanings, and word forms could be more easily explained in the area of inflectional morphology than in the area of derivational morphology. It also suggested that the underlying computational machinery might involve rules. Although in recent years derivational processes have begun to attract as much attention as inflectional processes, it has been in the area of inflectional morphology that most current ideas and theories were formed.

## Regulars and Rules

Indeed, for many years, regular inflection such as the *-ed* English past tense suffix was used as the showcase example for symbolic rules in mental computation. Two main observations were most often cited. The first is that speakers readily apply the regular rule to new words they haven't heard before, regardless of the new words' similarity to other words that conform to the regular pattern. This observation has received much empirical support from numerous studies using variants of Berko's (1958) well-known "Wug test" in which a subject is asked to complete a fragment like: "Here is one *wug*. These are two___." Adults and children from about age three usually apply the regular English plural suffix and respond "wugs" despite never having heard the word *wug* before. Similar results have been obtained with the English past tense in that subjects aged three and older readily inflect a novel verb with the regular *-ed* suffix. The second observation thought to support symbolic rules was children's over-regularization errors. It has long been observed that children exhibit what may seem like a paradoxical decline in language performance starting at around three years of age. At this age, children who may have previously used irregular forms correctly suddenly start inappropriately regularizing many irregular forms. A child who may have already used the past tense form *went* in her speech might suddenly start using *goed* or *wented.* This over-regularization lasts well into the elementary school years. This learning pattern is usually referred to as a "U-shaped learning curve" because when plotted against age, children's performance worsens and then improves, thus resembling the shape of the letter U. U-shaped learning was believed to reflect children's switch from rote memorization of both regular and irregular past tense forms to the use of symbolic rules. By this account, at around age three, children's ability to use rules matures and they start applying rules across the board, occasionally producing over-regularization errors.

## The Past Tense Debate

The view that regular inflection shows the working of an underlying rule was challenged by Rumelhart and McClelland's (1986) landmark connectionist model. This model was trained to map phonological representations of stem forms into output phonological representations of past tense forms. By using a general error-correcting learning algorithm, the statistical relations between the input stem phonemes and the output past form phonemes were encoded in the weights of the links. These learned associations enabled the model to generalize and produce the regular past tense form for novel verbs it was not trained on, thus exhibiting behavior that could be described as rule-governed even though no rules were involved in producing this behavior. Remarkably, without implementing any underlying rules, the model's course of learning mimicked the U-shaped curve characteristic of children. The model thus illustrated how the generalization ability previously thought to be the signature of an underlying rule mechanism can arise in a connectionist network without explicit rules. This model had a substantial effect on the fields of psycholinguistics and cognitive science. After two decades in which statistical learning was considered inadequate as an explanation of language (mainly due to an influential critique of statistical learning by Chomsky, 1959), Rumelhart and McClelland's work showed that statistical learning can provide a viable alternative to symbolic rules.

Rumelhart and McClelland's challenge to symbolic rules met with considerable criticism, starting with Pinker and Prince (1988). Critics argued that the behavior of the model diverges in important ways from human behavior. For example, unlike humans, the model did not generalize well to novel forms that have an unusual sound (e.g., the model mapped the stem *tour*, which was not in the training set, to the past tense *toureder*.) Critics also argued that the most impressive feat of the model, its U-shaped learning curve, is the result of an implausible and carefully engineered training regime that does not parallel the input to the child or the child's own output. Indeed, many critics argued that in order for a connectionist model to properly handle regular inflections, it must implement rules albeit using connectionist machinery. While this view concedes that such "implementation models" can help explain how rules are represented and executed by the brain, it nevertheless maintains that such models do not provide a theoretical alternative to rule based theories (for a summary of the criticism of Rumelhart and McClelland's model, see Pinker, 1999).

The combination of successes and problems of the Rumelhart and McClelland model led many researchers to propose that while connectionist models may provide an adequate account for how irregularly inflected forms are processed, the processing of regular inflections must be driven by a rule-based mechanism. This "dual mechanism" approach maintains both a rule-based mechanism and a connectionist memory system living side by side. The latter contains memorized mappings from stem to inflected forms for all the irregular mappings but, being nonselective, may also include frequently encountered (and possibly irregular sounding) regular mappings. To explain how processing in the two components is coordinated, this view also stipulates a "blocking mechanism" that allows an activated memorized inflected form to block the usage of the default rule (for a detailed presentation of the dual route model, see Pinker, 1999.)

The critique of Rumelhart and McClelland's model and the subsequent development of the dual mechanism approach provided the road map for much of the research that has followed since. A new generation of connectionist models attempted to address the design flaws and empirical shortcomings of the original Rumelhart and McClelland model as well as to broaden the scope of the empirical data covered. Many models added hidden layers and clean-up units to allow for a wider range of learnable mappings. Other models included semantic representations, which enabled them to address more than one type of inflection and to assign different inflections to homophonic stems. For example, MacWhinney and Leinbach (1991) developed a model that handled both noun plurals and verb past tenses and that could further distinguish past tense forms of homophones (*break-broke* vs. *brake-braked*). Plunkett and Marchman's (1993) model addressed many of the developmental issues related to the U-shaped learning curve.

Although these and many other models have successfully addressed many of the problems in the original Rumelhart and McClelland model, they nevertheless met with new criticism from dual mechanism theorists. One line of criticism continued to be directed at specific design aspects of various models, with some models accused of stealthily implementing the past tense rule. For example, the MacWhinney and Leinbach's (1991) model was accused of implementing a rule because, in addition to the regular input to output connections, it had special connections between the corresponding phonological units in the input and output (Pinker, 1999). The value of this line of criticism is questionable because, as connectionist theorists are quick to admit (e.g., Seidenberg, 1997), implemented models require many simplifying assumptions. Broadly criticizing models for making these assumptions without considering their specific implications risks missing important insights about the connection between behavior and underlying computation.

Moreover, this kind of criticism can be equally directed at the dual mechanism account, which makes its own set of problematic assumptions. In particular, it does not make clear how the blocking mechanism works, how and why it develops, and why is it not triggered by the many regulars that were already learned before the rule mechanism matured. As is often the case with theoretical constructs that are hard to explain or motivate, blocking is assigned the status of an innate mechanism. This not only relieves the theory from having to explain how this mechanism works and develops, but also adds one more marvel to the bag of wonders that cannot be explained without an arsenal of highly specialized language-specific mental machinery.

Besides debating details of implementation, much research has focused on behavioral and neuropsychological differences between the processing of regulars and irregulars and on the implications of such differences for the single and dual mechanism theories.

## Frequency of Inflected Forms

One way in which regulars and irregulars differ has to do with how the frequency of inflected forms affects their processing. The use of irregularly inflected forms is strongly affected by their frequency, and to the extent that regularly inflected forms show frequency effects, these effects are quite small (see Pinker, 1999, for details). According to the dual mechanism view, these differences indicate that regulars and irregulars are processed by two separate mechanisms. This is because the memorized irregular mappings are strengthened each time an irregularly inflected form is encountered, but the application of the regular symbolic rule is not sensitive to the properties of the individual stems or inflected forms. The small frequency effects with regularly inflected forms found in some experiments is explained as a result of special circumstances that encourage the use of the memory system, for example when subjects are presented with a list containing an unnaturally high number of irregular forms.

Single mechanism accounts can also explain differences in the frequency dependence of regulars and irregulars. In these systems, frequency by regularity interactions can arise because "regular" input to output mappings, which are shared by a large number of different inputs, are less dependent on the frequency of individual input-output mappings, whereas "irregular" mappings that are shared by only a small number of inputs are more sensitive to the frequency of individual mappings (Seidenberg and McClelland, 1989). By this account, regularity itself, and by extension frequency effects, fall along a continuum defined by the number and similarity of input-output mappings.

A frequency effect that can better distinguish between the two theories is related to whether the frequency of regular forms makes their production less or more prone to interference by similarly sounding irregulars. Empirical evidence shows that such irregularization errors are more likely for low frequency regular verbs than for high frequency regular verbs and that the latency of correct regular production for high frequency regulars is less affected by interference from phonologically similar irregulars than the latency of correct responses for low frequency regulars (Long and Almor, 2000). These findings are compatible with a single mechanism view in which regulars and irregulars are processed similarly such that more frequent items are processed more quickly and with fewer errors than less frequent items. These results are not compatible with the dual mechanism view. Because, by this account, the only kind of *regularly* inflected forms that are stored in the memory system and are therefore prone to interference are high frequency regulars, this account falsely predicts that competition between similarly sounding irregular and regular stems would only occur for high frequency regulars but not for low frequency regulars (Pinker, 1999, page 303, fn 22). Obviously, the dual mechanism account can be easily modified to say that regular past tense production can benefit from (rather than be hindered by) the existence of a stored mapping in the associative network. Alternatively, the dual mechanism account could be modified to say that regular mappings of stems that rhyme with irregularly inflected stems are stored in the associative network regardless of frequency. The apparent ease with which such post hoc modifications can be applied to the theory highlights its underspecification and in particular the vagueness of the blocking mechanism.

Further frequency-related arguments have been made on the basis of inflectional systems in other languages such as German and Hebrew in which, unlike English, the default inflection was argued not to apply to the majority of stems (see Pinker, 1999, chapter 8, for details). According to dual mechanism theorists, an inflection that applies to a minority of the stems in the language but that is productively applied to new forms is not compatible with the statistical learning of connectionist models. Some of the relevant data, however, has been called into question (Bybee, 1995). In particular, even if the stems that undergo the so-called regular inflection are not the majority of stems, the combined instances of these stems can still be more frequent than the instances of other inflections. Although to date the implications of inflections in other languages have not been fully explored, they may eventually help resolve some of these issues in ways that are not possible using the morphologically impoverished English.

## Neurological Impairments and Imaging

Findings from different neurological impairments that selectively affect the processing of either regulars or irregulars, as well as imaging findings of different brain activation patterns associated with processing regulars vs. irregulars, have also been cited as evidence for separate mechanisms. Marslen-Wilson and Tyler (1997) found that although some aphasic patients seem to lose the knowledge that regular stems and inflected forms are related (exposure to *walked* did not speed their subsequent response to *walk*) but not the knowledge that uninflected regular forms are related to their stems (exposure to *found* speeded their subsequent response to *find*), other aphasic patients show exactly the opposite loss pattern. Other researchers found similar double dissociations in other neurological disorders. Aphasic patients with agrammatism, patients with Parkinson's disease, and children with Williams syndrome have been reported to have more trouble with regulars than irregulars, while anomic aphasics, patients with Alzheimer's disease, and some children with SLI have been reported to have more trouble with irregulars than regulars (see Pinker, 1999, chapter 9; and Ullman, 2001, for details). Functional imaging studies have also revealed temporal as well as location differences in the brain activation accompanying the processing of regulars vs. irregulars. Although the exact temporal patterns and brain areas vary from study to study (and sometimes from one experiment to the next within the same study), it seems that the processing of regulars more strongly involves left frontoparietal cortex, whereas the processing of irregulars involves tempoparietal areas in both hemispheres. Dual mechanism supporters have interpreted these dissociations as indicating that the grammar areas in the brain handle regular processing, and lexical semantics areas handle irregular processing. An interesting variation of this account has been proposed by Ullman (2001), who views regular processing as relying on procedural memory, the mental storage for skills and other routine mental operations, and irregular processing as relying on declarative memory, the storage for events and idiosyncratic facts. Ullman's view differs from that of many other dual mechanism theorists because inflectional rules are not considered a specialized language mechanism any more than bicycle riding skills are considered a specialized bicycling mechanism. Arguably, the only language-specific machinery in Ullman's account is the blocking mechanism.

Although these neurological dissociations seem to favor the dual mechanism view, connectionist models that include both semantic and phonological representations can also show selective impairments to regulars or irregulars as a result of certain artificial lesions. These dissociations occur because irregulars depend more on semantics than on phonology, whereas regulars depend more on phonology than on semantics. By this argument, brain impairments that affect regulars more than irregulars simply involve more damage to phonological than to semantic representations while brain impairments that affect regulars more than irregulars involve more damage to semantic than to phonological representations (Joanisse and Seidenberg, 1999).

## Discussion

Despite the active controversy surrounding the mental processing of regular inflections, most researchers agree that the mental processing of irregular inflections is not rule governed but rather works much like a connectionist network. It is therefore important to remember that Rumelhart and McClelland's model and its successors are important even if dual mechanism theories are correct and regular inflection is rule based.

Despite failing to flesh out important parts of their models, dual mechanism proponents enjoy the advantage that rules provide an intuitively appealing explanation to regular behavior. Rules, however, need not be part of the language processing mechanism, as is assumed by the dual mechanism account. Instead, rules could be meta-linguistic. People are clearly able to consciously identify regularities and describe them with explicit rules that can then be deliberately followed. This is often used in second-language learning when students are explicitly instructed about certain "rules." Meta-linguistic rules may also be used in tasks that require overt responses such as the "Wug" test, which requires people to inflect a novel form. The underlying language processing system may be only involved insofar as it supplies probabilistic input to the meta-linguistic rule (as in the "Wug" test), or as it is modified as a result of being exposed to the output of the explicit rule (as in second-language learning). This means that the linguistic processes underlying inflection should be studied by tasks that do not require making a choice of inflection but that instead rely on activation-based measures such as priming between inflected and stem forms. Comparing the results of such studies to the results of explicit response tasks would provide a better assessment of whether rules are meta-linguistic.

# Pattern Formation, Biological

*James D. Murray*

## Introduction

The generation of biological spatial patterns is fundamental to many disciplines, among them bacteriology, developmental biology, physiology, neurobiology, epidemiology, ecology, and tumor growth. In population biology, patchiness in population densities is the norm rather than the exception. In developmental biology, groups of previously identical cells follow different developmental pathways, depending on their position. The rich spectrum of mammalian coat patterns and the patterns found on fishes, reptiles, molluscs, and butterflies reflect developmental processes that are still not fully understood; Figure 1 shows some examples. Stationary patterns as well as a wide variety of waves have been observed in chemical reactions. Ocular dominance stripes reflect patterns in the connectivity of the visual cortex, while hallucination patterns can be partially explained as activity patterns in the visual cortex. These patterns have been used by shamans for millennia.

The discovery in 1998 of anti-angiogenic drugs, such as Angiostaten and Endostatin, opened up exciting new possibilities for anticancer therapy. The new therapy is based on a revolutionary idea put forward by Dr. Judah Folkman in the 1970s, namely, that if tumors are starved of nutrients, they will die, and that starvation could be achieved if angiogenesis (genesis of blood vessels) in the tumor could be prevented. Only recently (1998) has the success of this concept been reported: anti-angiogenic drugs stopped tumor growth in mice. This result refocused attention on the patterning process of angiogenesis and network formation of endothelial cells in extracellular matrix; it is one of the exciting research areas in pattern formation. In this article we briefly discuss a mechanical model for generating such networks. The model's mechanism is firmly based on known biology. A comparison of the model's predictions with experimental results shows remarkable correlations. The book on vascular morphogenesis edited by Little, Mironov,

and Sage (1998), with a foreword and brief description by Folkman (1998) of anti-angiogenic therapy as opposed to conventional therapy, provides an extensive review of current knowledge in the field. In this article we also touch on a new approach for predicting brain tumor growth in which angiogenesis does not play a role.

Although biological patterns occur on a wide range of spatial scales, spanning the molecular, cellular, individual, and population levels, a common feature is that macroscopic patterns result from microscopic interactions. Although genes play a crucial role in developmental outcomes, they do not actually produce the pattern. Mathematical models have been proposed for the mechanisms that generate these biological patterns, based on the principle of interactions between the relevant components. We describe two of the main classes, reaction-diffusion models and mechanical models, and briefly mention some others. Each model can exhibit spontaneous pattern formation; that is, patterns develop in homogeneous environments without particular initial conditions, boundary conditions, or other external forces to drive them. The patterns are therefore self-organizing and symmetry breaking. The cancer cell patterns discussed in the brain tumor diffusion model are closely related, but there the patterns are not self-organizing.

Our goal is to develop a mechanism from knowledge of biology and to determine (1) the range of parameters attending this mechanism in which pattern formation is expected, (2) the nature of the pattern (steady, oscillating, or moving through space), (3) the scale of the pattern, and (4) perhaps the most important, the relation of the theoretical results, conclusions, and predictions to the actual biomedical problem. Relating model predictions to actual problems frequently suggests new experimental avenues and new biological insights. One of the major strategies to investigate such a relationship is as follows. First, a suggested biological mechanism is translated into a set of mathematical equations (the model). An appreciation of the pattern formation potential of existing models is invaluable here, and we hope that this brief survey will be useful in that regard. Once the model has been specified, we determine a homogeneous steady state and use linear stability analysis to determine whether perturbations of such an unpatterned state will grow or decay. For parameters supporting pattern formation, we isolate unstable modes and use the dominant modes to predict the scale and shape of the pattern. Although we generally cannot estimate all the parameters from the experiment, nevertheless we can use our knowledge of the biology to suggest broad ranges for some of the key parameters. The development of sophisticated mathematical models bearing little or no relation to the underlying biology, even if they are interesting mathematically, is of scant interdisciplinary value.

## Reaction-Diffusion Models

To date, reaction-diffusion models have been the most widely studied of the models we discuss. They have been applied with effect, for example, in developmental biology, tumor growth, wound healing, population biology, epidemiology, neurophysiology, chemistry, and physics (see Murray, 2002). The variables, which depend on time and space, may be a type of molecule or cell; we refer to them generally as species. Species disperse and react, and these two processes are independent. Developing expressions for local interactions between species and their flux, and invoking conservation laws, we obtain the general form

$$\frac{\partial n}{\partial t} = f(n) + D\nabla^2 n \tag{1}$$

where $n(x, t)$ is the vector of species densities, $f$ is the vector of reaction terms, $D$ is the diffusion coefficient matrix, and $\nabla^2$ is the diffusion operator in one, two, or three space dimensions; $t$ denotes time. Initial conditions and boundary conditions must also be specified.

The patterns we are most interested in are stable, stationary ($\partial n/\partial t = 0$), inhomogeneous solutions to Equation 1. For a single species in a single spatial dimension, it can be shown that a homogeneous steady state cannot be destabilized by diffusion: in two dimensions this is not always the case. Two-species models are very much more interesting, while three-species (and higher) models have not been studied in any depth, even though in most pattern formation situations several species are involved. The aim in practical modeling is to isolate the key dependent variables.

### *Two-Species Models*

In 1952, Alan Turing (of Turing machine fame) suggested that the differential diffusion of two interacting species could act to destabilize a homogeneous steady state. Since diffusion is usually thought of as a stabilizing (or smoothing) force, this was a startlingly original idea. It has since been supported both mathematically and experimentally (see Murray, 2002, who describes many applications and gives numerous references).

Consider the two-species system in one dimension, $x$, given by

$$\frac{\partial A}{\partial t} = f(A, B) + d_A\left(\frac{\partial^2 A}{\partial x^2}\right), \quad \frac{\partial B}{\partial t} = g(A, B) + d_B\left(\frac{\partial^2 B}{\partial x^2}\right) \tag{2}$$

in which a steady state exists at $(A_0, B_0)$, where $f(A_0, B_0) = g(A_0, B_0) = 0$. Linearizing around $(A_0, B_0)$, we get

$$\begin{aligned}\frac{\partial A}{\partial t} &= f_A A + f_B B + d_A\left(\frac{\partial^2 A}{\partial x^2}\right),\\ \frac{\partial B}{\partial t} &= g_A A + g_B B + d_B\left(\frac{\partial^2 B}{\partial x^2}\right)\end{aligned} \tag{3}$$

where $f_A = \partial f/\partial A$ is evaluated at $(A_0, B_0)$, and so on. We assume that the steady state is stable in the absence of spatial interaction (diffusion) and therefore that $g_B < 0$ without loss of generality.

We look for solutions of the form $e^{\lambda t + ikx}$ and generate a *dispersion relation* relating eigenvalues, $\lambda$, to modes, $k$ (the growth rate of mode $k$ is $Re(\lambda(k))$. The dispersion relation provides conditions for unstable modes to exist (see Murray, 2002, vol. II, for a full exposition and many other practical uses of dispersion relations):

$$f_A + g_B < 0 \quad \Delta = f_A g_A - f_B g_A > 0$$

($g_B < 0$ without loss of generality)

$$d_A > 0, \quad \delta f_A + g_B > 0, \quad (\delta f_A + g_B)^2 > 4\delta\Delta \tag{4}$$

where $\delta = d_B/d_A$

Some necessary conditions for Turing instability are (1) the self-inhibiting species, $B(g_B < 0)$, must diffuse at the higher rate, and (2) $A$ must be self-activating ($f_A > 0$). Also, $f_B$ and $g_A$ must have opposite signs. The species that promotes growth of the other is the *activator*, and the other species is the *inhibitor*. The two possible cases are illustrated schematically in Figure 2. In case 1, $A$ is the activator (which is also self-activating), while the inhibitor, $B$, diffuses at a higher rate and inhibits not only $A$ but also itself. In case 2, $B$ is the activator, again self-inhibiting, and again diffuses at a higher rate. It can be shown that in case 1 the two species occur at high or low density together (Figure 2*C*), whereas in case 2, $A$ is at high density where $B$ is low, and vice versa (Figure 2*D*).

We now give two analogies, one ecological for conceptual simplicity, for the mechanisms underlying Turing instabilities and the evolution of spatial patterns. Consider case 1, and refer to Figure 3*A*, which are sketches of the local phase plane. Let $A$ be prey to a predator, $B$. How can patterns arise as in Figure 2*C* when predators disperse more rapidly than their prey? Suppose there were an area of increased prey density. In the absence of diffusion, this would be damped out after a temporary increase in both populations. However, with high predator dispersal, it is possible that the local increase in predators partially disperses and hence is not strong enough to push the prey population back toward equilibrium. Furthermore, when predators disperse, they lower the prey density in neighboring regions and cause the opposite effect. It is thus possible to have alternating clumps of high and low population density of both species.

Consider the second type of dynamics (Figures 2*B*, *D*, and 3*B*). Suppose now that $A$ is a slowly dispersing, *autocatalytic* ($f_A > 0$) predator and $B$ is its prey. In an area of high prey density, without diffusion, predator numbers would increase at the expense of prey, and eventually both populations would return to the steady state. However, there is a transient increase in the predator population and a reduction in the prey population to below its steady-state value. The resulting net influx of rapidly dispersing prey from neighboring regions would cause the predator population to drop in those regions while prey flourished. A pattern can become established in which areas of few predators and many prey supply prey to areas that contain few prey and large numbers of predators.

The dispersion relation also indicates the scale on which a pattern occurs, through the wavelength, $l_c$, of the fastest growing mode:

$$l_c = \frac{2\pi(d_B - d_A)^{1/2}}{[(\delta + 1)((-f_B g_A)/\delta)^{1/2} - f_A + g_B]^{1/2}}, \quad \text{where } \delta = \frac{d_B}{d_A} \tag{5}$$

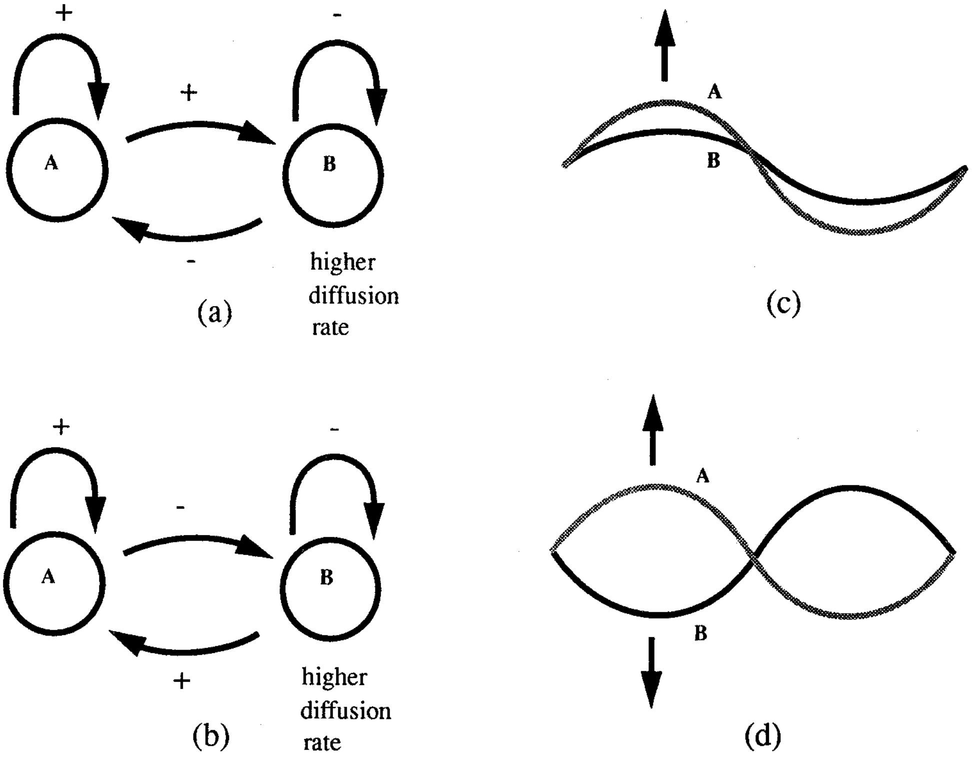

**Figure 2.** Some interactions support diffusion-driven instabilities. In part *A*, self-activing *A* also activates *B*, which inhibits both species. The resulting spatial pattern is shown schematically in part *C*. In part *B*, self-activitating *A* now inhibits *B* but is itself activated by *B*. The resulting pattern is shown in part *D*. Corresponding reaction phase planes are shown in Figure 3.

(see Murray, 2002, vol. II). Equation 5 indicates that Turing instabilities can occur on a broad range of spatial scales. For large $\delta$, $l_e \approx 2\pi[(d_A d_B)/(-f_B g_A)]^{1/4}$.

Mathematical analysis can also provide insight into the effect of boundary size and shape on pattern formation. In models for animal coat patterns (Murray, 2002, vol. II, and references there), one finds that only crosswise stripes can occur in long narrow domains, whereas spots can occur on wider domains. This is a possible explanation for why animals that have spots over most of their bodies (e.g., leopards) tend to have hooped patterns, or no pattern at all, on their tails; it also explains why a striped animal cannot have a spotted tail. The qualitative form of the pattern is governed by the size and shape of the animal at the time the pattern is determined.

In Turing's theory of morphogenesis, the developmental concept is that a chemical two-species system generates a landscape of chemical concentration to which cells react differentially and hence form spatial patterns. These chemicals are referred to as morphogens. Although these types of models have prompted enlightening experiments, their use has been limited because of the illusive nature of the morphogens in real biological situations. This view is changing; see the important paper by Lander, Nie, and Wan (2002).

## Virtual Brain Tumors: Predicting Growth and Enhancing Medical Imaging

A medical use of classical diffusion models is that of predicting the growth (and control) of brain tumors (gliomas). This involves the spatial spread from an initial source of cancerous cells. Gliomas differ from most other cancers by their diffuse invasion of the surrounding normal tissue. Although medical imaging has increased the detection of gliomas, it has still a long way from defining accurately enough the degree of tumor cell invasion peripheral to the bulk of the tumor mass. This inadequacy of current medical imaging is substantiated by the fact that even extensive surgical removal (resection) or local irradiation of gliomas is followed by tumor recurrence at or near the edge of the resection bed.

Since the mid-1990s, E. C. Alvord, M.D. (neuropathology), J. D. Murray (applied mathematics), and their research group at the University of Washington have developed mathematical models to quantify the spatiotemporal growth and invasion of gliomas in three dimensions throughout a virtual human brain with a resolution of 1 mm$^3$ in which, latterly, the anatomically correct distributions of gray and white matter have been defined (Swanson, Alvord, and Murray, 2000, 2002; see also Murray, 2002, vol. II, for a full review). These mathematical models quantify the extent of tumorous invasion of individual gliomas to a degree beyond the capability of present medical imaging, including even microscopy. They also quantify the consequences of certain control therapies such as chemotherapy and resection.

We briefly describe their approach here. Our basic model can vary the two key characteristics, proliferation and cell motility (diffusion), in heterogeneous, anatomically accurate brain tissue. We allow the motility coefficient to differ depending on the local tissue composition.

Our basic mathematical model quantifying the differential motility of gliomas in gray and white matter is quantified mathematically by

$$\frac{\partial c}{\partial t} = \nabla \cdot (D(\mathbf{x})\nabla c) + \rho c, \tag{6}$$

where $c(\mathbf{x}, t)$ is the concentration of tumor cells at location $\mathbf{x}$ and time $t$. $D(\mathbf{x})$, a function of position $\mathbf{x}$ in the brain, is the diffusion coefficient defining the random motility of the glioma cells with $D(\mathbf{x}) = D_g, D_w$, constants for $\mathbf{x}$ in gray and white matter, respectively. $\rho$ represents the net proliferation rate of the glioma cells. This term predicts exponential growth of the cancer cells, but within the survival period of the patient it has been shown to be a very good approximation. The diffusion coefficient in white matter

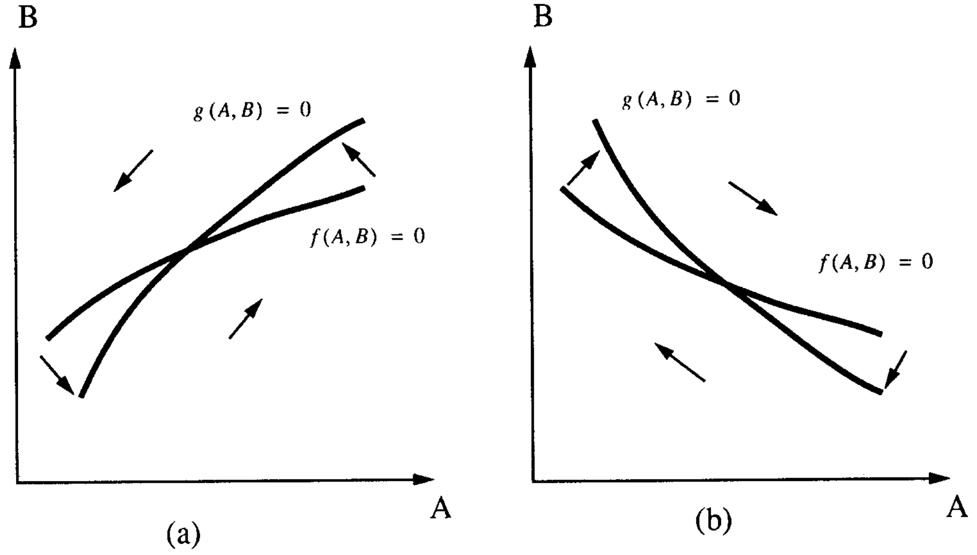

**Figure 3.** Reaction phase planes for diffusion-driven instabilities. Part *A* shows the phase plane corresponding to parts *A* and *C* of Figure 2. Part *B* shows the phase plane corresponding to parts *B* and *D* of Figure 2. The steady state is at the intersection of the two null clines. Arrows represent the direction of change due to local species interaction.

is larger than that in gray matter; that is, $D_w > D_g$. The model assumes that the tumor has grown to about 4,000 cells as a local mass before it begins to diffuse and the model Equation 6 applies.

For every medical imaging technique there is a threshold of detection below which glioma cells are not detectable. A tumor boundary detected by enhanced computed tomography (CT) corresponds to a tumor cell concentration of only about 8,000 cells/mm$^3$. Mathematically, of course, in our virtual tumor, we can set the detection at any level we choose.

Based on the medical literature, the models assumed that a medical diagnosis is made when the volume of an enhanced CT–detectable tumor has reached a size equivalent to an average 3 cm in diameter and that death occurs when the volume reaches an average 6 cm in diameter. The difference between these two times can be defined as the survival time of the hypothetical or virtual patient. We can estimate these times from the model results, and they agree well with the average survival times for each grade of gliomas we have studied.

Crucial to the models' use is the ability to determine reasonable estimates of the critical parameters, the growth rate $\rho$ and the diffusion coefficient $D$. We have estimates, but they vary quite widely. Some of the current research is focused on determining the values for individual patients, and these values can be then used in prognosis and treatment protocols.

Figure 4 shows three perpendicular cross-sections (coronal, sagittal, and horizontal or axial) of the virtual human brain, intersecting in a point marked by an asterisk in the superior frontal region where the virtual tumor originates. The gray and white matters of the brain domain appear gray and white, respectively. In each image, a single thick black curve defines the edge of the tumor that the model suggests would be detectable on enhanced CT, associated with a threshold of detection of 8,000 cells/mm$^3$. The outermost profile corresponds to an arbitrary threshold of detection 80 times more sensitive than enhanced CT (i.e., 100 cells/mm$^3$). The left column of images in Figure 4 represents the tumor at the time of detection, defined as an enhanced CT–detectable tumor with average diameter of 3 cm, while the right column represents the tumor at the time of death, defined by an enhanced CT–detectable tumor with average diameter of 6 cm. The simulations clearly reveal the subthreshold invasion of the tumor well beyond the detectable portion of the tumor. No matter the extent of resection, the mathematical model indicates that the gross tumor will ultimately recur and kill.

Unlike real patients with real gliomas, virtual patients with virtual gliomas can be analyzed by letting any particular factor vary while keeping all the other determining factors constant. Such isolation techniques, of course, require a mathematical model that has sufficient complexity to contain a realistic number of variables. The recent availability of simulated MRI, with proportions of gray and white matter accurately indicated, permitted the development of this model, which is sufficiently complex to allow different diffusion rates in gray and white matter (e.g., a 5-fold increase in diffusion or migration in white matter).

## Murray-Oster Mechanical Models

The Murray-Oster mechanical theory is based on the fact that mesenchymal cells exert significant traction forces on the surrounding extracellular matrix, thereby influencing their movement and the density of the surrounding matrix. The model simply consists of conservation equations for the cells and matrix and a force balance equation for the interaction between the cell-generated forces and the viscoelastic resistive properties of the matrix. An extensive pedagogical review is given in Murray (2002, vol. II). Harris, Stopak, and Warner (1984) first presented graphic experimental confirmation of some of the predictions made with the original model system.

The overriding feature of the Murray-Oster mechanical theory of pattern formation is its simplicity (in spite of its relative mathematical complexity): complicated patterns arise solely as a consequence of the interaction of the cell traction forces and the viscoelastic properties of a deformable matrix in which they are embedded. We give an intuitive description of the process below. The theory has been widely used in a variety of problems, especially in wound healing studies (for example, Tranquillo and Murray, 1993; Olsen, Maini, and Sherratt, 1998; and the review by Sherratt and Dallon, 2002).

The cell-matrix network patterns found experimentally (Vernon et al., 1995) when vascular endothelial cells are placed on a basement extracellular membrane provide a unique theoretical and experimental opportunity to determine the important components in the morphogenetic process of the complex network formation. Figure 5 shows an example of typical patterns obtained from the model mechanism and experiment. In these experiments, endothelial cells were placed on a gelled basement membrane matrix (BMM, Ma-

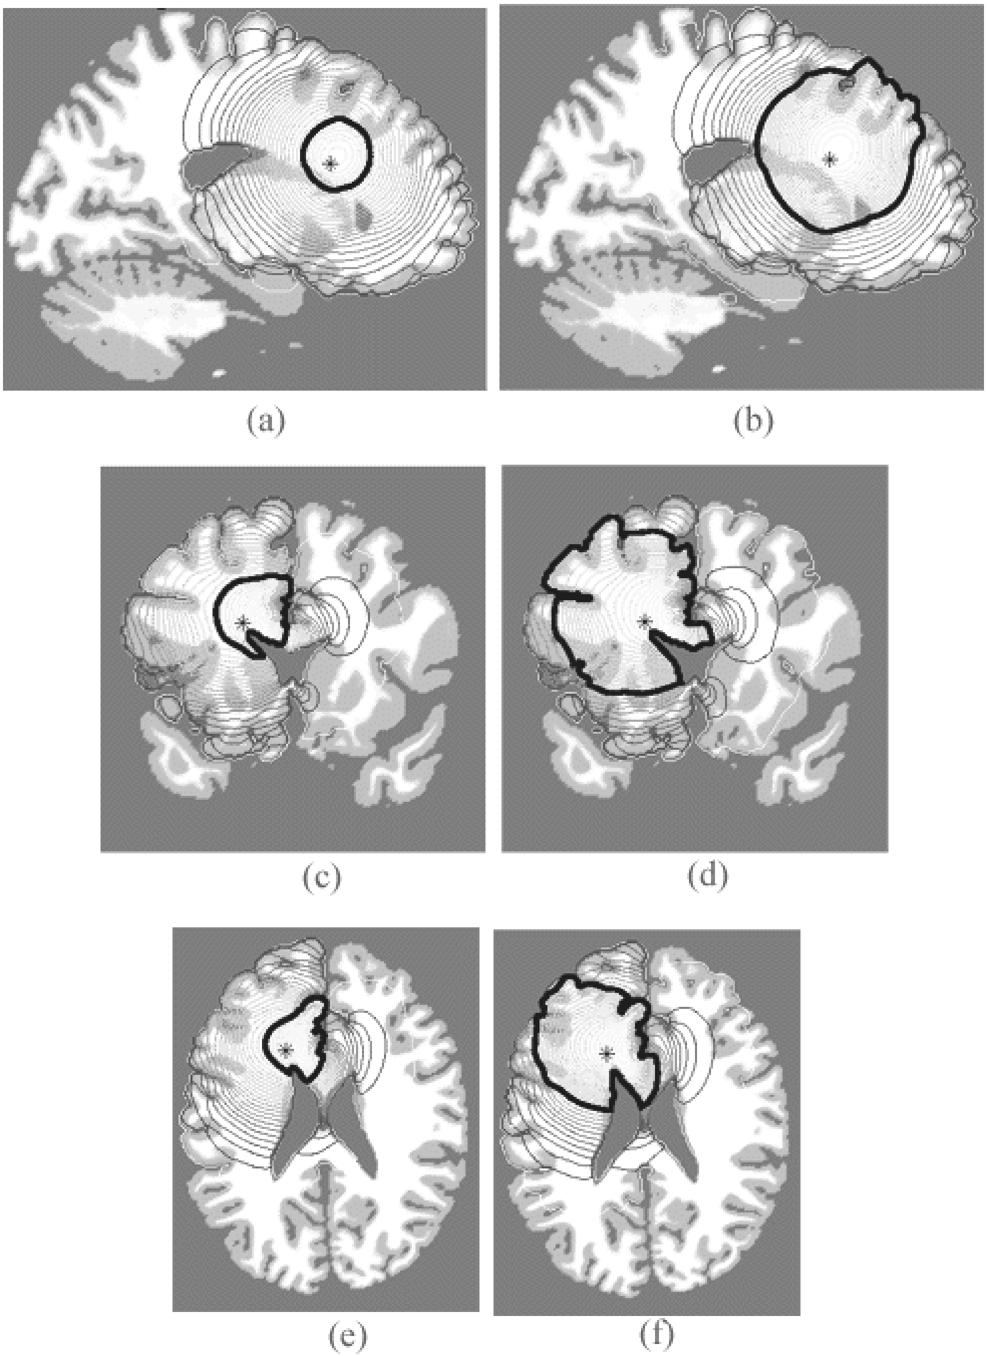

**Figure 4.** Sections of the virtual brain in sagittal, coronal, and horizontal planes that intersect at the site of the brain tumor (glioma) originating in the thalamus denoted by an asterisk. A thick black contour defines the edge of the tumor detectable by enhanced computed tomography. Cell migration was allowed to occur in an anatomically accurate three-dimensional representation of the human brain.

trigel). In the course of a few hours, aggregates started to form, and after 24 hours all of the BMM had been pulled into an aggregate network.

In view of the importance of angiogenesis in cancer therapy, we describe a version of the theory that generates networks of cells and matrix and that has been suggested (Manoussaki et al., 1996; Murray et al., 1998) as the possible mechanism of network formation (Vernon et al., 1995). The model shows unequivocably that cell-matrix contact guidance plays a crucial role. There is no cell proliferation in the case of the cell-Matrigel patterns mimicking early network patterns of angiogenesis, in which the complex strand-like structures of matrix are formed. The pattern forms purely from cellular traction forces and their interaction with the fibrous matrix: there are no external forces, cell proliferation, or other complicating factors. We can thus isolate, in our models, the central mechanical interaction underlying a range of biological phenomena in development and other contexts. There are a number of well-determined parameters, such as cell density, matrix density, matrix thickness, pattern wave number, time scale, and some parameters that we can confine to a range of possible values, as well as the Young modulus and the magnitude of cellular traction forces.

The conservation equations in this (experimental) situation are

$$\frac{\partial n}{\partial t} + \nabla \cdot [nv - D(\varepsilon)\nabla n] = 0, \quad \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho v) = 0 \qquad (7)$$

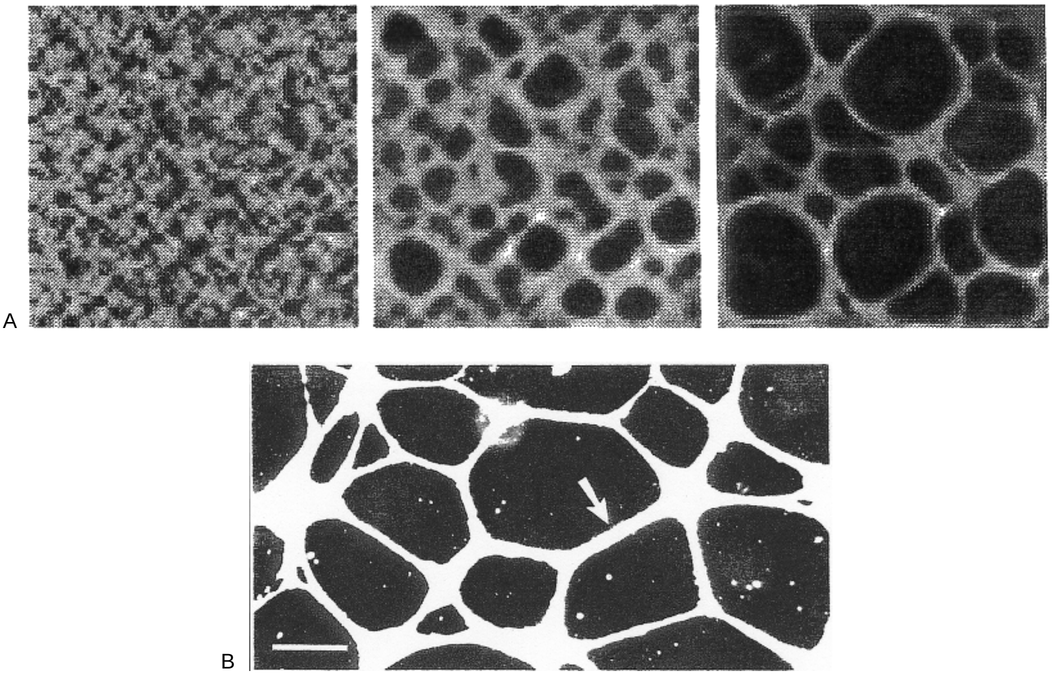

**Figure 5.** Cell density network formation when cells are embedded in a matrix gell: white areas denote high cell densities. *A*, Initially the cells were uniformly distributed and the model equations simulated numerically with the parameters obtained from the literaure and related experiments: the time scale for the pattern formation is 24 hours: the complete square is 800 $\mu m$. *B*, Experimental patterns obtained with bovine aortic endothelial cells cultured on Matrigel. Each cord (example arrow) consists of many cells; the image is viewed by darkfield illumination (bar = 200 $\mu m$). (Photograph courtesy of R. B. Vernon.)

where cells ($n$) and matrix ($\rho$) convect as a single phase with material velocity $v = Du/Dt$. $D(\varepsilon)$ is the cell motility tensor, dependent on the matrix strain, $\varepsilon$, defined by

$$\varepsilon = \tfrac{1}{2} (\nabla \cdot u + \nabla \cdot u^T)$$

where $u$ is the vector of matrix displacement and $u^T$ its transpose.

The force balance equation simply says that the traction forces generated by the cells, $T(n, \rho)$; the induced response stress of the matrix, $\sigma$; and the substrate anchoring, $(s/\rho)(\partial u/\partial t)$, where $s$ is the strength of the fluid-like drag force of the matrix attachment, are in equilibrium, namely

$$\nabla \cdot [\sigma + T(n, \rho)] = \frac{s}{\rho} \frac{\partial u}{\partial t} \tag{8}$$

The detailed form of $D(\varepsilon)$ and each term in the force equation have to be specified; they are crucial elements in the modeling.

This particular model is analyzed in detail by Manoussaki et al. (1996) and by Murray et al. (1998). They took

$$\sigma = \tau \frac{n}{1 + \alpha n^2}$$

where $\alpha$ is a positive parameter: this form reflects the reduction in traction as the cell density becomes large. Tranqui and Tracqui (2000; see earlier references there) have developed experimental techniques to determine the detailed form and estimate the parameters.

The derived biased diffusion $D(\varepsilon)$ is

$$D(\varepsilon) = D_0 \begin{pmatrix} 1 + \dfrac{\varepsilon_{xx} - \varepsilon_{yy}}{2} & \dfrac{\varepsilon_{xy} + \varepsilon_{yx}}{2} \\ \dfrac{\varepsilon_{xy} + \varepsilon_{yx}}{2} & 1 - \dfrac{\varepsilon_{xx} - \varepsilon_{yy}}{2} \end{pmatrix}$$

where $D_0$ is the motility coefficient when there is no strain present.

The viscoelastic matrix stress must account for the density and reorientation of the matrix fibers as well as their strength. This was taken to be made up of a viscous and an elastic part given by a Voigt form, namely

$$\sigma = \frac{E(\varepsilon)}{1 + \nu} \left( \varepsilon + \frac{\nu}{1 - 2\nu} \theta I \right) + \left( \mu_1 \frac{\partial \varepsilon}{\partial t} + \mu_2 \frac{\partial \theta}{\partial t} I \right)$$

where $E$ is the strain-dependent elastic modulus and $\nu$ is the Poisson ratio, which measures how a strip of gel will contract in one direction when stretched in the transverse direction. $\mu_1$, $\mu_2$ are the shear and bulk visosities, $\theta(= \nabla \cdot u)$ is the dilation tensor, and $I$ is the unit tensor.

Intuitively we can see how the mechanism generates the observed complex cellular and matrix patterns. Cells initially uniformly distributed on the matrix (essentially a two-dimensional geometry in the experiments) pull the matrix and hence cause stress lines to appear, resulting in realignment of the matrix fibers. The cells can move more easily along the directions of stress and form regions of higher cell density. These clusters of cells in turn generate higher traction forces because of their higher cell density, which in turn increases the deformation of the matrix and enhances "highways" of matrix along which the cells move more freely. In this way a network of fiber bundles is formed, giving rise to the quasi-hexagonal network observed in experiments (see Figure 5). The formation of these fiber bundles/highways we associate with the process of angiogenesis, or, in the context here, vasculogenesis.

Murray et al. (1998) analyzed the model using parameters estimated from the literature. Figure 5 illustrates some time-evolving network patterns together with one of the typical networks found experimentally by Vernon et al. (1995). Various other hypothetical scenarios were studied that also compared well with subsequent experiments. Clearly, no patterns form if there is no cell traction, as found experimentally. The case for such a mechanical model of cell-matrix network patterns is further strengthened by the way the patterns are formed in vitro and mathematically. The evolution is from irregular polygons that increase in size and decrease in number, with the smallest polygons pinching off and disappearing. Also, on thicker gels, larger polygons form. They also found, surprisingly, that if the cell traction is sufficiently high, networks formed even in the *absence* of biased diffusion. The effect of matrix thickness on the patterns also reflected what was observed experimentally.

This mechanical model was the first mathematical description of cell-matrix interactions for the formation of network patterns in which all of the component variables were measurable.

## Discussion

We have seen how two fundamentally different types of model can give rise to patterns. Here we briefly mention other mechanisms that have been studied.

### Negative and Long-Range Diffusion

If, in a reaction-diffusion equation, the diffusion coefficient was negative, this would intuitively cause clumping (imagine viewing a movie of diffusion in reverse). Although such a problem is ill-posed mathematically, this can be rescued by adding a biharmonic term, as in the Cahn-Hilliard equation (Cahn, 1968). Murray (2002, vol. I) shows that a biharmonic term is a natural practical modification when fluxes have a long-range component (they depend on densities in a neighborhood of the reference point). Such long-range effects are present in the Murray-Oster mechanical model via the extracellular matrix and the finger-like filapodia of the cells.

### Chemotaxis

*Chemotaxis* is the name given to the process whereby cells move up or down a chemical (chemoattractant or chemorepellent) gradient. Typically, chemoattractant ($c$) is secreted and degraded by cells ($n$), and the cells respond to gradients in $c$ with a convection speed of $\chi(\partial c/\partial x)$, with typical equations, in one dimension, given by

$$\frac{\partial n}{\partial t} = D_n \frac{\partial^2 n}{\partial x^2} - \frac{\partial}{\partial x}\left(n\chi \frac{\partial c}{\partial x}\right), \quad \frac{\partial c}{\partial t} = f(n, c) + D_c \frac{\partial^2 c}{\partial x^2} \tag{9}$$

where $\chi$ is the chemotactic parameter (in fact usually a function of $c$), the $D$s are diffusion coefficients, and $f(n, c)$ is the source function of $c$. For spatial patterns to form, cells must diffuse at a lower rate than the chemoattractant, and the chemoattractive (destabilizing) force need only be slightly stronger than the diffusive (stabilizing) force. There is a single dimensionless parameter that determines whether or not a pattern will form.

Bacteria such as *E. coli* and *Salmonella* exhibit strong chemotactic respones and have been the subject of intense study since the early 1990s. The experimental work of Budrene and Berg (1995; see earlier references therein) graphically illustrates the complex regular patterns that can be formed. This work was the basis for the mathematical models that reflect the detailed biology by Tyson and her colleagues, including the experimentalists (Tyson, Lubkin, and Murray 1998; see other references there and Murray, 2002, vol. II, for a full survey). This specific paper shows the minimum requirements a model and the biology must have to produce the observed patterns.

### Cross-Taxis

Two species can exhibit taxis with respect to one other:

$$\begin{aligned} \frac{\partial A}{\partial t} &= D_1 \frac{\partial^2 A}{\partial x^2} - \chi_1 \frac{\partial}{\partial x}\left(A \frac{\partial B}{\partial x}\right), \\ \frac{\partial B}{\partial t} &= D_2 \frac{\partial^2 B}{\partial x^2} - \chi_2 \frac{\partial}{\partial x}\left(B \frac{\partial A}{\partial x}\right) \end{aligned} \tag{10}$$

(if $\chi_1 > 0$ and $\chi_2 > 0$, for example, constant here, the two species move up each other's gradient). Although not greatly studied, such models are known to be susceptible to blow-up (see Murray, 2002, vol. II, for references and a brief analysis).

### Mathematical Techniques

We have barely scratched the surface of the mathematical analysis of pattern formation. Close to bifurcation (loss of stability), it is possible to analyze the behavior of small-amplitude patterns. For example, one can determine whether two basic spatial patterns, hexagonal and striped, are stable with respect to each other (Murray, 2002, vol. II). We have only briefly confronted the fact that pattern formation generally takes place on a finite domain, perhaps with a particular geometry. At the very least, this reduces the number of modes that can occur: we refer the reader to Murray's (2002, vol. II) modeling of mammalian coat pattern formation as a graphic example. The most important aspect of mathematical models for biological pattern formation must remain, however, their close relation to the real world of biology.

# Pattern Formation, Neural

*Paul C. Bressloff and Jack D. Cowan*

## Introduction

In studying the large-scale functional and anatomical structure of cortex, two distinct questions naturally arise: How did the structure develop and what forms of spontaneous and stimulus-driven neural dynamics are generated by such a cortical structure? It turns out that in both cases, the Turing mechanism for spontaneous pattern formation plays an important role. Turing originally considered the problem of how animal coat patterns develop. He suggested that chemical markers in the skin make up a system of diffusion-coupled chemical reactions among substances called morphogens. Turing showed that in a two-component reaction-diffusion system, a state of uniform chemical concentration can undergo a diffusion-driven instability, leading to the formation of a spatially inhomogeneous state (see PATTERN FORMATION, BIOLOGICAL). Wilson and Cowan (1973) proposed a nonlocal version of this mechanism based on competition between short-range excitation and longer-range inhibition. In the neural context, interactions are mediated not by molecular diffusion, but by long-range axonal connections; hence the term *nonlocal*. Since then, this neural version of the Turing instability has been applied to many problems concerning the dynamics (Bressloff and Cowan, 2002; see also DYNAMICS AND BIFURCATION IN NEURAL NETS) and development (Swindale, 1980) of cortex. In the former case, pattern formation occurs in neural activity; in the latter, it occurs in synaptic weights. In most cases, there exists some underlying symmetry in the model that plays a crucial role in the selection and stability of the resulting patterns.

## Feature Selectivity and Tuning

Probably the simplest example of neural pattern formation is that of orientation tuning in the ring model of a cortical hypercolumn (Somers, Nelson, and Sur, 1995). The one-population version of this model consists of a continuous distribution of neural populations labeled by their orientation preference $\phi \in [0, \pi)$. The state of the network is expressed in terms of an activity variable $a(\phi, t)$ evolving according to the equation

$$\tau \frac{\partial a}{\partial t} = -a + w \circ \sigma[a] + h \tag{1}$$

where $\tau$ is a time constant, $w \circ \sigma$ signifies the convolution

$$(w \circ \sigma[a])(\phi) = \int_0^\pi w(\phi - \phi')\sigma[a(\phi')]\,\frac{d\phi'}{\pi} \tag{2}$$

and $\sigma$ denotes a firing rate function (typically taken to be a smooth sigmoid function of activity). The weight distribution $w$ represents nonlocal neural interactions within the hypercolumn, whereas $h$ denotes an external drive generated by some oriented visual stimulus.

First, consider the case of constant external drive, $h(\phi) = h_0$, and suppose that $\bar{a}$ is a homogeneous fixed-point solution of Equation 1, that is, $\bar{a} = w \circ \sigma[\bar{a}] + h_0$. Linearizing about this fixed point by setting $a(\phi, t) = \bar{a} + u(\phi)e^{\lambda t/\tau}$ leads to the eigenvalue equation

$$(\lambda + 1)u(\phi) = \mu\, w \circ u(\phi) \tag{3}$$

where $\mu = \sigma'[\bar{a}]$. Expanding the $\pi$-periodic functions $u(\phi)$ and $w(\phi)$ as Fourier series

$$w(\phi) = \sum_{n=-\infty}^{\infty} W_n e^{2in\phi}, \quad u(\phi) = \sum_{n=-\infty}^{\infty} U_n e^{2in\phi} \tag{4}$$

we can diagonalize the eigenvalue equation to find the discrete set of eigenvalues

$$\lambda_n = -1 + \mu W_n \tag{5}$$

for integer $n$, with corresponding eigenfunctions $U_n e^{2in\phi}$. We assume that $w(\phi)$ is a real, symmetric function of $\phi$ so that $W_{-n} = W_n$ with $W_n$ real. It follows that for sufficiently small $\mu$ (corresponding to a low activity state $\bar{a}$), $\lambda_n < 0$ for all $n$, and the fixed point $\bar{a}$ is stable. However as $\mu$ increases beyond a critical value $\mu_c$, the fixed point becomes unstable, owing to excitation of the eigenfunctions associated with the largest Fourier component of $w$. We refer to such eigenfunctions as *excited modes*.

Two examples of Fourier spectra are shown in Figure 1. In the first case, $W_1$ is maximal, so $\mu_c = W_1^{-1}$, and the excited modes are of the form

$$u(\phi) = ze^{2i\phi} + z^* e^{-2i\phi} = |z| \cos(2[\phi - \phi_0]) \tag{6}$$

with complex amplitude $z = |z|\, e^{-2i\phi_0}$. Since these modes have a single maximum around the ring, the network supports an activity profile consisting of a tuning curve centered about the point $\phi_0$ (see Figure 1*C*). The location of this peak is arbitrary and depends only on random initial conditions, reflecting the rotation invariance or *symmetry* of the weight distribution $w$. This follows from the assumption that $w$ depends only on the difference between the orientation preferences $\phi$ and $\phi'$ as in Equation 2. Such a symmetry is said to be spontaneously broken by the action of the pattern-forming instability. Also note that since the dominant component is $W_1$, the distribution $w$ is excitatory (inhibitory) for neurons with sufficiently similar (dissimilar) orientation preferences. (This is analogous to the Wilson-Cowan "Mexican hat" function; see below.) On the other hand, when the inhibitory component is weakened such that $W_0$ is maximal, the network undergoes a bulk instability at the critical point $\phi_c = W_0^{-1}$ in which no particular orientation $\phi_0$ is favored, since the excited eigenmode reduces to $U_0$.

So far, we have shown how linear stability analysis can be used to establish the growth of an inhomogeneous state from a homogeneous state through a pattern-forming instability. However, as

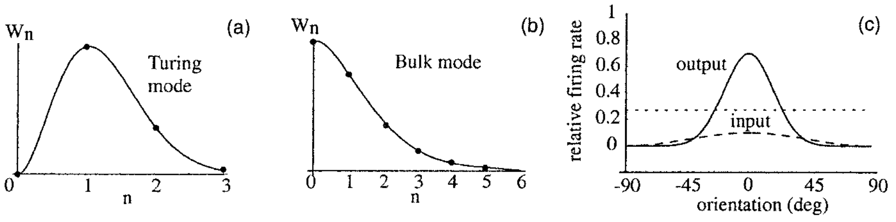

**Figure 1.** Orientation tuning in the ring model. Fourier spectrum $W_n$ of local weight distribution $w(\phi)$ with (*A*) a maximum at $n = 1$ (Turing mode) and (*B*) a maximum at $n = 0$ (bulk mode). *C*, Tuning curve generated by a pattern-forming instability. Recurrent excitation and inhibition amplifies a weakly biased external input. The dotted line is baseline output without orientation tuning.

the new state increases in amplitude, the linear approximation breaks down, so one has to use nonlinear theory to investigate whether or not a stable pattern ultimately forms. Sufficiently close to the bifurcation point at $\mu = \mu_c$, where the homogeneous state becomes unstable, we can treat $\varepsilon = \mu - \mu_c$ as a small parameter and carry out a perturbation expansion of Equation 1 in powers of $\varepsilon^{1/2}$ (see Dynamics and Bifurcation in Neural Nets). First, Taylor expand the nonlinear term $\sigma[a]$ about the fixed point $\bar{a}$:

$$\sigma[a] = \sigma[a_0] + \gamma_1(a - a_0) + \gamma_2(a - a_0)^2 + \gamma_3(a - a_0)^3 + \cdots$$

where $\gamma_n = n!^{-1}d^n\sigma[a_0]/da^n$. Second, substitute the series expansion

$$a(\phi, t) = a_0 + \varepsilon^{1/2}[z(t)e^{2im\phi} + z^*(t)e^{-2im\phi}] + O(\varepsilon)$$

into Equation 1 and equate equal powers of $\varepsilon^{1/2}$. A standard perturbation calculation then yields a nonlinear ordinary differential equation at order $\varepsilon^{3/2}$ for the amplitude $z(t)$ of the excited modes (Bressloff and Cowan, 2002):

$$\frac{dz}{dt} = z(\mu - \mu_c - \Lambda|z|^2) \tag{7}$$

where

$$\Lambda = -\frac{3\gamma_3}{\gamma_1^2} - \frac{2\gamma_2^2}{\gamma_1^2}\left[\frac{W_2}{1 - \gamma_1 W_2} + \frac{2W_0}{1 - \gamma_1 W_0}\right] > 0 \tag{8}$$

It follows that if $\mu > \mu_c$, then the fixed point $z = 0$ is unstable, and there is a new branch of stable tuning curves with arbitrary phase and steady-state amplitude $|z| = (\mu - \mu_c)/\Lambda$.

Now suppose that there is a weakly biased external drive of the form

$$h(\phi) = h_0[(1 - \kappa) + \kappa\cos(2[\phi - \Phi])] \tag{9}$$

representing a visual stimulus with orientation $\Phi$. Assuming that $\kappa = O(\varepsilon^{3/2})$, one finds that there is an additional term $h_0\kappa e^{-2i\Phi}$ on the right-hand side of the $O(\varepsilon^{3/2})$ amplitude equation (Equation 7). The phase of the stable inhomogeneous state is now equal to $\Phi$. Hence, when the network is operating in the tuned or *Turing mode*, recurrent interactions amplify a weakly biased input, leading to an orientation tuning curve whose peak coincides with the stimulus orientation; the circular symmetry of the network is now explicitly broken by the presence of a biased input. This amplification mechanism has received recent experimental support in that optical imaging of visual cortical responses in the presence of voltage-sensitive dyes reveals responses sharply tuned for orientation whose amplitude then grows in a manner consistent with the onset of the Turing mode (Sharon and Grinvald, 2002).

It is also possible to extend the above ideas to incorporate other stimulus features for which cortical neurons exhibit tuned responses, including spatial frequency, color, and motion. An interesting question then arises, namely, "What is the appropriate symmetry of the associated pattern forming instability?" For example, it has recently been suggested that orientation and spatial frequency preferences can be combined by replacing the ring network, which has circular symmetry, by a network with the topology of the surface of a sphere (Bressloff and Cowan, 2002). Motivated by recent optical imaging data on orientation and spatial frequency preference maps (Issa, Trepel, and Stryker, 2000), such feature preferences are represented by angular coordinates on the sphere. (Note that such a coordinate system refers to the feature preferences; it does not imply that the actual distribution and connections of visual cortex neurons fit on a sphere—in fact, they fit on a plane.) High and low spatial frequency preferences are located at the poles of the sphere, which are identified with the singularities of the orientation preference map, commonly referred to as *orientation pinwheels*. Cortical amplification through spontaneous breaking of spherical (rather than circular) symmetry leads to a sharply tuned, contrast-invariant response to both stimulus features.

## Geometric Visual Hallucinations

Geometric visual hallucinations are seen by many observers after taking hallucinogens such as LSD, cannabis, or mescaline; on viewing bright flickering lights; on waking up or falling asleep; in "near death" experiences; and in many other syndromes. The Chicago neurologist Klüver organized such images into four groups called *form constants*: (I) tunnels and funnels, (II) spirals, (III) lattices, including honeycombs and triangles, and (IV) cobwebs, all of which contain repeated geometric structures. Figure 2*A* shows their appearance in the visual field. Note in particular the difference between the first two *noncontoured* images, which consist of alternating regions of light and dark, and the *contoured* nature of the last two images.

Ermentrout and Cowan (1979) provided a first account of the generation of visual hallucinations, based on the idea that some disturbance such as a drug or flickering light can destabilize the primary visual cortex (V1), inducing spontaneous pattern of cortical activity that reflects the underlying architecture of V1. They studied interacting populations of excitatory and inhibitory neurons distributed within a two-dimensional cortical sheet. Modeling the evolution of the network in terms of a set of Wilson-Cowan equations, they showed how spatially periodic patterns such as stripes, squares, and hexagons bifurcate from a low-activity homogeneous state via a Turing instability. They then noted that there is an orderly retinotopic mapping of the visual field onto the surface of cortex, with the left and right halves of visual field mapped onto the right and left cortices, respectively. Except close to the fovea (the center of the visual field), this map can be approximated by a complex logarithm (Schwartz, 1977) as illustrated in Figure 2*B*. Applying the inverse of this retinocortical map, they showed that when the periodic cortical patterns are mapped back into visual field coordinates, noncontoured hallucinatory images such as the form constants (I) and (II) of Figure 2*A* are reproduced.

Interestingly, the model cannot reproduce the contoured images (III) and (IV), since there is no information in it regarding the orientation selectivity of neurons in V1. Recently, a much more detailed model of the functional and anatomical structure of V1 has been developed that treats the cortex as a continuum of interacting hypercolumns, each of which has the internal structure of the ring

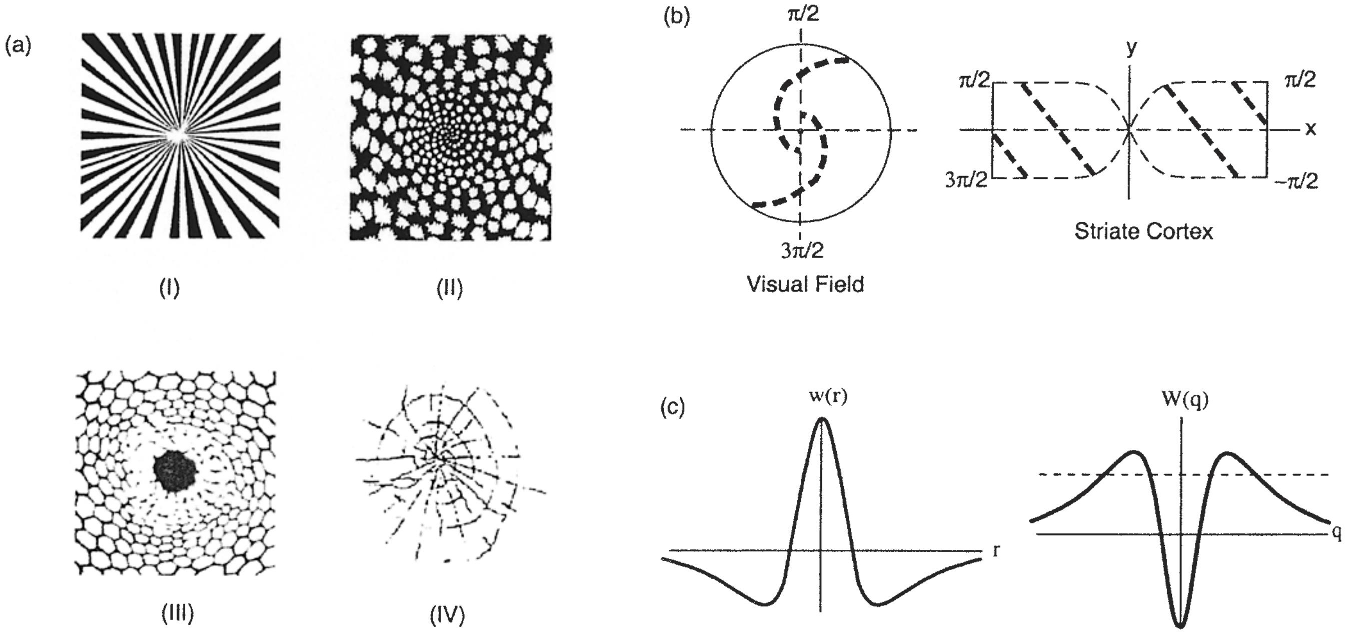

**Figure 2.** *A*, Hallucination form constants: (I) funnel and (II) spiral images seen following ingestion of LSD, (III) Honeycomb generated by marijuana, (IV) cobweb petroglyph. *B*, Retinocortical map showing how a spiral image in visual field is mapped to a stripe of activity in cortex. *C*, Mexican hat interaction function $w(r)$ showing short-range excitation and long-range inhibition together with its Fourier transform $W(q)$.

model for orientation tuning (Bressloff et al., 2001). In this new model, both contoured and noncontoured hallucinatory images can be generated depending on whether each isolated hypercolumn undergoes a local Turing or bulk instability with respect to orientation (see Figure 1*A*).

We now consider the theory of cortical pattern formation in more detail. For simplicity, we describe the earlier version due to Ermentrout and Cowan. Let $a_E(\mathbf{r}, t)$ be the activity of excitatory neurons in a given volume element of a slab of neural tissue located at $\mathbf{r} \in R^2$, and let $a_I(\mathbf{r}, t)$ be the corresponding activity of inhibitory neurons; $a_E$ and $a_I$ can be interpreted as local spatiotemporal averages of the membrane potentials or voltages of the relevant neural populations. When neuron activation rates are low, they can be shown to satisfy nonlinear evolution equations of a similar form to Equation 1:

$$\tau \frac{\partial a_l}{\partial t} = -a_l + \sum_{m=E,I} w_{lm} \cdot \sigma[a_m] + h_l \qquad (10)$$

where $w \cdot \sigma$ now signifies the convolution

$$(w \cdot \sigma[a])(\mathbf{r}) = \int_{R^2} w(|\mathbf{r} - \mathbf{r}'|)\sigma[a(\mathbf{r}', t)]d\mathbf{r}' \qquad (11)$$

with $w_{lm}(|\mathbf{r} - \mathbf{r}'|)$ giving the weight per unit volume of all synapses to the $l$th population from neurons of the $m$th population a distance $|\mathbf{r} - \mathbf{r}'|$ away. Note that $w_{IE} > 0$ and $w_{II} < 0$ and the external input $h_l$ is assumed to be constant. An important property of the weight distributions $w_{lm}$ is that they are invariant under the action of the planar Euclidean group—the group of rigid motions in the plane consisting of translations, rotations, and reflections. This symmetry plays a crucial role in determining the types of pattern that emerge through a Turing instability.

For a sigmoid firing rate function $\sigma$, it can be shown that there exists at least one fixed-point solution $\bar{a}_l$ of Equation 10:

$$\bar{a}_l = \sum_{m=E,I} W_{lm} \cdot \sigma[\bar{a}_m], \quad W_{lm} = \int_{R^2} w_{lm}(\mathbf{r})d\mathbf{r} \qquad (12)$$

If the external input $h_1$ is sufficiently small relative to the threshold for firing, then this fixed point is unique and stable. There are thus two ways to increase the excitability of the network and thus destabilize the fixed point: either by increasing the external input or reducing the threshold. The latter can occur through the action of drugs on certain brainstem nuclei, which therefore provides a mechanism for generating geometric visual hallucinations. The local stability of the fixed point is found by linearization. Setting $a_l(\mathbf{r}, t) = \bar{a}_l + u_l(\mathbf{r})e\lambda^{t/\tau}$ leads to the eigenvalue equation

$$(\lambda + 1)u_l(\mathbf{r}) = \sum_{m=E,I} \mu_m(w_{lm} \cdot u_m)(\mathbf{r}) \qquad (13)$$

where $\mu_l = \sigma'(\bar{a}_l)$. This can be diagonalized by introducing Fourier transforms $W_{lm}(\mathbf{k})$ and $U_m(\mathbf{k})$ and using the convolution theorem. The result is a matrix dispersion relation for $\lambda$ as a function of $q = |\mathbf{k}|$ given by solutions of the characteristic equation det $([\lambda + 1]\mathbf{I} - \mathbf{\Lambda}(q)) = 0$, where $\mathbf{\Lambda}_{lm}(q) = \mu_m W_{lm}(|\mathbf{k}|)$ and $\mathbf{I}$ is the unit matrix. One can simplify the formulation by assuming that $w_{EE} = w_{IE}$ and $w_{II} = w_{EI}$ so that the dispersion relation reduces to $\lambda(q) = -1 + \mu W(q)$, where $W(q)$ is the Fourier transform of $w(\mathbf{r}) = [\mu_E w_{EE}(\mathbf{r}) + \mu_I w_{II}(\mathbf{r})]/\mu$.

It is then relatively straightforward to set up the conditions under which the homogeneous state undergoes a Turing instability, namely, that $W(q)$ be *bandpass*. This can be achieved with the "Mexican hat" function shown in Figure 2*C*, representing short-range excitation and long-range inhibition. It is simple to establish that $\lambda$ then passes through zero at the critical value $\mu_c = 1/W(q_c)$, signaling the growth of spatially periodic patterns with wave number $q_c$, where $W(q_c) = \max_q\{W(q)\}$. Close to the bifurcation point, these patterns can be represented as linear combinations of plane waves:

$$u(r) = \sum_{n=1}^{N} [z_n e^{i\mathbf{k}_n\cdot\mathbf{r}} + z_n^* e^{-i\mathbf{k}_n\cdot\mathbf{r}}] \qquad (14)$$

where the sum is over all wave vectors with $|\mathbf{k}_n| = q_c$. Rotation symmetry implies that the space of such modes is infinite dimensional. That is, all plane waves with wave vectors on the critical circle $|\mathbf{k}_n| = q_c$ are allowed (see Figure 3*A*). However, translation symmetry means that we can restrict the space of solutions to that of doubly periodic functions corresponding to regular tilings of the plane. The symmetry group is then reduced to that of certain crystal lattices: square, rhomboid, and hexagonal lattices (see Figure 3*B*). The sum over $n$ in Equation 14 is now finite with $N = 2$ (square, rhomboid) or $N = 3$ (hexagonal), and depending on the boundary conditions, various patterns of stripes or spots can be obtained as solutions. Amplitude equations for the coefficients $z_n$ can then be obtained by using the perturbation approach described in the discussion of orientation tuning. Here the rotation and translation symmetries introduced above restrict the structure of the amplitude equations. In the case of a square or rhombic lattice, we can take $\mathbf{k}_1 = q_c(1, 0)$ and $\mathbf{k}_2 = q_c(\cos \varphi, \sin \varphi)$ such that

$$\frac{dz_n}{dt} = z_n\left[\mu - \mu_c - \gamma_0|z_n|^2 - 2\gamma_\varphi \sum_{m\neq n} |z_m|^2\right] \qquad (15)$$

for $n = 1, 2$, where $\gamma_\varphi$ depends on the angle $\varphi$. In the case of a hexagonal lattice, we can take $\mathbf{k}_n = q_c(\cos \varphi_n, \sin \varphi_n)$ with $\varphi_1 = 0$, $\varphi_2 = 2\pi/3$, and $\varphi_3 = 4\pi/3$ such that

$$\begin{aligned}\frac{dz_n}{dt} &= z_n[\mu - \mu_c - \gamma_0|z_n|^2 - \eta z^*_{n-1}z^*_{n+1}] \\ &\quad - 2\gamma_{\varphi_2} z_n(|z_{n-1}|^2 + |z_{n+1}|^2) \qquad (16)\end{aligned}$$

where $n = 1, 2, 3 \pmod 3$.

These ordinary differential equations can then be analyzed to determine which particular types of pattern are selected and to calculate their stability. The results can be summarized in a bifurcation diagram as illustrated in Figure 3*C* for the hexagonal lattice with $\eta > 0$ and $2\gamma\varphi_2 > \gamma_0$. (Note that such patterns have also been observed in fluids in the form of convection rolls and honeycombs as well as in animal coat markings in the form of stripes and spots. This indicates that although the physics may be very different, the interactions in all these phenomena are such that they can all be represented within the framework of the Turing mechanism.)

## Cortical Development

Essentially the same analysis can be applied to a variety of problems concerning the neural development of feature maps and connectivity patterns (see also Ocular Dominance and Orientation Columns). Consider, for example, the development of topographic maps from eye to brain (von der Malsburg and Willshaw, 1977; Development of Retinotectal Maps). Such maps develop by a process that involves both innate and activity-dependent factors. The actual growth and decay of connections are activity dependent, involving synaptic plasticity. However, the final solution is constrained by innate factors in the form of gene products acting as *morphogens* (see Pattern Formation, Biological), which act like boundary conditions. The key insight was provided by von der Malsburg (1973), who showed that pattern formation can occur in a developing neural network whose synaptic connectivity or weight matrix is activity dependent and modifiable, provided that some form of *competition* is present. Thus, Haüssler and von der Malsburg (1983) formulated the topographic mapping problem (in the case of a one-dimensional cortex) as follows: let $w_{rs}$ be the weight of connections from the retinal point $r$ to the cortical point $s$, and let $\mathbf{w}$ be the associated weight matrix. An evolution equation for $\mathbf{w}$ embodying synaptic plasticity and competition can then be written as

$$\frac{d\mathbf{w}}{dt} = \alpha\mathbf{J} + \beta\mathbf{w} \cdot C(\mathbf{w}) - \mathbf{w} \cdot \mathrm{B}[\alpha\mathbf{J} + \beta\mathbf{w} \cdot C(\mathbf{w})] \qquad (17)$$

where $\mathbf{J}$ is a matrix with all elements equal to unity, $C_{rs}(\mathbf{x}) = \Sigma_{rs}c(r - r', s - s')x_{r's'}$, and

$$\mathrm{B}(\mathbf{x}) = \frac{1}{2}\left[\frac{1}{N}\sum_{r'} x_{r's} + \frac{1}{N}\sum_{s'} x_{rs'}\right] \qquad (18)$$

One can easily show that $\mathbf{w} = \mathbf{J}$ is an unstable fixed point of Equation 17. Linearizing about this fixed point leads to an equation that can be written as

$$\tau\frac{d\mathbf{v}}{dt} = -\mathbf{v}(\mathbf{r}, t) + \tau(\mathrm{I} - \mathrm{B})[(\mathrm{I} + \mathrm{C})(\mathbf{v})] \qquad (19)$$

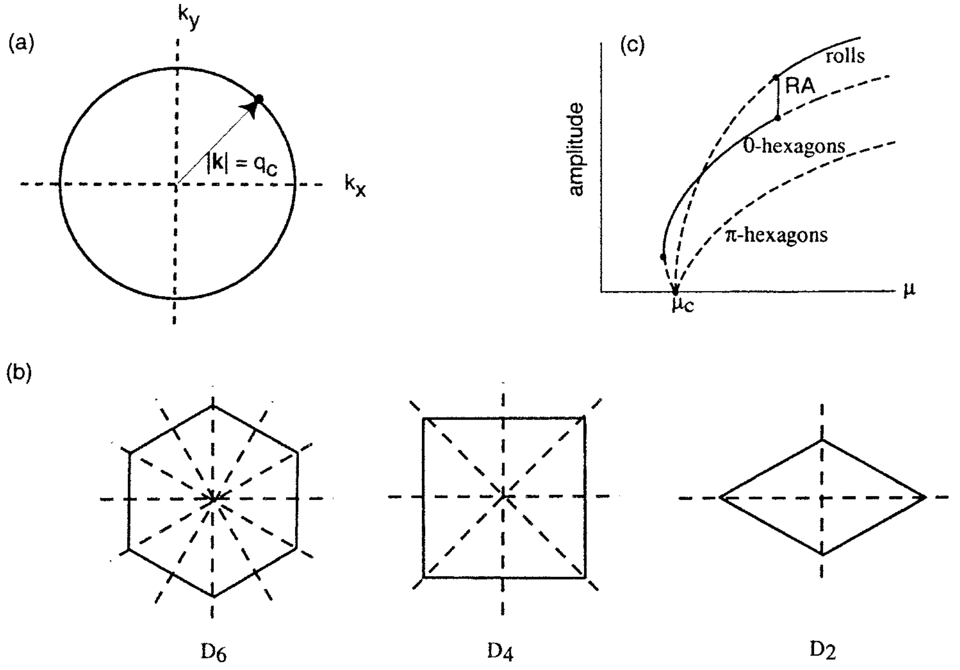

**Figure 3.** *A*, Critical circle for Turing instability. *B*, Crystal lattice groups: hexagonal ($D_6$), square ($D_4$), and rhomboid ($D_2$). *C*, Bifurcation diagram showing the variation in amplitude $C$ with parameter $\mu$ for patterns on a hexagonal lattice. Solid and dashed curves indicate stable and unstable solutions, respectively. The different patterns are distinguished by the coefficients $\mathbf{z} = (z_1, z_2, z_3)$ with $\mathbf{z} = (1, 0, 0)$ for roll or stripe patterns, $\mathbf{z} = (1, 1, 1)$ for 0-hexagons, and $\mathbf{z} = (1, 1, -1)$ for $\pi$-hexagons. It is also possible for additional patterns to form through secondary bifurcations (such as rectangular (RA) patterns). However, higher-order contributions to the amplitude equation (Equation 16) are needed to determine such bifurcations.

where $\tau = (1 - \alpha)^{-1}$. It is not too difficult to see that the term $(I - B)[(I + C)(\mathbf{v})]$ is equivalent to the action of an effective convolution kernel of the form $w(\mathbf{r}) = w_+(\mathbf{r}) - w_-(\mathbf{r})$, so Equation 19 can be rewritten in the familiar form:

$$\tau \frac{d\mathbf{v}}{dt} = -\mathbf{v}(\mathbf{r}, t) + \tau \int_{\mathbf{R}^2} w(\mathbf{r} - \mathbf{r}')v(\mathbf{r}', t)d\mathbf{r}' \qquad (20)$$

where in this case $\mathbf{r} = \{r, s\}$ and $\mathbf{v}$ is a matrix. Once again there is a dispersion relation of the form $\lambda = -1 + \mu W(\mathbf{k}) \equiv \lambda(\mathbf{k})$, where $k = \{k, l\}$, and given appropriate boundary conditions, it is the Fourier transform $W(\mathbf{k})$ of $w(\mathbf{r})$ that determines which of the eigenmodes

$$\sum_{kl} c_{kl} \exp\left[i \frac{2\pi}{N}(kr + ls)\right]$$

emerges at the critical wave number $\mathbf{k}_C = \{k_C, l_C\}$. It can be shown that in the *rs* plane, $w(\mathbf{r})$ looks like a circular Mexican hat except that the inhibitory surround is in the form of a cross. This forces the eigenmodes emerging from the Turing instability to be diagonal in the *rs* plane. If $\mathbf{k}_C$ is selected so that only one wave is present, and if the initial conditions or some morphogen favor the NW → SE diagonal rather than the NE → SW one, then this corresponds to an ordered and correctly oriented retinocortical map. Figure 4 shows details of the emergence of such an eigenmode.

A second example involves the development of ocular dominance maps (Swindale, 1980). Let $n_R(\mathbf{r}, t)$ and $n_L(\mathbf{r}, t)$ be the normalized right and left eye densities of synaptic connections to the visual cortex modeled as a two-dimensional sheet of neurons. Such densities are assumed to evolve according to the equation

$$\frac{\partial u_l(\mathbf{r}, t)}{\partial t} = \sum_{m=R,L} \int_{\mathbf{R}^2} w_{lm}(|\mathbf{r} - \mathbf{r}'|)\sigma[u_m(\mathbf{r}', t)]d\mathbf{r}' \qquad (21)$$

where $u_m = \log n_m - \log(1 - n_m)$ so that $\sigma[u_m] = n_m$, and the coupling matrix $\mathbf{w}$ is given by

$$\mathbf{w}(|\mathbf{r}|) = w(r)\begin{pmatrix} +1 & -1 \\ -1 & +1 \end{pmatrix}.$$

With the additional constraint $n_R + n_L = 1$, Equation 21 reduces to a one-variable form in $n_R$:

$$\frac{\partial n_R(\mathbf{r}, t)}{\partial t} = \left[2 \int_{\mathbf{R}^2} w(|\mathbf{r} - \mathbf{r}'|)n_R(\mathbf{r}', t)d\mathbf{r}' - \int_{\mathbf{R}^2} w(|\mathbf{r}'|)d\mathbf{r}'\right] \times n_R(\mathbf{r}, t)(1 - n_R(\mathbf{r}, t)) \qquad (22)$$

The fixed points of this equation are easily seen to be 0, 1, and 0.5. The first two are stable; however, the third is unstable to small perturbations. Linearizing about this fixed point generates the dispersion relation $\lambda = 0.5W(|\mathbf{k}|)$. Once again, the Fourier transform of the interaction kernel $w(|\mathbf{r}|)$ controls the emergence of the usual eigenmodes, in this case plane waves of the form $\exp(i\mathbf{k} \cdot \mathbf{r})$ in the cortical plane. Note that the fixed point $n_R = n_L = 0.5$ corresponds to $u_R = u_L = 0$ and is a point of reflection symmetry of the function $\sigma[u]$. It is this additional symmetry that generates stripes rather than spots or blobs when the fixed point destabilizes.

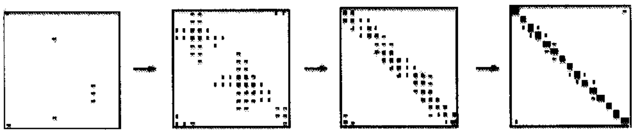

**Figure 4.** Stages in the development of an ordered and correctly oriented retinotopic map. A single stripe develops in the *rs*-plane. (Redrawn from Haussler and von der Malsburg, 1983.)

## Discussion

It will be seen that many examples of both spontaneous and stimulus-driven neural pattern formation can be formulated and analyzed within the framework of the Turing instability. Many other examples exist of the role of this instability in visual neuroscience, such as stereopsis (Dev, 1975; Marr and Poggio, 1976; see STEREO CORRESPONDENCE) and the development of iso-orientation patches (Swindale, 1982; see OCULAR DOMINANCE AND ORIENTATION COLUMNS). All such models contain the same basic mechanism of competition between excitation and inhibition, and most have some underlying symmetry that plays a crucial role in the selection and stability of the ensuing patterns. It is an interesting question as to how universal this mechanism is for neural pattern formation.

# Pattern Recognition

*Yann LeCun and Yoshua Bengio*

## Introduction

Pattern recognition (PR) addresses the problem of classifying objects, often represented as vectors or as strings of symbols, into categories. The difficulty is to synthesize, and then to efficiently compute, the *classification function* that maps objects to categories, given that objects in a category can have widely varying input representations. In most instances, the task is known to the designer through a set of example patterns whose categories are known, and through general, a priori knowledge about the task, such as "the category of an object is not changed when the object is slightly translated or rotated in space."

Historically, the field of PR started with the early efforts in neural networks (perceptrons, adalines, etc.; see PERCEPTRONS, ADALINES, AND BACKPROPAGATION). Whereas in the past, neural networks (NNs) sometimes played the role of an outsider in PR, recent progress in learning algorithms and the availability of powerful hardware have made them the method of choice for many PR applications.

Because most PR problems are too complex to be solved entirely by handcrafted algorithms, machine learning has always played a central role in PR. Learning automatically synthesizes a classification function from a set of labeled examples. Unfortunately, no learning algorithm can be expected to succeed unless it is guided by prior knowledge. The traditional way of incorporating knowledge about the task is to divide the recognizer into a feature extractor and a classifier. Since most learning algorithms work better in low-dimensional spaces with easily separable patterns, the role of the feature extractor is to transform the input patterns so that they can be represented by low-dimensional vectors, or short strings of symbols, that (1) can be easily compared or matched, and (2) are relatively invariant to transformations that do not change the nature of the input objects. The feature extractor contains most of the prior knowledge and is rather specific to the task. It also requires most of the design effort because it is often handcrafted, although unsupervised learning methods, such as PRINCIPAL COMPONENT ANALYSIS (q.v.), can sometimes be used. The classifier, on the other hand, is often general purpose and trainable. One of the main problems with this approach is that the recognition accuracy is largely determined by the ability of the designer to come up with an appropriate set of features. This turns out to be a daunting task which, unfortunately, must be redone for each new problem.

One of the main contributions of NNs to PR has been to provide an alternative to this design: properly designed multilayer networks can learn complex mappings in high-dimensional spaces without requiring complicated handcrafted feature extractors. Networks containing hundreds of inputs and tens of thousands of parameters can be trained on databases containing several hundreds of thousands examples. This allows designers to rely more on learning and less on detailed engineering of feature extractors. Crucial to success is the ability to tailor the network architecture to the task, which allows incorporating prior knowledge and therefore learning complex tasks without requiring excessively large networks and training sets.

The success of multilayer networks relies on one surprising fact: gradient-based minimization techniques can be used to learn very complex nonlinear mappings. Generalizations of the concept of gradient-based learning have allowed one to view many PR techniques, neural and nonneural, in a unified way, including not only traditional multilayer feedforward nets with sigmoid units and dot products but also many other structures such as radial basis functions, hidden Markov models (HMMs), vector quantizers, etc. Many recent efforts have been directed toward combining adaptive modules of different types into a single system and training them cooperatively by propagating gradients through them, particularly for recognizing composite objects such as handwritten or spoken words (see LeCun et al., 1998, for a review and applications).

## Learning and Generalization

Owing to the presence of noise, the high dimension of the input, and the complexity of the mapping to be learned, PR applications create some of the most challenging problems in machine learning. Most learning methods are trained by minimizing a *cost function* computed over a set of training examples. The cost function is generally of the form

$$C(W) = \sum_{X} Q(X, F(X, W)) + H(W) \tag{1}$$

where $X$ is a training example, $F(X, W)$ is the recognizer output for pattern $X$ and "parameters" $W$, $Q(X, F(X, W))$ is a cost function (the training error), and $H(W)$ is a measure of "capacity" of the recognizer (the *regularizer*). Such cost functions attempt to model the real measure of performance, i.e., the *testing error* (error rate on a test set disjoint from the training set) (see LEARNING AND GENERALIZATION: THEORETICAL BOUNDS).

System designers have to strike the right balance between learning the training set (by using powerful learning architectures) and minimizing the difference between the training error and the test error (by limiting the capacity of the machine). Large machines can learn the training set but may perform poorly if the training set is not large enough, a problem known as overparameterization, or overfitting. On the other hand, too little capacity yields underfitting—i.e., large error on both training and test sets.

Most adaptive recognizers stand between two extremes of a continous spectrum. At one end, parameter-based methods, in which a set of learned parameters determines the input-output relation, put the emphasis on minimizing the first term in Equation 1 with a fixed $H$ (e.g., multilayer neural networks). At the other end, memory-based methods, which rely on matching or comparing the incoming pattern with a set of learned or stored prototypes, keep the first term close to zero, and attempt to minimize the regularizer (e.g., nearest-neighbor algorithms).

Although in principle, any appropriate functional form for $F$, $Q$, and $H$ can be used, the choice is largely determined by (1) the belief that it is well suited to the task and (2) the efficiency of the available minimization algorithms. There is a strong incentive to choose smooth and well-behaved functions whose gradient can be computed easily, so that gradient-based minimization algorithms can be used, as opposed to inefficient combinatorial search methods. Preferably, $F$ will be a smooth real-valued function (e.g., layers of sigmoid units) rather than a discrete function (e.g., layers of threshold units); $Q$ is often chosen to be the mean square error between the actual output and a target, rather than the number of misclassified patterns, which would be more relevant but is practically impossible to minimize.

## A Few Basic Classification Methods

### *Linear and Polynomial Classifiers*

A linear classifier is essentially a single neuron. An elementary two-class discrimination is performed by comparing the output to a threshold (multiple classes use multiple neurons). Training algorithms for linear classifiers are well studied (see Perceptrons, Adalines, and Backpropagation). Their limitations are well known: the likelihood that a partition of $P$ vectors of dimension $N$ is computable by a linear classifier decreases very quickly as $P$ increases beyond $N$ (Duda and Hart, 1973). One method to ensure separability is to represent the patterns by high-dimensional vectors (large $N$). If necessary, the dimension of original input vectors can be enlarged using a set of basis functions $\phi_i$:

$$F(X, W) = \sum_i w_i \phi_i(X) \tag{2}$$

A simple example is when the basis functions are cross-products of $K$ or fewer coordinates of the input vector $X$ ($F$ is a polynomial of degree $K$). Such polynomial classifiers have been studied since the early 1960s and have been "renamed" in the context of NNs as sigma-pi units or high-order nets. Unfortunately, polynomial classifiers are often impractical because the number of features scales like $N^K$. Nevertheless, *feature selection* methods can be used to reduce the number of product terms, or to reduce the number of original input variables.

### *Local Basis Functions*

Another popular kind of space expansion (Equation 2) uses *local* basis functions, which are activated within a small area of the input space. A popular family consists of the radial basis functions (RBFs; see Radial Basis Function Networks): $\phi_i(X) = e^{-(X-P_i)^2}$, where the $P_i$ are a set of appropriately chosen "prototypes." Methods based on such expansions can cover the full spectrum between parameter-based and purely memory-based methods by varying the number of prototypes, the way they are computed, and the classifier that follows the expansion (which can be more complex than a simple weighted sum). At one extreme, each training sample is used as a prototype, to which the sample's label is attached. In the K-nearest neighbors algorithms, the $K$ nearest prototypes to an unknown pattern vote for its label. In the Parzen windows method, the normalized sum of all the $\phi_i(X)$ associated with a particular class is interpreted as the conditional probability that $X$ belongs to that class (Duda and Hart, 1973). In the RBF method the output is a (learned) linear combination of the outputs of the basis functions. Associating a prototype with each training sample can be very inefficient and increases the complexity term. Therefore, several methods have been proposed for *learning* the prototypes. One way is to use unsupervised clustering techniques such as $K$-means to put prototypes in regions of high sample density, but supervised methods can also be used (see Radial Basis Function Networks). An important one is LVQ2, in which prototypes that are near a training sample are moved away from it if its assigned class differs from the sample's, and moved toward it if its class is equal to the sample's (see Learning Vector Quantization). Another important supervised method for RBF networks is simply gradient descent. The partial derivatives of the cost function with respect to the parameters of the basis functions (the prototype vectors) can be computed using a form of backpropagation: in the same way that gradients can be backpropagated through sigmoids and dot products, they can be backpropagated through exponentials and Euclidean distances. The parameters can then be adjusted using the gradient. It has been argued that the local property leads to faster learning than standard multilayer nets, and to good rejection properties (Lee, 1991). Several authors enhance the power of prototype-based systems by using distance measures that are more complex than just Euclidean distance between the prototypes and the input patterns (such as general bilinear forms with learned coefficients). Methods that add prototypes as needed have also been proposed, notably the RCE algorithm.

### *Support Vector Machines*

A recently proposed and elegant way of avoiding the curse of dimensionality in polynomial and local classifiers rests on the fact that, if the $w_i$ in Equation 2 are computed to maximize the *margin* (the minimum distance between training points and the classification surface), the $W$ obtained after training can be written as a linear combination of a small subset of the expanded training examples (Boser, Guyon, and Vapnik, 1992). Points in this subset are called *support vectors*, hence the name support vector machines (SVMs). This leads to a surprisingly simple way of evaluating high-degree polynomials in high-dimensional spaces without having to explicitly compute all the terms of the polynomial. For example, maximum-margin polynomials of degree $K$ can be computed using

$$F(X) = \sum_{j \in S} \alpha_j (X \cdot P_j + 1)^K \tag{3}$$

where the $P_j$ are the support points (subset of the training set) and the $\alpha_j$ are coefficients that uniquely determine the weights $W$. Learning the $\alpha_j$ amounts to solving a quadratic programming problem with linear inequality constraints. Besides polynomial kernels, Support Vector Machines (q.v.) can be built for a variety of kernels, such as RBFs and neuron-like kernels. SVMs have also been extended beyond classification problems to regression and density estimation. Excellent results for the classification of handwritten digit images have been obtained with a fourth-degree polynomial computed using this method (Bottou et al., 1994). The number of multiply-adds per recognition was a few hundred thousands, much less than the $O(400^4)$ multiply-adds required to directly evaluate the polynomial.

### *Complex Distance Measures*

Although many memory-based methods use simple distance measures (Euclidean distance) and large collections of prototypes, some applications can take advantage of more complex, problem-dependent, distance measures and use fewer prototypes. Ideal distance measures should be invariant with respect to transformations of the patterns that do not change their nature (e.g., translations and distortions for characters, time or pitch distortion for speech). With invariant distances, a single prototype can potentially represent many possible instances of a category, reducing the number of necessary prototypes. An important family of invariant distance measures entails *elastic matching*. Elastic matching comes down to finding the point closest to the input pattern on the surface of all possible deformations of the prototype. Naturally, the exhaustive search approach is prohibitively expensive in general. However, if the surface is smooth, better search techniques can be used, such as gradient descent or conjugate gradient. If the deformations are along one dimension (as in speech), dynamic programming can find the best solution efficiently. Simard, LeCun, and Denker (1993) approximated the surface of a deformed prototype by its tangent plane at the prototype. The matching problem reduces to finding the minimum distance between a point and a plane, which can be done efficiently. This has been applied to handwritten character recognition with great success.

## Multilayer Networks and Gradient-Based Learning

The vast majority of applications of NNs to PR are based on multilayer feedforward networks trained with backpropagation. At first it seems almost magical that an algorithm as simple as gradient descent works at all to learn complex nonlinear mappings (nonconvex, ill-conditioned error surfaces). Minsky and Selfridge's warning about the limitations of "hill-climbing" methods for machine learning in the late 1950s is an indication of the general belief that it could not work. Surprisingly, experiments show that local minima are rarely a problem with large networks. As evidence of the success of backpropagation, all but two of the entries in the last NIST character recognition competition used some form of backpropagation network.

PR problems are often characterized by large and redundant training sets with high-dimensional inputs, which translates into large networks and long learning times. Much effort has been devoted to speeding up training using refined nonlinear optimization methods (conjugate gradient, quasi-Newton methods, and so on). These are essentially batch methods (the weights are updated after a complete pass through the training set) and can rarely compete with "carefully tuned" stochastic (on-line) gradient descent (where the weights are updated after each pattern presentation). This is due to the presence of redundancy in large natural training sets. On typical large-scale image or speech recognition tasks, stochastic gradient descent converges in one to a few dozen epochs. To avoid overlearning, a validation set should be set aside, and training should be stopped when the error rate on the validation set stops decreasing. An important limitation to the popularity of NN techniques for PR is that certain simple tricks must be used and many common pitfalls must be avoided that are part of the "oral culture" rather than scientific facts.

Once backpropagation with feedforward networks of sigmoid units and dot products established the value of gradient-based learning, it seemed natural to extend the idea to other structures. Minimizing a cost function through gradient-based learning can be seen as the unifying principle behind many methods: RBFs or mixtures of Gaussians, learning vector quantization, HMMs, and many prototype-based methods that use various distance measures. Experiments have shown the advantage of using different types of modules in different parts of a learning system. In particular, sigmoids and dot products seem better for processing large amounts of high-dimensional and low-level information (early feature extraction), while RBFs or other more local modules seem better suited for final classification, a more memory-intensive task. With the gradient-based learning framework, modules of different types can be connected in any configuration and trained cooperatively by backpropagating gradients through them. To achieve this, one needs only to be able to compute the partial derivatives of each output of a module with respect to each input and each parameter of the module (see MODULAR AND HIERARCHICAL LEARNING SYSTEMS). In addition, many cost functions can be considered as just another module (with a scalar output) through which gradients can be backpropagated. Examples include the mean squared error, modified LVQ cost functions, maximum likelihood, maximum mutual information, cross-entropy, classification figure of merit, and several types of statistical or graphical postprocessors (LeCun et al., 1998).

### *Local/Global and Modular Methods*

It has recently been suggested that good PR systems should behave differently in different parts of the input space. For example, parts of the input space may be very sparsely populated, requiring a low-capacity learner, while denser areas may require a more complex one. A simple idea is to use a collection of modules, each of which is activated when the input lies in a particular region. A separate module called a *gater* decides which module should be activated. When the gater is differentiable, the whole system (modules plus gater) can be trained cooperatively (see MODULAR AND HIERARCHICAL LEARNING SYSTEMS). In such multimodular systems, parameters are relatively decoupled across modules, which is believed to allow faster training (or better scaling of training time). In another interesting "semilocal" method, a simple network (e.g., single layer) is trained each time a new test pattern is presented, using training patterns in the neighborhood of this test pattern; training is done "on demand" during recognition (Bottou and Vapnik, 1992).

In general, local methods learn fast, but they are expensive at runtime in terms of memory and, often, of computation. In addition, they may not be appropriate for problems with high-dimensional inputs. Global methods, such as multilayer networks, take longer to train, but they are quite compact, and they execute quickly. They can handle high-dimensional inputs, particularly when specialized architectures are used.

### *Specialized Architectures, Convolutional Networks*

The great hope that multilayer networks brought with them was the possibility of eliminating the need for a separate handcrafted feature extractor, relying on the first layers to automatically learn the right set of features. Although fully connected networks fed with "raw" character images (or speech spectra) have very large numbers of free parameters, they have been applied with some success (Martin and Pittman, 1991). This can be explained as follows. With small initial weights, a multilayer network is almost equivalent to a single-layer network (each layer is quasilinear). As incremental learning proceeds, the weights gradually increase, thereby progressively increasing the effective capacity of the system (to the authors' knowledge, this explanation was first suggested by Léon Bottou in 1988).

On the other hand, using a specialized network architecture instead of a fully connected net can reduce the number of free parameters and facilitate the learning of invariances. In certain applications, the need for a separate handcrafted feature extractor can be eliminated by wiring the first few layers of the network in a way that forces it to learn relevant features and eliminate irrelevant variability. Convolutional networks, including time-delay neural networks (TDNNs), are an important class of specialized architectures well suited for dealing with one- or two-dimensional signals such as time series, images, or speech (see CONVOLUTIONAL NETWORKS FOR IMAGES, SPEECH, AND TIME SERIES). Convolutional networks use the techniques of local receptive fields, shared weights, and subsampling (loosely based on the architecture of the visual cortex) to ensure that the first few layers extract and combine local features in a distortion-invariant way. Although the wiring of the convolutional layers is designed by hand, the values of all the coefficients are learned with a variant of the backpropagation algorithm. The main advantage of this approach is that the feature extractor is totally integrated into the classifier and is produced by the learning process rather than by the hand of the designer (LeCun et al., 1990). Because of the weight-sharing technique, the number of free parameters in a convolutional network is much less than in a fully connected network of comparable power, which has the effect of reducing the complexity term in Equation 1 and improving the generalization. The success of convolutional nets of various types has had a major impact on several application domains, among them speech recognition, character recognition, and object spotting. On handwriting recognition tasks they compare favorably with other techniques (Bottou et al., 1994) in terms of accuracy, speed, and memory requirements. Character recognizers using convolutional nets have been deployed in commercial applications. A very promising feature of convolutional nets is that they can be efficiently replicated, or scanned, over large input fields, resulting in the so-called *space displacement neural net* (SDNN) architecture (see below, and CONVOLUTIONAL NETWORKS FOR IMAGES, SPEECH, AND TIME SERIES).

Networks with recurrent connections can be used to map input sequences to output sequences, while taking long-term context into account. The main advantage of recurrent networks over TDNNs for analyzing sequences is that the span of the temporal context

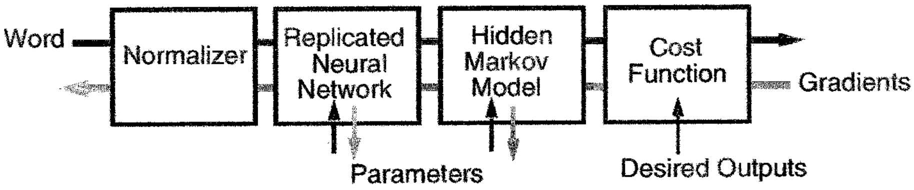

**Figure 1.** A multimodule architecture combining a convolutional NN with a postprocessor such as an HMM.

that the network can take into account is not hard-wired within a fixed temporal window by the architectural choices but can be learned by the network. However, theoretical and practical hurdles (Bengio, Simard, and Frasconi, 1994) limit the span of long-term dependencies that can be learned efficiently.

## Recognition of Composite Objects

In many real applications, the diffculty is not only to recognize individual objects but also to separate them from context or background. For example, one approach to handwritten word recognition is to *segment* the characters out of their surrounding and *recognize* them in isolation. A typical handwritten word recognizer uses heuristics to form multiple, possibly overlapping character candidates by cutting the word or by joining nearby strokes. Then the recognizer must either classify each candidate as a character or reject it as a noncharacter. In many applications, such as cursive handwriting or continuous speech, it is diffcult or even impossible to devise robust segmentation heuristics. One approach to avoid explicit segmentation is simply to scan the recognizer over all possible locations on the input (character string or spoken sentence) and collect the sequence of corresponding recognizer outputs. Although this is very computationally expensive in general, replicated convolutional networks (SDNNs or TDNNs) can be used to do that very efficiently. In the case of handwriting recognition, an SDNN output will contain a well-identified label when centered on a character. Between characters, the output should indicate a reject. However, combinations of off-center characters may cause ambiguous outputs (e.g., *cl* labeled as *d*). Since both methods, explicit segmentation and scanning, generate many extraneous candidates, a postprocessor is required to resolve ambiguities and pull out the most consistent interpretation, retaining genuine characters and rejecting erroneous stroke combinations, possibly taking linguistic constraints into account (a lexicon or grammar) Figure 1. For this to succeed, the recognizer must be trained not only to classify characters but also to reject noncharacters. The search for the best interpretation is easily done within the framework of graph transducers (LeCun et al., 1998), which generalize HMMs. A graph is built in which each path corresponds to a possible interpretation of the input and in which each node is given probabilities of matching recognizer outputs. Dynamic programming can be used to find the path of highest probability, which yields the most likely interpretation. Furthermore, it is possible to backpropagate errors through this graph in order to train the system to maximize the a posteriori probability of the correct sequence of labels.

### *Multimodule Architectures and Cooperative Training*

Such combinations of neural networks and HMMs (or other graph-based postprocessors) have been proposed by several authors, mostly for speech recognition (see SPEECH RECOGNITION TECHNOLOGY), but also for handwriting recognition (see LeCun et al., 1998, and CONVOLUTIONAL NETWORKS FOR IMAGES, SPEECH, AND TIME SERIES).

The main technical difficulty is in training such hybrid systems. Training the recognizer exclusively on presegmented characters is neither sufficient nor always possible, since (1) the recognizer must be trained to reject noncharacters and (2) in many cases, such as cursive handwriting, segmented characters are not available, only whole words are. The solution is to simultaneously train the recognizer and the postprocessor to minimize an error measure at the *word level.* This means being able to backpropagate gradients through the postprocessor, down to the recognizer, or to generate desired outputs for the recognizer using the best path in the graph (see Franzini, Lee, and Waibel, 1990, and SPEECH RECOGNITION TECHNOLOGY). Simultaneous training of such hybrids has been reported to yield large reductions in error rates over independent training of the modules in speech recognition (for TDNN/dynamic time warping, see Driancourt, Bottou, and Gallinari, 1991, and Haffner, Franzini, and Waibel, 1991; for TDNN/HMM, see Bengio et al., 1992), and on-line handwriting recognition (for SDNN/HMM, see Bengio, LeCun, and Henderson, 1994). See LeCun et al. (1998) for a review and applications to document analysis.

## Discussion

Neural networks, particularly multilayer backpropagation NNs, provide simple yet powerful and general methods for synthesizing classifiers with minimal effort. However, most practical systems combine NNs with other techniques for pre- and postprocessing. On isolated character recognition tasks, multilayer nets trained with variants of backpropagation have approached human accuracy, at speeds of about 1,000 characters per second using NN hardware. NNs have allowed workers to minimize the role of detailed engineering and maximize the role of learning. Despite the recent advances in multimodule architectures and gradient-based learning, several key questions are still unanswered, and many problems are still out of reach. How much has to be built into the system, and how much can be learned? How can one achieve true transformation-invariant perception with NNs? Convolutional nets are a step in the right direction, but new concepts will be required for a complete solution (see DYNAMIC LINK ARCHITECTURE). How to recognize compound objects in their context? The accuracy of the best NN/HMM hybrids for written or spoken sentences cannot even be compared with human performance. Topics such as the recognition of three-dimensional objects in complex scenes are totally out of reach. Human-like accuracy on complex PR tasks such as handwriting and speech recognition may not be achieved without a drastic increase in the available computing power. Several important questions may simply resolve themselves with the availability of more powerful hardware, allowing the use of brute-force methods and very large networks.

# Perception of Three-Dimensional Structure

*James T. Todd*

## Introduction

Human observers have a remarkable ability to perceive the three-dimensional (3D) layout of the environment from patterns of light that project onto the retina. Were it not for the facts of our day-to-day experiences, it would be tempting to conclude that the perception of 3D form is a mathematical impossibility, because the properties of optical stimulation appear to have so little in common with the properties of real objects encountered in nature. Whereas real objects exist in 3D space and are composed of tangible materials, an optical image of an object is confined to a two-dimensional (2D) projection surface and consists of nothing more than flickering patterns of light. Nevertheless, for many animals, including humans, these seemingly uninterpretable patterns of light are the primary source of sensory information about the layout of surfaces in the surrounding environment.

There are many different aspects of optical stimulation that are known to provide perceptually salient information about 3D form. Some of these properties—the so-called pictorial depth cues—are available within individual static images. These include texture gradients, contour configurations, and patterns of shading. Others are defined by systematic transformations among multiple images, including the disparity between each eye's view in binocular vision and the optical deformations that occur when objects are observed in motion.

There are two important issues that need to be considered in evaluating any computational model of 3D form perception. The first of these issues involves how 3D structure is perceptually represented. After all, in order to compute an object's shape from visual information, one must first define precisely what shape is. There are numerous attributes of 3D structure that could potentially be represented by the visual system (e.g., curvature, relative depth, local orientation), and the relative computational complexity of analyzing these different attributes can vary dramatically. It is much more difficult, for example, to determine the precise euclidean distance between a pair of visible points than to merely assess which point is closer in depth.

A second related issue concerns ambiguities that are inherent in the nature of visual information. The primary goal of all 3D vision problems is to invert (or partially invert) a function of the following form: $\Lambda = f(\phi)$, where $\phi$ is the space of environmental properties that can influence patterns of ambient light and $\Lambda$ is the space of measurable image properties at a point of observation. What can make these problems so difficult is that this is a many-to-one mapping: for any give pattern of optical structure, there is often an infinity of possible 3D structures that could potentially have produced it.

For many problems in 3D vision, it can be useful to separate the properties of environmental structure into two distinct categories. There are some aspects of environmental structure that are invariant over the transformation $\Lambda = f(\phi)$. These properties can be determined with relative ease by measuring the appropriate relationships within available image data. Other properties that are not invariant over this transformation are much more difficult to estimate. Because these properties are inherently ambiguous, a computational analysis must restrict the set of possible interpretations by assuming the existence of environmental constraints. Unfortunately, many of the constraints that have been employed for this purpose seem to have been adopted more for their mathematical convenience than for their ecological validity. The problem with this approach is that the resulting analyses of 3D form may only function effectively within narrowly defined contexts, which have a small probability of occurrence in the natural environments of real biological organisms.

This article reviews various computational models that have been proposed in the literature for analyzing an object's 3D structure from different types of optical information, both individually and in combination. It also examines how the performance of these models compares with the capabilities and limitations of actual human observers in judging different aspects of 3D structure under varying viewing conditions. The goal is to identify the specific representations and computational mechanisms by which 3D form is perceptually analyzed within the human visual system.

## Shape from Shading

The most basic type of information available to any visual system is the light that stimulates different regions of the retina from illuminated surfaces in the environment. Smooth gradations in surface luminance are often referred to as shading, and they are one of the primary cues used by artists for the pictorial representation 3D form. The analysis of image shading is made especially difficult because the luminance of any visible surface region can depend on several factors, including the positions and spectral composition of its sources of illumination, the local reflectance and orientation of the surface, and the position of the observer. In order to compute shape from shading it is necessary to somehow decompose these different factors. Most existing algorithms for analyzing 3D shape from shading achieve this decomposition by making several strong assumptions to constrain the structure of an observed scene (Horn and Brooks, 1989). It is typically assumed, for example, that a scene is composed of smoothly curved surfaces that have a known uniform reflectance function, with no specular components, and that there is a uniform pattern of illumination with a known direction and spectral composition.

An important limitation on theoretical analyses of 3D shape from shading is that an image of a surface with homogeneous lambertian reflectance has an infinity of possible 3D interpretations that are all related by an affine transformation (Belhumeur, Kriegman, and Yuille, 1999). Thus, a pattern of image shading provides sufficient information to specify the affine properties of an object, such as the parallelism of local surface patches or relative distance intervals in parallel directions, but it does not allow a unique determination of metric properties involving relative distance intervals in different directions. A similar ambiguity is also evident in judgments of 3D shape from shading by human observers. Recent psychophysical experiments have shown that these judgments are often idiosyncratic and task dependent (Koenderink et al., 2001), such that the correlations between observers or response tasks can in some cases be close to zero. Despite these variations in judged metric structure, however, the affine properties of perceived shape from shading have a high degree of reliability.

A fundamental assumption of almost all existing models of the perception of 3D shape from shading is that illumination and reflectance remain constant throughout a scene, such that all variations in shading can be attributed to the geometry of an observed surface. The problem with this approach, however, is that these assumptions are seldom satisfied in an unconstrained natural environment. Other common factors that can produce variations of image shading include the attenuation of light with distance, interreflections among different surfaces, variations in surface reflectance, cast shadows, specular highlights, and transparency. Existing computational models of 3D shape from shading cannot cope with any of these phenomena, yet human observers seem to have little difficulty in correctly identifying them.

## Shape from Surface Contours and Texture

It has long been recognized that a convincing pictorial representation of an object can sometimes be achieved by drawing just a few critical lines, and there have been numerous attempts in both human and machine vision to analyze how line drawings of 3D scenes might be perceptually interpreted. The earliest models to address this issue were developed for interpreting line drawings of simple plane-faced polyhedra whose vertices are all formed by the junction of three faces. The different types of vertices that can arise in line drawings of these objects were exhaustively catalogued, and then used to label which lines in a drawing correspond to convex, concave, or occluding edges. Similar procedures were later developed to label line drawings of arbitrary polyhedral scenes (Malik, 1987), and to deal with other types of lines corresponding to shadows or cracks.

Another type of image feature that provides useful information for the perception of 3D shape is the contour that separates the visible and occluded parts of a smoothly curved surface. Indeed, an occlusion contour presented in isolation can often provide sufficient information to recognize an object, and to reliably segment it into distinct parts. Koenderink (1984) has shown that the relative sign of curvature at each point on a smooth occlusion contour uniquely specifies the sign of Gaussian curvature of visible surface regions in its immediate local neighborhood. More recent research has combined this analysis with earlier work on polyhedral objects to perform edge labeling on complex surfaces with both smoothly curved and faceted regions (Malik, 1987).

Still another important source of information for the perception of 3D shape comes from patterns of reflectance on smoothly curved surfaces, which are often referred to as texture. Some popular textures that are used in optical art for creating an appearance of 3D shape include random patterns of polka dots or networks of roughly parallel contours (see Todd and Oomes, 2002). Several potential models have been proposed for the computational analysis of these patterns. Some of these models are based on the assumption that all texture elements are approximately circular. Others assume that the depicted surface is singly curved, and that the contours lie along lines of curvature or surface geodesics (e.g., Knill, 2001). The empirical evidence suggests, however, that these assumptions are too restrictive to account for the perceptions of human observers (Todd and Oomes, 2002). A more general approach to this problem has recently been developed by Malik and Rosenholtz (1997). This approach computes local surface structure by measuring the affine distortions between texture patches in neighboring image regions, based on a more ecologically reliable assumption about texture homogeneity.

## Shape from Binocular Disparity

Some of the most powerful analyses for estimating 3D shape from visual information are designed to exploit the systematic transformations of optical structure that occur when an object is viewed over multiple vantage points. For example, human observers have two eyes with overlapping visual fields, such that each eye receives a slightly different view of the same scene. It is especially interesting to note that binocular overlap reduces the size of the combined visual field relative to what would otherwise be possible if the two eyes faced in opposite directions, as is the case with many other animals. For the ecology of human observers, however, this cost is apparently outweighed by the useful information that is provided by the disparities between each eye's view in the region of overlap.

In order to compute 3D shape from binocular disparity, it is first necessary to determine the correspondence relations between the patterns of stimulation in each eye. The difficulty of this problem is demonstrated most clearly by the ability of observers to perceive 3D structure from random dot stereograms, in which each stereoscopic half-image contains a dense configuration of small dots. For any given dot presented to one eye, the visual system must somehow determine a single corresponding dot with which it should be matched among the many possible targets presented to the other.

Numerous computational models have been developed for solving this stereo correspondence problem, many of which are designed to simulate the physiological properties of the primate visual system (see Anderson and Julesz, 1995, for a recent review).

Like other sources of visual information, the horizontal disparity between each eye's view is inherently ambiguous with respect to the metric structure of an observed scene. The ambiguity in this case arises from the fact that the disparity produced by a given depth interval varies with viewing distance. In principle, there are a variety of ways that disparity could be scaled based on other sources of information, such as knowledge of the convergence angle or an analysis of vertical disparities, but there is considerable evidence to indicate that human observers are incapable of doing so with any reasonable degree of accuracy. Although observers can make accurate judgments about some aspects of 3D shape from stereoscopic vision, their judgments of metric structure typically exhibit large systematic distortions, even when viewing real 3D scenes in a fully illuminated natural environment (see Hecht, van Doorn, and Koenderink, 1999).

A fundamental assumption for most existing models of binocular stereopsis is that the corresponding features in each eye's view are projectively related to the same physical points in 3D space. This assumption is generally valid for certain types of image structures, such as those that arise from discontinuities of surface orientation or surface reflectance, but there other types of optical phenomena for which this assumption can be violated. There are two important cases that need to be considered in this regard. One is the occurrence of features that are occluded in one eye but not the other, which are sometimes referred to as half-occlusions. These would be treated as noise by most existing models of binocular stereopsis, but there is a growing body of evidence to indicate that they provide an important source of information for human perception (Anderson and Julesz, 1995). A second important case to consider is the occurrence of optical structures such as smooth occlusion contours or specular highlights, whose location on a surface varies with viewing direction. Because each eye sees these structures at a different surface location, their binocular disparities should therefore provide misleading information about 3D shape. Recent evidence suggests, however, that highlights and smooth occlusions provide perceptually useful information that enhances the appearance of stereoscopic depth (Todd et al., 1997).

## Shape from Motion

Another relevant source of information for the perceptual analysis of 3D shape includes the systematic transformations of optical structure that occur when an object is observed in motion. The analysis of structure from motion is similar in some respects to the analysis of shape from binocular disparity in that it generally requires two distinct stages of processing. The first of these stages is to compute an optical flow field from changing patterns of light on the retina, and numerous models have been proposed to describe how this process is accomplished within the primate visual system (see Watanabe, 1998, chaps. 4–6).

The next stage of the problem is to incorporate these motion measures to estimate the 3D structure of an observed scene. When an object rotates in depth under appropriate conditions, its pattern of projected motion over three or more views provides sufficient information to determine its complete metric structure. However, there is a growing body of evidence that human observers have low sensitivity to this information and that the perception of 3D structure from motion is primarily determined by first-order relations between pairs of views (Watanabe, 1998, chap. 12). First-order motion measures under weak perspective are similar to shading in that they allow an infinity of possible 3D interpretations that are all related by an affine transformation (Koenderink and van Doorn, 1991). Thus, they can uniquely specify the affine structure of an object, while being inherently ambiguous with respect to metric structure. A similar distinction between these structural attributes is also characteristic of human perception. Observers are often quite accurate at judging structural properties that are uniquely specified by first-order motion measures, whereas judgments of metric structure are inaccurate and unreliable.

Another similarity between models for computing 3D shape from motion or binocular disparity is their dependence on a limited subset of the possible optical structures that can occur under natural conditions. Most shape-from-motion algorithms are based on a strong assumption that moving features within a visual image remain projectively attached to fixed locations on an object's surface, but a wide variety of common optical phenomena violate this assumption. These phenomena include the deformations of smooth occlusion contours and specular highlights, which do not remain fixed on an object's surface when it is observed in motion. Similarly, when an object moves relative to its sources of illumination, then the optical deformations of shadows and lambertian shading will violate this assumption as well. Although these aspects of optical motion are degenerate for most current models, they are easily interpretable for human observers (Norman and Todd, 1994).

## Shape from Multiple Sources

All of the models considered thus far are designed to be used with a particular source of information presented in isolation. Under natural viewing conditions, of course, it is likely that these different sources of information would occur in combination with one another, thus providing a certain degree of redundancy for the perceptual specification of 3D shape. The presence of these redundancies could be potentially quite useful for resolving ambiguities that are often inherent in visual information. If two sources of information allow different families of possible interpretations, then their simultaneous occurrence could be used to mutually constrain those interpretations in order to obtain a more accurate estimate of 3D metric structure. There is some disagreement in the literature about the extent to which this strategy can be exploited in human perception. A majority of investigators have found, however, that observers' judgments of 3D metric structure are inaccurate and unreliable even when multiple sources of information are available simultaneously (e.g., Tittle et al., 1995).

## Discussion

A fundamental problem for the computational analysis of 3D shape from various aspects of optical stimulation is that most known sources of visual information are inherently ambiguous with respect to the precise metric structure of an observed scene. There are two general strategies for dealing with problems. One is to incorporate prior assumptions about environmental constraints to limit the set of possible interpretations. The primary weakness of this approach is that it will produce large systematic errors when objects are observed in an unconstrained natural environment, in which these assumptions may frequently be violated. An alternative strategy that seems to be more characteristic of human perception is to limit the analysis of shape to those structural properties that can be estimated with a higher degree of confidence. Depending on the particular source of information being analyzed, this could involve a perceptual representation of affine, ordinal, or topological relations. The evidence suggests that biological visual systems prefer robustness over precision.

Another important problem for the computational analysis of 3D shape from visual information is that changes in image intensity can be caused by a wide variety of environmental phenomena, including surface occlusions, specular highlights, transparency, variations in surface reflectance, variations in the pattern of illumination, and smooth or abrupt changes in surface orientation. Because all current models of 3D shape perception are appropriate for just a limited subset of these phenomena, their successful application in an unconstrained environment would seem to require an early-level process for labeling image intensity changes. It is interesting to note that contour labeling is one of the oldest problems in computational vision, but the successes in this area have been largely limited to line drawings (see Malik, 1987). In order to develop more robust models of 3D shape estimation, it is important that this work be extended to include natural scenes with shading and texture.

# Perceptrons, Adalines, and Backpropagation

*Bernard Widrow and Michael A. Lehr*

## Introduction

The field of neural networks has enjoyed major advances since 1960, a year which saw the introduction of two of the earliest feedforward neural network algorithms: the perceptron rule (Rosenblatt, 1962) and the LMS algorithm (Widrow and Hoff, 1960). Around 1961, Widrow and his students devised Madaline Rule I (MRI), the earliest learning rule for feedforward networks with multiple adaptive elements. The major extension of the feedforward neural network beyond Madaline I took place in 1971, when Paul Werbos developed a backpropagation algorithm for training multilayer neural networks. He first published his findings in 1974 in his doctoral dissertation (see BACKPROPAGATION: GENERAL PRINCIPLES). Werbos's work remained almost unknown in the scientific community until 1986, when Rumelhart, Hinton, and Williams (1986) rediscovered the technique and, within a clear framework, succeeded in making the method widely known.

The development of backpropagation has made it possible to attack problems requiring neural networks with high degrees of nonlinearity and precision (Widrow and Lehr, 1990; Widrow, Rumelhart, and Lehr, 1994). Backpropagation networks with fewer than 150 neural elements have been successfully applied to vehicular control simulations, speech generation, and undersea mine detection. Small networks have also been used successfully in airport explosive detection, expert systems, and scores of other applications. Furthermore, efforts to develop parallel neural network hardware are advancing rapidly, and these systems are now becoming available for attacking more difficult problems such as continuous speech recognition.

The networks used to solve the above applications varied widely in size and topology. A basic component of nearly all neural networks, however, is the adaptive linear combiner.

## The Adaptive Linear Combiner

The adaptive linear combiner has as output a linear combination of its inputs. In a digital implementation, this element receives at time $k$ an input signal vector or input pattern vector $\mathbf{X}_k = [x_0, x_{1_k}, x_{2_k}, \ldots, x_{n_k}]^{\mathrm{T}}$ and a desired response $d_k$, a special input used to effect learning. The components of the input vector are weighted by a set of coefficients, the weight vector $\mathbf{W}_k = [w_{0_k}, w_{1_k}, w_{2_k}, \ldots, w_{n_k}]^{\mathrm{T}}$. The sum of the weighted inputs is then computed, producing a linear output, the inner product $s_k = \mathbf{X}_k^{\mathrm{T}}\mathbf{W}_k$. The components of $\mathbf{X}_k$ may be either continuous analog values or binary values. The weights are essentially continuously variable and can take on negative as well as positive values.

During the training process, input patterns and corresponding desired responses are presented to the linear combiner. An adaptation algorithm automatically adjusts the weights so the output responses to the input patterns will be as close as possible to their respective desired responses. In signal processing applications, the most popular method for adapting the weights is the simple LMS (least mean square) algorithm (Widrow and Hoff, 1960), often called the Widrow-Hoff Delta Rule (Rumelhart et al., 1986). This algorithm minimizes the sum of squares of the linear errors over the training set. The linear error $\varepsilon_k$ is defined to be the difference between the desired response $d_k$ and the linear output $s_k$ during presentation $k$. Having this error signal is necessary for adapting the weights. Both the LMS rule and Rosenblatt's perceptron rule will be detailed in later sections.

An important element used in many neural networks is the ADAptive LInear NEuron, or *adaline* (Widrow and Hoff, 1960). In the neural network literature, such elements are often referred to as *adaptive neurons*. The adaline is an adaptive threshold logic element. It consists of an adaptive linear combiner cascaded with a hard-limiting quantizer that is used to produce a binary ±1 output, $y_k = \text{sgn}(s_k)$. A bias weight, *threshold*, $w_{0_k}$, which is connected to a constant input, $x_0 + 1$, effectively controls the threshold level of the quantizer. Such an element may be seen as a McCulloch-Pitts neuron augmented with a learning rule for adjusting its weights.

In single-element neural networks, the weights are often trained to classify binary patterns using binary desired responses. Once training is complete, the responses of the trained element can be tested by applying various input patterns. If the adaline responds correctly with high probability to input patterns that were not included in the training set, it is said that generalization has taken place. Learning and generalization are among the most useful attributes of adalines and neural networks.

With $n$ binary inputs and one binary output, a single adaline is capable of implementing certain logic functions. There are $2^n$ possible input patterns. A general logic implementation would be capable of classifying each pattern as either $+1$ or $-1$, in accordance with the desired response. Thus, there are $2^{2^n}$ possible logic functions connecting $n$ inputs to a single binary output. A single adaline is capable of realizing only a small subset of these functions, known as the linearly separable logic functions or threshold logic functions. These are the set of logic functions that can be obtained with all possible weight variations. With two inputs, a single adaline can realize 14 of the 16 possible binary logic functions. The two it cannot learn are exclusive OR and exclusive NOR functions. With many inputs, however, only a small fraction of all possible logic functions are realizable, i.e., linearly separable. Combinations of elements or networks of elements can be used to realize functions that are not linearly separable.

## Nonlinear Neural Networks

One of the earliest trainable layered neural networks with multiple adaptive elements was the *Madaline I* structure of Widrow and Hoff. In the early 1960s, a 1,000-weight Madaline I was built out of hardware and used in pattern recognition research (Widrow and Lehr, 1990). The weights in this machine were memistors—electrically variable resistors, developed by Widrow and Hoff, that are adjusted by electroplating a resistive link in a sealed cell containing copper sulfate and sulfuric acid.

Madaline I was configured in the following way. Retinal inputs were connected to a layer of adaptive adaline elements, the outputs of which were connected to a fixed logic device that generated the system output. Methods for adapting such systems were developed at that time. An example of this kind of network is shown in Figure 1. Two adalines are connected to an AND logic device to provide an output. With weights suitably chosen, the separating boundary in pattern space for the system can implement any of the 16 two-input binary logic functions, including the exclusive OR and exclusive NOR functions.

Madalines were constructed with many more inputs, with many more adaline elements in the first layer, and with various fixed logic devices such as AND, OR, and majority vote-taker elements in the second layer. Those three functions are all threshold logic functions.

### *Multilayer Networks*

The madaline networks of the 1960s had an adaptive first layer and a fixed threshold function in the second (output) layer (Widrow and Lehr, 1990). The feedforward neural networks of today often have many layers, all of which are usually adaptive. The backpropagation networks of Rumelhart et al. (1986) are perhaps the best-known examples of multilayer networks. A three-layer feedforward adaptive network is illustrated in Figure 2. It is "fully connected" in the sense that each adaline receives inputs from every output in the preceding layer.

During training, the responses of the output elements in the network are compared with a corresponding set of desired responses. Error signals associated with the elements of the output layer are thus readily computed, so adaptation of the output layer is straightforward. The fundamental difficulty associated with adapting a layered network lies in obtaining *error signals* for hidden-layer adalines, that is, for adalines in layers other than the output layer. The backpropagation algorithm provides a method for establishing these error signals.

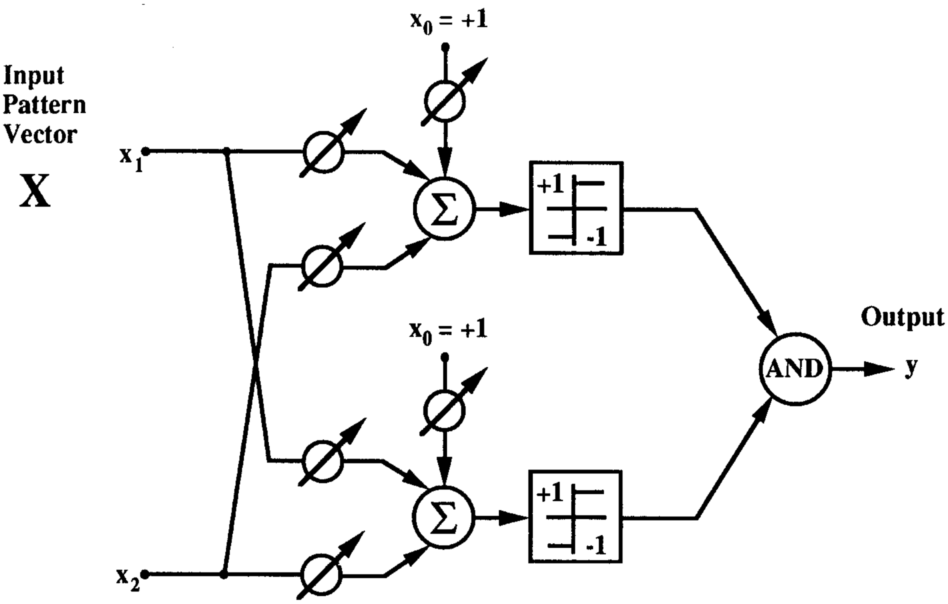

**Figure 1.** A two-adaline form of madaline.

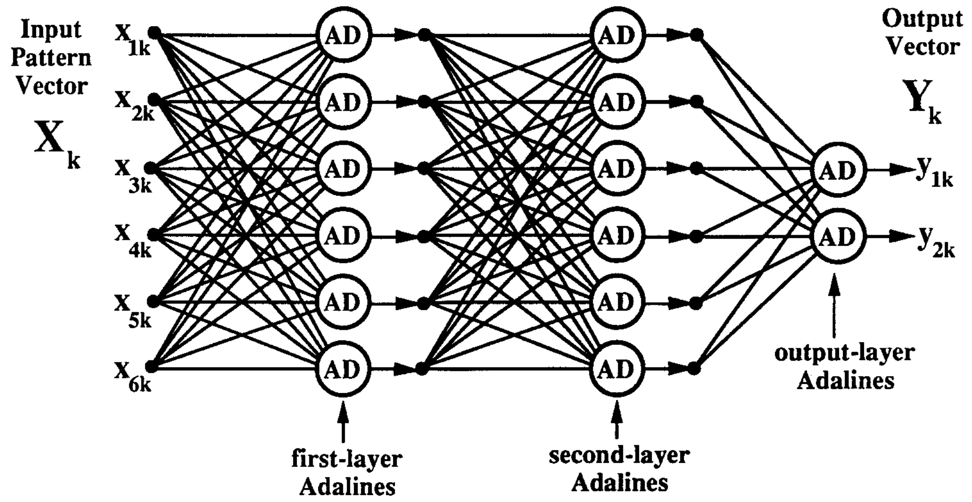

**Figure 2.** A three-layer adaptive neural network.

## Learning Algorithms

The iterative algorithms described here are all designed in accord with the *Principle of Minimal Disturbance: Adapt to reduce the output error for the current training pattern, with minimal disturbance to responses already learned.* Unless this principle is practiced, it is difficult to simultaneously store the required pattern responses. The minimal disturbance principle is intuitive. It was the motivating idea that led to the discovery of the LMS algorithm and the madaline rules. In fact, the LMS algorithm had existed for several months as an error reduction rule before it was discovered that the algorithm uses an instantaneous gradient to follow the path of steepest descent and minimizes the mean square error of the training set. It was then given the name LMS (least mean square) algorithm.

### *The LMS Algorithm*

The objective of adaptation for a feedforward neural network is usually to reduce the error between the desired response and the network's actual response. The most common error function is the mean square error (MSE), averaged over the training set. The most popular approaches to mean-square-error reduction in both single-element and multielement networks are based on the method of gradient descent.

Adaptation of a network by gradient descent starts with an arbitrary initial value $\mathbf{W}_0$ for the system's weight vector. The gradient of the mean-square-error function is measured and the weight vector is altered in the direction opposite to the measured gradient. This procedure is repeated, causing the MSE to be successively reduced on average and causing the weight vector to approach a locally optimal value.

The method of gradient descent can be described by the relation

$$\mathbf{W}_{k+1} = \mathbf{W}_k + \mu(-\nabla_k) \tag{1}$$

where $\mu$ is a parameter that controls stability and rate of convergence and $\nabla_k$ is the value of the gradient at a point on the MSE surface corresponding to $\mathbf{W} = \mathbf{W}_k$.

The LMS algorithm works by performing approximate steepest descent on the mean-square-error surface in weight space. This surface is a quadratic function of the weights and is therefore convex and has a unique (global) minimum. An instantaneous gradient based on the square of the instantaneous error is

$$\hat{\nabla}_k = \frac{\partial \varepsilon_k^2}{\partial \mathbf{W}_k} = \begin{Bmatrix} \dfrac{\partial \varepsilon_k^2}{\partial w_{0k}} \\ \vdots \\ \dfrac{\partial \varepsilon_k^2}{\partial w_{nk}} \end{Bmatrix} \tag{2}$$

LMS works by using this crude gradient estimate in place of the true gradient $\nabla_k$. Making this replacement into Equation 1 yields

$$\mathbf{W}_{k+1} = \mathbf{W}_k = \mu(-\hat{\nabla}_k) = \mathbf{W}_k - \mu \frac{\partial \varepsilon_k^2}{\partial \mathbf{W}_k} \tag{3}$$

The instantaneous gradient is used because (1) it is an unbiased estimate of the true gradient (Widrow and Stearns, 1985) and (2) it is easily computed from single data samples. The true gradient is generally difficult to obtain. Computing it would involve averaging the instantaneous gradients associated with all patterns in the training set. This is usually impractical and almost always inefficient.

The present error or *linear* error $\varepsilon_k$ is defined to be the difference between the desired response $d_k$ and the linear output $s_k = \mathbf{W}_k^{\mathrm{T}}\mathbf{X}_k$ before adaptation:

$$\varepsilon_k \triangleq d_k - \mathbf{W}_k^{\mathrm{T}}\mathbf{X}_k \tag{4}$$

Performing the differentiation in Equation 3 and replacing the linear error by the definition in Equation 4 gives

$$\mathbf{W}_{k+1} = \mathbf{W}_k - 2\mu\varepsilon_k \frac{\partial(d_k - \mathbf{W}_k^{\mathrm{T}}\mathbf{X}_k)}{\partial \mathbf{W}_k} \tag{5}$$

Noting that $d_k$ and $\mathbf{X}_k$ are independent of $\mathbf{W}_k$ yields

$$\mathbf{W}_{k+1} = \mathbf{W}_k + 2\mu\varepsilon_k\mathbf{X}_k \tag{6}$$

This is the LMS algorithm. The learning constant $\mu$ determines stability and convergence rate (Widrow and Stearns, 1985).

### *The Perceptron Learning Rule*

The Rosenblatt $\alpha$-perceptron (Rosenblatt, 1962), diagrammed in Figure 3, processed input patterns with a first layer of sparse, randomly connected, fixed-logic devices. The outputs of the fixed first layer fed a second layer, which consisted of a single adaptive linear threshold element. Other than the convention that its input signals and its output signal were {1,0} binary and that no bias weight was included, this element was equivalent to the adaline element. The learning rule for the $\alpha$-perceptron was very similar to LMS, but its behavior was in fact quite different.

Fixed Threshold Elements

**Figure 3.** Rosenblatt's $\alpha$-perceptron.

Adapting with the perceptron rule makes use of the *quantizer* error $\tilde{\tilde{\varepsilon}}_k$, defined to be the difference between the desired response and the output of the quantizer

$$\tilde{\tilde{\varepsilon}}_k \overset{\Delta}{=} d_k - y_k \tag{7}$$

The perceptron rule, sometimes called the *perceptron convergence procedure*, does not adapt the weights if the output decision $y_k$ is correct, i.e., if $\tilde{\tilde{\varepsilon}}_k = 0$. If the output decision disagrees with the binary desired response $d_k$, however, adaptation is effected by adding the input vector to the weight vector when the error $\tilde{\tilde{\varepsilon}}_k$ is positive, or subtracting the input vector from the weight vector when the error $\tilde{\tilde{\varepsilon}}_k$ is negative. Note that the quantizer error $\tilde{\tilde{\varepsilon}}_k$ is always equal to either 1, 1, or 0. Thus, the product of the input vector and the quantizer error $\tilde{\tilde{\varepsilon}}_k$ is added to the weight vector. The perceptron rule is identical to the LMS algorithm, except that with the perceptron rule, one-half of the quantizer error, $\tilde{\tilde{\varepsilon}}_k/4$, is used in place of the linear error $\varepsilon_k$ of the LMS rule. The perceptron rule is nonlinear, in contrast to the LMS rule, which is linear. Nonetheless, it can be written in a form which is very similar to the LMS rule of Equation 6:

$$\mathbf{W}_{k+1} = \mathbf{W}_k + 2\mu \frac{\tilde{\tilde{\varepsilon}}_k}{2} \mathbf{X}_k \tag{8}$$

Rosenblatt normally set $\mu$ to 1. In contrast to LMS, the choice of $k$ does not affect the stability of the perceptron algorithm, and it affects convergence time only if the initial weight vector is nonzero. Also, while LMS can be used with either analog or binary desired responses, Rosenblatt's rule can be used only with binary desired responses.

The perceptron rule stops adapting when the training patterns are correctly separated. There is no restraining force controlling the magnitude of the weights, however. The direction of the weight vector, not its magnitude, determines the decision function. The perceptron rule has been proved capable of separating any linearly separable set of training patterns (Rosenblatt, 1962; Nilsson, 1965). If the training patterns are not linearly separable, the perceptron algorithm goes on forever, and in most cases the weight vector gravitates toward zero. As a result, on problems that are not linearly separable, the perceptron often does not yield a low-error solution, even if one exists.

This behavior is very different from that of the LMS algorithm. Continued use of LMS does not lead to an unreasonable weight solution if the pattern set is not linearly separable. Nor, however, is this algorithm guaranteed to separate any linearly separable pattern set. LMS typically comes close to achieving such separation, but its objective is different, i.e., error reduction at the linear output of the adaptive element.

### *"Backpropagation" for the Sigmoid Adaline*

A *sigmoid adaline* element incorporates a sigmoidal nonlinearity. The input-output relation of the sigmoid can be denoted by $y_k = \text{sgm}(s_k)$. A typical sigmoid function is the hyperbolic tangent

$$y_k = \tanh(s_k) = \left(\frac{1 - e^{-2s_k}}{1 + e^{-2s_k}}\right) \tag{9}$$

We shall adapt this adaline with the objective of minimizing the mean square of the *sigmoid error* $\tilde{\varepsilon}_k$, defined as

$$\hat{\varepsilon}_k \overset{\Delta}{=} d_k - y_k = d_k - \text{sgm}(s_k) \tag{10}$$

The method of gradient descent is used to adapt the weight vector. By following the same line of reasoning used to develop LMS, the instantaneous gradient estimate obtained during presentation of the $k$th input vector $\mathbf{X}_k$ can be found to be

$$\hat{\nabla}_k = \frac{\partial(\tilde{\varepsilon}_k)^2}{\partial \mathbf{W}_k} = 2\tilde{\varepsilon}_k \frac{\partial \tilde{\varepsilon}_k}{\partial \mathbf{W}_k} = -2\tilde{\varepsilon}_k \, \text{sgm}'(s_k)\mathbf{X}_k \tag{11}$$

Using this gradient estimate with the method of gradient descent provides a means for minimizing the mean square error even after the summed signal $s_k$ goes through the nonlinear sigmoid. The algorithm is

$$\mathbf{W}_{k+1} = \mathbf{W}_k + \mu(-\hat{\nabla}_k) = \mathbf{W}_k + 2\mu\delta_k\mathbf{X}_k \tag{12}$$

where $\delta_k$ denotes $\tilde{\varepsilon}_k \, \text{sgm}'(s_k)$. The algorithm of Equation 12 is the *backpropagation* algorithm for the single adaline element, although the backpropagation name makes sense only when the algorithm is utilized in a layered network, which will be studied later.

If the sigmoid is chosen to be the hyperbolic tangent function (Equation 9), then the derivative $\mathrm{sgm}'(s_k)$ is given by

$$\begin{aligned}\mathrm{sgm}'(s_k) &= \frac{\partial(\tanh(s_k))}{\partial s_k}\\ &= 1 - (\tanh(s_k))^2 = 1 - y_k^2 \end{aligned} \qquad (13)$$

Accordingly, Equation 12 becomes

$$\mathbf{W}_{k+1} = \mathbf{W}_k + 2\mu\tilde{\varepsilon}_k(1 - y_k^2)\mathbf{X}_k \qquad (14)$$

The single sigmoid adaline trained by backpropagation shares some advantages with both the adaline trained by LMS and the perceptron trained by Rosenblatt's perceptron rule. If a pattern set is linearly separable, the objective function of the sigmoid adaline, the mean square error, is minimized only when the pattern set is separated. This is because, as the weights of the sigmoid adaline grow large, its response approximates that of a perceptron with weights in the same direction. The sigmoid adaline trained by backpropagation, however, also shares the advantage of the adaline trained by LMS: it tends to give reasonable results even if the training set is not separable.

Backpropagation training of the sigmoid adaline does have one drawback, however. Unlike the linear error of the adaline, the output error of the sigmoid adaline is a nonlinear function of the weights. As a result, its mean square error surface is not quadratic, and may have local minima in addition to the optimal solution. Thus, unlike the perceptron rule, it cannot be guaranteed that backpropagation training of the sigmoid adaline will successfully separate a linearly separable training set. Nonetheless, the single sigmoid adaline performs admirably in many filtering and pattern classification applications. Its most important role, however, occurs in multilayer networks, to which we now turn.

### *Backpropagation for Networks*

The backpropagation technique is a substantial generalization of the single sigmoid adaline case discussed in the previous section. When applied to multilayer feedforward networks, the backpropagation technique adjusts the weights in the direction opposite to the instantaneous gradient of the sum square error in weight space. Derivations of the algorithm are widely available in the literature (Rumelhart et al., 1986; Widrow and Lehr, 1990). Here we provide only a brief summary of the result.

The instantaneous sum square error $\varepsilon_k^2$ is the sum of the squares of the errors at each of the $N_y$ outputs of the network. Thus

$$\varepsilon_k^2 = \sum_{i=1}^{N_y} \varepsilon_{ik}^2 \qquad (15)$$

In its simplest form, backpropagation training begins by presenting an input pattern vector $\mathbf{X}$ to the network, sweeping forward through the system to generate an output response vector $\mathbf{Y}$, and computing the errors at each output. We continue by sweeping the effects of the errors backward through the network to associate a *square error derivative* $\delta$ with each adaline, computing a gradient from each $\delta$, and finally updating the weights of each adaline based on the corresponding gradient. A new pattern is then presented and the process is repeated. The initial weight values are normally set to small random values. The algorithm will not work properly with multilayer networks if the initial weights are either zero or poorly chosen non-zero values.

The $\delta$s in the output layer are computed just as they are for the sigmoid adaline element. For a given output adaline,

$$\delta = \tilde{\varepsilon}\ \mathrm{sgm}'(s) \qquad (16)$$

where $\tilde{\varepsilon}$ is the error at the output of the adaline and $s$ is the summing junction output of the same unit.

Hidden-layer calculations, however, are more complicated. The procedure for finding the value of $\delta^{(l)}$ the value of $\delta$ associated with a given adaline in hidden layer $l$, involves respectively multiplying each derivative $\delta^{(l+1)}$ associated with each element in the layer immediately downstream from the given adaline by the weight connecting it to the given adaline. These weighted square error derivatives are then added together, producing an error term $\varepsilon^{(l)}$, which in turn is multiplied by $\mathrm{sgm}'(s^{(l)})$, the derivative of the given adaline's sigmoid function at its current operating point. Thus, the $\delta$ corresponding to adaline $j$ in hidden layer $l$ is given by

$$\delta_j^{(l)} = \mathrm{sgm}'(s_j^{(l)}) \sum_{i \in N^{(l+1)}} \delta_i^{(l+1)} w_{ij}^{(l+1)} \qquad (17)$$

where $N^{(l+1)}$ is a set containing the indices of all adalines in layer $l + 1$ and $w_{ij}^{(l+1)}$ is the weight connecting adaline $i$ in layer $l + 1$ to the output of adaline $j$ in layer $l$.

Updating the weights of the adaline element using the method of gradient descent with the instantaneous gradient is a process represented by

$$\mathbf{W}_{k+1} = \mathbf{W}_k + \mu(-\hat{\nabla}_k) = \mathbf{W}_k + 2\mu\delta_k\mathbf{X}_k \qquad (18)$$

where $\mathbf{W}$ is the adaline's weight vector and $\mathbf{X}$ is the vector of inputs to the adaline. Thus, after backpropagating all square error derivatives, we complete a backpropagation iteration by adding to each weight vector the corresponding input vector scaled by the associated square error derivative. Equations 16, 17, and 18 comprise the general weight update rule of the back propagation algorithm for layered neural networks.

Many useful techniques based on the backpropagation algorithm have been developed. One popular method, called *backpropagation through time*, allows dynamical recurrent networks to be trained. Essentially, this is accomplished by running the recurrent neural network for several time steps and then "unrolling" the network in time. This results in a virtual network with a number of layers equal to the product of the original number of layers and the number of time steps. The ordinary backpropagation algorithm is then applied to this virtual network and the result is used to update the weights of the original network. This approach was used by Nguyen and Widrow (1989) to enable a neural network to learn without a teacher how to back up a computer-simulated trailer truck to a loading dock (Figure 4). This is a complicated and highly nonlinear steering task. Nevertheless, with just six inputs providing information about the current position of the truck, a two-layer neural network with only 26 sigmoid adalines was able to learn of its own accord to solve this problem. Once trained, the network could successfully back up the truck from any initial position and orientation in front of the loading dock.

## Discussion

Although this article has focused on pattern classification issues, nonlinear neural networks are equally useful for such tasks as interpolation, system modeling, state estimation, adaptive filtering, and nonlinear control. Unlike their linear counterparts, which have a long track record of success, nonlinear neural networks have only recently begun proving themselves in commercial applications. The capabilities of multielement neural networks have improved markedly since the introduction of Madaline Rule I. This has resulted largely from development of the backpropagation algorithm, easily the most useful and popular neural network training algorithm currently available. As we have seen, backpropagation is a generalization of LMS that allows complex networks of sigmoid adalines to be efficiently adapted. Backpropagation and related algorithms

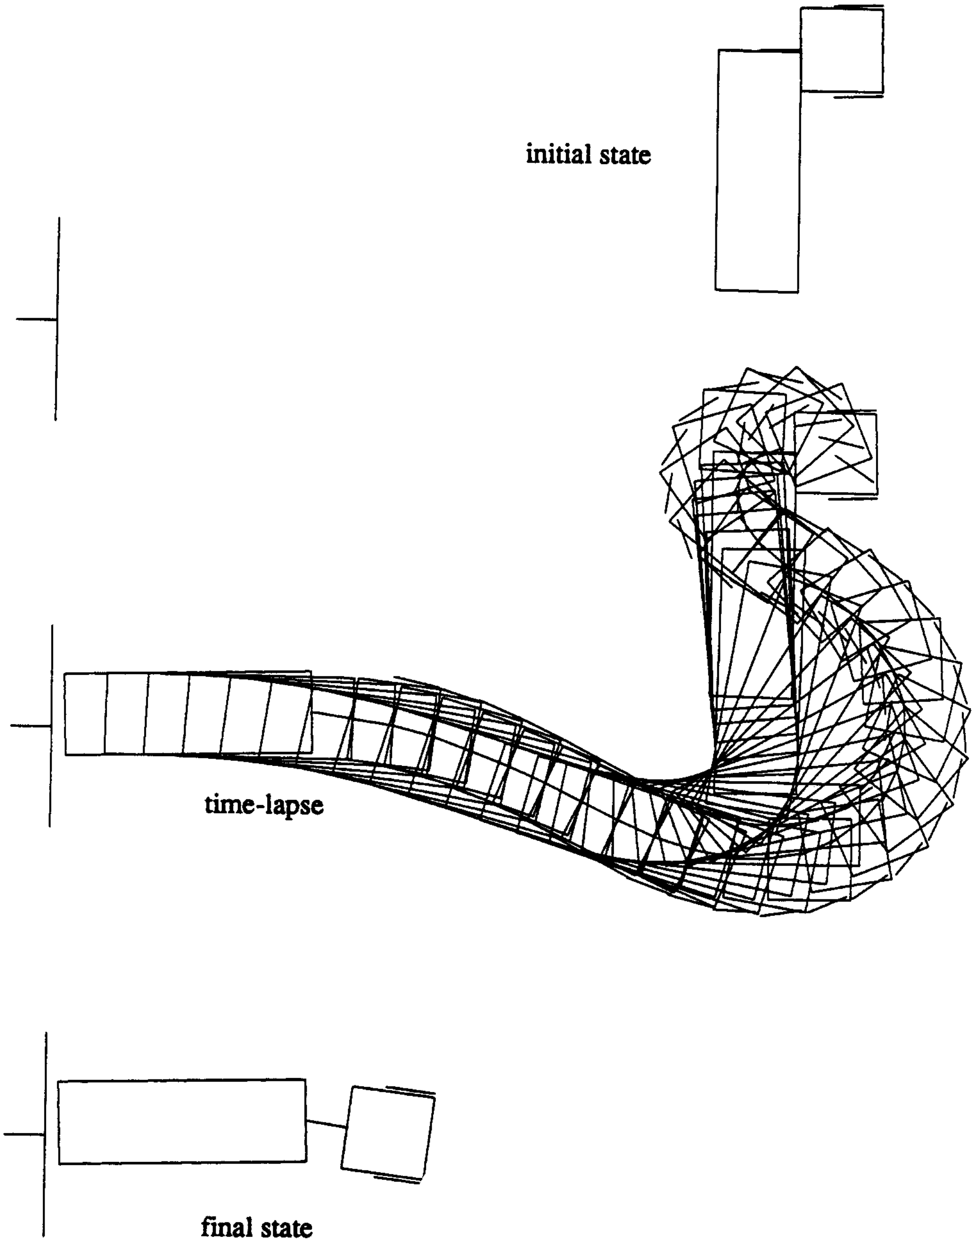

**Figure 4.** Example of a truck backup sequence.

are in large part responsible for the dramatic growth the field of neural networks is currently experiencing.

The timing of the current boom in the field of neural networks is also due to the rapid advance in computer and microprocessor performance, which continues to improve the feasibility and cost-effectiveness of computationally expensive techniques in relation to classical approaches of engineering and statistics. Although single-element linear adaptive filters are still used more extensively than nonlinear multielement neural networks, the latter are potentially applicable to a much wider range of problems. Furthermore, the applications for which multielement neural networks are best suited often involve complicated nonlinear relationships for which classical solutions are either ineffective or unavailable. The continued advancement of neural network algorithms and techniques, in conjunction with improvements in the special and general purpose computer hardware used to implement them, sets the stage for a future in which neural networks will play an increasing role in commercial and industrial applications.

# Perspective on Neuron Model Complexity

*Wilfrid Rall*

## Introduction

There is a wide range of choice in model complexity, from very simple to rather complex neuron models. Which model to choose depends, in each case, on the context. How much information do we already have about the neurons under consideration? What questions do we wish to explore?

Sometimes we wish to model a particular biological neuron whose anatomy and physiology are known in considerable experimental detail. In such cases, we may choose to specify a model that includes at least some of the dendritic branching of the neuron, because synapses from one source may be distributed preferentially to either a distal or a proximal dendritic location, while synapses from another source may end mainly at the soma, or on a different dendritic tree of the same neuron. Also, there may be a functionally significant nonuniformity in the distribution of channel densities of several ion channel types over the surface of the soma and dendrites. How much detail is needed depends on the biological experiments to be simulated and the questions asked.

Conversely, many network modelers are not constrained by anatomical or physiological data. For some network modeling, this is partly justified by a paucity of available data. However, more often, network modelers are constrained by their mathematical methods, which lead them to focus on abstract networks composed of extremely simple units. The simplest units are two-state, binary units, analogous to atomic spin, previously studied for condensed matter physics (see, e.g., Optimization, Neural). Such binary units do not resemble neurons, but they do have a strong appeal for nerve-net modelers, who have generated an extensive literature. That literature lies outside the scope of the current article.

When simple binary units are compared with a dendritic neuron model (especially with nonuniform distributions of synapses and ion channels), it becomes apparent that one dendritic model neuron can perform tasks that would require a network of many simple units to duplicate. For the purpose of machine design, it may seem quite appropriate to consider the trade-offs in cost and flexibility (between the one realistic model and the many binary units), but for functional insights and understanding of biological nervous systems, I freely state my bias for the more realistic neuron models. I do not choose the most complex, in the sense of including all known anatomical and physiological details; I favor an intermediate level of complexity that preserves the most significant distinctions between regions (soma, proximal dendritic, distal dendritic, different trees), especially when further justified by nonuniform distributions of synapses and ion channels (see also Segev, 1992).

The claim is sometimes made that network properties depend primarily on the connectivity between the units, and not on the properties of the units. Although this may be true for some gross network properties, I do not believe it to be true for many of the actual biological networks that perform important, complicated tasks. I regard it as a worthwhile challenge for like-minded neural modelers to provide interesting demonstrations in support of this belief. The challenge is to demonstrate a useful computation or discrimination that can be accomplished with a dendritic neuron model, or a network composed of such models, and then show that this useful capacity is lost when all of the dendritic membrane is lumped with the soma, and all of the inputs to each neuron are now delivered to that lumped membrane. There are valuable examples that already meet this challenge, several of which are presented in three later sections of this article. Other examples can be found in a review by Borst and Egelhaaf (1994; see also Visual Course Control in Flies).

## Brief Historical Notes

Neurons are biological cells, and their electrical properties depend on ions and the cell membrane, in a manner brilliantly elucidated by Hodgkin, Huxley, and Katz during the period 1948–1952. It is a fascinating historical coincidence that two seeds of their important insights can be found in a single 1902 volume of *Pfluegers Archiv*, in pioneering articles by Bernstein and by Overton. Following the earlier theoretical insights of Nernst and Planck, Bernstein recognized the importance of the potassium ion concentration difference across the membrane in determining a non-zero resting potential; he regarded excitation as a brief breakdown of the membrane, a concept that prevailed until 1948, when Hodgkin and Katz showed that the key is a sudden overwhelming increase in membrane permeability to sodium ions. Overton's 1902 paper had correctly emphasized the importance of the external sodium ion concentration to the excitability properties of nerve, but no one put these ideas together in 1902. Between 1900 and 1914, several investigators, including Hermann, Lucas, and Lapique, recognized the importance of membrane capacitance; the concept of nerve membrane as a leaky integrator, with a threshold for an action potential, was used to understand the strength-duration curve for a threshold stimulus. During the 1930s, several investigators, including Rashevsky, Hill, and Monnier, developed mathematical models of excitation and inhibition; Rashevsky's textbook *Mathematical Biophysics* (1948) includes many examples of network modeling by himself; by Householder, Landahl, and others; and by McCulloch and Pitts, whose famous 1943 paper arose in the context of Rashevsky's research seminars at the University of Chicago (see also the historical notes in Schwartz, 1990). Ever since that time, many neuron modelers have been content with the leaky integrator neuron model, which reduces a neuron to a single node that integrates synaptic excitation (+) and synaptic inhibition (−) delivered to it by other neurons. Several errors caused by these oversimple assumptions were demonstrated by compartmental computations in 1962; see Rall's chapter in Reiss (1964) or in Segev, Rinzel, and Shepherd (1995). Other chapters in Reiss (1964) also provide several interesting early perspectives on neural modeling. The mathematical modeling of nonlinear membrane properties has been presented and discussed in an outstanding early review by FitzHugh (1969), and in a chapter by Rinzel and Ermentrout that appears in Koch and Segev (1989).

The concept of a nerve axon as an extended core conductor (i.e., membrane cylinder with ionic conducting media inside and outside) goes back to the 1870s, when it was treated mathematically by Hermann and Weber; both the concept of passive electrotonus in membrane cylinders and the mathematics (of passive cable theory) were explored over the years, culminating in classic papers by Hodgkin and Rushton and by Davis and Lorente de Nó, both around 1946–1947; see references in Rall (1977). Before 1900, neuroanatomical studies by Ramón y Cajal demonstrated the extensiveness of dendritic branching for most neuron types; this was confirmed by many anatomists, and later (in the 1950s), use of the electron microscope made it possible to verify the existence of very many synapses on the dendritic branches and on the dendritic spines of neurons. These anatomical facts, together with the introduction of intracellular microelectrode recording from single dendritic neurons (in the 1950s), made it urgent to extend cable theory to the dendrites of individual neurons. This was begun in the late 1950s and carried forward into the 1960s and 1970s; for a review, see Jack, Noble, and Tsien (1975) or Rall (1977); see also Koch and Segev (1989), McKenna, Davis, and Zornetzer (1992), Rall et al. (1992), Segev et al. (1995), and DENDRITIC PROCESSING.

## Dendritic Neuron Model Complexity: Geometric Versus Membrane Complexity

The concept of complexity in dendritic neuron models can be explored quite efficiently by making a two-dimensional chart. One dimension would be membrane complexity, ranging from the simple case of a passive linear membrane to that of postsynaptic membrane models with time-varying ion permeability (or conductance), and then to excitable membrane models with voltage-dependent ion conductances as described by Hodgkin and Huxley (see AXONAL MODELING), or as now described with increasing detail in terms of many different species of ion channels whose voltage and time dependence are currently being characterized (see ION CHANNELS: KEYS TO NEURONAL SPECIALIZATION). The other dimension would be geometric complexity, ranging from the simple case of an isopotential region of membrane (a soma, or a space-clamped section of a cylinder) to that of a uniform membrane cylinder with two sealed ends (or with one end voltage clamped, or current clamped), and then to several dendritic trees attached to a soma (with or without an axon), where the soma may be shunted and the branching of the trees may be specified to varying degrees of arbitrariness. The most complicated geometric case, with arbitrary branching and shunted soma, has recently been solved analytically (for transients, assuming passive membrane) in a mathematical tour de force by Major, Evans, and Jack (1993); see also Holmes, Segev, and Rall (1992). The less complicated, but illuminating, case of idealized branching with a point soma was solved earlier by Rall and Rinzel; see the 1973 and 1974 papers reprinted in Segev et al. (1995). However, these analytical methods do depend on the assumption of linear membrane properties. When nonlinear membrane complexity is combined with geometric complexity, the transient solutions can be obtained computationally by using compartmental models; see 1964 and 1968 papers reprinted in Segev et al. (1995); see also DENDRITIC PROCESSING and several chapters in Koch and Segev (1989) and in McKenna et al. (1992).

## Dendritic Model Can Provide Spatiotemporal Discrimination

Figure 1 summarizes a demonstration of how a dendritic neuron model could perform a discrimination between two contrasting spatiotemporal patterns of synaptic input (i.e., possible movement detection); this discrimination is lost if the compartments and inputs are lumped together. A neuron is represented by a chain of ten compartments; compartment 1 represents the soma, while compartments 2 to 10 represent dendritic membrane of the same neuron, with increasing cable distance from the soma. One spatiotemporal input sequence, A-B-C-D, has the proximal dendritic input first, followed in time by progressively more distal dendritic input locations. The other input pattern, D-C-B-A, is opposite in having the most distal input first, followed in time by progressively more proximal input locations. Comparison of the resulting computed voltage transients (EPSP at the soma), shown in Figure 1, reveals that input sequence D-C-B-A yields a significantly larger voltage amplitude than does input sequence A-B-C-D. Intuitive understanding of this computed result is obtained by noting that the delayed proximal input builds on membrane depolarization that has spread to the soma (with delay) from the distal dendrites (which were activated earlier). If the voltage threshold for spiking at the soma were tuned between these two peak amplitudes, a spike would be produced by sequence D-C-B-A, but a spike would not be produced by sequence A-B-C-D; this would constitute a discrimination between these two sequences. The dashed curve in the figure shows the computed result when the compartments are lumped together; either sequence of input synapse activation then produces the same intermediate result, and no discrimination would be possible.

## Models for Mitral and Granule Cell Populations in Olfactory Bulb

A rather different example is provided by the neuron models used for the mitral cell and granule cell populations in simulating experiments on the OLFACTORY BULB (q.v.) of rabbit; see the 1968 paper of Rall and Shepherd in Segev et al. (1995); or see figures 2.11 and 2.12 in Koch and Segev (1989). Here, the task was to model and compute extracellular field potentials that matched those observed experimentally in olfactory bulb when the mitral cell population was activated in near synchrony by means of an antidromic volley. Compartmental models were used; a nine-compartment model (three axonal, one somatic, and five dendritic) was used to simulate antidromic activation of a mitral cell, while a ten-compartment model was used to simulate nonspiking activity in the dendrites of an axonless granule cell. The dendritic compartments were absolutely essential for the computation of electric current flow between different dendritic regions of each granule cell and between the dendrites and soma of each mitral cell; without these currents, it would have been impossible to compute the field potentials generated by the synchronously activated neuron populations. Also, this modeling led to a critically important distinction in the depth distribution of the two fields: the larger, longer-lasting field potentials generated by the very large population of granule cells extended to significantly greater depth in the olfactory bulb than did the earlier, smaller, briefer field potentials generated by the mitral cell population. The difference between these two fields was such that neither population could have generated the other field. This provided the key to our prediction of (and the functional interpretation of subsequent electron microscopic evidence for) dendrodendritic synaptic interactions between the mitral secondary dendrites and the distal dendrites of the granule cells, which are

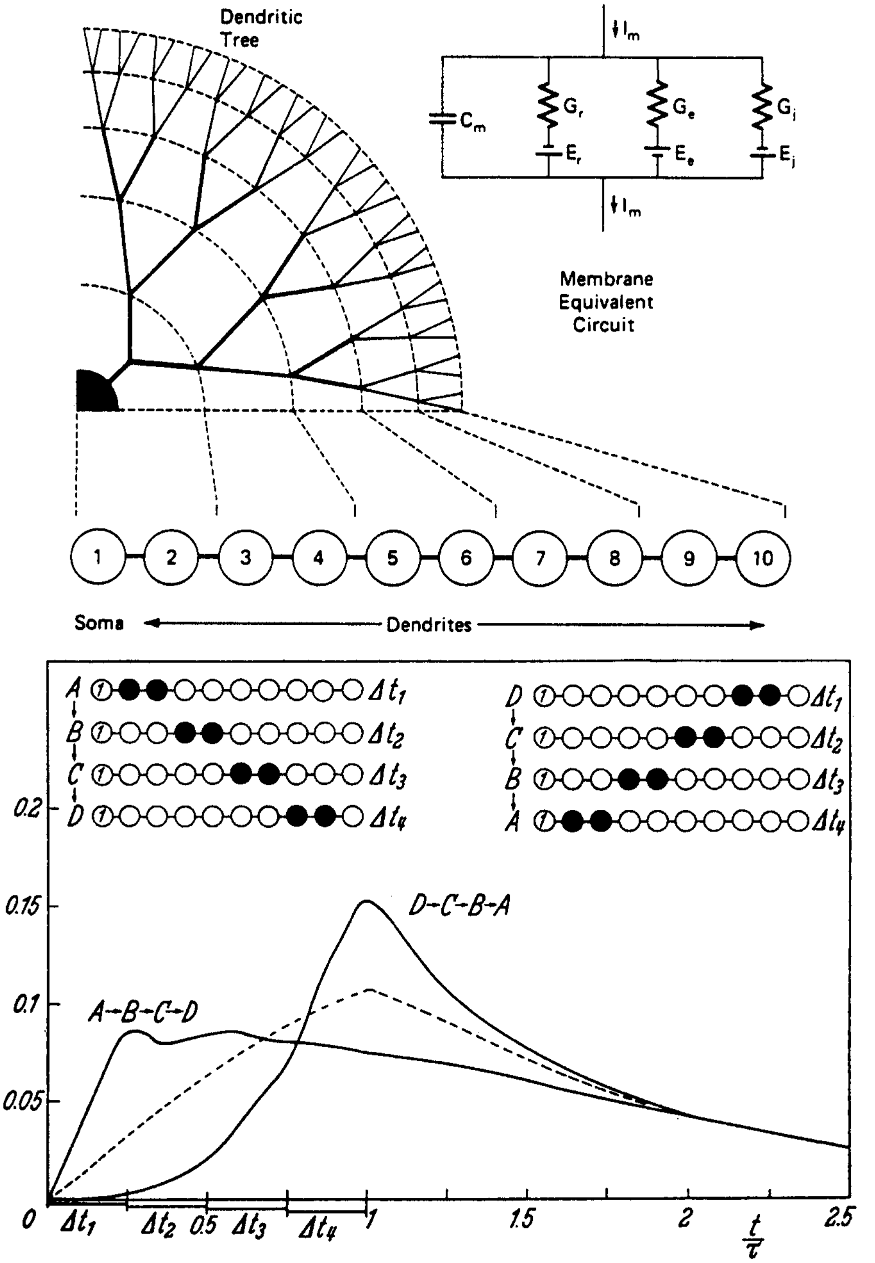

**Figure 1.** Effect of spatiotemporal dendritic pattern of synaptic input on the computed EPSP at the soma, for a ten-compartment model. Upper diagram indicates the mapping of a soma and dendritic tree into a chain of ten equal compartments. Compartment 1 represents the soma membrane, while compartments 2 to 10 represent dendritic membrane, from proximal to distal locations. The middle diagram (at left) shows the synaptic input sequence A-B-C-D, meaning proximal dendritic input location active first, followed by successive activation at increasingly more distal input locations; this input pattern produced the soma voltage transient (computed composite EPSP) labeled A-B-C-D at lower left. The middle diagram (at right) shows the opposite synaptic input sequence. D-C-B-A, meaning distal dendritic input location first, followed by successively more proximal input locations; this input pattern produced a significantly different soma voltage transient (computed composite EPSP), having a delayed rise to a larger peak amplitude, labeled D-C-B-A. In both cases, each input compartment (shown in black) received a synaptic excitatory conductance pulse ($G_e = G_r$, for a duration $0.25\tau$) during one of the four labeled periods. The same total amount of synaptic input produced the dashed curve when the spatiotemporal pattern was eliminated by smearing the synaptic conductance in space and time ($G_e = 0.25\ G_r$ in eight compartments (compartments 2 to 9) for the full time duration from $t = 0$ to $t = \tau$). The membrane equivalent circuit (upper right) holds for each compartment. Further details can be found in the 1964 chapter by Rall in Reiss (1964), reprinted in Segev et al. (1995).

intermingled in the external plexiform layer of the bulb. If these cells had been modeled as lumped somas, without dendrites, neither the successful simulation of the experimental field potentials nor the exciting new insights about a dendrodendritic pathway for recurrent inhibition would have been possible.

Similarly, for the earlier simulations and insights obtained for motor neurons of cat spinal cord, we found that observations made at the soma seemed paradoxical until they were understood in terms of synaptic events that occur in distal dendrites (see the 1967 paper in Segev et al., 1995); these results and insights would not have been possible without dendritic compartments in the neuron field.

## Comment on Functional Aspect of Dendrodendritic Interactions

To highlight an important functional difference, note first that motor neurons do exhibit the classical functional polarity envisaged by Ramón y Cajal and Sherrington (as well as most modelers). The dendrites receive inputs from many sources (their effects converge on the soma); the output (when spike threshold is exceeded) is an all-or-nothing action potential propagated by the axon to muscle units that may be quite distant; i.e., classically, input is received by the dendrites and output is delivered by the axon. In contrast, the dendrites of both the mitral cells and the granule cells are functionally different, because they both send as well as receive synaptic information, locally. The mitral secondary dendrites, which are smooth and spineless, send nonspiking synaptic excitatory output, which is received as input by the spines (see DENDRITIC SPINES) of the adjacent granule cells. The granule cells have no axons and perhaps no action potentials; their spines receive graded synaptic excitatory input and then send graded synaptic output that is inhibitory to the adjacent mitral cell dendrites. It is important to emphasize that this is not a rare anomaly found only in the olfactory bulb; evidence for dendrodendritic synapses and for graded local synaptic interactions is now found in many parts of the brain (e.g., retina and inferior olive). In 1965, when we (Rall et al.; see 1966 and 1968 papers reprinted in Segev et al., 1995) first presented our interpretations of dendrites that send as well as receive, some critics resisted this concept as heretical; however, our functional interpretation of these dendrodendritic synapses is now widely accepted by physiologists and anatomists. This kind of graded two-way synaptic interaction is very different from the classical functional polarity just described for motor neurons; it provides graded functional coupling between neurons (without axonal impulses). The implications have so far hardly been explored in theoretical networks. Such exploration will require explicit modeling of dendritic compartments; a point neuron model would be useless for this. Note also that computational exploration of localized plastic changes at synapses and at dendritic spines depends on neuron models that include dendritic compartments.

## Network Rhythmogenesis Using the Traub Model and a Reduced Model

A 19-compartment cable model for the pyramidal cells of the CA3 region of guinea pig hippocampus was developed by Traub et al. (1991; see also the chapter by Traub and Miles in McKenna et al., 1992). Based on experimental measurements, parameters were chosen for each compartment, using up to six active ionic conductances, and controlled by ten-channel gating variables. They succeeded in finding a set of physiologically reasonable parameters for which the network of model neurons could simulate several important aspects of the experimental repertoire of the slightly disinhibited hippocampal slice preparation. Although Traub et al. recognized that their successful simulations of network behavior depended on specifying significantly different ion channel densities for the soma and for the dendrites, the critical importance of this difference was made starkly clear by the modeling of Pinsky and Rinzel (1994); they obtained essentially the same behavioral repertoire by using a network composed of a severely reduced neuron model consisting of only two compartments per pyramidal cell. One compartment represented the soma and proximal dendrites, while the other compartment represented the distal dendrites. To be more specific, the ion channels for fast-spiking currents (inward sodium, and delayed rectifier) were restricted to the soma-like compartment, and the ionic channels for the slower calcium currents (calcium-inward and calcium-modulated currents) were restricted to the dendrite-like compartment. I hasten to add that these results also show that at least two compartments are needed for simulations of this behavior; a single lumped compartment, with all of the ion channels in parallel, could not produce the same behavior, especially the rhythm, which basically involves an alternating flow of current between the two coupled compartments. A special advantage of the reduced neuron model is that much simpler computations can explore how much the interesting behavior depends on the values of key parameters, especially the parameter that defines the tightness of coupling between the two compartments. Also, the behavior of very large networks can be explored more efficiently using such a reduced neuron model. Further study may show that the two-compartment model cannot match the fuller model in certain important tests, but, in any case, these findings so far represent a very satisfying example that illustrates the thesis of this article.

## Discussion

In an earlier essay offering perspective on neural modeling (a chapter in Binder and Mendell, 1990), I provided a completely different set of examples. One of these provided a detailed consideration of the number of degrees of freedom to be found in a neuron model composed of a thousand compartments. Such models exist today because of tremendous improvements in anatomical methods and in computation facilities now available to experimental investigators. Because they have the morphological data and a computer, why not put everything into the model? The answer is that you can if you wish to, but you should be aware of the huge number of degrees of freedom implied by the large number of parameters that must be specified; as someone once pointed out, given enough free parameters, he could fit an elephant. Is the membrane uniform, or do we know the density of every channel species in every membrane compartment? How are the inputs distributed to the many compartments? Today, the data needed for such detailed specifications are largely missing; however, such data are beginning to become at least partly available for some neurons. Where the data are not available, the modeler must make reasonable guesses. If it seems reasonable to assign the same parameter values to many neighboring compartments, one should consider lumping those compartments together to produce a simpler model with fewer compartments. Nevertheless, one important merit of the larger model is that it can be used to test whether it can perform some interesting task that cannot be performed by the reduced model.

As stated earlier, my preference is for intermediate levels of complexity; I vote for the smallest number of compartments that can preserve what one judges to be the functionally important differences between dendritic regions with regard to ion channel densities and to distributions of synapses from different sources. If a five-compartment model can provide a good approximation of the interesting properties of a 1,000-compartment model, I would prefer the smaller model, for two important reasons: (1) it helps sharpen our intuitive understanding about what is essential to obtaining the behavior of interest, and (2) it can greatly facilitate computations with networks composed of such neuron models. I expect modeling of this kind will continue to be particularly fruitful in the near future (see also the discussion by Segev, 1992).

## Concluding Comment

As when drawing, painting, sculpting, or composing music, so too, when deeply engaged in neural modeling, I believe that much of the fun and satisfaction comes from interactions between my conscious mind and my subconscious sources of creativity. It seems that preliminary sketching serves to plant seeds in the subconscious, where they can grow, if nurtured. Conscious pursuit of the problem can then stimulate differentiation and development in the subconscious and may produce fruits that can reach conscious awareness (popping up like mushrooms produced by an underground mycelium). Such fruits may provide exciting new insights for the conscious mind. Indeed, the pleasure of such creative discovery can become almost addictive for those fortunate enough to have both the interest and the opportunity for creative activity. I hasten to add that a lot of hard work is usually required to test and polish before one can produce a finished product. Pioneering in dendritic neuron modeling provided me with such an opportunity; now [at the time of the First Edition], with retirement upon me, I hope to persist by sculpting, painting, and by designing a house for a natural mountain setting.

# Phase-Plane Analysis of Neural Nets

*Bard Ermentrout*

## Introduction

Models of neural networks often involve the solutions to differential equations that describe the time evolution of these complex systems. The dynamical behavior of these networks ranges from the convergence to an equilibrium (generally desired in connectionist applications) to oscillatory behavior (in models of central pattern generators and bursting) through possibly chaotic behavior. There are many ways to analyze these models; the most commonly used techniques entail simulation. In this article I will give an overview of an alternative technique for studying the *qualitative* behavior of small systems of interacting neural networks. One form that the models take is (Ellias and Grossberg, 1975; Hopfield, 1984; Wilson and Cowan, 1972):

$$\tau_i \frac{dx_i}{dt} = -x_i + f_i\left(\sum_{j=1}^{n} w_{ij}x_j + s_i\right) \quad i = 1, \ldots, n \tag{1}$$

where $x_i$ represents the activity or firing rate of the $i$th neuron, $\tau_i$ is the time constant, $w_{ij}$ are the connection weights, $s_i$ are inputs, and $f_i$ are typically saturating nonlinear functions that have the form shown in Figure 1. That is, the nonlinear functions are increasing and bounded. Some typical examples are:

$$f(x) = \tanh(x) \tag{2}$$

$$f(x) = \tan^{-1}(x) \tag{3}$$

$$f(x) = \frac{1}{1 + \exp(-x)} \tag{4}$$

Often, a slightly different form of (1) is chosen where the nonlinearities are inside the sums. The transformation from one to the other is elementary and all of the following holds for either type of model.

A complete analysis of networks of the form in Equation 1 is obviously impossible. However, if $n \leq 2$, then a fairly complete description of Equation 1 can be given. Thus, the goal of this article is to introduce the reader to the qualitative theory of differential equations in the plane. In particular, I will analyze two neuron networks that consist of (1) two excitatory cells, (2) two inhibitory cells, and (3) an excitatory and an inhibitory cell. The advantages of restricting the analysis to these small networks are the special topology of the plane, the completeness of the analysis possible, and finally the case of exposition. Indeed, an overview of nonlinear dynamics can be obtained through these simple examples. Beer (1995) has attempted to exhaustively study the dynamics in the case $n = 2$ and gives a nearly complete overview of the possible types of behavior that can be expected. However, he does miss several interesting examples (Ermentrout, 1998, pp. 371–373). Another more general approach for the analysis of large numbers of coupled systems is to use bifurcation methods that enable one to *reduce* the dimensionality of the resulting equations and then apply techniques such as those used here. While planar systems may seem to be a rather extreme simplification, there is some justification for it. For example, in some local cortical circuits, there is no structure in the connectivity and there are essentially two types of neurons, excitatory and inhibitory. Thus, we can view the simple planar system as representing a population of coupled excitatory and inhibitory neurons. This approach was used successfully to study cortical processing in the rodent somatosensory system (Pinto et al., 1996) and to explain the effects of altering inhibitory interneurons in the hippocampus (Tsodyks et al., 1997).

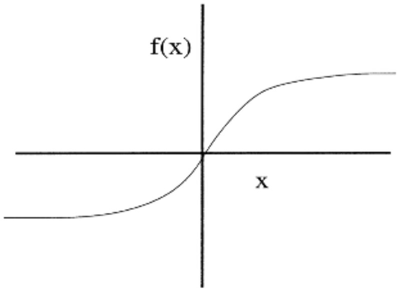

**Figure 1.** Typical nonlinear input-output function of a single model neuron.

The approach of this article is not restricted to neural networks and can be applied to a variety of other systems such as positive-feedback biochemical models (Segel, 1984), activator-inhibitor systems (Edelstein-Keshet, 1988), population and disease models (Murray, 1989), and membrane models of the action potential (Rinzel and Ermentrout, 1998). The techniques are powerful and provide insights into the behavior of these systems that would otherwise only be accessible through simulation. Computational methods are a very powerful adjunct to this type of analysis and, together with the qualitative analysis of this article, enable the researcher to understand his or her system.

In the next section, I will describe a pair of neurons coupled with mutual inhibition and mutual excitation. The penultimate section is devoted to a summary of the rich behavior of an excitatory-inhibitory pair. Finally, some comments on numerical methods and software close the review. In Dynamics and Bifurcation in Neural Nets (q.v.), a systematic analysis of a particular case is given in order to illustrate alternative techniques.

## Two Coupled Cells of the Same Type

In this section, we analyze the behavior of two cells that act via mutual inhibition or mutual excitation. I will use phase-plane analysis to draw a complete picture of the phase space.

### *General Considerations*

Before analyzing the two-component neural network, I will first give a brief description of phase-plane techniques in general. Consider a planar differential equation:

$$x' = f(x, y) \tag{5}$$

$$y' = g(x, y) \tag{6}$$

At each point $(x_0, y_0)$ there is a solution $(x(t), y(t))$ such that $(x(0), y(0)) = (x_0, y_0)$ and such that the tangent to the trajectory is $(f(x(t), y(t)), g(x(t), y(t)))$. Thus, at any point in the plane, one can easily determine the direction of the trajectory by simply evaluating $f$ and $g$ at that point. These directions enable one to paint a qualitative picture of the dynamics of Equations 5 and 6; i.e., I can determine where $x$ and $y$ are increasing and decreasing with time. The most crucial points are those values of $x$ and $y$ at which the direction of the trajectory changes. Thus, setting $f(x, y) = 0$ defines a curve in the plane where $x$ does not change and breaks the plane into regions where $x$ is either increasing or decreasing. This curve is called the *x-nullcline*. The curve $g(x, y) = 0$ defines the *y-nullcline*. The two curves together usually break the plane into regions of four distinct types: (1) $x$ and $y$ are increasing, (2) $x$ and $y$ are decreasing, (3) $x$ increases and $y$ decreases, and (4) $x$ decreases and $y$ increases. The intersection of the two nullclines occurs at points where both $x$ and $y$ are not changing, that is, at *equilibria* or *rest states* of Equations 5 and 6.

The behavior of trajectories away from equilibria is straightforward and is found by simply looking at the signs of $f$ and $g$. Near the equilibria, one can look at the linearization of $(f, g)$ about the equilibrium. This results in a two-by-two matrix called the *Jacobian*:

$$A = \begin{pmatrix} \dfrac{\partial f}{\partial x} & \dfrac{\partial f}{\partial y} \\ \dfrac{\partial g}{\partial x} & \dfrac{\partial g}{\partial y} \end{pmatrix} \equiv \begin{pmatrix} a & b \\ c & d \end{pmatrix} \tag{7}$$

where the partial derivatives are evaluated at the equilibrium. The eigenvalues of $A$ determine the behavior of the equilibria. If they both have negative real parts, the equilibrium is stable, and if any have positive real parts, the equilibrium is unstable. If both are real and of the same sign, the point is called a *node*. Nodes consist of infinitely many trajectories emanating from (unstable) or entering (stable) the equilibrium. If both eigenvalues are complex, the rest state is a *vortex*, and trajectories spiral into (stable) or out of (unstable) the rest point. If the eigenvalues have opposite signs, the rest state is a *saddle point*. Then a single pair of trajectories that define the *stable manifold* or *set* enter the rest point, and a single pair of trajectories, defining the *unstable manifold*, leave the equilibrium. When the determinant of $A$ (i.e., $ad - bc$) is negative, the rest point is a saddle; if it is positive and the trace of $A(a + d)$ is non-zero, the equilibrium is a node or vortex. Cases for which the real part is zero do not persist for small changes in the parameters and often indicate the appearance of new equilibria or periodic solutions. A simple necessary and sufficient criterion for linear stability is that the trace $a + d$ be negative and the determinant of $A$, $ad - bc$, be positive. A complete description of phase-plane methods can be found in Edelstein-Keshet (1988) and in most texts on ordinary differential equations.

### *Crossed Excitatory and Inhibitory Networks*

The first result I want to establish in systems that have mutual coupling of the same sign is that periodic solutions are impossible. Once this is established, then a complete characterization can be made simply by studying the intersections of the nullclines.

*Theorem 1. Suppose that* $w_{21}w_{12} \geq 0$. *Then there are no periodic solutions to*

$$\tau_1 x_1' = -x_1 + f(w_{11}x_1 + w_{12}x_2 + s_1) \tag{8}$$

$$\tau_2 x'_2 = -x_2 + f(w_{21}x_1 + w_{22}x_2 + s_2) \tag{9}$$

As the proof of this theorem was given in the previous edition of the *Handbook* (p. 733, Theorem 1), I will not prove it again here.

All solutions to Equations 8 and 9 are bounded, and Theorem 1 implies that trajectories are monotone, so this means that all solutions tend to equilibria. This in turn means that the time constants can be set to 1 without loss of generality, as the dynamics is completely trivial. The intersections of the nullclines and some observations on the signs of the coefficients in the linearized matrix based on the nullclines allow one to completely determine the number and stability type of the equilibria.

Recall that $f$ is increasing and bounded. Without loss of generality, one can assume that the minimum of $f$ is 0 and the maximum is 1. $f$ is invertible, and the inverse is also monotone, with asymptotes at 0 and 1. The formula for the $x_1$-nullcline is

$$x_2 = (-w_{11}x_1 - s_1 + f^{-1}(x_1))/w_{12} \tag{10}$$

The $x_2$-nullcline satisfies:

$$x_1 = (-w_{22}x_2 - s_2 + f^{-1}(x_2))/w_{21} \tag{11}$$

If $h(x) = (-w_s x - s + f^{-1}(x))/w_c$, then $h$ is monotone if $w_s$ is either positive or small and negative. However, if $w_s$ is large enough, $h$ develops a kink and is "cubic"-shaped (Figure 2*A*). If $w_c$ is positive (mutual excitation) then $h \to -\infty$ as $x \to 0$ and $h \to \infty$ as $x \to 1$ (Figure 2*A*). When $w_c$ is negative (mutual inhibition), the asymptotes are switched (Figure 2*B*). Finally, the stimulus parameter $s$ merely translates the nullclines up and down in the case of the $x_1$-nullcline and left-right for the $x_2$-nullcline. The phase plane is easy to construct with these observations.

In both cases, there can be up to nine different equilibria, and there is always at least one. Figure 3 shows some typical configurations for mutually inhibitory interactions. To assess the stability of the equilibria, one need only look at the positions of the nullclines at the equilibria. Referring to Equation 7, I will use the nullclines to determine the signs and relative magnitudes of the entries

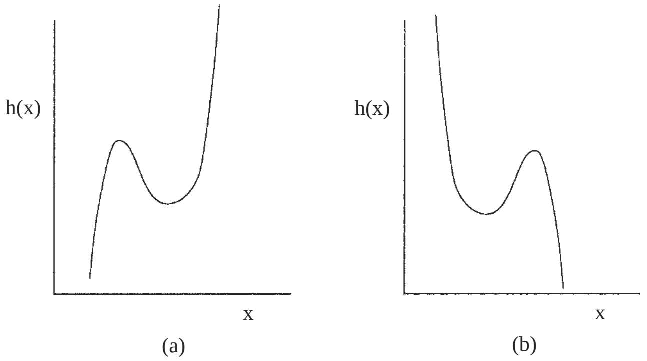

**Figure 2.** Nullcline shape for (*A*) mutual excitation and (*B*) mutual inhibition.

in this matrix. For mutually inhibiting cells, the following are necessary and sufficient for stability:

1. The slope of both nullclines is negative through an equilibrium.
2. The slope of the $x_1$ nullcline is steeper than the $x_2$ nullcline through the equilibrium.

If either of these is violated, the equilibrium is unstable.

For mutually excitatory cells, the conditions for stability are:

1. The slope of both nullclines is positive through an equilibrium.
2. The slope of the $x_1$ nullcline is steeper than the $x_2$ nullcline through the equilibrium.

Tangential intersections are saddle nodes and, as some parameter varies, will lead either to two new equilibria or to the disappearance of the pair. The matrix $A$ has a zero eigenvalue when there are tangential crossings, for then the slopes of the nullclines are the same. That is, $-a/b = -c/d$, so $ad - bc = 0$. A bit of counting shows that when there are nine equilibria, four are stable nodes, four are saddle points, and one is an unstable node. As the parameters vary, a pair of equilibria is lost, a saddle point and either a stable node or the unstable node, leaving seven equilibria. Further losses of equilibria (or gains, up to a maximum of nine) are obtained as the parameters vary, ending in the minimum of a single globally stable equilibrium.

When there are several stable equilibria, it is important to determine what initial conditions lead to which of the equilibria. The set of all initial data that tend to a particular equilibrium point is called the *domain of attraction* of the equilibrium point. For the present networks, this is very easy to determine geometrically. Figure 3 depicts a network of mutually inhibitory cells that has five equilibria (labeled *a*–*e*). The above discussion allows one to conclude that *a*, *c*, and *e* are stable nodes and *b* and *d* are saddle points. Each saddle point has associated with it one positive eigenvalue and one negative eigenvalue. Corresponding to this negative eigenvalue is the stable manifold for the saddle point. It consists of the set of all initial conditions that tend to the equilibrium point as $t \to \infty$. For two-dimensional neural nets, this is a one-dimensional set and is then often called a *separatrix*. I have drawn it for each of the two saddle points in Figure 3 as the dashed lines pointing into *b* and *d*. These curves divide the two-dimensional plane into three regions, which I have labeled *A*, *C*, and *E*. All initial data in *A* tend to equilibrium point *a*, and so on. Thus, although the saddle points are unstable, their stable manifolds provide the boundaries that determine the final states of the network given the initial state. From this description the reader should be able to construct complete qualitative pictures for other configurations of the nullclines for mutually excitatory or inhibitory nets.

Summarizing, I have used phase-plane analysis to show that for a pair of coupled neurons with mutual excitation or inhibition, the only stable solutions are equilibria. The stable manifolds of the saddle points divide the plane into domains of attraction for each of the stable equilibria. All equilibria are approached monotonically, and there can be up to four stable steady states.

## A Pair of Excitatory and Inhibitory Cells

In many regions of cortex, and in fact throughout the central nervous system, many of the coupled excitatory and inhibitory cells

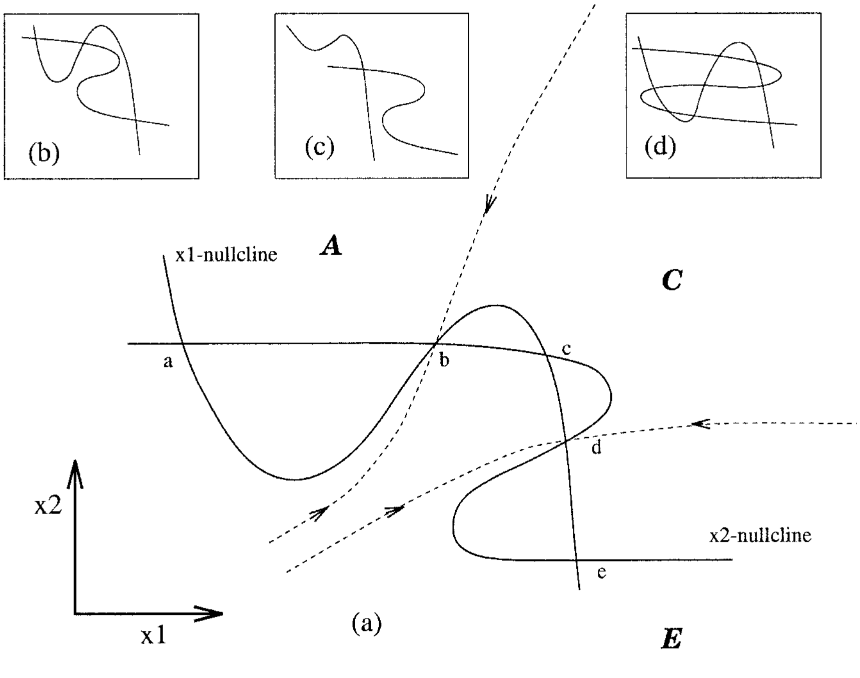

**Figure 3.** Phase plane for two mutually inhibitory neurons. Nullclines are solid lines and the stable manifolds of the saddle points *b* and *d* are shown dashed. *a*, *c*, and *e*, are stable nodes with domains of attraction *A*, *C*, and *E*, respectively. Insets show other some other possible nullcline configurations.

constitute a local neural network. These networks have been the subject of numerous mathematical and computational investigations (Wilson and Cowan, 1972; Ellias and Grossberg, 1975; Ermentrout and Cowan, 1979; Beer, 1995; Pinto et al., 1996). One can view such systems either as two neurons acting in isolation (a difficult experiment to imagine) or, more reasonably, as a two-layer network with spatially homogeneous activity. Then each component is the activity of a *pool* of cells rather than the activity of a single cell.

I will consider a network of the form:

$$x_1' = -x_1 + f(w_{11}x_1 - w_{12}x_2 + s_1) \tag{12}$$

$$x_2' = (-x_2 + f(w_{21}x_1 - w_{22}x_2 + s_2))/\tau \tag{13}$$

where all of the weights are non-negative. I have introduced a time constant for the inhibitory neurons because one cannot expect them to have the same temporal behavior as the excitatory cells. The Jacobian matrix $A = [\partial x_i'/\partial x_j]$ at an equilibrium point $(\bar{x}_1, \bar{x}_2)$ has coefficients:

$$a = -1 + w_{11}f'(w_{11}\bar{x}_1 - w_{12}\bar{x}_2 + s_1) \tag{14}$$

$$b = -w_{12}f'(w_{11}\bar{x}_1 - w_{12}\bar{x}_2 + s_1) < 0 \tag{15}$$

$$c = (w_{21}f'(w_{21}\bar{x}_1 - w_{22}\bar{x}_2 + s_2))/\tau > 0 \tag{16}$$

$$d = (-1 - w_{22}f'(w_{21}\bar{x}_1 - w_{22}\bar{x}_2 + s_2))/\tau < 0 \tag{17}$$

It is clear that all of the coefficients except for $a$ have a fixed sign independent of the parameters. If $w_{11}f' > 1$, then $a > 0$, and the system is called an *activator-inhibitor* system, since $x_1$ activates both itself and $x_2$, while $x_2$ inhibits everything to which it connects. Activator-inhibitor models occur ubiquitously in biology, and their dynamics is rich and varied (see, e.g., PATTERN FORMATION, BIOLOGICAL). Oscillations, excitability, and multiple steady states are among the possible behaviors of these networks. Since a very complete analysis of these systems as applied to neural excitation is given in Rinzel and Ermentrout (1998), I only sketch some of the dynamic behavior possible for this network.

The qualitative behavior of any planar model can be understood by combining nullcline analysis with local stability analysis of the equilibria, which depends on the coefficients of the Jacobian $A$. The neural model studied in Rinzel and Ermentrout (1998) has exactly the same nullcline structure and has a Jacobian matrix with the same structure as the neural net model. Hence, I will only outline the dynamics of this system; details can be extracted from the aforementioned article.

It is instructive to first consider the effects of parameters on the shapes of the nullclines. A typical nullcline configuration is shown in Figure 4 for Equations 12 and 13. The $x_2$-nullcline is always monotonically increasing; $w_{21}$ sharpens it, while $w_{22}$ makes it shallower and $s_2$ shifts it left and right. As described earlier, the effect of $w_{11}$ is to kink the $x_1$-nullcline, while $w_{12}$ makes it less kinked; $s_1$ shifts it up and down. Finally, the parameter $\tau$ has no effect on the nullclines but dramatically alters the dynamics and stability of the equilibria. Changing $\tau$ has no effect on the determinant of $A$ (so a saddle point cannot become a node), but it can switch the sign of the trace of $A$ and so change a point from a stable node to an unstable node.

The positions of the nullclines make it clear that there can be up to five equilibria and at least one equilibrium point. Furthermore, all equilibria that occur on the "unkinked" part of the $x_1$-nullcline are necessarily asymptotically stable, since then $a < 0$ in Equation 14. Thus, the trace, $a + d < 0$, and the determinant, $ad - bc > 0$. If $w_{11}$ is sufficiently small so that the $x_1$-nullcline is monotone, then there is only one equilibrium point, and it is globally stable. This statement follows from the facts that all solutions are bounded and from application of Bendixson's negative criterion (Edelstein-Keshet, 1988), which eliminates periodic orbits when $a + d < 0$. Any time the inhibitory nullcline has a lesser slope than the excitatory nullcline, the equilibrium is a saddle point. These considerations, along with the preceding discussion, show how the parameters affect the local existence and stability of various rest states. The global dynamics is much more complicated since one cannot eliminate the possibility of limit cycle solutions.

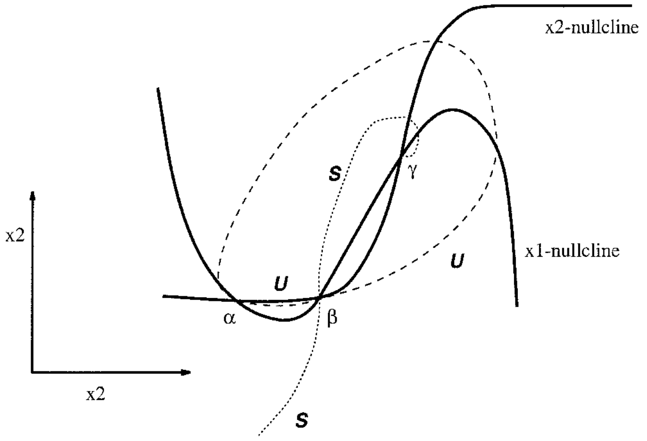

**Figure 4.** Typical phase plane for an excitatory-inhibitory pair. Nullclines and a typical trajectory are shown. There is a unique globally attracting equilibrium point.

## *Excitability*

One important difference between networks consisting of one excitatory and one inhibitory layer and the networks described earlier in this article is the possibility of excitable dynamics. As was shown earlier, trajectories of the activity of cells are necessarily monotone. Thus, if, say, $x_1$ is increasing, then it can never decrease again. However, in mixed networks, no such restriction occurs, and it is possible for $x_1$ to initially increase before decreasing again. In particular, a network is said to be *excitable* if there is a *unique globally stable* rest state with the following property: Small perturbations from rest decay monotonically back to rest, but perturbations larger than some *threshold* continue to grow before decaying back to the stable rest state (Figure 5). There are at least two qualitatively different types of excitability for networks with the present structure. In type I excitability there are three equilibria, while in type II there is one. These two cases are described in Rinzel and Ermentrout (1998). In the context of neural networks, this type of behavior has been called an *active transient*. It can be viewed

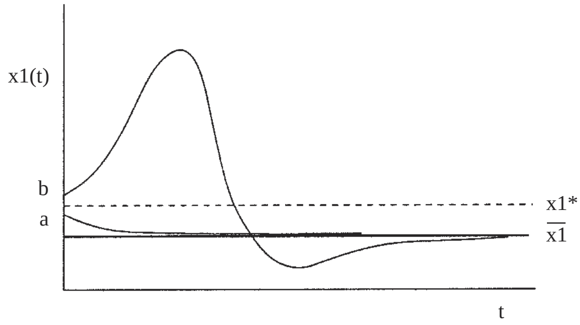

**Figure 5.** Excitable dynamics. $\bar{x}_1$ is the globally stable rest state and $x_1^*$ is the threshold. Trajectory $a$ is subthreshold and $b$ is superthreshold.

as a transient excitatory activity due to a stimulus that is eventually quelled by the inhibitory interneuronal feedback.

### *Periodic Solutions*

Periodic solutions occur generally (although not strictly) when there is a single rest state on the middle branch and it is unstable. This point must necessarily be a node, and the boundedness of solutions thus implies that a limit cycle exists. If some parameter (say $\tau$) is varied in such a way as to make the unique equilibrium go from a stable point to an unstable point (without introducing any new rest states), then a *Andronov-Hopf bifurcation* generically occurs, and this implies that a periodic solution exists near the rest state. For planar systems, easily checked necessary conditions for an Andronov-Hopf bifurcation are that the determinant of $A$ remain positive and the trace change from negative to positive as the parameter is varied. If this new limit cycle is unstable, then there can be regimens in parameter space where there are two stable behaviors: (1) a stable rest state and (2) a stable *large-amplitude* periodic solution (Figure 6). This is known as *bistability*.

### *Other Behavior*

In addition to excitability, multiple equilibria, oscillations, and bistability, other types of dynamic behavior can be found in these simple models. Infinite period oscillations and homoclinic trajectories can be obtained in some parameter regimens. (A *homoclinic* trajectory is one that leaves a saddle point from one side and enters it from another, and can occur as the period of a limit cycle tends to infinity.) Homoclinics are important because they separate qualitatively different types of behavior. Furthermore, when one periodically stimulates a system with homoclinics, it is possible to obtain a complex irregular behavior called *chaos* that cannot occur in planar systems without forcing (see Guckenheimer and Holmes, 1983.)

There are many other pictures possible with this simple model and I urge the reader to explore the phase-plane dynamics of this excitatory inhibitory net. Phase-plane methods provide a powerful analytic and qualitative tool for studying small neural networks. When combined with sophisticated numerical tools, a complete understanding of the global dynamics is possible.

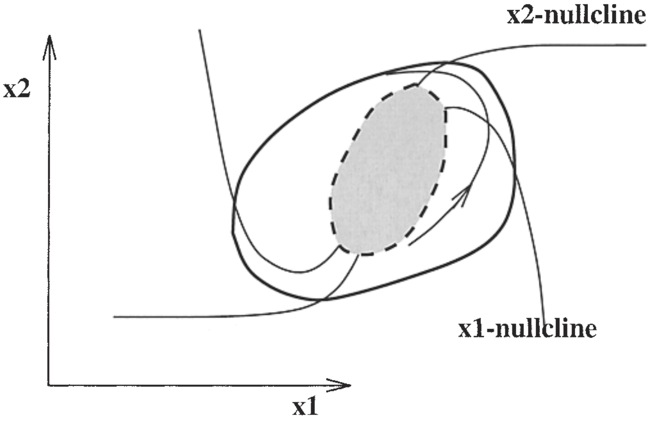

**Figure 6.** Phase plane for bistable regimen of parameters. Nullclines are shown, as is the stable periodic orbit (dark line), the unstable periodic orbit (dashed line), and representative trajectories (thin lines). The gray area denotes the domain of attraction for the fixed point. The rest of the plane is attracted to the stable periodic orbit.

In systems with more than two components, it is difficult to make any general comments on behavior. For symmetrically coupled networks with no self-connections, a complete analysis can be given (Hopfield, 1982). Weakly coupled systems of intrinsically oscillatory networks can be analyzed with the techniques described in Chains of Oscillators in Motor and Sensory Systems. Bifurcation methods and averaging techniques can often be used to reduce higher-dimensional systems to a simpler set of equations that is in a much lower dimension (see Hoppensteadt and Izhikevich, 1997; see also Canonical Neural Models).

## Numerical Methods

The computer is a valuable adjunct in the exploration of systems of differential equations. For this article, I have used a program called XPPAUT that is available for both Windows 95/NT/98 computers (Winpp) and Unix workstations. Both are available through http://www.pitt.edu/~phase. To get *global* pictures of the dynamics as one or two parameters are varied, a powerful numerical package written by Doedel et al. (1997) called AUTO can be used. A version is available at http://indy.cs.concordia.ca/auto/.

# Philosophical Issues in Brain Theory and Connectionism

*Andy Clark and Chris Eliasmith*

## Introduction

In this article, we highlight three questions: (1) Does human cognition rely on structured internal representations? (2) How should theories, models, and data relate? (3) In what ways might embodiment, action, and dynamics matter for understanding the mind and the brain?

The first question concerns a fundamental assumption of most researchers who theorize about the brain. Do neural systems exploit classical compositional and systematic representations, distributed representations, or no representations at all? The question is not easily answered. Connectionism, for example, has been criticized for both holding and challenging representational views. The second question concerns the crucial methodological issue of how results emerging from the various brain sciences can help to constrain cognitive scientific models. Finally, the third question focuses attention on a major challenge to contemporary cognitive science: the challenge of understanding the mind as a controller of embodied and environmentally embedded action.

## Does Cognition Need Representations?

This question is the most difficult and least well defined of our three questions. But it addresses one of the most philosophically interesting features of many connectionist models, especially those most closely related to brain theory. The intuition is that connectionism poses a challenge to the classical view of the brain as a syntax-sensitive engine. This idea involves depicting all or most of human cognition as involving something akin to logical operations applied to something akin to linguistic (sentential) structures. The prime philosophical exponent of the identification of genuine cognitive processes with such operations on quasi-sentential entities is Fodor (see Fodor, 1987; Fodor and Pylyshyn, 1988). Fodor argues in favor of an innate symbolic code (the *language of thought*) and mental processes involving operations defined over the syntactically structured strings of that code. The underlying image is of an inner economy in which symbol strings are operated on by procedures sensitive to the structure of the string.

In contrast, a typical trained-up network does not employ grammatical strings or, a fortiori, processing operations sensitive to the structure of such strings. Instead, we find prototypical complexes of properties represented in a high-dimensional space (see Churchland, 1995). The space is highly organized in the sense that data items that need to be treated in closely related ways become encoded in neighboring regions of the space. It is this *semantic metric* that allows the network to generalize and to respond well under conditions of noise, for example. But this organization of the encoded knowledge does not amount to the provision of a genuine syntax. One way to see this difference is to ask what rules of combination of represented elements apply, and in what systematic ways we can operate on complexes of represented items. As Fodor and Pylyshyn (1988) point out, there is no analog in distributed representations for the logical operations of detaching an element from one string (complex representation) and adding it to another.

Nevertheless, a variety of connectionist techniques have been developed to allow for structure-sensitive processing, but such techniques have been described (van Gelder, 1990) as providing *functional*, as opposed to *concatenative*, compositional structure. A complex representation has concatenative structure if it embeds the individual constitutive elements unaltered within it. It has functional compositional structure if such components are usable or retrievable, but the complex expression does not itself embed unaltered tokens of these parts. Most connectionist schemes for dealing with compositional structure are functionally compositional (e.g., RAAM architectures, tensor product encodings, holographic reduced representations [HRRs]), although synchrony binding is concatenative. (For a review, see CONNECTIONIST AND SYMBOLIC REPRESENTATIONS.) Of these, HRRs are perhaps best suited to bridging the traditional gap between connectionist and symbolicist approaches to understanding language-like processing. HRRs are supremely structure sensitive, do not suffer from the dimensional increases of tensor products, and can be implemented in standard connectionist networks, yet they are not concatenative (Eliasmith and Thagard, 2001).

In our opinion, a major benefit of exploring the space of connectionist cognitive models is that it may help us expand our sense of the possible nature of internal representation and hence better understand what is truly essential to notions such as *structure, syntax*, and *complex representation*. Doing so, we may discover which aspects of our models are simply artifacts of our (over)familiarity with one representational format, viz., the format of atomic elements and grammar common to language and logic.

## How Do Theories, Models, and Data Relate?

As a computational formalism, connectionism is quite powerful, allowing us to approximate nearly any function or performance profile that we desire. However, the mere fact that some input-output pattern $P$ is found in human cognition and can be mimicked using some connectionist model is, in itself, of only marginal psychological interest. The demands of cognitive science, unlike those of artificial intelligence, require more. Ideally, we must provide models that are both consistent with neurological data and comprehensible. However, the relation between data and models is not unidirectional. Models are constrained by data, but they also help us determine what sorts of experiments to use in looking for more relevant details. The role of theory in unifying the brain sciences and connectionism is an important but (for the time being) mysterious one (but see Eliasmith and Anderson, 2002, chap. 1, for one possibility).

The data that constrain models come largely from two sources: higher levels (i.e., from the mind "down") from work in disciplines such as psychology and psycholinguistics, and lower levels (i.e., from the neuron "up"), from work in neuroscience and brain theory with behavior as the meeting ground for these diverse approaches. From psychology and psycholinguistics we can extract vast bodies of constraining data that go far beyond the mere specification of a task-specific input-output mapping. Such data can concern, for example, the relative difficulty of parsing certain sentences or solving certain problems, the time course of problem solving, the developmental profile of skill acquisition, and the way in which new and old knowledge interact in the context of new learning (for detailed examples, see Karmiloff-Smith, 1992; see also DEVELOPMENTAL DISORDERS).

For current purposes, however, it is the lower-level constraints that we seek to highlight. The question here concerns the proper relation between connectionist-computational modeling and the detailed constraints emerging from the various brain sciences. Such sciences include neuroanatomy, neurochemistry, lesion studies, and research at the single-cell, circuit, and systems level. It seems clear that any acceptable model of human information processing must respect the results of such studies. To do so, some intelligible relation must exist between the theories put forward by, for example, connectionist-computational modeling and the entities and lawful interactions studied by the brain sciences. It is a duty sadly neglected by both classical artificial intelligence and a great deal of connectionist work to make some effort to display the precise nature of such relations.

Such a task is complicated by the variety of levels of interest that may characterize the brain sciences. These include the levels of biochemical specification: single cells, circuits, subsystems, and networks of subsystems. Marr's suggestion that studies at each level can be independently pursued is highly dubious. Our top-level decomposition of a task into subtasks appropriate for computational modeling may be challenged once we become familiar with the distribution of information-processing resources in the brain. What we originally thought of as two distinct functions may actually share circuitry in the brain (see Arbib, 1989). Such a result will not be devoid of psychological significance, since it will figure in an explanation of the breakdown profile as revealed by, for example, lesion studies of the system.

How, then, should we conceive the bridge between idealized artificial intelligence models and brain theory? It is precisely the complex relations between implementation and function that have spawned a recent surge of interest in computational neuroscience. With the explicit goal of taking biological constraints as seriously as computational ones, computational neuroscience has begun to explore a vast range of realistic neural models. For example, Reike et al. (1997) provide an information-theoretic analysis of spike trains, allowing accurate stimulus signal reconstruction. The combination of such spike train analyses and, for example, Abbott's higher-level discussions of basis function representations can provide valuable insights into the functioning of populations of neurons (see Eliasmith and Anderson, 2002). Though preliminary, the tools developed by such research are promising candidates for generating biologically realistic connectionist models.

Such models should prove useful in providing constraints of their own. Insights from basis function analyses suggest new experiments for neurophysiologists. In particular, it seems that neurons may have higher-dimensional tuning profiles than previously imagined. Although neurological techniques for determining complex profiles have yet to be perfected, connectionist modeling suggests that such tuning properties are important to the everyday functioning of neurons. So, not only does biology inform the construction of computational models, but, ideally, those same models can help suggest important experiments for neuroscientists to perform. In this sense, models and data can be mutually beneficial. Of course, the benefits are highly constrained by assumptions of both the model and the experimental design.

Although no model can be expected to do justice to all aspects of its target, what justice it can do depends on the biological realism of the assumptions behind the model. Biological realism, of course, can be incorporated into a model in many ways, such as by including neurochemical diffusion, single neuron morphology, spike train statistics, neuroanatomical constraints, population dynamics, or system-level organization (see Eliasmith and Anderson, 2002, for examples). In any case, what we can and should expect from a modeler is a clear statement of what aspects of the target phenomenon are supposed to be explained, and (if it is a computational model) at what level the computational story is intended to capture real neurophysiological facts. Successful attempts to exploit the close relation between experiment and model are still something of a rareity. This is largely because theoreticians (typically mathematicians, physicists, and engineers) and experimentalists (typically neuroscientists and biologists) do not yet have many conceptual tools in common. In order to reap the benefits of mutual, interlevel constraint, this will likely have to be rectified.

## In What Ways Might Embodiment Matter for Understanding the Mind and the Brain?

In recent years, an important challenge has been issued to cognitive science. It stems from the work of researchers espousing the *dynamicist hypothesis* (van Gelder, 1995). The dynamicist commitment to making time central to cognitive modeling is inspired by the broader realization that cognitive systems are real physical systems acting in the real world in real time. Given the finite, though vast, computational resources of the brain, it also seems that evolution has often off-loaded complex computational tasks to the body and to the environment. This double "situatedness" of cognitive systems needs to be reckoned with if we are to develop an accurate picture of precisely the kinds of computation neural systems perform. Connectionism and brain theory must conspire to explain this kind of representational and computational economy. Thus, while looking *inside* to the brain and the results of neuroscience, we can not afford to turn a blind eye to constraints and resources that come from the *outside*, from the gross body and environment of a cognitive system (Clark, 1997).

Consider vision. There is now a growing body of work devoted to so-called animate vision (Ballard, 1991). The key insight here is that the task of vision is not to build rich inner models of a surrounding three-dimensional reality, but rather to use visual information efficiently and cheaply in the service of real-world, real-time action. Animate vision thus rejects Marr's analysis, what Churchland et al. nicely dub the paradigm of "pure vision"—the idea (associated with work in classical AI and in the use of vision for planning) that vision is largely a means of creating a world model rich enough to let us "throw the world away," targeting reason and thought to the inner model instead. Real-world action, in these "pure vision" paradigms, functions merely as a means of implementing solutions arrived at by pure cognition.

The animate vision paradigm, by contrast, gives action a starring role. Computational economy and temporal efficiency are purchased by a variety of bodily actions and local environment–exploiting tricks and ploys, including

- the use of cheap, easy-to-detect (possibly idiosyncratic) environmental cues (e.g., searching for Kodak film in a drug store: Seek "Kodak yellow");
- the use of active sensing (e.g., use motor action, guided by rough perceptual analysis, to seek further inputs yielding *better* perceptual data—move head and eyes for better depth perception, etc.); and
- the use of repeated consultations of the world in place of rich, detailed inner models.

Ballard et al. (1997) have recently demonstrated that subjects do not bind color and location information in a block-copying task until it is absolutely required by current problem solving. As a result, changes made to the display (such as switching the color of blocks during a saccade) are very often undetected.

Vision, this body of work suggests, is a highly active and intelligent process. It is not the passive creation of a rich inner model so much as the active retrieval (typically by moving the high-resolution fovea in a saccade) of useful information *as it is needed* from the constantly present real-world scene. Ballard et al. speak of "just-in-time representation," while the roboticist Rodney Brooks coined the phrase, "The world is its own best model" (Brooks, 1991). The combined moral is clear: Vision makes the most of the persisting external scene, and gears its computational activity closely and sparingly to the task at hand.

The general thrust of the animate vision research program, however, is not to reject the ideas of internal models and representations so much as to reconfigure them in a sparser and more interactive image. We thus read of inner databases that associate objects (such as car keys) and locations (on the kitchen table) of internal feature representations, of indexical representations, and so on. What is being rejected is not the notion of inner content-bearing states per se, but only the much stronger notion of rich, memory-intensive, all-purpose forms of internal representation.

The crucial distinction, it seems to us, is thus not between representational and nonrepresentational solutions so much as between rich and action-neutral forms of internal representation (which may increase flexibility but require additional computational work to specify a behavioral response) and sparse and action-oriented forms (which exploit the body and world and which begin to build the response into the representation itself).

## Discussion

Our vision of basic biological reason is changing rapidly. There is a growing emphasis on the computational economies afforded by real-world action, and an increasing appreciation of the way larger structures (of agent and artifacts) both scaffold and transform the shape of individual reason. These twin forces converge on a rather more minimalist account of individual cognitive processing, an account that tends to eschew rich, all-purpose internal models and sentential forms of internal representations. Such minimalism, however, has its limits. Despite some ambitious arguments, there is currently no reason to doubt the guiding vision of individual agents as loci of internal representations and the individual agents as users of a variety of inner models. Rather than opposing representationalism against interactive dynamics, we should be embracing a broader vision of the inner representational resources themselves.

The sciences of the mind are thus in a state of productive flux, the product of multiple converging influences coming from real-world robotics, systems-level neuroscience, cognitive psychology, evolutionary theory, AI, and philosophical analysis. This flux has forced us to reconsider earlier accounts of the relation between theory, models, and data relevant to cognitive systems. More important, we can see a new vision of mind emerging. The point at which many of these influences currently converge is captured by seeing mind as in essence a controller of embodied and environmentally embedded action. Mind is an organ for orchestrating real-time responses to a real world.

One major player in these recent events has been the explosion of work on artificial neural networks (ANNs). Such networks amounted to an existence proof of the possibility of adaptive intelligent behavior without reliance on explicitly formulated rules or language-like data structures. Moreover, the networks integrated representation and action in a very direct manner: knowledge became encoded in a form dictated by its use in a particular type of problem solving. But the neural networks revolution was incomplete. It was incomplete because it was still burdened with much of the unnecessary baggage of the previous, disembodied, symbol-crunching approach to understanding cognition. Mind was still treated as an essentially timeless locus of abstract problem-solving capacities.

All this changed with the surge of interest, in the late 1980s and early 1990s, in what became known as autonomous agent research (see, e.g., essays in Beer, Ritzmann, and McKenna, 1993). This research aimed to model and understand the adaptive success of single, complete, embodied systems: insects that walk and seek food, the cockroach's amazingly sophisticated mechanisms for detecting and evading attackers, robots that learn to swing from branch to branch using real mechanical arms, and many other kinds of systems. Many of these models exploit ANNs as control systems. But the constraints on success became very different.

Finally, the constraints on computation using ANNs are very different from the constraints on real biological computation. It is here that the relation among theory, model, and data again becomes pivotal. Interestingly, reconceptualizing mind in each of these previous cases has depended on rethinking the relevant constraints (i.e., linguistic versus nonlinguistic symbols, partial versus full-bodied systems). Introducing the complexities of natural neural computation is bound to have a similar impact on our concept of mind.

Many important questions remain open. Can work in ANNs come to grips with the real complexity of biological computation? What kinds of systems-level models can help make sense of the complex balance between specialization and cooperation that we find in real brains? Can a representation-sparse approach make headway with all aspects of human cognition, or is it limited to cases of perceptuomotor control and on-line reasoning? How does the command of public language impact and transform human thought and reason?

The cognitive science of the biological, embodied mind is still in its infancy, and the full power and scope of the new vision remain to be determined. But the issues raised will, we believe, shape the agenda of the next decade of research into mind and its place in nature.

# Photonic Implementations of Neurobiologically Inspired Networks

*B. Keith Jenkins and Armand R. Tanguay, Jr.*

## Introduction

Technological implementations of neural networks in both software and hardware forms have been largely motivated by biological neural networks, but also include network topologies, synaptic interconnection rules, and neuron unit functionalities that combine to yield novel system-level properties. Software implementations of such networks are highly flexible in design and reconfiguration but are time-, power-, and computational-resource-consumptive for even modest numbers of neuron units and interconnections. Neural network implementations in both electronic and photonic hardware are designed to circumvent these limitations in applications that require compact systems, low latencies, and high computational throughputs.

In VLSI-based neural networks (Mead, 1989), the neuron units and weighted (synaptic) interconnections are incorporated on one or more planar microelectronic chips (see NEUROMORPHIC VLSI CIRCUITS AND SYSTEMS; ANALOG VLSI IMPLEMENTATIONS OF NEURAL NETWORKS; DIGITAL VLSI FOR NEURAL NETWORKS; SILICON NEURONS). An important advantage of this approach is the capability for near-term technology insertion, with leverage provided by a well-established technology base. An equally important limitation, however, is the difficulty of scaling up or interconnecting multiple neural chips to incorporate large numbers of neuron units in highly interconnected architectures without significantly increasing the computational time. This inherent trade-off derives from the limited pin counts, off-chip communication bandwidths, and on-chip interconnection densities available in both current generation and projected chip designs.

In this article we consider the photonic implementation of neurobiologically inspired networks, in which optical (free-space or through-substrate) techniques are utilized to enable an increase in the number of neuron units and the interconnection complexity by using the off-chip (third) dimension (Jenkins and Tanguay, 1992; Wagner and Psaltis, 1993; Jutamulia, 1994). This merging of optical and photonic devices with electronic circuitry provides additional features such as parallel weight implementation, adaptation, and modular scalability.

## General Principles Extracted from Biological Systems

In this section, we discuss the key general principles that can be extracted from neurobiological systems and then crafted in hybrid electronic/photonic form, a base technology substrate that exhibits wide-ranging differences with respect to human wetware (Hubel, 1988). Although the discussion below is framed within the human visual system (retina through early visual cortex), these architectural principles apply throughout the mammalian brain to a large extent, and can potentially be used to advantage in biologically inspired neural systems.

Biological vision systems exhibit a number of common themes that have pertinence to hardware implementations, including (1) a propensity for layering of the processing architecture (Wandell, 1995), (2) the employment of massive parallelism with simple local processing units and minimal local storage within each processing unit, (3) the use of a multiplicity of neuron unit types and associated fan-out and fan-in patterns, (4) the incorporation of dense synaptic/dendritic interconnections at all scales (from local to global, among multiple brain regions) with a high degree of fan-out and fan-in at each processing node, (5) adaptivity on multiple time scales as exhibited by both short- and long-term plasticity, (6) distributed storage of information, and (7) an associative memory organizational construct.

Although many of these themes can be individually incorporated into hardware implementations using existing technology, to our knowledge no implementation has included all of these themes together using a single technology base. Primate visual systems, for example, use several types of photoreceptors and neurons at the lowest levels of vision processing, with primarily local, fixed, and weighted interconnections among multiple layers within the retina (Dowling, 1992). The photoreceptors are densely packed, ranging from about 1–3 × $10^7$ cm$^{-2}$ in the fovea (1-$\mu$m-diameter cones) to 4 × $10^6$ cm$^{-2}$ in the periphery, with a mixture of 4- to 10-$\mu$m-diameter cones separated by a much higher density of 1-$\mu$m-diameter rods (Wandell, 1995). This density can be instructively compared with the current pixel densities of solid-state imaging sensor arrays (including focal plane arrays in the visible, infrared, and ultraviolet frequencies; CCD arrays; and active pixel sensor (APS) arrays), which range from about 1 × $10^6$ cm$^{-2}$ to 4 × $10^6$ cm$^{-2}$. Current smart pixel arrays have not yet achieved even these densities because of the incorporation of local processing circuitry within each pixel.

The biological propensity for incorporation of dense interconnections is evident within the retina and the lateral geniculate nucleus, and extends into the lowest levels of the visual cortex. Throughout, the interconnection mappings tend to be local, highly regular (retinotopic), and only partially adaptive. Higher up the processing stream (within the primate visual cortex), interconnections tend to become gradually less local, less regular, and more adaptive, with a degree of interconnectivity (fan-out from and fan-in to a given neuron) that is typically $10^3$ to $10^4$ (Hubel, 1988; Dowling, 1992; Wandell, 1995).

The biological imperative for layering is also of considerable interest to examine further. In primate visual systems, layering accomplishes a number of computationally important functions. (1) Layering provides a convenient mechanism for the implementation of multiple concatenated operations comprising nonlinearities and weighted fan-out/fan-in functions. The latter operation can be viewed as the convolution of a 2D input function with a set of 2D kernels (weighting functions), and provides the basis for implementing both space-invariant and space-variant operations across multiple spatial scales. The separation of a given complex operation into several sequential steps of nonlinearity/convolution also allows access to intermediate scale results for both feedforward and feedback connections that project beyond intervening layers, as observed throughout biological vision systems. (2) Layering also provides for the implementation of higher-order complexity (hierarchical) operations that can be derived from simple primitives implemented over multiple spatial scales. (3) Layering naturally provides for the hierarchical buildup of the size of the receptive field, so that nonlocal operations such as contrast enhancement and color constancy can be implemented with invariance to object size. (4) Finally, layering carries with it the potential for increased algorithmic efficiency, in that certain operations (e.g., even certain linearly decomposable convolutions at a given kernel size) can be performed in multiple layers with less cost in computational resources (e.g., fan-out from neurons via axons, synapses, and dendrites; total number of equivalent primitive operations; computational energy).

## The Holographic Paradigm

With these general principles in mind, in this section we consider the potential implementation of neurobiologically inspired networks based on the holographic recording and readout of weighted interconnection patterns. In volume holography, the storage of a set of recorded holographic images in a volume holographic optical element by means of the coherent interference between a set of image-bearing signal beams and a corresponding set of reference beams (multiplexed in angle, wavelength, or position) can also be thought of as the storage of a set of weighted interconnection patterns; each input pixel (picture element) in a given reference beam is connected to a given output pixel in the reconstructed image with a weight (diffraction efficiency) that governs the brightness or intensity of the reconstructed pixel. Sets of weighted interconnection patterns can be read out in parallel to form multiple inputs to each output pixel, providing a dense interconnection network with a high degree of fan-out from each reference beam pixel and fan-in to each output image pixel.

The storage of such weighted interconnection patterns in volume holographic optical elements exhibits a number of characteristics that are similar to characteristics observed in the neurobiological processes of memory and learning as well as in many neural networks (Pribram, 1991). For example, the information (memory) associated with the set of holographically stored weighted interconnection patterns is distributed over a significant portion of the volume hologram; such distributed memory storage is also characteristic of neural networks. Holographically stored weighted interconnection patterns can implement dense interconnections at all scales from local to global, and can exhibit degrees of fan-out and fan-in from unity (a point-to-point connection) to upward of $10^3$ or $10^4$. Recall of such stored patterns can be configured in many ways, including both retinotopic-like (highly structured) and associative-memory-like mappings, and can provide for both feedforward and feedback connections, depending on the specific network architecture.

If appropriate real-time recording and readout materials are employed, such as photorefractive crystals or polymers, the interconnection weights can be updated by means of holographic recording principles, so that weight updates analogous to those characteristic of adaptivity and learning in certain neural network models can be performed. These weights will typically decay with time (and also with multiple exposures), suggestive of short-term memory. In many such real-time materials, the capability exists to “fix” all or part of the recorded interconnection patterns, thereby greatly extending the storage time, suggestive in turn of long (or at least longer) term memory. In addition, the properties of real-time holographic recording lead naturally to the incorporation of a dependence for weight updates on temporal correlations between the signal and reference beams (as derived, for example, from two temporally correlated neuron units).

In the following sections, we describe several approaches for implementing photonic neurobiologically inspired networks. All such architectures incorporate dense fan-out/fan-in interconnections but range in the type and degree of connectivity from compact photonic multichip modules with local interconnections between layers to photonic neural networks that incorporate global holographic interconnections. Descriptions of the various photonic components that comprise such architectures can be found in the previous edition of the *Handbook* (Jenkins and Tanguay, 1995).

## Compact Photonic Multichip Modules for Layered Networks

A conceptual diagram of one possible three-dimensional (3D) integrated electronic/photonic multichip module (PMCM) structure is shown in Figure 1 (Veldkamp, 1993; Tanguay et al., 2000; Tanguay and Jenkins, 2002). Multiple layers of pixellated silicon VLSI chips (chips that are divided into arrays of nearly identical functional regions) are densely interconnected by a combination of electronic, optical, and photonic devices to produce either a space-invariant or space-variant degree of fan-out and fan-in to each individual pixel (neuron unit, or processing node). These weighted fan-out/fan-in interconnections are suggestive of the axonal projections, synapses, and dendritic tree structures that characterize biological organisms. The use of optical and photonic devices in particular allows for the implementation of these interconnections *between* adjacent physical layers within the stack of chips. In addition, the use of silicon VLSI for neuron units or processing elements allows considerable flexibility in the neuron model or neuron-unit function implemented.

In one such implementation (Tanguay et al., 2000; Tanguay and Jenkins, 2002), shown schematically in Figure 2, two-dimensional (2D) arrays of bottom-emitting vertical-cavity surface-emitting lasers (VCSELs) fabricated on a gallium arsenide (GaAs) substrate provide optical outputs from a given integrated layer of the structure. These VCSEL arrays are flip-chip bonded on a pixel-by-pixel basis to the silicon VLSI chips, which typically incorporate local optical detectors (for optical inputs from the previous layer) and electronics comprising processing elements (either acting alone or in concert with electrical inputs from nearest and next-nearest neighbors within the plane), memory elements (in the analog or digital domain), and VCSEL drivers. Proximity-coupled diffractive optical element (DOE) arrays, designed to incorporate both focal power (lens) and weighted fan-out functions, are used to establish interconnections that are modulated (temporally varied) in intensity by each individual VCSEL element and its associated silicon driver circuit. Alternatively, separate concatenated DOE and microlens arrays can be used.

Other implementations of compact photonic multichip modules include a similar 3D stacked structure using a different materials system and an array of one-to-one (digital) photonic interconnections between adjacent chips (Bond et al., 1999); and a set of

chips laid out on a planar substrate, with neural network interconnections implemented in the third dimension using photonics (Fey et al., 2000).

For the specific case of adaptive vision sensors, the design of the individual silicon VLSI chips, and in particular the use of spatiotemporal multiplexing techniques for network implementation and signal processing functions, is motivated by the recent development of several promising neurobiologically inspired vision algorithms that can potentially be mapped onto the emerging 3D PMCM platform (Tanguay et al., 2000, and references therein).

## Extended Photonic Multichip Modules for Layered Networks

As the level of representation extends from low-level vision through mid-level vision to high-level vision operations, interconnections tend to become both more sparse and more global; in some cases, particularly between functionally partitioned vision processing modules, dense global interconnections may be required. Both local and global interconnection cases can potentially be accommodated within the PMCM architecture by incorporating novel stratified volume diffractive optical elements (SVDOEs; Tanguay et al., 2000, and references therein) as shown schematically in Figure 3. These SVDOEs consist of multiple layers of proximity-coupled and aligned DOEs that implement either space-variant or space-invariant interconnection patterns with properties characteristic of volume holograms. They also offer the advantages of planar fabrication methods compatible with VLSI design rules.

In Figure 3, several sets of compact PMCMs that implement primarily local interconnections, and perhaps also implement hierarchical functions, are interconnected across the faces of a cubic submodule by each SVDOE, offering the potential for more global interconnectivity. The mappings might be retinotopic in some cases, and columnar or fully space-variant in others.

## Volume Holographic Systems for Large-Scale Adaptive Networks

Volume holographic optical elements are capable of global, dense interconnections that are adaptive at the hardware level. The potential exists for the implementation of large numbers of weighted interconnections (e.g., $10^{10}$ in one module) that adapt by means of outer-product learning algorithms (e.g., Hebbian learning, or single- or multiple-layer least-mean squares [backpropagation], including weight decay). These learning algorithms exploit the physics of holographic (typically photorefractive) materials, the properties of which currently limit both adaptation and retention times. Such holographic interconnection systems for adaptive neural network implementations are not yet practical, but have been extensively researched (e.g., Jenkins and Tanguay, 1992; Wagner and Psaltis, 1993; Li et al., 1996; and references therein).

A conceptual diagram of one particular optical implementation of a large-scale artificial neural network with both local and global fan-out/fan-in adaptive interconnections is given in Figure 4. Many related implementations are possible, with similar overall characteristics. Two smart pixel spatial light modulators (SLMs, such as pixellated silicon VLSI chips mated to GaAs chips that comprise arrays of optical modulators rather than arrays of lasers; see also Jenkins and Tanguay, 1995, p. 679; Worchesky et al., 1996) are used to implement a 2D array of training term generators ($SLM_1$) and a 2D array of neuron units ($SLM_2$). A volume holographic

medium serves as the key interconnection element. The interconnection outputs occur in a plane that typically comprises the detector array of another SLM (for example, the output SLM). This SLM may serve as the input to subsequent signal processing stages, or as the training-term array ($SLM_1$) or input neuron-unit-array ($SLM_2$) in the case of a system with feedback.

In the computing phase (i.e., hologram readout), the beam from each input-neuron-unit pixel of $SLM_2$ ($x_j$) illuminates the holographic medium at a unique position, angle, and/or wavelength. The selective nature of volume holograms then allows only the appropriate interconnection weights $w_{ij}$ to be multiplied by each input beam, yielding the set of products $w_{ij}x_j$. The output beam optics then sums over $j$ of these terms at the location of each output term $\rho_i$ in the interconnection output plane, yielding $\rho_i = \Sigma_j w_{ij} x_j$.

During the learning phase (i.e., hologram recording), each pixel of $SLM_1$ generates the appropriate training term, $\delta_i$. An exposure is made of the interference pattern between beams emanating from the two SLMs in Figure 4. With appropriate choices of parameters, this exposure can increment the value of each interconnection weight $w_{ij}$ by an amount that is approximately proportional to $\delta_i x_j$. In the Hebbian case, for example, $\delta_i = y_i$, in which $y_i$ is the output-neuron-unit signal. It should be noted that when designing an architecture that will generate and record these weight increments, care must be taken to ensure that the appropriate interference terms are recorded with minimal crosstalk. One of the key differences among full-scale optical neural network architectures is the technique used to avoid such crosstalk (Wagner and Psaltis, 1993). In addition, the actual weight increment that physically occurs in holographic systems depends on the particular architecture employed (Wagner and Psaltis, 1993; Petrisor et al., 1996).

The interconnections within the particular implementation depicted in Figure 4 are based on a technique for multiplexed volume holography that uses double angular multiplexing and incoherent/coherent recording and readout (Jenkins and Tanguay, 1992). This interconnection technique exhibits an advantageous combination of total number of channels and interchannel crosstalk, in the case of high total optical throughput efficiency. One of its key features is the use of a source array that consists of an array of lasers, each of which generates light independently of the others. Because of this independence, a pair of beams from *different* lasers is not capable of interfering and recording a hologram, whereas a pair of beams generated from the *same* laser can interfere and thereby record a hologram in a holographic medium. From this source array, a set of coherent beam pairs is formed, one pair from each laser, that can record holograms pairwise.

In the computing phase of most volume hologram–based implementations of neural networks, the overall computing time is determined by the SLM response time. During learning, the holographic material sensitivity or response time typically limits the weight increment rate, which in turn puts an upper bound on the achievable learning gain constant; such holographic material response times depend on the material and vary over many orders of magnitude from one material to another. Similarly, the minimum decay rate (or maximum retention time) of holograms in read/write holographic materials puts a lower bound on the weight decay constant, and is similarly material dependent.

Large-scale optical *nonadaptive* networks are important as well. In this case the interconnection hologram need not be recorded in accordance with a specific learning algorithm. If the weights are known a priori, then any standard technique can be used to prerecord the hologram. In many cases, however, the weights may not be known. A common scenario may involve the training of a “master” network; once it has been trained, multiple copies of the network would be produced. If the network is large, and particularly if it utilizes volume holographic interconnections, then making direct copies of the volume hologram may be more practical than probing the values of all of the weights and then loading those weight values into a recording system. Thus, the capability of rapidly copying a multiplexed volume interconnection hologram may be important (Jenkins and Tanguay, 1995, and references therein, especially to Piazzolla et al.).

Most optical and photonic neural network architectures (or “modules”) of this class can be generalized in the following additional ways. First, multiple modules can be cascaded with fully parallel communication. Second, multiple neural network layers can be implemented either by adding feedback capability to the single module described or by cascading multiple modules. And finally, smart pixel SLMs can be employed to implement various neuron-unit models.

## Discussion

Research to date on optical and photonic neural network implementations has included the development and analysis of new architectures, analysis of scalability issues, development of the technology base for near-optimal individual components, and experimental proof-of-concept demonstrations. Additional research and development directions that are key for the eventual realization of physically small, high-performance, reasonable-cost photonic neural networks include increased focus on the manufacturability of the photonic and optical components, development of packaging and miniaturization techniques for hybrid electronic/photonic systems, and increased design automation and flexibility. Substantial progress has already been made along these lines. Significant leverage is also provided by rapid advances in the related areas of photonic digital interconnection systems, digital volume holographic memory systems, and components for early vision.

As the technology base evolves, photonic neural network implementations inspired by more sophisticated neuron, synapse, dendrite, axon, and network models should become feasible (e.g., models that include temporal correlations or dynamic synapses; see Dynamic Link Architecture; Self-Organization and the Brain; and Synchronization, Binding and Expectancy). Furthermore, the eventual implementation of photonic neural networks will likely engender a concomitant development of application areas for large-scale networks, and a deeper understanding of their properties.

# Population Codes

*Alexandre Pouget and Peter E. Latham*

## Introduction

Many sensory and motor variables in the brain are encoded by coarse codes, i.e., by the activity of large populations of neurons with broad tuning curves. For example, the direction of visual motion is believed to be encoded in the medial temporal (MT) visual area by a population of cells with bell-shaped tuning to direction, as illustrated in Figure 1*A*. Other examples of variables encoded by populations include the orientation of a line, the contrast in a visual scene, the frequency of a tone, and the direction of intended movement in motor cortex. These encodings extend to two dimensions—a single set of neurons might contain information about both orientation and contrast—or more.

Population codes are computationally appealing for at least two reasons. First, the overlap among the tuning curves allows precise encoding of values that fall between the peaks of two adjacent tuning curves (Figure 1*A*). Second, bell-shaped tuning curves provide basis functions that can be combined to approximate a wide variety of nonlinear mappings. This means that many cortical functions, such as sensorimotor transformations, can be easily modeled with population codes (see Pouget, Zemel, and Dayan, 2000, for a review).

In this article we focus on decoding, or reading out, population codes. Decoding is the simplest form of computation that one can perform over a population code, and as such, it is an essential step toward understanding more sophisticated computations. It is also important for accurately identifying which variables are encoded in a particular brain area and how they are encoded.

A key element of population codes—and the main reason why decoding them is difficult—is that neuronal responses are noisy, meaning that the same stimulus can produce different responses. Consider, for instance, a population of neurons coding for a one-dimensional parameter: the direction, $\theta$, of a moving object. An object moving in a particular direction produces a *noisy* hill of activity across this neuronal population (Figure 1*C*). On the basis of this noisy activity, one can try to come up with a good guess, or estimate, $\hat{\theta}$, of the direction of motion, $\theta$. In the second and third sections of this article we review the various estimators that have been proposed, and in the fourth section we consider their neuronal implementations.

Additional sources of uncertainty, beside neuronal noise, can come from the variable itself. For example, there is intrinsically more variability in one's estimate of, say, motion on a dark night than motion in broad daylight. In cases such as this, it is not unreasonable to assume that population activity codes for more than just a single value, and in the extreme case the population activity could code for a whole *probability distribution*. The goal of decoding is then to recover an estimate of this probability distribution. We consider an example of this later in the article.

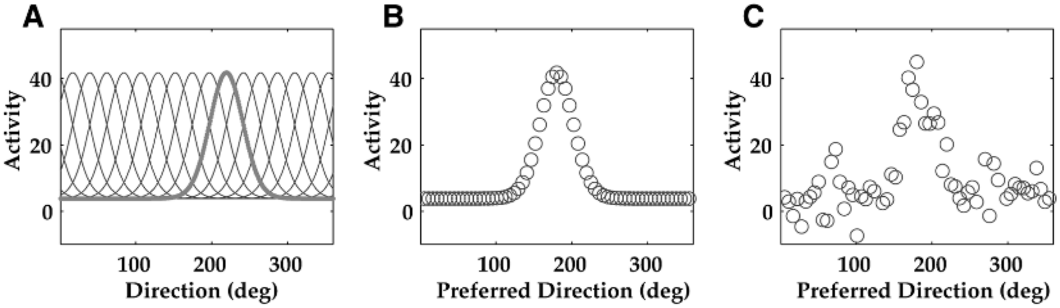

**Figure 1.** *A*, Idealized tuning curves for 16 direction-tuned neurons. *B*, Noiseless pattern of activity (○) from 64 simulated neurons with tuning curves like the ones shown in *A*, when presented with a direction of 180°. The activity of each neuron is plotted at the location of its preferred direction. *C*, Same as *B*, but in the presence of Gaussian noise.

## Models of Neuronal Noise and Tuning Curves

To read a population code, it is essential to have a good understanding of the relation between the patterns of activity and the encoded variables. One common assumption, particularly in sensory and motor cortex, is that patterns of activity encode a single value per variable at any given time. This is a reasonable assumption in many situations (although there are exceptions, as discussed later). For example, an object can move in only one direction at a time, so the neurons encoding its direction of motion have only one value to encode.

Under the assumption of a single value, neuronal responses are generally characterized by tuning curves, noted $f_i(\theta)$, which specify the mean activity of cell $i$ as a function of the encoded variable. These tuning curves are typically bell shaped, and are often taken to be Gaussian for nonperiodic variables and circular normal for periodic ones.

Simply measuring the mean activity, however, is not sufficient for performing estimation. A neuron may fire at a rate of 20 spikes/s on one trial but only 15 spikes/s on the next, even though the same stimulus was presented both times. This trial-to-trial variability is captured by the noise distribution, $P(a_i = a|\theta)$, where $a_i$ is the activity of cell $i$. The noise distribution is often assumed to be Gaussian, either with fixed variance or with a variance proportional to the mean (the latter being more consistent with experimental data), and independent. Such a distribution has the form

$$P(a_i = a|\theta) = \frac{1}{\sqrt{2\pi\sigma_i^2}} \exp\left(-\frac{(a - f_i(\theta))^2}{2\sigma_i^2}\right) \tag{1}$$

where $\sigma_i^2$ is either fixed or equal to the mean, $f_i(\theta)$. Another popular choice, especially useful if one is counting spikes, is the Poisson distribution:

$$P(a_i = k|\theta) = \frac{f_i(\theta)^k e^{-f_i(\theta)}}{k!} \tag{2}$$

Figure 1*C* shows a typical pattern of activity with Gaussian noise and $\sigma_i^2$ fixed.

## Estimating a Single Value

We now consider various approaches to reading out a population code under the assumptions that (1) a single value is encoded at any given time, and (2) the only source of uncertainty is the neuronal noise. Most of these methods, known as estimators, seek to recover an estimate, $\hat{\theta}$, of the encoded variable. We first discuss how one assesses the quality of an estimator in general; we then provide descriptions of common estimators used for decoding population activity.

### *Fisher Information*

An estimate, $\hat{\theta}$, is obtained by computing a function of the observed activity $\mathbf{A}$, where $\mathbf{A} \equiv (a_1, a_2, \ldots)$. Because of neuronal noise, $\mathbf{A}$ is a random variable and thus so is $\hat{\theta}$. This means that $\hat{\theta}$ will vary from trial to trial even for identical presentation angles. The best estimators are ones that are unbiased and efficient. An unbiased estimator is right on average: the conditional mean, $E[\hat{\theta}|\theta]$, is equal to the encoded direction, $\theta$, where $E$ denotes an average over trials. An efficient estimator, on the other hand, is consistent from trial to trial: the conditional variance, $E[(\hat{\theta} - \theta)^2|\theta]$, is minimal.

In general, the quality of an estimator depends on a compromise between the bias and the conditional variance. In this chapter, however, we consider unbiased estimators only, for which the conditional variance is the important measure because it fully determines how well one can discriminate small changes in the encoded variable based on observation of the neuronal activity. There exists a theoretical lower bound on the conditional variance, which is known as the Cramér-Rao bound. For an unbiased estimator, this bound is equal to the inverse of the Fisher information (Paradiso, 1988; Seung and Sompolinsky, 1993), which leads to the inequality

$$E[(\hat{\theta} - \theta)^2|\theta] \geq \frac{1}{I_{\text{Fisher}}}$$

where

$$I_{\text{Fisher}} \equiv E\left[-\frac{\partial^2}{\partial\theta^2} \log P(\mathbf{A}|\theta)\right]$$

An efficient estimator is one whose conditional variance is equal to the Cramér-Rao bound, $1/I_{\text{Fisher}}$. When $P(\mathbf{A}|\theta)$ is known, it is often straightforward to compute $I_{\text{Fisher}}$. For example, for the Gaussian distribution given in Equation 1,

$$I_{\text{Fisher}} = \sum_{i=1}^{N} \frac{f_i'(\theta)^2}{\sigma_i^2}$$

and for the Poisson distribution given in Equation 2,

$$I_{\text{Fisher}} = \sum_{i=1}^{N} \frac{f_i'(\theta)^2}{f_i(\theta)}$$

(Seung and Sompolinsky, 1993).

In both of these expressions, the neurons that contribute most strongly to the Fisher information are those with a large slope (large $f_i'(\theta)$). Therefore, the most active neurons are not the most informative ones. In fact, they are the *least* informative: the most active neurons correspond to the top of the tuning curve, where the slope is zero, so these neurons make no contribution to Fisher information.

### *Voting Methods*

Several estimators rely on the idea of interpreting the activity of a cell, normalized or not, as a vote for the preferred direction of the cell. For instance, the optimal linear estimator is given by

$$\hat{\theta}_{\text{OLE}} = \sum_{i=1}^{N} \theta_i a_i$$

where $\theta_i$ is the preferred direction of cell $i$, that is, the peak of the function $f_i(\theta)$. A variation on this theme is the center of mass estimator, defined as

$$\hat{\theta}_{\text{COM}} = \frac{\sum_{i=1}^{N} \theta_i(a_i - \gamma)}{\sum_{i=1}^{N} (a_i - \gamma)}$$

where $\gamma$ is the spontaneous activity of the cells.

A third variation is known as a population vector estimator (Figure 2*A*). This has been extensively used for estimating periodic variables, such as direction, from real data (Georgopoulos et al., 1982). It is equivalent to fitting a cosine function through the pattern of activity and using the phase of the cosine as the estimate of direction:

$$\hat{\theta}_{\text{COMP}} = \text{phase}(z)$$

where

$$z = \sum_{j=1}^{N} a_j e^{i\theta_j}$$

The first two methods work best for nonperiodic variables; the third one can only be used when the variables are periodic. All

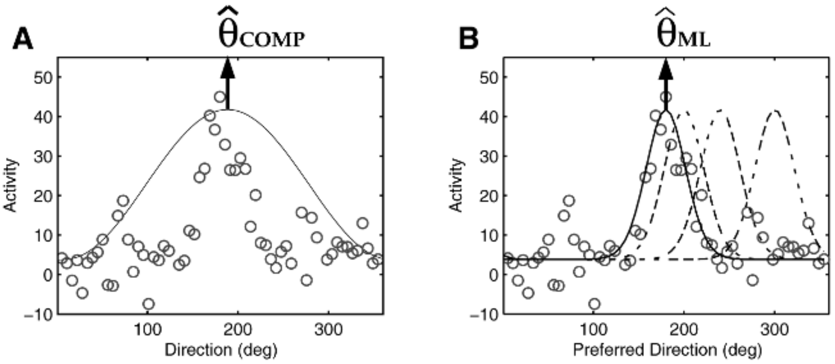

**Figure 2.** *A*, The population vector estimator uses the phase of the first Fourier component of the input pattern (solid line) as an estimate of direction. It is equivalent to fitting a cosine function to the input. *B*, The maximum likelihood estimate is found by moving an "expected" hill of activity (dashed line) until the squared distance with the data is minimized (solid line).

three estimators are subject to biases, although careful tuning of the parameters can often correct for them. More important, all three methods are almost always suboptimal (the variance of the estimator exceeds the Cramér-Rao bound). The exceptions occur for a very specific set of tuning curves and noise distributions (Salinas and Abbott, 1994): the center of mass is optimal only with Gaussian tuning curves and Poisson noise, and the population vector is optimal only for cosine tuning curves and Gaussian noise of fixed variance.

### *Maximum Likelihood*

A better choice than the voting methods, at least from the point of view of statistical efficiency, is the maximum likelihood (ML) estimator

$$\hat{\theta}_{\text{ML}} = \arg\max_{\theta} P(\mathbf{A}|\theta)$$

When there are a large number of neurons, this estimator is unbiased and its variance is equal to the Cramér-Rao bound for a wide variety of tuning curve profiles and noise distribution (Paradiso, 1988; Seung and Sompolinsky, 1993). The term maximum likelihood comes from the fact that $\hat{\theta}_{\text{ML}}$ is obtained by choosing the value of $\theta$ that maximizes the conditional probability of the activity, $P(\mathbf{A}|\theta)$, also known as the likelihood of $\theta$.

Finding the ML estimate reduces to template matching (Paradiso, 1988), i.e., finding the noise-free hill that is closest to the activity, as illustrated in Figure 2*B*. If the noise is independent and Gaussian, then "closest" is with respect to the Euclidean norm, $\Sigma_i(a_i - f_i(\theta))^2$. For other distributions the norm is more complicated. Template matching involves a nonlinear regression, which is typically performed by moving the position of the hill until the distance from the data is minimized, as shown in Figure 2*B*. The position of the peak of the final hill corresponds to the ML estimate.

The main difference between the population vector and the ML estimator is the shape of the template being matched to the data. Whereas the population vector matches a cosine, the ML estimator uses a template that is directly derived from the tuning curves of the neurons that generated the activity (Figures 2*A* and 2*B*). (When all neurons have identical tuning curves, as for our examples, the template has the same profile as the tuning curves.) It is because the ML estimator uses the correct template that its variance reaches the Cramér-Rao bound. There is, however, a cost: one needs to know the profile of all tuning curves to use ML estimation, whereas only the preferred directions, $\theta_i$, are needed for the population vector estimator.

### *Bayesian Approach*

An alternative to ML estimation is to use the full posterior distribution of the encoded variable, $P(\theta|\mathbf{A})$. This is related to the distribution of the noise, $P(\mathbf{A}|\theta)$, through Bayes's theorem:

$$P(\theta|\mathbf{A}) = \frac{P(\mathbf{A}|\theta)P(\theta)}{P(\mathbf{A})}$$

where $P(\mathbf{A})$ and $P(\theta)$ are the prior distributions over $\mathbf{A}$ and $\theta$. The value that maximizes $P(\theta|\mathbf{A})$ can then be used as an estimate of $\theta$. This is known as a maximum a posteriori estimate, or MAP estimate. The main advantage of the MAP estimate over the ML estimate is that prior knowledge about the encoded variable can be taken into account. This is particularly important when the conditional distribution, $P(\mathbf{A}|\theta)$, is not sharply peaked compared to the prior, $P(\theta)$. This happens, for example, when only a small number of neurons are available, or when one observes only a few spikes per neuron. The MAP estimate is close to the ML estimate if the prior distribution varies slowly compared to the conditional, and the two are exactly equal when the prior is flat. Several authors have explored and/or applied applied this approach to real data (Foldiak, 1993; Sanger, 1996; Zhang et al., 1998).

## Neuronal Implementations

Methods such as the voting schemes or ML estimator are biologically implausible, for one simple reason: they extract a single value, the estimate of the encoded variable. Such explicit decoding is very rare in the brain. Instead, most cortical areas and subcortical structures use population codes to encode variables. This means that, throughout the brain, population codes are mapped into population codes. Hence, V1 neurons, which are broadly tuned to the direction of motion, project to MT neurons, which are also broadly tuned, but in neither area is the direction of motion read out as a single number. The neurons in MT are nevertheless confronted with an estimation problem: they must choose their activity levels on the basis of the noisy activity of V1 neurons.

What is the optimal strategy for mapping one population code into another? We cannot answer this question in general, but we can address it for the broad class of networks depicted in Figure 3. In these networks, the input layer is a set of neurons with wide tuning curves, generating noisy patterns of activity like the one shown in Figure 1*C*. This activity, which acts transiently, is relayed to an output layer through feedforward connections. In the output layer the neurons are connected through lateral connections.

An update rule (discussed later) causes the activity in the output layer to evolve in time. In the next section we consider networks in which the update rule leads to a smooth hill. The peak of that hill can be interpreted as an estimate of the variable being encoded. As previously, we can assess how well the network did by looking at the mean and variance of this estimate.

We will consider two kinds of networks: those with a linear activation function and those with a nonlinear one.

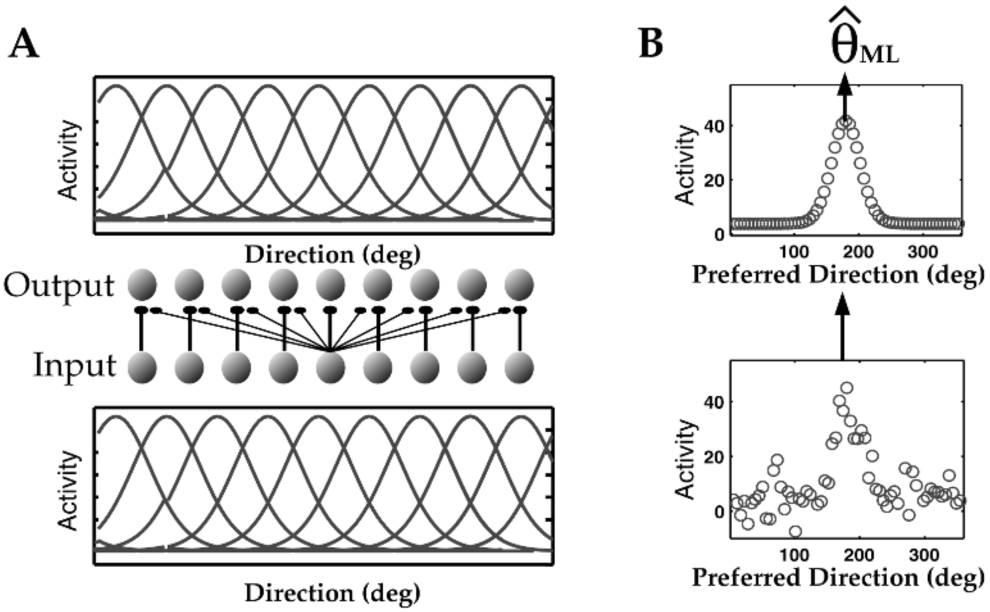

**Figure 3.** *A*, A set of units with broad tuning to a sensory variable (in this case direction) projects to another set of units also broadly tuned to the same variable. This type of mapping between population codes is very common throughout the brain. In this particular network, the output layer is fully interconnected with lateral connections, and receives feedforward connections from the input layer. *B*, Temporal evolution of the activity in the output layer for a nonlinear network. The activity in the output layer is initiated with a noisy hill generated by the input units (bottom). For an appropriate choice of weights and activation function, these activities converge eventually to a smooth hill (top), which peaks close to the location of the maximum likelihood estimate of direction, $\hat{\theta}_{\text{ML}}$. This network is performing the template-matching procedure used in maximum likelihood and illustrated in Figure 2*B*.

### *Linear Networks*

We first consider a network with linear activation functions in the output layer, so that the dynamics is governed by the difference equation

$$\mathbf{O}_t = ((1 - \lambda)I + \lambda W)\mathbf{O}_{t-1} \tag{3}$$

where $\lambda$ is a number between 0 and 1, $I$ is the identity matrix, and $W$ is the matrix for the lateral connections. The activity at time 0, $\mathbf{O}_0$, is initialized to $W\mathbf{A}$, where $\mathbf{A}$ is an input pattern (like the one shown in Figure 1*C*) and $W$ is the feedforward weight matrix (for simplicity, the feedforward and lateral weights are the same, although this is not necessary).

The dynamics of such a network is well understood: each eigenvector of the matrix $(1 - \lambda)I + \lambda W$ evolves independently, with exponential amplification for eigenvalues greater than 1 and exponential suppression for eigenvalues less than 1. When the weights are translation invariant ($W_{ij} = W_{i-j}$), the eigenvectors are sines and cosine. In this case the network amplifies or suppresses independently each Fourier component of the initial input pattern, $\mathbf{A}$, by a factor equal to the corresponding eigenvalue of $(1 - \lambda)I + \lambda W$. For example, if the first eigenvalue of $(1 - \lambda)I + \lambda W$ is more than 1 (respectively less than 1), the first Fourier component of the initial pattern of activity will be amplified (respectively suppressed). Thus, $W$ can be chosen such that the network amplifies selectively the first Fourier component of the data while suppressing the others.

As formulated, the activity in such a network would grow forever. However, if we stop after a large yet fixed number of iterations, the activity pattern will look like a cosine function of direction with a phase corresponding to the phase of the first Fourier component of the data. The peak of the cosine provides the estimate of direction. That estimate turns out to be the same as the one provided by the population vector discussed above.

The unchecked exponential growth of a purely linear network can be alleviated by adding a nonlinear term to act as gain control. This type of network was proposed by Ben-Yishai, Bar-Or, and Sompolinsky (1995) as a model of orientation selectivity.

Although such networks keep the estimate in a coarse code format, they suffer from two problems: it is not immediately clear how to extend them to periodic variables, such as disparity, and they are suboptimal, since they are equivalent to the population estimator.

### *Nonlinear Networks*

To obtain optimal performance, one needs a network that can implement template matching with the correct template—the one used by the ML estimator (see Figure 2*B*). This requires templates that go beyond cosines to include curves that are consistent with the tuning curves of the input units (see Figure 2*B*).

Nonlinear networks that admit line attractors have this property (Deneve, Latham, and Pouget, 1999). In such networks, the line attractors correspond to smooth hills of activity, with profiles determined by the patterns of weights *and* the activation functions. For a given activation function, it is therefore possible to select the weights to optimize the profile of the stable state. Pouget et al. (1998) demonstrated that this extra flexibility allows these networks to act as ML estimators (see Figure 3*B*).

More recent work by Deneve et al. (1999) has shown that the ML property is preserved for a wide range of nonlinear activation functions. In particular, this is true for networks using divisive normalization, a nonlinearity believed to exist in cortical microcircuitry. It is therefore possible that all cortical layers are close approximations to ML estimators.

## Estimating a Probability Distribution

So far we have reviewed decoding methods in which only one value is encoded at any given time and the only source of uncertainty comes from the neuronal activity. Situations exist, however, in which either (or both) of these assumptions are violated. For instance, imagine that you are lost in Manhattan on a foggy day, but you can see, faintly, the Empire State building and the Chrysler building in the distance. Because of the poor visibility, the views of these landmarks are not sufficient to specify your exact position, but they are enough to provide a rough idea of where you are (Harlem versus Little Italy). In this situation, it would be desirable to compute the probability distribution of your location given that you are seeing the landmarks; i.e., compute $P(\theta|w)$ where $\theta$ is the position (now a two-dimensional vector) in Manhattan and $w$ represents the views of the buildings. Here, the uncertainty about $\theta$ comes from the fact that you do not have enough information to tell precisely where you are. In such a situation, the neurons could encode the *probability distribution,* $P(\theta|w)$.

Because the encoded entity is a probability distribution rather than a single value, we can no longer use either Equation 1 or Equation 2 as a model for the responses of the neurons; these equations provide only the likelihood of $\theta$, $P(\mathbf{A}|\theta)$. What we need instead is a model that specifies the likelihood of the whole encoded probability distribution, $P[\mathbf{A}|P(\theta|w)]$. Note that $P(\theta|w)$ plays the same role as $\theta$ previously, which is to be expected, now that $P(\theta|w)$ is the encoded entity. It is beyond the scope of this discussion to provide equations for such models, but examples can be found in Zemel, Dayan, and Pouget (1998).

Since $\mathbf{A}$ is now a code for the probability distribution, the relevant quantity to estimate is $P(\theta|w)$, which we denote $\hat{\mathrm{P}}(\theta|w)$. This is still within the realm of estimation theory, so we can use the same tools that we used for the simpler case, such as ML decoding (see Zemel et al., 1998).

To see the difference between encoding a single value and encoding a probability distribution, it is helpful to consider what happens when the neurons are deterministic—that is, when the neuronal noise goes to zero. In this case, the encoded variable can be recovered with infinite precision, since the only source of uncertainty, the neuronal noise, is gone. Thus the ML estimate would be exactly equal to the encoded value, and the posterior distribution, $P(\theta|\mathbf{A})$, would be a Dirac function centered at $\theta$. If the activity encodes a probability distribution, on the other hand, one would recover the *distribution* with infinite precision. However, the uncertainty about $\theta$ may still be quite large (as was the case in our Manhattan example), potentially far from a Dirac function.

It is too early to tell whether neurons encode probability distributions; more empirical as well as theoretical work is needed. But if the cortex has the ability to represent probability distributions, it might be possible to determine how, and whether, the brain performs Bayesian inferences. Bayesian inference is a powerful method for performing computation in the presence of uncertainty. Many engineering applications rely on this framework to perform data analysis or to control robots, and several studies are now suggesting that the brain might be using such inferences for perception and motor control (see, e.g., Knill and Richards, 1996).

## Conclusions

Understanding how to decode patterns of neuronal activity is a critical step toward developing theories of representation and computation in the brain. This article concentrated on the simplest case, a single variable encoded in the firing rates of a population of neurons. There are two main approaches to this problem. In the first, the population encodes a single value, and decoding can be done with Bayesian or maximum likelihood estimators. The underlying assumption in this case is that neuronal noise is the only source of uncertainty. We also saw that within this framework, one can design neural networks that perform decoding optimally. In the second approach, the population encodes a full probability distribution over the variable of interest. Here both the variable and its uncertainty can be extracted from the population activity. This scheme could be used to perform statistical inferences—a powerful way to perform computations over variables whose value is not known with certainty. The challenge for future work will be to determine whether the brain uses this type of code, and, if so, to understand how realistic neural circuits can perform statistical inferences over probability distributions.

# Post-Hebbian Learning Algorithms

*Péter Érdi and Zoltán Somogyvári*

## Post-Hebbian Learning Rules: A Retrospective

Hebb's introduction of his learning rule inaugurated a new era and resulted in the appearance of many new branches of theory and new models of learning. Two characteristics of the original postulate (Hebb, 1949) played key roles in the subsequent development of post-Hebbian learning rules. First, despite being biologically motivated, Hebb's learning rule was a verbally described, *phenomenological* rule, unlinked to detailed physiological mechanisms. Second, because the learning rule was extremely convincing, it was widely adopted both as a theoretical framework and as a formal tool in the field of neural networks.

As a result, the etiolation of Hebb's idea occurred in two principal directions. First, the postulate inspired an intense and long-lasting search for the molecular and cellular basis of learning phenomena, which were assumed to be Hebbian; thus, this particular development has been absorbed by neurobiology. Second, because of its computational usefulness, many variations of the *biologically inspired* learning rules appeared and were applied to a huge number of very different problems in artificial neural networks, without any relation to a biological foundation being claimed. Several families of rules sprouted from the original idea. Before discussing them, we should note that what we consider a Hebbian, post-Hebbian, or non-Hebbian learning rule to be is subjective and time varying.

This *Handbook* includes a broad overview of the subject in the article Hebbian Synaptic Plasticity (q.v.). Here we focus predominantly on computational implementations of Hebbian rules. First, however, we discuss the different roots and new developments related to Hebb's hypothesis, such as psychologically motivated conditioning, neural development, and physiologically realistic cellular level learning phenomena. Thereafter families of formal Hebbian learning, or *algorithms*, are considered.

## Variations on the Hebbian Theme: Motivations

### Conditioning

Since the end of the nineteenth century, physiologists have known that mature nerve cells cannot divide (though in the late 20th century they changed their minds!). Thus, because learning could not result from the proliferation of new neurons, the locus of learning had to be *the connections between cells*. Such phenomena are related to the neural basis of classical conditioning. The first attempt to model conditioning in terms of synaptic change was by Hebb.

Hebb's original intent was to connect the behavior of whole organisms to neural mechanisms by using concepts represented by cell assemblies. Specifically, classical conditioning involves the development of an association between two otherwise unrelated events over a number of trials in which the events are temporally paired. Typically, a neutral stimulus, one that does not naturally provoke behavior, is presented, immediately followed by an unconditioned stimulus, or an event that does not require training to produce a response, resulting in the eliciting of an unconditioned response.

Classical conditioning (see Conditioning) has been described by Rescorla and Wagner's (1972) model. They proposed a formal model of conditioning that expresses the capacity of a conditioned stimulus (CS) to become associated with an unconditioned stimulus (US) at any given time. The fulcrum of the Wagner-Rescorla model is that learning occurs if and when events violate expectations. More specifically, learning occurs whenever the actual level of US received during a trial differs from the level expected. The Rescorla-Wagner rule can be interpreted as saying that the discrepancy between expected and actual values determines the measure of reinforcement. So, the rule and its many later modifications act over the unsupervised learning paradigm. One drawback of the Rescorla-Wagner model, however, is that it completely ignores the temporal sequence in which information is presented.

### Development

The formation and refinement of neural circuits involves both the establishment of new connections and the elimination of already existing connections. The leading mechanism in synaptic elimination is considered to be *axonal* or *synaptic competition*. Neuromuscular junctions and the visual system are the two best investigated examples in which synaptic competition plays an important role.

A large variety of generalized Hebbian learning rules have been applied to neural development (see review by van Ooyen, 2001). An example is the different mechanisms of competition elaborated in the context of population biology that have been adopted in the neural context. In *consumptive competition* in systems of consumers and resources (e.g., predators and prey), each individual consumer tries to avoid other consumers and hinders other consumers solely by consuming resources that they might have consumed. In other words, consumers hinder each other because they draw on the same resources. In neurobiology, competition is commonly associated with this dependence on shared resources. In *interference competition*, instead of hindrance through dependence on shared resources, there is direct interference between individuals. Such interference occurs, for example, if there are direct negative interactions (e.g., aggressive or toxic interactions) between individuals. In axonal competition, nerve terminals could seek to destroy each other by releasing proteases.

### Long-Term Potentiation—Long-Term Depression

Long-term potentiation (LTP) was first discovered in the hippocampus and is very prominent there. LTP is an increase in synaptic strength that can be rapidly induced by brief periods of synaptic stimulation. It has been reported to last for hours in vitro, and for days to weeks in vivo.

LTP (and later long-term depression, or LTD) became regarded as the physiological basis of Hebbian learning. Subsequently, the properties of LTP and LTD became clearer, and the question then arose as to whether LTP and LTD could really be considered the microscopic basis of the phenomenological Hebbian type of learning. Formally, the question is how to specify the general function $F$ to serve as a learning rule with the known properties of LTP and LTD. Recognizing the existence of this gap between biological mechanisms and the long-used Hebbian learning rule, many workers have attempted to derive the corresponding phenomenological rule based on more or less detailed neurochemical mechanisms.

The time course of LTP may be insufficient to sustain long-term memory, but there appear to be multiple LTP mechanisms, and one dependent on protein synthesis might serve long-term memory: inhibition of protein synthesis disrupts the maintenance of LTP but leaves the induction of LTP relatively or totally intact. It is possible to relate the properties and mechanisms of long-term synaptic plasticity in the mammalian brain to learning and memory.

An example of the new synaptic bidirectional Hebbian rules was introduced by Grzywacz and Burgi in 1998. When this rule was compared with physiological homosynaptic conditions in the hippocampus, the results indicated that this rule was consistent with LTP and LTD phenomenologies. The phenomenologies considered included the reversible dynamics of LTP and LTD and the effects of *N*-methyl-D-aspartate (NMDA) blockers and phosphatase inhibitors.

### *Timing*

Studies in cortical and hippocampal slices have shown that backpropagating action potentials may contribute to the induction of persistent synaptic potentiation or depression. The timing of presynaptic and postsynaptic action potentials plays a decisive role in determining the sign of synaptic modification (Markram et al., 1997). The temporal order of the synaptic input and the postsynaptic spike within a narrow window of time determines whether LTP or LTD is elicited, according to a temporally asymmetric Hebbian learning rule.
