Bi and Poo (1998) showed that postsynaptic spiking that peaked within 20 ms *after* synaptic activation resulted in LTP, whereas spiking within 20 ms *before* synaptic activation led to LTD. They suggested that a narrow and asymmetric window for the induction of synaptic modification should be taken into account.

Most generalized Hebbian rules are based on the statistical properties of presynaptic and postsynaptic activity (e.g., activity product, activity covariance) and do not consider the detailed temporal structure of the spike patterns. Relative spike timing, however, had been taken into account as early as 1981 by Sutton and Barto.

Since changes in synaptic efficacy can depend on the precise temporal relations of pre- and postsynaptic spikes, phenomenological "temporal learning rules" generate opposite changes in synaptic efficiency, depending on whether the postsynaptic spike occurs before or after the presynaptic spike. Roberts (1999) attempted to show that differential Hebbian learning could take into account the timing effects.

## Generalized Hebbian Rules and Their Phenomenological Derivations

Hebb's idea has been formalized in many variations. The first and simplest versions of the Hebbian learning rule have the important properties of being *local* and *interactive* (specifically, *conjunctional* and *time dependent*), as we will now explain. We will consider what happens when we attempt to preserve these properties in the course of generalizing the Hebbian learning rule.

The most general form of Hebb's rule is that the synaptic weight from neuron $i$ to neuron $j$ changes according to

$$\frac{d}{dt} w_{ij}(t) = F(a_i, a_j) \tag{1}$$

where $F$ is a functional, and $a_j$ and $a_i$ are presynaptic and postsynaptic activity functions (i.e., they may include activity levels over some period of time and not just the current activity values). To define specific learning rules (i.e., the form of $F$), a few points should be clarified.

1. What are the assumptions about the *locality* of the modifying signal? In many cases the modification of a synapse between neurons $i$ and $j$ depends on the state of these two cells alone; i.e., the mechanism is local. In this case, teacher or external reinforcement signals are not explicitly involved: local synapses are the bases of the unsupervised learning.
2. How, if at all, do the presynaptic and postsynaptic cells *interact?* Consider first the potential answers for the "if at all" part of the question. The modification can be interactive if both the pre- and postsynaptic cells are involved, and noninteractive if either the pre- or postsynaptic cell alone influences the modification. The mechanism of the interaction may be conjunctional or correlational. In the first case, co-occurrence of pre- and postsynaptic activity is sufficient to cause synaptic change, while in the second case, covariance of the two activities must be taken into account. (From a formal point of view, additive interactions, such as those given by the function $F(a_i \pm a_j)$, could have been defined, but they are considered as noninteractive rules. In other words, not only an entire rule but each term of it can be evaluated as interactive or noninteractive.)
3. What are the assumptions about the form of the *time-dependent* activity functions? In the simplest case, only the actual activity values are involved. In somewhat more complex situations, short-term averaged activity values determine the synaptic change. More generally, the history of the activity values plays a role in the modification process.

The simplest Hebbian learning rule can be formalized as

$$\frac{d}{dt} w_{ij}(t) = ka_i(t)a_j(t), \qquad k > 0 \tag{2}$$

This rule expresses the conjunction among pre- and postsynaptic elements (using neurobiological terminology) or associative conditioning (in psychological terms), by a simple product of the actual states of pre- and postsynaptic elements, $a_j(t)$ and $a_i(t)$.

A characteristic and unfortunate property of the simplest Hebbian rule in Equation 1 is that the synaptic strengths are ever increasing (see Hebbian Learning and Neuronal Regulation for solutions to the problems this property raises).

$$\frac{d}{dt} w_{ij}(t) = kg(a_i(t))h(a_j(t)) \tag{3}$$

where $g$ and $h$, functions of the actual activity, serve as some measure of the post- and presynaptic activity (i.e., $g$, $h > 0$), and

$$\frac{d}{dt} w_{ij}(t) = kg(a_i(\cdot))h(a_j(\cdot)) \tag{4}$$

where $g$ and $h$ are now functionals of the activity function. A special case is

$$\frac{d}{dt} w_{ij}(t) = k \int_0^t a_i(t)dt \int_0^t a_j(t)dt \tag{5}$$

which takes into account the total activity history.

There is a particular time-dependent, local, and conjunctional rule that does not increase the synaptic weight. This is the case in which the pre- and postsynaptic activities are negatively correlated:

$$\frac{d}{dt} w_{ij}(t) = ka_i(t)a_j(t), \qquad k < 0 \tag{6}$$

This "anti-Hebbian" rule (there is some confusion in the literature concerning this terminology; here it is used in the sense that $k < 0$) or "decorrelation" rule was suggested to describe features of dissociations of patterns (Barlow and Földiak, 1989).

There are both brutal and sophisticated methods to eliminate the unpleasant property of ever-increasing weights, which, unless compensated for, yield a network with saturated synaptic weights, and thus no effective pattern discrimination. The adjective "brutal" was adopted for the situation in which some external constraint (somehow taking into account the finiteness of resources) is applied to the internal mechanism. First, a predetermined upper bound can be given, such as the maximal value of the synaptic strength. Second, the so-called normalization procedure (described in Rochester et al., 1956) gives a finite-sum constraint on all synaptic strengths, and can be interpreted as a competition of the presynaptic elements for postsynaptic resources (therefore, it violates locality). Such rules may explain some aspects of neural development

More sophisticated methods decrease the synaptic strengths selectively. Brown, Kairiss, and Keenan (1990) use the expression *generalized Hebbian synaptic mechanism* for cases in which interactive synaptic increase is combined with activity-dependent synaptic depression. The underlying mechanism behind synaptic depression may be of interactive or noninteractive type.

Instead of giving a formal derivation of the rules that are able to describe selective decrease, we will mention two important special cases. First, the rule

$$\frac{d}{dt} w_{ij}(t) = kg(a_i(t))(h(a_j(t)) - \theta(t)) \tag{7}$$

implements synaptic increase only if the $h(a_j(t))$ presynaptic activity is larger than the $\theta(t)$ modification threshold. If the presynaptic activity is smaller than the threshold, the synaptic weight decreases. Second,

$$\frac{d}{dt} w_{ij}(t) = k(g(a_i(t)) - \theta(t))h(a_j(t)) \tag{8}$$

implements a postsynaptic control mechanism on the modification process.

The learning rules in Equations 8 and 9 can be written in the form $kgh - k\theta g$ and $kgh - k\theta h$, respectively. Each of these expressions may be interpreted as the sum of a Hebbian interactive term and a noninteractive term. In the first case, the decrease is due to postsynaptic activity $g$ and is called *heterosynaptic depression*, while in the second case it depends on the presynaptic activity $h$ and is called *homosynaptic depression*. Learning rules of the form of Equation 9 were suggested by Bienenstock, Cooper, and Munro (1982) and so are sometimes referred as the BCM theory; they are used to model the plasticity of visual cortex. $\theta(t)$ was identified with a nonlinear function of the averaged postsynaptic activity:

$$\theta(t) = [g(t)]^2 \tag{9}$$

where $[\cdot]$ is the average taken for a period of time. The suggestion that the occurrence of either homosynaptic LTP or LTD depends on the strength of the depolarizing current induced by an NMDA blocker (which increases the modification threshold) in the visual cortex seemed to be justified experimentally.

The learning expression has also been described in the form $\phi(g, [g])h$, where the two-variable function $\phi$ depends on an actual value and an averaged quantity, so an underlying microscopic stochastic mechanism should exist behind the phenomenological and deterministic formalism.

The weaker form of the interactive rule (namely, when correlational and nonconjunctional interactions were assumed), or

$$\frac{d}{dt} w_{ij}(t) = k(a_i(t) - [a_i(t)])(a_j(t) - [a_j(t)]) \tag{10}$$

was offered by Rochester et al. (1956). Depending on the sign of the correlation, the rule is capable of describing either synaptic enhancement or decrease. Covariance was suggested to induce associative LTD in the hippocampus.

Another way to describe the decrease of synaptic weights is the introduction of a spontaneous decay (or "forgetting") term. The original Hebbian rule (Equation 2) supplemented with a decay term reads as

$$\frac{d}{dt} w_{ij}(t) = -k_1 w_{ij}(t) + k_2 a_i(t)a_j(t) \tag{11}$$

(Instead of first-order decay, a quadratic forgetting term was also introduced and studied to improve the stability properties of the learning rule.) If the decay is not spontaneous but modulated with the postsynaptic activity, the rule has the form

$$\begin{aligned}\frac{d}{dt} w_{ij}(t) &= -k_1 w_{ij}(t)a_i(t) + k_2 a_i(t)a_j(t)\\ &\equiv a_i(t)(k_2 a_j(t) - k_1 w_{ij}(t))\end{aligned} \tag{12}$$

and describes the phenomenon called competitive learning. Postsynaptic neurons compete for incoming resources: the larger the postsynaptic activity, the larger the measure of learning:

$$\frac{d}{dt} w_{ij}(t) = k \frac{d}{dt} a_i(t) \frac{d}{dt} a_j(t) \tag{13}$$

This rule is an example of a differential learning mechanism (Klopf, 1986). Obviously, the rate of change of activities may be positive or negative; that is, both synaptic increase and decrease may occur. The differential competitive rule,

$$\frac{d}{dt} w_{ij}(t) = \frac{d}{dt} a_i(t)(k_2 a_j(t) - k_1 w_{ij}(t)) \tag{14}$$

implements the "learn only if change" principle.

In some cases, the time delay due to signal transmission is explicitly taken into account; consequently, earlier presynaptic activities, rather than current activities, are in conjunction:

$$\frac{d}{dt} w_{ij}(t) = ka_i(t)a_j(t - \tau) \tag{15}$$

This spirit of "timing sensitivity" is materialized in the rule

$$\frac{d}{dt} w_{ij}(t) = k_1 \frac{d}{dt} a_i(t)[a_j(t)] \tag{16}$$

used to describe conditioning (see, e.g., Sejnowski and Tesauro, 1990).

## Hebbian Mechanisms and Hebbian Algorithms

Hebb proposed that the connection between two neurons will increase if activity in the neurons is temporally paired. More specifically, the Hebbian model proposes that the strength of a particular connection will increase if use of the synapse contributes to the occurrence of an action potential in the postsynaptic neuron. This account critically depends on coincidence detectors in the postsynaptic neuron.

The underlying biophysical mechanisms and algorithms of even generalized Hebbian synaptic modification were reviewed by Brown et al. (1990). Over the next several years, system-level computational models of the neural bases of learning and memory began to proliferate.

The general question has been, and still is, how to connect the formal algorithms of the neural basis of learning phenomena. Although many commonly used learning rules lead to successful models of plasticity and learning, they are inconsistent with what is known about neurophysiology. Other, more physiologically plausible rules fail to specify relevant properties, such as bidirectionality and the biological mechanism that prevents synapses from changing from excitatory to inhibitory, and vice versa. More recent attempts have tried to overcome these difficulties.

## Discussion: Over the Hebbian Paradigm

It is certainly not true that all learning rules could be interpreted in even a generalized Hebbian sense. It is difficult, however, to discriminate precisely between Hebbian and non-Hebbian frameworks. One way to do so might be to consider a learning rule Hebbian if only two elements, one presynaptic, one postsynaptic, are involved. If we accept this limitation, we know by exclusion what a non-Hebbian learning rule is. Many types of supervised learning rules used in artificial neural networks, such as delta rules, and their variations certainly belong to this category. Heterosynaptic plasticity and the modifiability of synaptic triads and glomeruli, in which more than two cells are explicitly involved in the modification process, could also be understood as non-Hebbian. Such a choice, however, would also exclude rules with the normalization procedure.

What is the relationship between homosynaptic (or Hebbian activity–dependent) and heterosynaptic (or modulatory input–dependent) plasticity? It has often been suggested (see, e.g., Bailey et al., 2000) that Hebbian mechanisms are used primarily for learning and for forming short-term memory traces, but they are not sufficient to recruit the events required to maintain a long-term memory. In contrast, heterosynaptic plasticity commonly recruits long-term memory mechanisms that lead to transcription and to synaptic growth. When jointly recruited, homosynaptic mechanisms ensure that learning is effectively established and heterosynaptic mechanisms ensure that memory is maintained.

The spirit of the Hebbian idea survived more than half a century. It will be interesting to see what kinds of phenomenological learning rules will be derived in the next several years, starting from cellular level experimental and modeling studies of synaptic modifiability.

# Potential Fields and Neural Networks

*Jiming Liu and Oussama Khatib*

## Introduction

In this article, we review the ideas and observations involved in the concept of potential fields. *Potential fields* are often defined to characterize the vector-field output of a behavior module, the impedance of a structure, or the external constraints of an environment. Such a characterization is useful for modeling motor behavior control in humans and robots. Here we also examine how neural networks are related to potential fields, as underlying architectures for enabling sensorimotor control and behavior learning.

## Biological Relevance of Potential Fields in Behavior Modeling

In biological studies, potential fields offer a way to represent and measure the motor output behavior of a physiological mechanism. Many of the reported biological studies that have taken into account potential fields have sought to understand how the neural circuits in the frog's spinal cord are organized and how the motor behaviors of the frog, such as postures, are governed by the neural control modules.

### *Complex Motor Behaviors and Vector Fields*

The theoretical work of Mussa-Ivaldi and Giszter (e.g., 1992), known as vector-field approximation, characterizes the elicited outputs of distinct postural control modules as basis fields. Simple motor tasks can therefore be described by the specific features of vector fields, such as stable equilibrium, impedance, unstable equilibrium, saddle point, uniform field, and circulation. In their simulations, they show that a repertoire of convergent force patterns can readily be approximated based on the superposition of basis fields (as training examples). Furthermore, by combining the field features, it is possible to produce a variety of more complex control patterns.

### *Linear Combination of Force Fields*

In relation to vector-field approximation and complex pattern generation, Mussa-Ivaldi, Giszter, and Bizzi (1994) have tested the hypothesis that vectorial superposition—that is, linear combination—of the motor primitives in the neural circuits of the frog's spinal cord can lead to a variety of motor behaviors. They conducted experiments to measure the force fields in the workspace of the frog's leg while stimulating the premotor sites in the frog's spinal cord. Their experimental results have shown that simultaneously stimulating two regions in the spinal cord generates the vector summation of the end-point forces generated by the separate stimulation of each spinal region (see MOTOR PRIMITIVES).

### *Adaptive Combination of Motor Primitives*

Based on results achieved in the linear combination of force fields, we might ask whether motor behavior learning can also be modeled in terms of changes in the primitive combination. Thoroughman and Shadmehr (2000) believe that a flexible combination of human motor primitives provides a model for experience-based complex movement learning. They suggest that the human brain builds a state-dependent internal model of muscle forces for generating the dynamic trajectories of movements. This internal model is essentially a sensorimotor map that is constructed by combining a set of motor primitives. The primitives have Gaussian-like turning functions for encoding arm velocities. The experience-based learning of a movement is therefore reflected in the adaptive adjustment of the weight matrix that defines the primitive combination.

### *Designing Force-Field Motor Primitives*

Insights into the organization of motor primitives and their role in the generation of force fields not only enhance our understanding of how biological neural circuits produce motor patterns, they also provide guidance in designing behavior-based robotic systems.

One of the earliest studies demonstrating the use of motor primitives in robot motion control was reported by Arkin in 1989. The object was to develop an experimental mobile robot system that would perform path planning and execution in a way resembling the Arbib and House (1987) model of detour behavior in the frog. The Arbib and House model is an abstraction that characterizes prey acquisition behavior in an obstacle-strewn environment, with primitive vector fields resulting from the frog's perception of its environment. The primitive vector fields are the prey-attractant field, barrier repellent field, and frog representation field. The path-determining vectors can therefore be calculated based on the summation of the primitive vector fields. In autonomous robot architecture (ARA), the path execution mechanism employs a set of concurrently activated motor behaviors called motor schemas. These schemas include *move-to-goal* (similar to the Arbib and House prey-attractant field), *avoid-static-obstacles* (similar to the Arbib and House repellant field), *stay-on-path, avoid-moving-obstacles, find-intersection*, and *find-landmark* behaviors (see REACTIVE ROBOTIC SYSTEMS).

### *Force-Field Motor Primitives in a Humanoid*

Mataric et al. (1998), drawing on biological findings concerning the organization of force-field motor primitives, have investigated the idea of generating complex motion based on a collection of basic motion primitives, and have demonstrated such a behavior-based motion control approach to a 20-degrees-of-freedom simulated humanoid torso. In their simulation, three behavior primitives are defined as a basic behavior set: *move-to-point, get-posture*, and *avoid. Move-to-point* is implemented using impedance control such that the arm of the humanoid, as if connected to virtual springs and dampers, can interact with complex environments with stability. *Get-posture* resembles the spinal field of the frog, which is generated by the spring-like muscles in the leg. Running concurrently with other two behavior primitives, *avoid* follows the virtual repulsive forces generated from the obstacles in the torso's environment. Based on the basic behavior primitives, more complex motor behaviors can be produced, such as *touch right hand to top of left shoulder*.

### *Behavior Templates and Anchors*

With the demonstration that complex motor behaviors can be induced in both animals and animats by incorporating various motor primitives, a new question concerning generalizing the concept of motor primitives arises: Can the dynamically coupled interactions between an organism and its environment, such as locomotion on land, be decoded as the neural control of motor primitives?

Full and Koditschek (1999) have suggested a neuromechanical approach to characterizing legged locomotion on land. Their approach involves the notions of template and anchor. The former provides a minimal behavioral model for guiding the control of locomotion; the latter offers elaborated morphological and physiological mechanisms for a template. Full and Koditschek hypothesize that the control of locomotion incorporates both neural and mechanical systems. During slow, variable-frequency locomotion, the neural system dominates. In the case of rapid, rhythmic locomotion, the mechanical system plays a key role.

## Artificial Potential Fields in Modeling External Task Constraints

The problem of robot motion planning has traditionally been treated as an optimization problem in which the configuration of a robot is represented in a parameter space and a solution to this problem is computed by searching the parameter space in an attempt to satisfy a predefined cost function, such as the distance between the robot and a goal point. The limitation of this approach is that it is computationally too costly to generate new plans when dealing with dynamic environments that involve unexpected obstacles. As a more practical approach to the real-time planning of collision-free motions for manipulators and mobile robots, the concept of an artificial potential field (APF) was proposed by Khatib (1986). The APF approach incorporates dynamic sensing feedback into robot control, and hence overcomes the aforementioned limitation by extending the reactiveness of the low-level motion control.

APF theory states that for any goal-directed robot in an environment that contains stationary or moving obstacles, an APF can be formulated and computed, taking into account an attractive pole at the goal position of the robot and repulsive surfaces of the obstacles in the environment. This potential field can be expressed as follows:

$$U_{\text{art}}(x) = U_{\text{goal}}(x) + U_{\text{obs}}(x) \tag{1}$$

where $U_{\text{art}}(x)$, $U_{\text{goal}}(x)$, and $U_{\text{obs}}(x)$ denote the APF, the attractive potential from the goal, and the repulsive potential from the obstacles, respectively, and $x$ denotes a set of independent parameters, called operational coordinates, that describe the position and orientation of the robot end-effector.

Generally speaking, $U_{\text{obs}}$ is chosen such that $U_{\text{art}}$ is a non-negative continuous and differentiable function that tends to infinity when $x$ approaches the surface of an obstacle and tends to zero when $x$ approaches the goal position, $x_{\text{goal}}$.

Given Equation 1, the force resulting from the APF at $x$ can therefore be derived as follows:

$$F_{\text{art}} = -\nabla[U_{\text{art}}(x)] \tag{2}$$

where $\nabla$ denotes a gradient.

## Potential Fields for Guiding Motion

Equation 2 tells us that applying APF $U_{\text{art}}(x)$ to a robot end-effector can here be realized by using $F_{\text{art}}$ as a command vector to control the end-effector in operational space (because the motion of the end-effector can be decoupled in operational space; Khatib, 1986). In so doing, the joint forces corresponding to $F_{\mathrm{art}}$ must be obtained using the Jacobian matrix. Under such a control, the robot will be able to avoid obstacles (as the repulsive force in the potential field "pushes" it away into the valleys of the field) and at the same time move toward a goal position (as the attractive force in the potential field "pulls" it in the direction of a global zero-potential pole).

By following the potential field that models the spatial constraints in an environment, a robot will be able to avoid obstacles and at the same time achieve stable configurations in its operational space. However, the stable configurations may not be guaranteed to include the goal configuration. In this case, a global motion plan may be used to guide the robot out of a local stable configuration and set it moving toward a goal position. Another alternative is to define an APF function that does not contain a local minimum. An example is a harmonic function defined in the configuration space of a robot where the boundaries of all obstacles and goals are treated as the boundary for the domain of the function.

## Other Forms of Potential Fields for Modeling External Task Constraints

Artificial potential fields for modeling external task constraints can take various forms. In the following discussion we consider two generalized APF formulations, *elastic bands* and *elastic strips*, that draw on and generalize the previous work on APF-oriented robot planning and control. These two approaches effectively allow real-time planning and control of robot motion that is both locally *reactive* to any dynamically changing obstacles and globally *optimal* with respect to any motion criteria for attaining a predefined goal.

### *Elastic Bands*

As implemented by Quinlan and Khatib (1993) in a mobile manipulation system, an elastic band has its own internal contraction force when it is in a stretched configuration; at the same time, it receives an external repulsive force if it is close to an obstacle. A *global* collision-free path corresponds to an elastic band at equilibrium that connects initial and goal locations. Whenever a new obstacle approaches, the elastic band will *react* to the situation by deforming itself until a new equilibrium is reached. To compute its artificial forces, an elastic band is represented as a series of consecutive *bubbles*. A bubble at a certain configuration is a spherical free subspace whose radius corresponds to the minimum distance between the configuration and the environment. The total force on the bubble is calculated as follows: The internal contraction force is created by a series of springs connecting the bubbles, whereas the repulsive force is exerted by an obstacle that pushes away the bubble and increases its size. Based on the calculated artificial forces, the position of the bubble will be locally updated, and hence the elastic band deforms.

### *Elastic Strips*

That elastic strips approach real-time motion planning and control was demonstrated by Brock and Khatib (1998). Their work generalizes the notion of bubbles centered at via points into protective hulls that consist of bubbles centered on the spines covering the individual rigid bodies of the manipulator and its mobile platform. Next, an elastic strip is formed by connecting consecutive configurations of the robot on its trajectory, and a tunnel of local free subspace is formed by connecting a series of consecutive protective hulls. With such a representation, it is possible to find the internal contraction force on the elastic strip by calculating the tension between two consecutive configurations for each respective joint of the robot. It is also possible to find the external repulsive force on the elastic strip by calculating the force acting on the bubbles of a protective hull. Hence, we can determine the deformation of the strip by taking into account the total force acting on the strip, and joint displacements by computing the respective joint torques. The equilibrium elastic strip provides a global collision-free trajectory for the robot that connects the initial and the goal configurations.

## Potential Fields in Interaction Controllers

So far we have discussed how potential fields are useful for representing the spatial constraints of a robot task environment in such a way as to effectively guide real-time motion planning and control. Another effective use of potential fields is in the design of robot dynamics that exhibit certain behaviors as if governed by a potential field.

This idea has been part of control systems theory for some time. For instance, Colgate and Hogan (1988) proposed designing a controller for a manipulator that would be capable of dynamically interacting with a diverse set of environments of unknown dynamics and parametric uncertainty. Their specifications for an *interaction controller* emphasize both coupled stability (in addition to nominal stability) and desirable interactive behavior (in addition to command following). The interactive behavior can be established by controlling the impedance of the manipulator as if it were connected with virtual springs and dampers. The stability of a linear system coupled to a passive environment can be guaranteed by making sure the driving point impedance of the system is real and positive.

## Artificial Neural Networks

Artificial neural networks (ANNs) are biologically inspired computational models. Each network is composed of a set of neurons connected by fixed synapses. A neuron receives stimuli from external input sources and exchanges messages with other neurons through the connecting synapses. As the strengths of connections between neurons are varied, the neural network builds an associative map between input data patterns and output values. With this computational capability, neural networks have been widely used to solve recognition and classification problems in control, pattern analysis, function learning, feature pattern extraction, and signal processing.

Depending on the homogeneity of neurons, the layered structure of networks, the algorithms for learning input-output associations, and the error propagation mechanisms, different ANNs can be developed, such as the multilayer perceptron, Hopfield networks, backpropagation networks, and Kohonen networks.

### *APF versus ANN Approaches*

Both APF and ANN approaches have been applied to solving practical problems ranging from robot motion planning and control to conceptual mapping and learning.

Given a certain geometric model of a physical environment, it is possible to derive an analytical form of APF for the environment as a function of operational coordinates. An advantage to having an analytical form of APF is that the analytical expression is easier to update if changes occur in the environment. An ANN, on the other hand, builds a numerical input-output map for a set of empirical observations based on a weight-updating and error-correction algorithm. When new empirical data arrive, it is necessary to update the existing ANN by iterating the learning algorithm with each sample of the new data set. As a result of such step-by-step relearning, the weights of an ANN will be modified to some extent, reflecting the discovery and acquisition of new patterns from the data.

With an APF, a robot can reach a stable configuration in its environment by following the negative gradient of its potential field. In this case, locally stable configurations are inevitable. Nevertheless, they can be readily overcome by either incorporating a global motion planner, or utilizing a harmonic function that does not contain any local minima, or applying generalized APF formulations such as elastic bands and elastic strips. The APF approach is particularly advantageous when dealing with robots with many degrees of freedom in dynamically changing environments.

Similarly, an ANN offers another practical way to solve optimization problems, especially when the search space is of high dimension. With an ANN, the goal is to build an optimal association from given input data patterns to desirable output values. Thereafter the optimal association can be incrementally obtained as the network evolves toward a stable equilibrium state. Unlike the case of an APF, where a stable configuration is approached through updating the configurations following a potential field, the evolution of the neural network relies on updating connection weights and error corrections for the network in accordance with a learning algorithm.

## Artificial Neural Network–Based Potential Field Motor Control

An important challenge in the practical applications of APF methodology is to formulate a potential field. For a given robot environment, this task can be decomposed into the subtasks of identifying geometrical primitives in the environment, calculating individual repulsive potential functions for the primitives, and composing a global potential field function based on the individual potential functions. The question that remains is how the APF methodology can be used if the robot environment concerned is not given as a priori knowledge. In such a situation, it would be essential to dynamically derive a numerical potential field representation based on the sensory data obtained during the interaction between the robot and its environment. As mentioned earlier, the ANN methodology is well suited to derive associative maps from certain available input data. In this respect, the ANN approach enables the application of APF in unknown environments.

### *Operational Space Motor Control*

In the past, several researchers have focused on the research question of how to build an operational space potential field map based on real-time sensory measurements. For instance, Prassler (1995) has proposed the use of a massively parallel network of simple processing elements, arranged in a rectangular grid structure, for computing and manipulating a two-dimensional (2D) potential field. The structure is of three layers: a long-term map (LTM) that describes the stationary parts in the environment, a short-term map (STM) that describes a more recent state of the environment, and an occupancy grid representation of the current sensory readings.

### *Collective Self-Organization*

One of the practical concerns in merging APF with an ANN approach is input data requirement. Generally speaking, evolving a stable APF is a time-consuming learning process that requires a large amount of input data coming from the robot-environment interaction. In order to overcome this shortcoming, Liu and Wu (2001) have proposed an evolutionary self-organization learning approach that can efficiently build a potential field map by determining and collecting locally most informative sensory measurements from an unknown environment. This approach can readily be used by a group of cooperative robots for collective exploration and world modeling.

### *Joint-Space Motor Control*

Besides developing an APF that explicitly models the geometrical characteristics (e.g., clearance) of a robot environment, some studies have focused on how to acquire an APF map directly encoded in the joint space of a robot. Falling into this category are efforts to enable the robot to learn reactive joint activation strategies in response to different external sensory conditions.

An example of such studies is the work on the operant conditioning–based learning of approach and avoidance behaviors in a mobile robot by Chang and Gaudiano (1998). In their study, a wheeled mobile robot is developed that uses a form of self-supervised learning based on an operant conditioning neural network. The output of this neural network is a one-dimensional (1D) population of neurons that encodes the robot's angular velocities, called an angular velocity map, for its left and right wheels. The robot learns its avoidance behavior through "punishment" signals produced by the collision of the robot during random exploratory motion. As a result, a given pattern of sensory inputs will tend to suppress movements that would yield punishment. On the other hand, an excitatory association may be acquired by the robot as it receives a reward such as higher light intensity, with the result that the robot reinforces its movements toward light sources. Unlike the aforementioned 2D operational space APF, the acquired angular velocity map is a 1D representation that directly encodes the potential fields in the joint space of the robot's two wheels.

## Artificial Neural Network–Based Perception and Inverse Kinematics for Navigation

Neural networks have been applied not only to build a robot's internal representation of its task environment but also to acquire the control strategies for its collision-free motion. In a vision-based manipulator navigation system, Blase, Pauli, and Bruske (1998) have shown the use of two layers of radial basis function (RBF) networks in the three-dimensional (3D) reconstruction of obstacles from their optical flow vectors. The RBF networks in the first layer are trained for respective image areas to give the depth coordinate $z$. The depth coordinate $z$ is in turn used by the second layer to generate the corresponding $x$ and $y$ coordinates of the obstacle. In addition, their system also uses one layer of RBF networks to construct the inverse kinematics of a manipulator. Based on the 3D models of obstacles and the inverse kinematics built, the manipulator knows where the obstacles are and how to reach a goal position. While navigating toward the goal position, it also avoids the detected obstacles. In so doing, it dynamically constructs and follows a vector field of simulated forces generated by repulsive forces encoding the obstacle constraints and attractor forces encoding the desired goal.

## Summary

In this article, we have examined some of the important biological findings in the use of potential fields to characterize the control and learning of motor primitives. Such biological insights can lead to the development of primitive motor behavior–based robots capable of interacting with dynamic environments. Similarly, the concept of potential fields can be incorporated to model the externally induced constraints as well as the internally constructed sensorimotor maps for robot motion control. Apart from its biological relevance, potential field–based motion control can benefit from the use of ANN-based learning.

# Prefrontal Cortex in Temporal Organization of Action

*Joaquín M. Fuster*

## Introduction

The prefrontal cortex is the association cortex of the frontal lobes. It is one of the cortical regions to develop last and most in the course of evolution (Figure 1). In the human brain it constitutes nearly one-third of the totality of the neocortex. Also in the course of individual ontogeny, the prefrontal cortex is one of the cortices to develop last and most. The cellular and connective architecture of the human prefrontal cortex does not reach full maturity until young adulthood. Presumably, the reason for the late morphological development of this cortex, in both phylogeny and ontogeny, is its support of higher cognitive functions related to the capacity to execute novel and complex actions, which reaches its maximum in the adult human brain. The prefrontal cortex of primates can be anatomically subdivided into three major regions: inferior or orbital, medial-cingulate, and lateral. Of the three, the lateral prefrontal cortex, that is, the association cortex of the convexity of the frontal lobe, is the one that undergoes the most development phylogenetically and ontogenetically and is the most implicated in cognitive functions. In the human it is appropriate to label it "the organ of creativity."

In primates, the cortex of the frontal lobe in its entirety can be considered *motor cortex* in the broadest sense of the term, for it is cortex dedicated to the representation and execution of all manner of actions of the organism: actions in the skeletal domain, in the oculomotor domain, in the visceral domain, in the language domain, and in the domain of complex cognitive operations, such as reasoning and problem solving. The inferior (orbital) and medial regions of the prefrontal cortex are involved in the representation and enactment of emotional behavior and related visceral and autonomic manifestations. The lateral region, on the other hand, is involved in the representation and temporal organization of sequential behavior and, in the human, of speech and reasoning. In this article I consider, in particular, the physiological functions of the lateral prefrontal cortex in the temporal organization of behavior.

## Anatomy and Connections

By anatomical definition, the prefrontal cortex of the primate is comprised of three major regions (Figure 2), each with a somewhat different cytoarchitecture (Petrides and Pandya, 1994): the *lateral* prefrontal cortex (LPC), or association cortex of the frontal convexity (Brodmann's area 46, and lateral parts of areas 8, 9, 10, and 11); the *medial* and *cingulate* prefrontal cortex, which is nearly flat and faces the medial surface of the contralateral frontal pole (areas 12, 24, and 32, and medial parts of areas 8, 9, 10, and 11); and the *inferior* or *orbital* prefrontal cortex, directly above the orbit of the eye (areas 13, 47, and inferior parts of 10, 11, and 13). The lateral region is bordered in the back by the premotor cortex (area 6); the medial and orbital prefrontal cortices lie anterior to the corpus callosum and limbic structures (piriform cortex and amygdala, cingulate cortex, septum, and hypothalamus).

The prefrontal cortex is one of the best connected of all cortices (Fuster, 1997). It maintains reciprocal fiber connections with a wide range of subcortical and cortical structures. Especially prominent are its connections with the anterior, medial, and dorsal nuclei of the thalamus. In addition, all three prefrontal regions are connected with several limbic structures, especially the hippocampus, the amygdala, and the hypothalamus. Further, the lateral region sends important efferents to the basal ganglia, notably the caudate nucleus, the globus pallidus, and the substantia nigra. Finally, the prefrontal cortex—especially its lateral component—is topologically and reciprocally connected with other frontal areas (premotor,

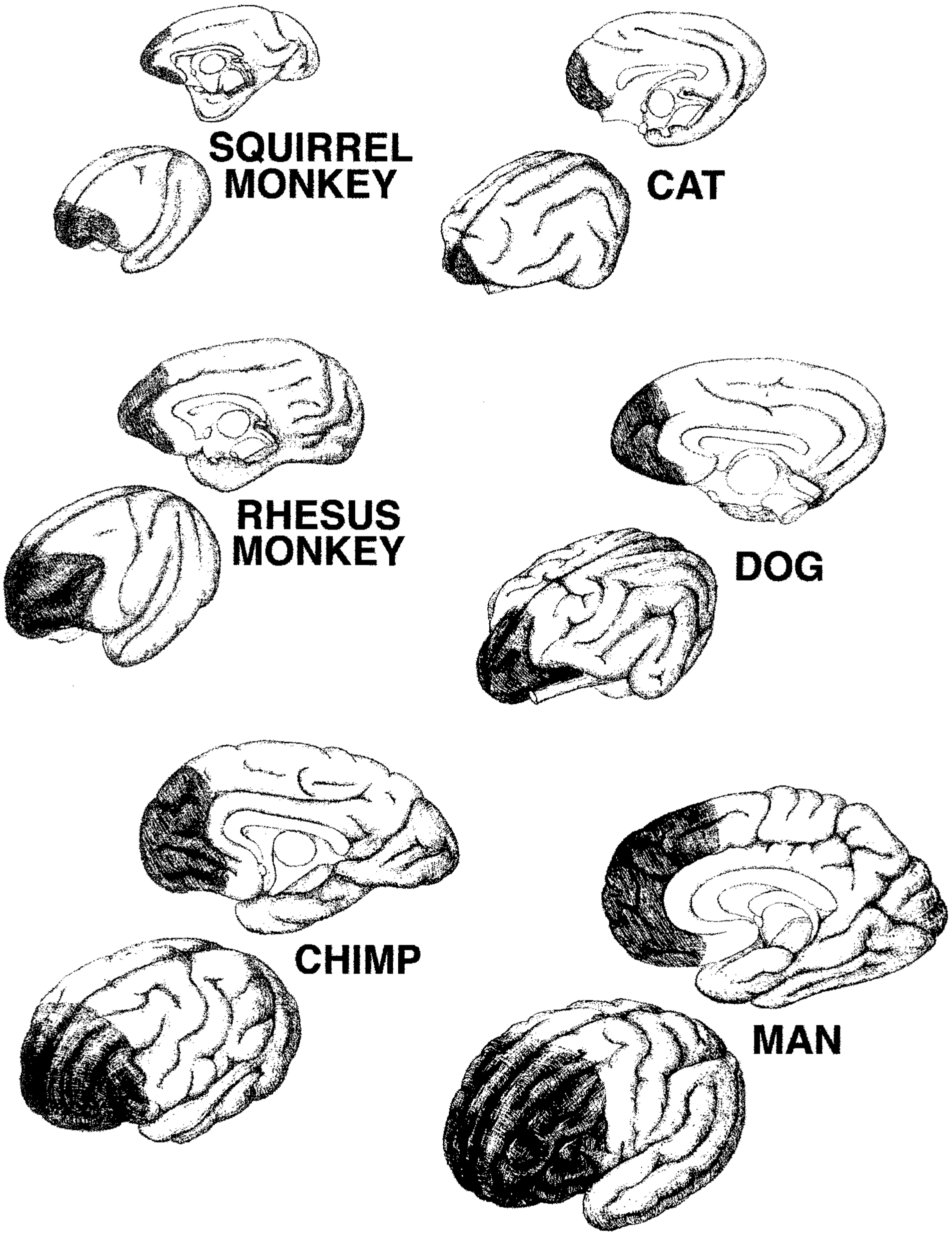

**Figure 1.** The prefrontal cortex (dark shading) in six mammalian species.

motor cortices) and with areas of posterior cortex, that is, with posterior cortical areas of association in the parietal and temporal lobes (Pandya and Yeterian, 1985).

The connections of the prefrontal cortex with the thalamus mediate inputs from the brainstem and limbic structures to that cortex, as well as inputs from itself (reentrant) and from other cortical regions. However, the functional role of the thalamic connectivity of the prefrontal cortex is still largely unknown. The direct limbic connections of the prefrontal cortex, especially with the amygdala and the hippocampus, are most likely essential for the formation of executive (motor) memory in that cortex, as well as for its retrieval. Connections of ventral and medial prefrontal cortex with limbic and brainstem structures probably serve the functions of the prefrontal cortex in drive, motivation, and the control of emotional behavior. Its outputs to basal ganglia are part of reentry loops that, beyond these nuclei, course through the thalamus and return to frontal cortex; those connective loops play a major, though still poorly understood, role in motor control. All the corticocortical connections of the prefrontal cortex, especially the lateral region, are important for the cognitive functions of that cortex in the temporal organization of behavior and, presumably, also speech and reasoning.

## Physiology

The medial and orbital prefrontal areas are involved in motivation, emotional behavior, and visceral functions. The precise nature of those involvements and their mechanisms is unknown, especially because the relevant evidence derives almost exclusively from the study of the effects of lesions. Large lesions of the medial prefrontal cortex in the human cause apathy and lack of spontaneity in speech, behavior, and reasoning. The orbital prefrontal cortex is essential for the inhibitory control of internal drives and instinctual behavior. Animals or humans with orbitofrontal lesions commonly manifest

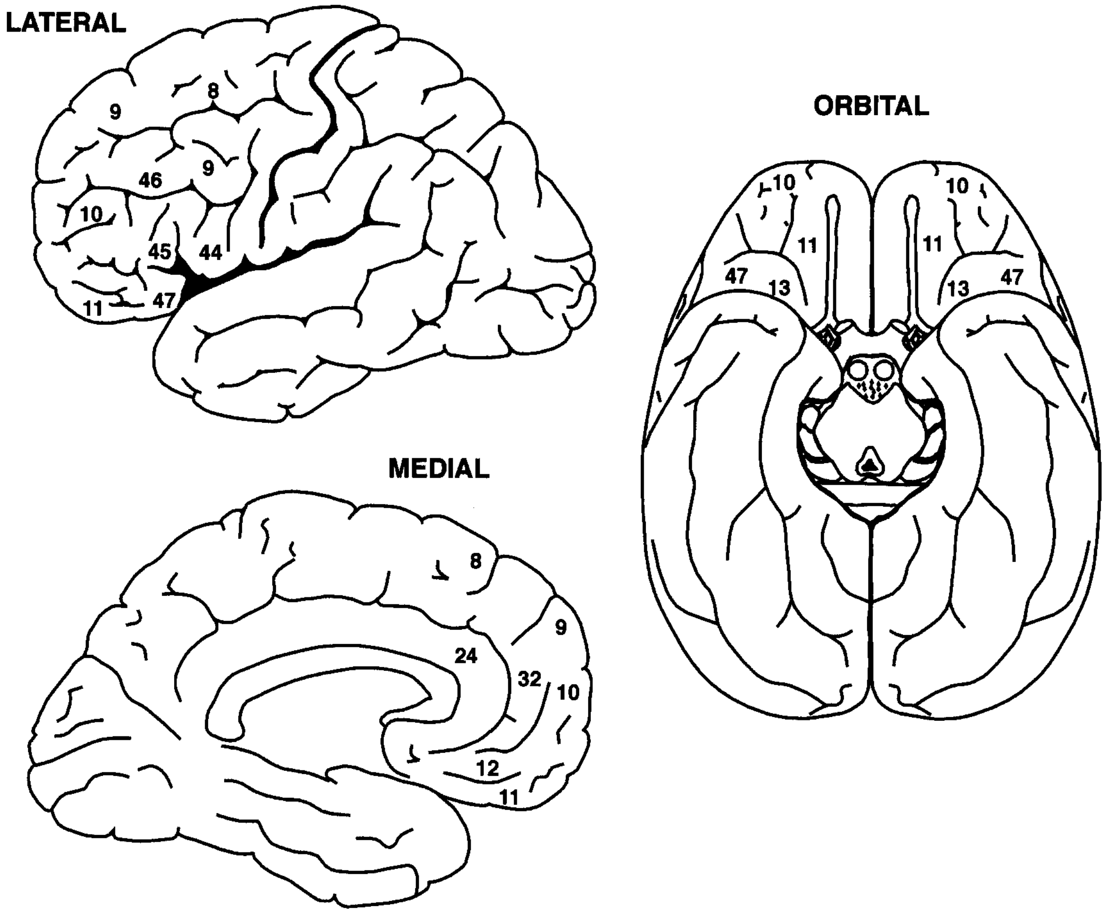

**Figure 2.** Three views of the frontal lobe. Prefrontal areas designated by numbers in accord with Brodmann's cytoarchitectonic map.

disinhibition of eating, sex, and aggression, as well as abnormal social behavior related to those disinhibitions. The human subject with lesions of that cortex is prone to impulsivity, risk taking, gross humor, and lack of moral judgment. Insofar as appropriate drive and impulse control are essential to sustain attention, the orbitomedial prefrontal cortex is important for the general role of the prefrontal cortex in rational decision making and the organization of cognition and behavior.

The prefrontal cortex of the lateral convexity plays a role in the representation as well as the execution of temporally organized sequences of behavior and cognition (Fuster, 1997); that role extends to language and reasoning. Those representations can be generally categorized as motor or executive memory. This form of memory includes, in particular, the representations of new and complex schemes of sequential action. After they have been learned and automatized, sequential behaviors become part of procedural executive memory and are no longer represented or enacted by the prefrontal cortex (Grafton et al., 1992) but by other structures at lower stages of the neural hierarchy for the organization of movement (e.g., premotor cortices, basal ganglia).

Anatomical, physiological, and neuropsychological studies have led some investigators to infer areas within LPC that specialize in various aspects of cognitive information. In the human as in the monkey, the so-called frontal eye field of area 8 is implicated in visual attention. Further, single-cell studies in the monkey support the commitment of that and other lateral areas to the representation of separate categories of visual information, such as spatial location or shape (Goldman-Rakic, 1995). Other studies, however, point to the supramodal associative characteristics of cells in all prefrontal areas. Lateral prefrontal cells have been found to associate information across sensory modalities and across time (Fuster, Bodner, and Kroger, 2000). Some of those cells associate sensory stimuli with subsequent motor actions (Rainer, Assad, and Miller, 1998) or rewards (Hikosaka and Watanabe, 2000). These associative properties of lateral prefrontal cells emphasize their integrative functions. Their apparent sensory or motor specificity may be determined by the specificity of their inputs from sensory structures or outputs to motor structures. That specificity seems subservient and secondary to their functions of cognitive integration, which are essential for the temporal organization of behavior.

The connections of the prefrontal cortex with the hippocampus may be critical for the formation of the procedural memory of behavioral sequences in that cortex, in a similar manner as connections between hippocampus and posterior cortex play an important role in the formation of so-called declarative memory (episodic and semantic). The procedural or executive memory networks of the cortex of the frontal lobe seem hierarchically organized (see Cortical Memory). The primary motor cortex, which is the lowest stage of that organization, represents the elementary motor "memories" of somatic movements executed by synergistic muscle groups. Above the motor cortex, the premotor cortex represents movements by goal and trajectory. At the summit of the cortical motor hierarchy, the LPC represents schemes and sequences of goal-directed action. In addition to representing those schemes and sequences, the LPC plays a critical role in their execution, especially if they are novel and complex.

## Temporal Organization of Behavior

The execution of a sequence of new and complex behavior is a highly elaborate, dynamic process of temporal integration that engages numerous cortical and subcortical brain regions. That process takes place under what may be called the orchestrating functions of the LPC, which ensure the structuring of behavior toward its ultimate goal, whether that goal is the satisfaction of a drive or the solution of a problem (Fuster, 2001). Two temporal integrative functions seem to be at the root of the role of LPC in the formation of behavioral structures. The two are temporally symmetrical and mutually complementary. One is a *retrospective* function of short-term memory, the other a *prospective* function of preparatory set. The two together help the organism to mediate cross-temporal contingencies of behavior. Both engage the executive networks of LPC in functional interactions with lower frontal cortices, subcortical structures, and posterior association cortex.

### *Short-Term Memory*

The LPC function of short-term memory in support of temporal integration approximately coincides with what in cognitive psychology has been named *working memory* (Baddeley, 1992). This function is essentially the temporary retention—"on-line"—of information, old or new, for the execution of an action in the short term, as required for complex behavior or the solution of problems. There is a wealth of evidence that the LPC is critically involved in this process of active short-term memory toward a goal (Fuster, 1997). Selective cortical lesion (or inactivation) of LPC induces deficits in the performance of "delay" tasks (e.g., delayed response, delayed matching). In these tasks, the animal is presented on successive trials with an item of sensory information (which varies from trial to trial) and is required to retain it in memory for executing a given motor response seconds or minutes later. Monkeys with lesions of LPC seem unable to keep the working memory of the stimulus for each trial, as they make many errors, even with short delays. Further evidence for prefrontal short-term memory derives from single-cell recording in animals performing delay tasks. Neurons of LPC fire persistently, and often at stimulus-specific frequency, during the delay (memory period) of every trial (Fuster and Alexander, 1971; Niki, 1974; Funahashi, Bruce, and Goldman-Rakic, 1989). These observations indicate the importance of the neuronal dynamics of LPC for working memory and for the performance of delay tasks that depend on this form of memory.

The function of the prefrontal cortex in active short-term memory is essentially defined by its teleological quality, that is, by the presence of an objective in the near future, which is the construction of prospective action toward a goal. As noted above, some prefrontal areas seem to specialize in the sensory and motor aspects of the information retained in working memory. That apparent specialization may derive from different concentrations of specific inputs and outputs in those areas. In general terms, however, each area is probably engaged in the temporary activation of specific sensory-sensory or sensory-motor associations leading to organized sequential action. In those terms, the cell groupings and areas of LPC are components of teleological associations, the mnemonic paths to prospective action.

The precise neural mechanism of working memory is still unknown. Based on physiological evidence from the monkey (summary review in Fuster, 1997), it appears that working memory is maintained by the persistent activation of the widely distributed cortical network that represents its content (see CORTICAL MEMORY). The network contains neuronal assemblies of sensory representation in posterior cortex and neuronal assemblies of motor or executive representation in LPC. A plausible assumption, still unproved, is that the activation of one such network serving working memory depends on the reverberation of neural excitation within it. The excitation of the network would thus be sustained through reentrant loops of reciprocal connection between lateral prefrontal and posterior—e.g., inferotemporal, parietal—cortex. Hence, recurrent cortical architecture is an essential feature of the most plausible and empirically testable computational models of working memory, as well as of other cognitive functions (Zipser et al., 1993; Duncan, 2001; Wang, 2001).

### *Prospective Set*

Likewise, from the teleological nature of the temporal structuring of behavior derives the prefrontal function of readiness to act. The setting of sensory receptors and motor effectors for prospective actions is, in the time domain, the mirror image of active short-term memory. This complementary integrative function of preparatory set is the counterpart of working memory. It serves to prepare the subject for anticipated actions; it is the "memory of the future" that will complement retrospective memory in the bridging of a cross-temporal contingency. The neural mechanisms of prospective set are not yet well understood. These mechanisms probably result in the priming of sensory and motor structures by way of efferent connections of the prefrontal cortex. In both human and nonhuman primates, the involvement of LPC in preparatory set is reflected by the progressive increase in cell discharge and the slow surface-negative potentials that take place in that cortex before a stimulus-contingent act. Both memory and set seem to occur at the same time and in the same areas of LPC, both simultaneously during the interval that separates two mutually contingent events. While some prefrontal neurons engage in the memory of the cue, others engage in the preparation of the consequent and subsequent behavioral response. Neuronal recording from the LPC shows that, while the memory of the sensory information wanes, the representation of the response in preparation increases (Quintana and Fuster, 1999).

The selection of an action among many is the motor equivalent of focusing sensory attention. Consequently, the prefrontal function of prospective set may be appropriately considered *motor attention*, that is, the selective focusing of attention on a motor act to ensure the prompt and efficient execution of that act in the near future. In conclusion, the symmetry of the two temporal integrative functions of the LPC, active memory and set, parallels the symmetry of attentive processes, one sensory and the other motor. Active short-term memory is attention focused on the representation of a recent sensory stimulus, while prospective set is attention focused on a subsequent and consequent act. Whereas attention, in particular sensory attention, is commonly associated with conscious awareness, neither of the two temporal integrative functions of the LPC, active memory or set, need be conscious to accomplish their objective.

## Perception-Action Cycle

The temporal organization of complex behavior requires a continuous succession of sensorimotor integrations, that is, a succession of temporal mediations of contingencies between sensory events and consequent motor acts. To some degree, each integration depends on previous ones. Each sensorimotor integration induces certain changes in the environment that will determine and modify subsequent sensory inputs, and these will determine and modify subsequent acts, and so on. This cybernetic cycle of interactions of the organism with its environment, through a series of sensorimotor integrations, is a fundamental principle in biology: the perception-action cycle.

The neural operations of the perception-action cycle ensure that mutually contingent percepts and acts are properly integrated in the progression of behavior toward its goal. The attainment of that goal requires the attainment of lesser or subordinate goals, each dependent on a particular translation of perception to action and its consequent change in the environment. Innumerable neural structures participate in the mediation of perception-action contingencies that one such sequence requires. These structures, both on the sensory side and on the motor side, are hierarchically organized throughout the nerve axis, from the spinal cord to the cerebral cortex, and also within the latter. Figure 3 shows highly schematically the cortical layers of the perception-action cycle. If the behavior is new, all layers of that cycle are involved in its temporal organization, up to and including the cortex. Routine and automatic sequences, such as walking, are relegated to and organized at lower levels. The cortex remains involved even if the behavioral sequence is old and well rehearsed but contains uncertainties or ambiguities.

Goal-directed behavioral sequences may contain delays or temporary interruptions imposed by the subject or by the environment. Such is the case with the so-called delay tasks, where time intervenes between a percept and an action that are contingent from each other. Because that contingency must be mediated cross-temporally, the correct performance of those tasks depends on the LPC. The LPC, through the two temporally integrative functions of short-term memory and prospective set, integrates perception with action across time at the highest level of the hierarchy of neural structures serving the perception-action cycle. There is considerable empirical evidence that the LPC performs those temporal integrative functions in dynamic cooperation with posterior cortical areas of association, which constitute the highest substrate for the perceptual side of the cycle. The highest and most characteristically human operations of the perception-action cycle take place in the construction of the spoken language. Given what we know about the role of posterior cortex (Wernicke's area) and LPC in the perceptual and motor aspects of language, respectively, it is reasonable to view those cortices as the highest levels of the perception-action cycle for speech. At the neural root of a dialogue between two persons, it is appropriate to hypothesize a dynamic interaction of the cycles of the two interlocutors. The action of one is the perception of the other, and vice versa. The frontal and postcentral cortices of the two subjects would thus interact reciprocally in the coordination of two perception-action cycles organizing the dialogue in the temporal domain.

## Discussion

The association cortex of the frontal lobe, or prefrontal cortex, is highly heterogeneous, anatomically as well physiologically. Further, this cortex is widely connected with many other brain structures, cortical and subcortical. The heterogeneity and diverse connectivity of the prefrontal cortex serve a variety of functions related to the organization of actions in the temporal domain. This article has focused on the temporal organizing functions of the LPC, the prefrontal region that undergoes the greatest phylogenetic and ontogenetic development in primates. Two of those functions have been highlighted that are especially evident in the primate: active short-term memory (working memory) and prospective set. The two cooperate toward temporally integrating sensory and motor information by mediating cross-temporal contingencies of behavior. This integrative role of the prefrontal cortex covers a wide range of sensory inputs and motor outputs; hence the apparent sensory or motor specificity of certain prefrontal areas. Temporal integration seems to be the overarching function that, despite their heterogeneity, unifies the many activities and functions of the LPC.

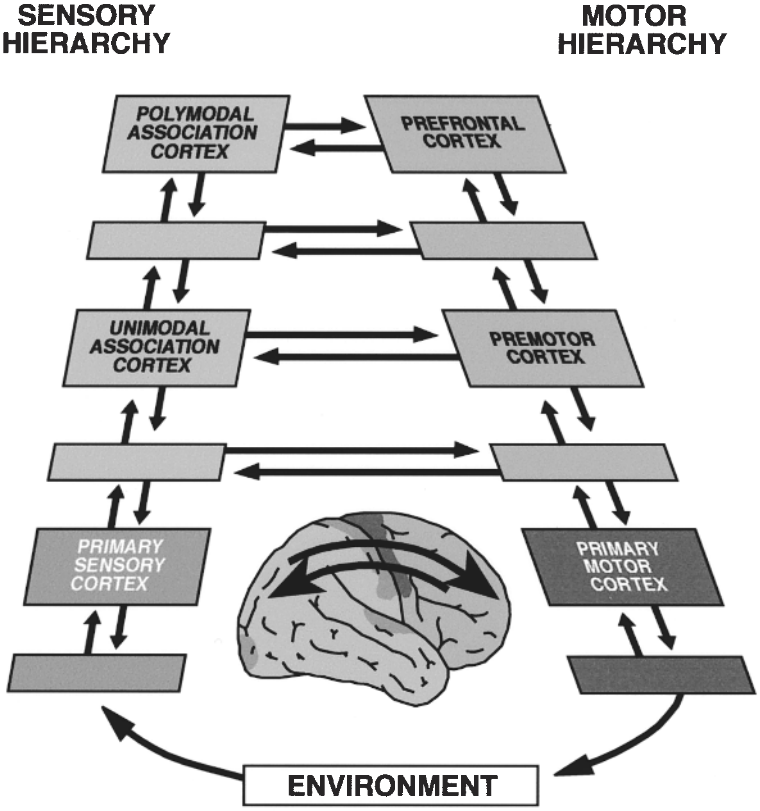

**Figure 3.** The cortical hierarchies of the perception-action cycle depicted around a lateral view of the human brain. Unlabeled cortical entities represent subareas of labeled regions or areas interposed between them. The arrows represent connections that have been demonstrated in the monkey.

Temporal integration, through memory and set, supports the goal-directed performance of the perception-action cycle. It is a role that extends to the temporal organization of higher cognitive operations, including spoken language.

# Principal Component Analysis

*Erkki Oja*

## Introduction

Principal Component Analysis (PCA) and the closely related Karhunen-Loève transform, or the Hotelling transform, are standard techniques in feature extraction and data compression (see, e.g., Devijver and Kittler, 1982; Oja, 1983). In general terms, the input vectors in PCA are random vectors $x$ with $K$ elements. In PCA, no assumptions on the probability density of the vectors are needed, as long as their means and covariances are known or can be estimated from a sample. This is in contrast to another well-known statistical technique, factor analysis, that is based on an explicit Gaussian model. Typically the elements of $x$ are measurements such as pixel gray levels or the values of a signal at different time instants. They are mutually correlated.

In the PCA transform, vector $x$ is linearly transformed to another vector $y$ with $N$ elements, $N < K$, so that the redundancy induced by the correlations is removed. This is done by finding a rotated coordinate system such that the elements of $x$ in the new coordinates become uncorrelated. For instance, if $x$ has a Gaussian density that is constant over ellipsoidal surfaces in the $K$-dimensional space, then the rotated coordinate system coincides with the principal axes of the ellipsoid. Even if the density is not Gaussian, similar principal axes can be computed. For most practical data, the density is not spherical but strongly elongated, and thus the axes have very different lengths. A considerable number of the axes are so small that the components they represent can be discarded altogether. Those components that are left constitute vector $y$.

As an example, take a sequence of small $32 \times 32$ digital images of hand-written characters. In real-time digital video transmission, it would be essential to reduce such images as much as possible without losing too much of the visual quality, because the total amount of data is very large: 1024 pixels for each image. Using PCA, a compressed representation vector is obtained for each image, which can be stored or transmitted. Figure 1 shows two examples of such characters from a large database and the reconstruction from the compressed PCA representation. This is the fundamental idea behind practical image and signal compression methods like the discrete cosine transform.

In mathematical terms, consider a linear combination

$$y_1 = \sum_{k=1}^{K} w_{k1} x_k = w_1^T x$$

of the elements $x_1, \ldots, x_K$ of vector $x$, where $w_{11}, \ldots, w_{K1}$ are scalar coefficients or weights, elements of a $K$-dimensional vector $w_1$, and $w_1^T$ denotes the transpose of $w_1$. Usually it is assumed that $x$ has zero mean; if not, then the mean vector is estimated separately and subtracted from $x$ to obtain a zero mean vector.

The factor $y_1$ is the first principal component of $x$ if the variance of $y_1$ is maximally large under the constraint that the norm of $w_1$ is constant (see, e.g., Devijver and Kittler, 1982). Then the weight vector $w_1$ maximizes the PCA criterion

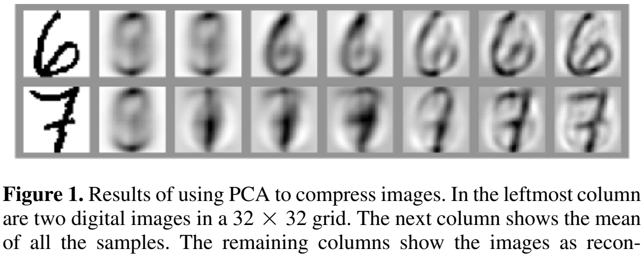

**Figure 1.** Results of using PCA to compress images. In the leftmost column are two digital images in a $32 \times 32$ grid. The next column shows the mean of all the samples. The remaining columns show the images as reconstructed by PCA when 1, 2, 5, 16, 32, or 64 principal components (out of the total of 1024) were used in the expansion.

$$J_1^{PCA}(w_1) = E\{y_1^2\} = E\{(w_1^T x)^2\} = E\{(w_1^T x)(x^T w_1)\}$$
$$= w_1^T E\{xx^T\} w_1 = w_1^T C w_1, \ \|w_1\| = 1 \tag{1}$$

where $E\{\cdot\}$ is the expectation over the density of input vector $x$, and the norm of $w_1$ is defined as

$$\|w_1\| = (w_1^T w_1)^{1/2} = \left[\sum_{k=1}^{K} w_{k1}^2\right]^{1/2}$$

The matrix $C$ in Equation 1 is the $K \times K$ covariance matrix defined by

$$C = E\{xx^T\} \tag{2}$$

The solution is given in terms of the unit-length eigenvectors $c_1, \ldots, c_K$ of the matrix $C$. With $\lambda_1, \ldots, \lambda_K$ the corresponding eigenvalues in decreasing order (or nonincreasing, in case of multiple eigenvalues), the solution is given by

$$w_1 = c_1$$

Thus the first principal component of $x$ is given by $y_1 = c_1^T x$.

The criterion $J_1^{PCA}$ in Equation 1 can be generalized to $N$ principal components, with $N$ any number between 1 and $K$. Denoting the $n$th ($1 \leq n \leq N$) principal component by $y_n = w_n^T x$ with $w_n$ the corresponding weight vector, the variance of $y_n$ is maximized under the constraints

$$\|w_n\| = 1, \ w_n^T w_m = 0, \ m < n \tag{3}$$

Note that compared to the first principal component, there is now the extra constraint that the weight vector $w_n$ must be orthonormal with all the previous weight vectors. The solution is

$$w_n = c_n$$

thus the $n$th principal component is $y_n = c_n^T x$. It follows that

$$E\{y_n^2\} = E\{c_n^T x x^T c_n\} = c_n^T C c_n = \lambda_n$$

This can often be used in advance to determine $N$, if the eigenvalues are known. The eigenvalue sequence $\lambda_1, \lambda_2, \ldots$ is usually sharply decreasing, and it is possible to set a limit below which the eigenvalues, hence principal components, are insignificantly small. This limit determines how many principal components are used.

Another possible extension of Equation 1 is:

$$J_N^{PCA}(w_1, \ldots, w_N) = E\left\{\sum_{n=1}^{N} y_n^2\right\} = E\left\{\sum_{n=1}^{N} (w_n^T x)^2\right\}$$
$$= \sum_{n=1}^{N} w_n^T C w_n = max \tag{4}$$

$$w_m^T w_n = \delta_{mn} \tag{5}$$

This criterion determines the subspace spanned by vectors $w_1, \ldots, w_N$ in a unique way as the subspace spanned by the $N$ first eigenvectors $c_1, \ldots, c_N$, but does not specify the basis of this subspace at all.

To use the closed-form solutions given above, the eigenvectors of the covariance matrix $C$ must be known. This is rarely true in practice. In an on-line data compression application like image or speech coding, it is usually not possible to solve the eigenvector-eigenvalue problem for computational reasons. The PCA solution is then replaced by suboptimal standard transformations. Another alternative is to derive gradient ascent algorithms for the maximization problems above. The algorithms will then converge to the solutions of the problems, i.e., to the eigenvectors. This approach is the basis of the neural network learning rules.

## PCA Learning Algorithms and Neural Networks

Neural networks provide a novel way for parallel on-line computation of the PCA expansion. The PCA network (Oja, 1992) is a layer of parallel linear artificial neurons (Figure 2). The output of the $n$th unit ($n = 1, \ldots, N$) is $y_n = w_n^T x$, with $x$ denoting the $K$-dimensional input vector of the network and $w_n$ denoting the weight vector of the $n$th unit. The number of units, $N$, will determine how many principal components the network will compute. Sometimes this can be determined in advance for typical inputs, or $N$ can be equal to $K$ if all principal components are required.

The PCA network learns the principal components by unsupervised learning rules, by which the weight vectors are gradually updated until they become orthonormal and tend to the theoretically correct eigenvectors. The network also has the ability to track slowly varying statistics in the input data, maintaining its optimality when the statistical properties of the inputs do not stay constant. Because of their parallelism and adaptivity to input data, such learning algorithms and their implementations in neural networks are potentially useful in feature detection and data compression tasks.

Some basic learning algorithms are listed here. In the following, $k$ denotes discrete time; thus $x(k)$ is a stream of input data vectors (e.g., image windows or segments of a time-varying signal) entering the learning neural network. The learning weight vectors are $w_j(k), j = 1, \ldots, N$.

### *The Stochastic Gradient Ascent (SGA) Algorithm*

This algorithm (Oja, 1983) is obtained from the maximum variance criterion by taking the gradients with respect to weight vector $w_j$ and using the normalization constraints. Denoting

$$\Delta w_j(k - 1) = w_j(k) - w_j(k - 1) \tag{6}$$

the learning rule is

$$\Delta w_j \ (k - 1) = \gamma(k) y_j(k)[x(k) - y_j(k) w_j(k - 1)$$
$$- 2 \sum_{i<j} y_i(k) w_i(k - 1)] \tag{7}$$

There, $\gamma(k)$ are the step sizes in the gradient ascent, typically a sequence of small numbers tending slowly to zero.

The first term on the right contains the product $y_j(k)x(k)$, which is a Hebbian term—note that $y_j(k) = w_j(k - 1)^T x(k)$ is the output of the $j$th neuron at time $k$, and $x(k)$ is the input—and the other terms are implicit orthonormality constraints. The case $j = 1$ gives

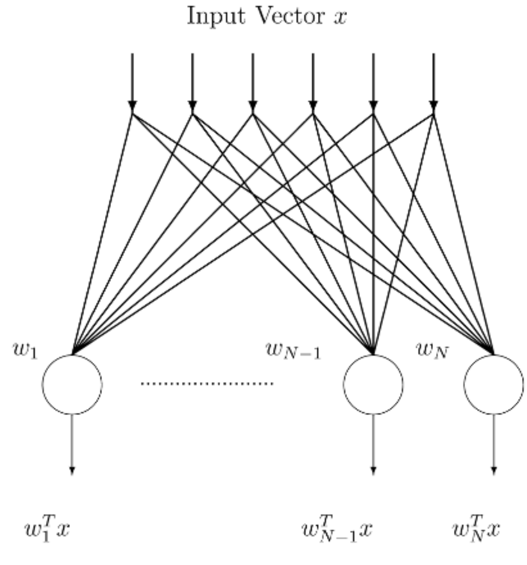

**Figure 2.** The basic linear PCA layer.

the constrained Hebbian learning rule of the basic PCA neuron introduced by Oja (1982). The convergence of the vectors $w_1(k)$, . . . , $w_N(k)$ to the eigenvectors $c_1, \ldots, c_N$ was established by Oja (1983). A modification called the generalized Hebbian algorithm (GHA) was presented by Sanger (1989), who also applied it to image coding, texture segmentation, and the development of receptive fields.

The algorithm may have significance in hierarchical clustering of learned cues in the cerebral cortex. Ambros-Ingerson, Granger, and Lynch (1990) performed simulations on the olfactory paleocortex receiving inputs from the olfactory bulb. They used a network model resembling the SGA algorithm in which the first neuron (in their case, a competitive subnet) learned the input as such, and consequent neurons (subnets) learned progressively masked versions of the input. Masking corresponds to subtracting from the input the previous weight vectors, as in Equation 7. The simulation revealed how perceptual hierarchies may arise for recognizing environmental cues.

### *The Subspace Network Learning Algorithm*

The subspace network learning algorithm (Oja, 1983; Williams, 1985) is formulated as follows:

$$\Delta w_j(k - 1) = \gamma(k) y_j(k)[x(k) - \sum_{i=1}^{N} y_i(k) w_i(k - 1)] \quad (8)$$

It is obtained as a gradient ascent maximization of criterion 4. The network implementation is analogous to the SGA algorithm but still simpler, because the feedback term, depending on the other weight vectors, is the same for all neuron units. Thus, learning at an individual connection weight $w_{ji}$ is local, as it depends only on $y_i$, $x_j$, and the feedback term, all of which are easily accessible at that position in a hardware network. The convergence was studied by Williams (1985), who showed that the weight vectors $w_1(k)$, . . . , $w_N(k)$ will not tend to the eigenvectors $c_1, \ldots, c_N$ but only to a rotated basis in the subspace spanned by them, in analogy with the subspace criterion discussed earlier. A global convergence analysis was given by Yan, Helmke, and Moore (1994).

### *The Recursive Least Squares Algorithm and Extensions*

On-line algorithms typically suffer from slow convergence. The learning rate would have to be tuned optimally. One way of doing this is to use recursive least squares methods. It is well known that they converge much faster at the expense of a somewhat larger computational cost. An efficient algorithm called the Projection Approximation Subspace Tracking (PAST) was introduced by Yang (1996).

Also, minor components defined by the eigenvectors corresponding to the smallest eigenvalues can be computed by similar algorithms (see Oja, 1992). A recent overview of these and related neural network realizations of signal processing algorithms is given by Cichocki and Unbehauen (1993) and Diamantaras and Kung (1996). Extensions to nonlinear PCA learning rules are given in Hyvärinen, Karhunen, and Oja (2001).

## Learning PCA by Backpropagation Learning

Another possibility for PCA computation in neural networks is the multilayer perceptron network, which learns by the backpropagation algorithm in unsupervised autoassociative mode. This network was suggested for data compression by Cottrell, Munro, and Zipser (1987).

In the three-layer autoassociative perceptron net, the input and output layers have $K$ units and the one hidden layer has $N < K$ units. The outputs of the hidden layer are given by

$$h = \sigma(W_1 x + w_1) \quad (9)$$

where $W_1$ is the input-to-hidden layer weight matrix, $w_1$ is the corresponding bias vector, and $\sigma$ is the usually nonlinear activation function, to be applied elementwise. The output $y$ is an affine linear function of hidden layer outputs:

$$y = W_2 h + w_2 \quad (10)$$

with obvious notation. In autoassociative mode, the same vectors $x$ are used both as inputs and as desired outputs in backpropagation learning. If $\sigma$ is linear, then the hidden layer outputs will become the principal components of $x$.

For the linear net, backpropagation learning is especially feasible because it was shown by Baldi and Hornik (1989) that the "energy" function has no local minima. The nonlinear case was analyzed by Japkowitz, Hanson, and Gluck (2000). The three-layer net has been used for image compression by Cottrell et al. (1987).

## Discussion

The algorithms reviewed in this article are typical learning rules for adaptive PCA extraction, and they are especially suitable for neural network implementations. In numerical analysis and signal processing, many other algorithms have been reported for different computing hardware (for a review, see Comon and Golub, 1990). PCA is a useful technique for, e.g., spatial decorrelation and denoising. Experimental results on the PCA algorithms both for finding the eigenvectors of stationary training sets and for tracking the slowly changing eigenvectors of nonstationary input data streams have been reported by Oja (1983) and Sanger (1989). An obvious extension of PCA neural networks would be to use nonlinear units, such as perceptrons, instead of the linear units, as suggested by Xu (1991). Such nonlinear PCA networks will in some cases give the independent components of the input $x$, instead of just uncorrelated components. This is due to the higher-order statistics that are induced by the nonlinearities. The technique of INDEPENDENT COMPONENT ANALYSIS (q.v.) is very useful in blind source separation (Hyvärinen et al., 2001). In fact, a useful preprocessing step in ICA is whitening, which means performing PCA followed by variance normalization.

# Probabilistic Regularization Methods for Low-Level Vision

*Jose L. Marroquin and Mariano Rivera*

## Introduction

Current research in computational vision follows two main paradigms. In the first paradigm, the primary task that a visual system must solve is considered to be reconstructing, from the set of images that constitute the sensory input, a set of fields that represent, on the one hand, the physical properties of the three-dimensional surfaces around the viewer, and on the other, the boundaries between patches that "belong together" in some sense and thus may correspond to the outlines of plausible physical objects in the scene. This process, which is usually called early or low-level vision, is supposed to be performed in natural systems by a set of loosely coupled neural networks (computational modules), each specializing in the reconstruction of a particular field. Thus, specific modules have been proposed for the computation of brightness edges; depth (from stereo, shading, and motion); color, lightness and albedo; velocity and optical flow; spatial and spatiotemporal interpolation and approximation, and so on.

In the second paradigm, many of the problems to be solved using vision are thought not to need a complete reconstruction of the three-dimensional world; for a given task, it may be possible to feed the raw sensory data to a network (such as a multilayer perceptron) that directly generates the desired control commands. The plausibility of this approach is illustrated, for example, in Pomerlau (1991), where such a network is used for an autonomous navigation task. In this case, however, it is also necessary to determine a set of fields defined on the same lattice as the observations: these fields represent the weights that indicate the relative importance of each pixel value for the subnetwork of the corresponding hidden unit.

In both cases, the determination of the corresponding fields exhibits an important common characteristic due to the loss of information inherent to imaging and sensory transduction processes and, in the second case, to the fact that one usually has a limited number of available examples to train the network: the values of the fields are constrained by the data but are not determined in a unique and stable way (i.e., the reconstruction problems are mathematically ill-posed). This means that the networks that implement the solutions must incorporate in their structure prior knowledge about the reconstructed fields.

For the sake of clarity, this article is focuses on the reconstruction (multimodule) paradigm, although most of the results may be extended to the action-oriented case as well. The general problem that we consider is the following.

Suppose that we are given sensory measurements in the form of a set of observed fields $g$ at the nodes of a regular lattice $L$ (usually a square lattice is assumed, although other arrangements are possible). From these measurements, we wish to reconstruct a field $f = \{f_i, i \in L\}$, given the "direct" equations that model $g$ in terms of $f$ and some noise process $n$:

$$\phi(g, f, n) = 0 \tag{1}$$

The simplest instance of this problem is image filtering, in which $g$ consists of a single field (the noisy observed image), $f$ is the desired reconstructed image, and the observation model is

$$g - f - n = 0 \tag{2}$$

Another example is the recovery of depth from stereoscopic pairs of images. Here, the observations $g = (g_L, g_R)$ are the gray levels measured in the left and right retinas, respectively, and $f$ is the associated disparity between pairs of corresponding points (if this "correspondence problem" is solved, and if the geometry of the sensors is known, the actual recovery of depth is a matter of simple geometric computations). If the sites of the lattice are identified by a two-dimensional (2D) index $i = (i_x, i_y)$, and assuming horizontal epipolar lines, a simplified direct equation is

$$g_L(i_x, i_y) - g_R(i_x + f_i, i_y) - n_i = 0$$

for each $i \in L$.

Another example is image segmentation. Here, the input lattice is partitioned into a set of nonoverlapping regions $\{R_1, \dots R_M\}$ so that the spatial variation of the observed images is represented by a parametric model $\Psi(i, \theta_k)$ inside region $R_k$:

$$g_i = \sum_{k=1}^{M} \Psi(i, \theta_k) f_{ik} + n_i \tag{3}$$

where $f_{ik}$ is the indicator variable of region $R_k$: $f_{ik} = 1$ iff $i \in R_k$ and $\{\theta_1, \dots, \theta_M\}$ are the parameter vectors.

In the first example, the field $f$ is underconstrained, because the noise field is not known. In the second example, even in the absence of noise, the field $f$ is not uniquely determined, because there may be many points in the right image with the same gray level of a given point in the left one. Finally, in the third example, nonuniqueness arises because of measurement noise and because neither the parameter vectors nor the indicator variables are known. Similar ambiguous situations arise in other early vision problems for different reasons, and in all these cases it is necessary to introduce additional prior constraints.

In this article we present systematic ways for adding prior constraints, and for embedding the solution algorithms in suitable networks.

## Probabilistic Regularization

The classical way of finding solutions to ill-posed problems is based on regularization methods, where stability and uniqueness of the solution are enforced by the introduction of prior smoothness constraints in the solution. A more general approach, and one that includes the classical solution as a particular case, is probabilistic, and considers $f$ and $g$ as realizations of random fields, so that the reconstruction of $f$ is understood as an estimation problem. The prior knowledge about the solution is expressed in the form of a joint probability distribution for $f$ that specifies the desired dependencies between values at neighboring sites. In this way, one may specify not only global smoothness constraints (as in standard regularization) but also piecewise smoothness, as well as constraints on the shape of the discontinuities.

The basic tool in this approach is Bayes's rule, which specifies the way in which prior information (i.e., the prior distribution $P_f$) is to be combined with the constraints generated by the observations (i.e., the conditional distribution $P_{g|f}$) to generate the posterior distribution $P_{f|g}$:

$$P_{f|g}(f;\, g) = \frac{P_f(f) P_{g|f}(f;\, g)}{P_g(g)} \tag{4}$$

Note that since the observations $g$ are given, $P_g(g)$ is a constant. The optimal estimator $\hat{f}^*$ is then obtained as the minimizer of the expected value (taken with respect to the posterior distribution) of an appropriate cost function $C(f, \hat{f})$.

This approach, then, requires the specification of three basic components (besides the cost function): the observation model $P_{g|f}$, the prior distribution $P_f$, and the network that will effect the reconstruction. We will now analyze them in detail.

### The Observation Model

The form of the constraints that sensor measurements impose on the reconstructed field depends on the particular assumptions that are made about the image formation process. If the random variables $n_i$, $i \in L$, are assumed to be independent, identically distributed with distribution $P_n$, then the conditional distribution is found by solving for $n$ in Equation 1: $n_i = \phi^{-1}(f, g)$ and setting

$$P_{g|f}(f;\, g) = \prod_{i \in L} P_n(\phi^{-1}(g, f))$$

which can be written in the general form:

$$P_{g|f}(f;\, g) = \exp\left[\sum_{i \in L} - \Phi_i(f,\, g)\right] \tag{5}$$

In most cases, the functions $\Phi_i$ are quadratic—i.e., the noise is assumed to be Gaussian—although other forms that reduce the influence of gross measurement errors have also been used (see Black and Rangarajan, 1996).

### Prior Distributions

The success of the Bayesian approach depends on the specification of a probability distribution $P_f(f)$ that models the desired behavior of the solution. In particular, one would like to be able to specify a distribution in which fields where neighboring sites exhibit the appropriate dependencies are more probable than those in which these local constraints are violated. A general way of constructing such distributions is by defining an "energy" function $U(f)$, which is formed by a sum of terms that measure the violation of the local constraints. The probability distribution of the field is then given by the Gibbs measure:

$$P_f(f) = \frac{1}{Z} \exp[-U(f)] \tag{6}$$

where $Z$ is a normalizing constant.

More precisely, if we define a neighborhood system $\{N_i, i \in L\}$, that is, a collection of subsets of sites indexed by the sites of $L$: $\{N_i \subset L, i \in L\}$ with the properties:

$$i \notin N_i$$

$$i \in N_j \Leftrightarrow j \in N_i$$

its *cliques* consist of either single sites or subsets of sites such that any two belonging to the same clique are neighbors of each other. With this definition, the energy may be written as:

$$U(f) = \sum_C V_C(f) \tag{7}$$

where $C$ ranges over all the cliques of the neighborhood system, and each "potential function" $V_C$ depends only on $\{f_i, i \in C\}$.

A random field $F$ whose probability distribution is given by Equations 5 and 6 is called a *Markov random field* on $L$ (Geman and Geman, 1984; Chellapa and Jain, 1993; Li, 2001). From (4), (5) and (7), one can see that the posterior distribution is also of the form (6), but now the energy includes the data term:

$$U(f) = \sum_{i \in L} - \Phi_i(f,\, g) + \sum_C V_C(f)$$

so that the Maximum a Posteriori (MAP) optimal estimator for $f$ is obtained by minimizing this function.

The potential functions represent the "user interface" of the model, since through them one may specify the desired characteristics of the sample fields. Although they may be arbitrarily specified, there are four basic types that are generally used, depending on the characteristics of the desired reconstruction:

1. *Piecewise constant fields*: Here, each $f_i$ may take only a finite (usually small) number of values. These fields are mostly used in segmentation problems, in which case it is often convenient that each $f_i$ takes the form of a binary unit vector whose elements correspond to the indicator variables in Equation 3. The most widely used potential is the generalized Ising potential for cliques of size 2:

$$\begin{aligned} V_C(f_i, f_j) &= -\beta, \quad \text{if } f_i = f_j \\ &= \beta, \quad \text{otherwise} \end{aligned}$$

2. *Globally smooth fields*: This case corresponds to standard regularization; the potentials are obtained as the squares of finite difference approximations of differential operators. For first-order differences, one obtains the "membrane" model:

$$V_C(f_i, f_j) = (f_i - f_j)^2 \tag{8}$$

where $i$ and $j$ denote a pair of nearest neighbor sites in the lattice.

If one adopts the observation model (Equation 2) and assumes that $P_n$ is a zero-mean Gaussian distribution, the posterior energy becomes equivalent to the discretized functional of standard regularization, and its (unique) maximizer corresponds to the MAP estimator (see below).

3. *Piecewise smooth fields*: This is a very important and general case. There are two basic approaches for the construction of the potentials. In the first case, the discontinuities of the field are explicitly modeled by means of an auxiliary "line field" $s$ (originally introduced by Geman and Geman, 1984), which is defined on a "dual" lattice whose sites are between each pair of (horizontal or vertical) neighboring sites of $L$; $s$ is thus indexed by a pair of indices corresponding to sites of $L$. Each line element $s_{ij}$ may take values on the set $\{0, 1\}$, indicating, respectively, the absence or presence of a line (discontinuity) (in some models, $s$ is allowed to take noninteger values in the interval $[0, 1]$ as well; see Geman and Reynolds, 1992; Black and Rangarajan, 1996).

The prior energy takes the form:

$$U(f, s) = \sum_{\langle i,j \rangle} [(f_i - f_j)^2 s_{ij} + \Psi(s_{ij})] + \sum_D W_D(s) \tag{9}$$

where $\Psi(s_{ij})$ is a function that assigns a penalty for the introduction of a discontinuity between pixels $i$ and $j$.

The line potentials $W_D(s)$ assign penalties to different local line configurations. They are summed over the cliques $D$ of a neighborhood system defined on the dual lattice, and they are used to favor, for example, piecewise smooth lines, and to prevent the formation of smooth patches that are too thin or too small.

In the second case, the discontinuities are implicitly modeled by nonquadratic potentials $\rho(f_i - f_j)$, where $\rho$ behaves like a quadratic function for small values of its argument but grows at a smaller rate as its argument becomes large. The derivatives of these potentials are related to influence functions of robust statistical estimators, and are therefore called *robust potentials*.

If the term $\Sigma_D W_D(s)$ is omitted, it is always possible to express Equation 9 in the form of a sum of robust potentials, simply by putting

$$\rho(f_i - f_j) = \inf_{s_{ij}} [(f_i - f_j)^2 s_{ij} + \Psi(s_{ij})]$$

where the right-hand side may be explicitly evaluated in many cases. If certain technical conditions on the $\rho$ function are fulfilled, it is also possible to write a robust potential in the line field form (Charbonnier et al., 1997). Being able to go from one representation to the other, one may add spatial interaction terms to robust potentials, or use continuation methods that have been developed for robust potentials in the line field case (see Blake and Zisserman, 1987; Black and Rangarajan, 1996).

4. *Piecewise parametric models*: In this case the smooth patches are assumed to follow a parametric model with a relatively small number of parameters; for example, in the case of the reconstruction of the velocity field (optical flow) from a sequence of images, an affine model for the velocity of the form $f_i = A_i + b$ is often used, e.g., Black, Fleet, and Yakoob, 2000. In other cases, spline models with controlled stiffness are more appropriate (Marroquin et al., 2000). The problem here is that not only the parameters for each model have to be determined, but also the domain of validity of each model, i.e., a field of indicator variables, as in Equation 3. The prior constraints refer in this case to the spatial coherence of these domains, and may be enforced by Ising potentials.

Other examples of the application of these approaches to a variety of problems, as well as extensions and theoretical results, may be found in Chellapa and Jain (1993), Li (2001), and Marroquin et al. (2000, 2001).

### *Networks*

Since the reconstruction is needed at the sites of the pixel lattice $L$, it is very natural to model the reconstructing network as a cellular automaton that consists of an array of processors or cells also located at the sites of $L$. The state of these processors at a given time $t$ is denoted by $\xi^{(t)} = \{\xi_i^{(t)}, i \in L\}$. The interconnection pattern between processors is specified by the defined neighborhood system. The state of each processor changes from time to time with a rule that depends on its own state and that of its neighbors:

$$\xi_i^{(t+1)} = R(\xi_j^{(t)}, j \in N_i \cup \{i\})$$

Cellular automata (CA) may be deterministic (DCA) or stochastic (SCA), depending on the nature of the rule $R$.

Given this model for the architecture of a computational module, the important question is how to specify $R$, so that, in the deterministic case, the DCA has a fixed point and the reconstructed field $f$ is obtained from it, and in the stochastic case, the automaton is regular and $f$ is obtained from time averages of functions of its state.

In the case of globally smooth reconstructions, the energy function is usually convex, and the best estimator is obtained by minimizing this energy. The reconstructing networks are in this case equivalent to distributed iterative methods for matrix inversion (Bertsekas and Tsitsiklis, 1989). They may also be implemented analogically with pure resistor networks (see Marroquin, Mitter, and Poggio, 1987).

In the case of piecewise smooth potentials, when these are represented in the line field form and the term $\Sigma_D W_D(s)$ is not included, the energy function becomes quadratic in $f$ for a given value of $s$, and therefore it may be minimized by the methods described in Bertsekas and Tsitsiklis (1989). On the other hand, if $f$ is kept fixed, one may find the value of the $s$ variables that minimizes $U$ in closed form. By alternating these two steps, one gets an effective algorithm for the computation of the optimal estimator (Geman and Reynolds, 1992; Charbonnier et. al., 1997). If the energy is represented in terms of robust potentials, often local descent schemes combined with continuation methods are most effective (Blake and Zisserman, 1987).

An important issue in all these cases is the determination of the parameters included in the energy function. In many cases these are hand-adjusted for a given class of images; it is better, however, to determine them automatically, as in Zhang (1993) or Chen, Chen, and Zhou, (2000).

## Discussion

The key idea of this article is that Bayesian Estimation Theory, using prior MRF models, constitutes a general method that permits the formulation of many reconstruction problems in computational vision, so that they become equivalent to the minimization of an energy function that includes two terms: one that requires the solution to be consistent with the data (the likelihood term), and another that embodies prior constraints about its behavior. For the case of piecewise constant fields, however, the best estimator is not necessarily obtained by minimizing the posterior energy (i.e., the maximum a posteriori or MAP estimator). It has been shown that the estimator that maximizes the posterior marginal probabilities (the MPM estimator) has better behavior, particularly for low signal-to-noise ratios (Marroquin et al., 1987). In both cases, the cost for the exact computation of the optimal estimators is too high, so that approximations must be made. The most precise approximations are obtained with stochastic cellular automata, which mathematically correspond to regular Markov chains whose invariant measures correspond to the posterior distribution $P_{f|g}$. In this case, one can estimate the posterior marginals, by counting the number of times a given cell is in each state, from which the MPM estimator may be obtained. It is also possible to approximate the MAP estimator by introducing a "temperature" parameter that goes slowly to zero (a procedure known as simulated annealing; see SIMULATED ANNEALING AND BOLTZMANN MACHINES and Geman and Geman, 1984).

The main drawback of these stochastic methods is their computational complexity, since many iterations are needed to obtain accurate results. This is especially important in the case of the estimation of piecewise parametric models, since here the most effective procedures consist of two steps that are performed alternately in an iterative manner until convergence is achieved. These steps are:

1. Estimate the best segmentation (i.e., the $f$ indicator variables in Equation 3), given the model parameters.
2. Estimate the model parameters given the segmentation.

An appropriate initialization step is also required. Instances of these procedures are found in Marroquin et al. (2000) and Black et al. (2000).

To perform step 1, it is necessary to have efficient estimators for piecewise constant fields. One way to obtain them is derived from mean-field (MF) theory of statistical physics. The MF-based estimation algorithm may be implemented by a deterministic cellular automaton with $M$ layers, where each unit corresponds to a specific marginal probability. The update rule for each node involves the computation of the exponential of the sum of the local contributions of neighboring sites plus a normalization step (see Zhang, 1993).

A different approach is based on the idea of constructing a random field of discrete probability distributions using a Gauss-Markov model, so that the mean value of this field corresponds to the posterior marginal probabilities. Since this field is Gaussian, its mean value is found by the minimization of a quadratic form, which, because of the Markovian property, has a particularly simple structure. The network that computes the optimal estimator is shown in Figure 1. Note that, unlike the MF network, in this case there is no need either of exponentiation or of normalization; as a result, one can get better results at a fraction of the computational cost (see Marroquin et al., 2000, 2001).

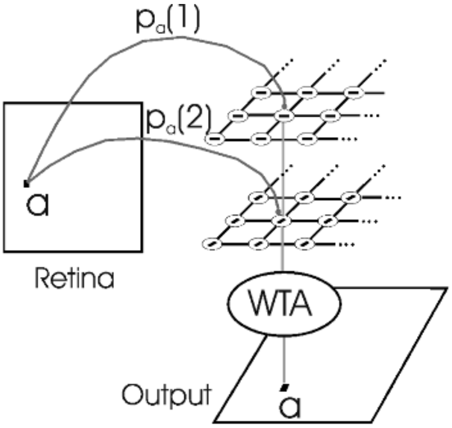

**Figure 1.** Network that computes the optimal estimator for a discrete-valued field. Each layer corresponds to a valid value for the field (in this example, orientation). Each cell computes the average of the state of its neighbors and the corresponding likelihood $p_a$ obtained from the retina. A Winner Takes All mechanism outputs the most probably state at each time. Note that the layers are decoupled; they must, however, be synchronized for the system to work properly.

# Programmable Neurocomputing Systems

*Krste Asanović*

## Introduction

General-purpose personal computers and workstations are the most popular computing platforms used by researchers to simulate artificial neural network (ANN) algorithms. They provide a convenient and flexible programming environment, and advances in technology have been rapidly increasing their performance and reducing their cost. But large ANN simulations can still overwhelm the capabilities of even the most powerful workstations. For example, computations may require more than $10^{15}$ arithmetic operations and may operate on data sets containing several gigabytes of data (Ellis and Morgan, 1999).

Many neural net algorithms are highly parallelizable, allowing simulation speed to be improved by employing a network of workstations (NOW) (Anderson et al., 1995). Compared with more specialized hardware, a NOW can be an expensive solution. Fast network hardware increases the cost per node, and parallelization overheads reduce the performance per node.

For constrained application domains, fixed-function neural computing circuits can provide extremely high compute speeds at low cost, but they do not have the flexibility required to support experimentation with ANN algorithms.

To meet the need for high performance on large ANN simulations with flexible software control and reasonable cost/performance ratio, several groups have proposed and built *programmable neurocomputers*. Programmable neurocomputers (hereafter abbreviated to "neurocomputers") attempt to maintain most of the flexibility of a general-purpose computer system while improving the cost/performance ratio by specializing processors for neural computation.

This article reviews the most significant neurocomputer architectures, discusses their design and use, and concludes with predictions of future trends.

## Survey of Neurocomputer Architectures

Programmable neurocomputers can be classified into four major categories. The first category uses commercial digital signal processors (DSP); the last three categories are based on custom-designed silicon.

### *Commercial DSP Arrays*

Several neurocomputers have been built using arrays of commercial DSPs. Two notable examples are the RAP (Ring Array Processor), developed at the International Computer Science Institute (Morgan et al., 1992), and the MUSIC system, developed at the Swiss Federal Institute of Technology. (Muller et al., 1992). Both of these systems connect the DSPs in a unidirectional ring topology with communication circuitry built from field-programmable gate arrays (FPGAs). The RAP supports up to 40 Texas Instruments TMS320C30 floating-point DSPs, with a peak performance of 32 MFLOPS per node. The MUSIC system connects up to 45 Motorola DSP96002 floating-point DSPs, with a peak performance of 60 MFLOPS per node.

Both of these systems have distributed memories and are programmed using a Single Program Multiple Data (SPMD) model, in which all nodes run identical programs but operate on different portions of the data. A separate host computer manages the overall program flow and handles data input and output.

### *SIMD Processor Arrays*

Another popular approach in neurocomputer design is a Single Instruction Multiple Data (SIMD) array of processors with some limited form of interprocessor interconnect. In these SIMD designs, a central sequencer broadcasts instructions that are executed simultaneously by all processors. The processors in a SIMD system can be much simpler than those in a SPMD system because they do not have to fetch and decode instructions. Also, SIMD processing elements do not require separate synchronizing operations because all processors work in lockstep.

Example SIMD neurocomputers include the CNAPS systems, from Adaptive Solutions (Hammerstrom, 1990), and the SNAP system, from HNC (Means and Lisenbee, 1991). The CNAPS system is built around large custom chips containing an array of 64 SIMD processing elements. Each processing element contains a fixed-point 16-bit × 8-bit multiplier, a 24-bit accumulator, a set of 32 16-bit registers, and 4 Kbytes of local on-chip memory. The processing elements are connected by two 8-bit broadcast busses and a 2-bit interprocessor ring connect. The HNC system is built from SNAP chips, each of which contains four 32-bit floating-point multiply-add datapaths with access to local off-chip memory. Both of these systems allow multiple chips to be interconnected and controlled by the same central sequencer.

### *Systolic Processor Arrays*

Several neurocomputers have been built around systolic processor arrays that perform the matrix operations at the heart of most neural algorithms. A systolic processor contains an array of interconnected pipelines through which operands flow in a regular rhythmic fashion.

The most advanced of these systems is the Synapse-1, constructed and sold by Siemens (Ramacher et al., 1991). This system is based on a custom systolic multiply-accumulate chip, the MA-16, which integrates 16 16-bit fixed-point multipliers. The Synapse-1 system employs multiple-chained MA-16 chips to give higher throughput. Large quantities of off-chip memory are provided, split into several disjoint memory areas. Operands must be located in the correct memory region before performing a given systolic matrix operation. Additional special-purpose fixed-point datapath hardware is provided to support ANN node activation functions not provided by the MA-16 chips, and Motorola 68040 CISC processors are used to perform all other operations. The entire system is controlled by a host workstation.

Another example of a systolic neural net engine is the Mantra machine, built at EPFL, Switzerland (Ienne and Viradez, 1994). Mantra can have up to 1600-bit serial processing elements arranged in a 40 × 40 systolic mesh. A commercial DSP acts as system controller.

### *Vector or SIMD Coprocessor*

The machines discussed to this point all rely on some form of off-chip control sequencer or host computer to manage the matrix computations occurring on the parallel processor arrays. An alternative approach is to tightly integrate the control processor with the parallel execution units on the same die. Two examples of this type of design are the T0 vector microprocessor (Wawrzynek et al., 1996) and the L-Neuro 2.3 multi-DSP (Duranton, 1996).

The T0 vector microprocessor integrates an industry-standard MIPS-II 32-bit integer scalar RISC processor with a tightly coupled fixed-point vector coprocessor. The vector coprocessor contains a central vector register file with 16 vector registers each holding 32 elements of 32 bits, two vector arithmetic units, and a vector memory unit. The two vector arithmetic units each contain eight parallel pipelines and can produce up to eight 32-bit results per clock cycle. One of the arithmetic units contains 16-bit fixed-point multipliers, but otherwise the two pipelines are identical. The memory unit connects to off-chip memory over a 128-bit data bus. T0 has a single flat memory space equally accessible by the scalar unit and any element in the vector unit. T0 is similar in design to vector supercomputers (Russel, 1978), and scalar and vector instructions can be freely intermixed in the single instruction stream. The instruction set was designed to enable object-code compatibility with future higher-performance implementations.

The L-Neuro 2.3 design contains a 16-bit RISC controller plus an array of 12 DSP datapaths. The DSP datapaths are controlled via a writable microinstruction store indexed by the RISC controller macroinstructions. The wide microinstruction words allow pairs of DSP datapaths to perform different functions, and a flexible inter-DSP communication network is provided. The L-Neuro 2.3 supports an off-chip memory connection for each DSP datapath.

## Neurocomputers Versus General-Purpose Processors

Neurocomputers are distinguished from general-purpose processors by their specialization for neural computations. If we examine the range of neurocomputers above, we find that three features specific to neural computation have been exploited to improve cost/performance:

- *Limited numeric precision.* Many neural algorithms can be coded to require only 8–16 bits of fixed-point arithmetic precision (Asanović and Morgan, 1991). The reduced precision allows reductions in the area required for arithmetic circuits, particularly multipliers, and also reduces the bandwidth required to transfer operands.

- *Data parallelism.* Most neural algorithms are inherently highly data parallel, where the same operation is performed across large arrays of data. Data parallelism is the simplest form of parallelism to exploit because a single block of control hardware can be shared over many datapaths.
- *Restricted communication patterns.* Broadcast buses or unidirectional rings are sufficient to support parallel execution of many common neural network algorithms. These simplified communication networks reduce the cost of interconnecting large numbers of parallel processing elements.

All neurocomputers aim to achieve high performance on the matrix computations at the heart of many neural algorithms by exploiting these features. But real-world neural net programs require operations other than these basic matrix operations. For example, an ANN training run may require significant disk I/O to retrieve training patterns and to checkpoint trained weights. Also, the training patterns may need preprocessing before being presented to the network, and the network outputs may require postprocessing to obtain results. If the neurocomputer is too slow at performing these other nonmatrix tasks, then the overall system performance will be dominated by these nonneural components. This result is well known in general-purpose computing as Amdahl's law (Amdahl, 1967):

$$S = \frac{1}{(1 - f) + f/E}$$

where $E$ is the factor by which performance is improved by some new technique, $f$ is the fraction of the program execution time for which the new technique is applicable, and $S$ is the resulting overall speedup. For example, if 90% of the execution time of a computation is taken by matrix arithmetic, then even an infinitely fast matrix computation engine will never achieve an overall speedup greater than 10. Some neural computer designs have exacerbated this problem by imposing a *slowdown* for nonneural computations by requiring slow communication to a remote host processor to implement the required functionality. Ideally, fast general-purpose computing should be tightly integrated with the special-purpose processing units.

Another related issue is that the existing neurocomputers have been primarily designed to accelerate neural algorithms with dense connectivity (e.g., backpropagation), which can be expressed using dense matrix-vector operations. However, researchers are also interested in algorithms that explore sparse connectivity and sparser activation. These require fast scatter/gather memory operations and support for rapid irregular communications.

Flexible software support is perhaps the most important aspect of a successful neurocomputer design. Most neurocomputers are intended to be programmed using libraries of optimized matrix-vector functions. This approach is adequate for the computation portion of the code provided the libraries are extensive and are easy to compose in arbitrary ways. In particular, difficulties can arise if the libraries place constraints on the location of operands when the machine has multiple distributed memories.

To support experimentation with new ANN models, it is important to provide tools to allow users to extend the libraries to provide missing functionality. Ideally, this would consist of an optimizing high-level language compiler, but in practice, assembler or microcode programming is usually required. Some of the neurocomputers have extremely complicated microarchitectures that are difficult to program efficiently at this low level. The features that complicate the task of the low-level programmer include:

- *Multiple distributed memories.* These require the programmer to carefully position data and to manage movement of data between memories.
- *Deep exposed execution pipelines.* These require the programmer to explicitly schedule operations occurring over many clock cycles.
- *Multiple levels of control flow.* Some systems have several levels of control flow (e.g., controller macroinstructions, microcontroller microinstructions, nanocontroller nanoinstructions) that must be jointly scheduled for peak performance.

Architectures that expose many details of an implementation to a programmer incur a significant programming overhead. If the same programmer-visible architecture is not preserved in subsequent machines, the software investment in low-level library code cannot be carried forward to new technology.

It is also important to provide libraries for I/O functions as well as computation, as often the amount of code required to manage data input and output dwarfs that required for matrix computation.

## Discussion

The development of programmable neurocomputers was based on the premise that neurocomputing was significantly different from general-purpose computing and thus that a new type of computer architecture was warranted. But the preceding sections outlined many concerns shared with conventional computer architectures, namely, the need for flexible software development, high-performance library code, reasonable performance on arbitrary code, and fast I/O.

The primary distinguishing characteristics, namely, limited numeric precision and large-scale data parallelism, are features not only of ANN algorithms but also of many other algorithms in the areas of digital signal processing and multimedia. In recent years, many general-purpose microprocessors have added multimedia processing extensions (Lee and Smith, 1996) that provide support for data-parallel fixed-point processing. Typically, these multimedia extensions partition an existing 64-bit-wide datapath into a short vector of lower-precision subword components, e.g., 4 × 16-bit values, with new instructions that operate on all subword components simultaneously, e.g., adding two vectors of 4 × 16-bit operands to produce a vector of 4 × 16-bit results. Microprocessors with multimedia extensions are very similar to the vector or SIMD coprocessor-based neurocomputer architectures, and share the same advantage of a tightly coupled general-purpose scalar unit.

Although the multimedia extensions implemented to date provide only a limited boost to the performance of general-purpose processors on fixed-point matrix code, they signal an intent by commercial microprocessor manufacturers to perform well on these types of code. As commercial design teams incorporate multimedia-style kernels into the workloads they consider during the design of new microprocessors, we can expect performance to increase rapidly also for ANN algorithms. The continuing tremendous investment placed in high-volume microprocessors ensures that these devices will use the most advanced fabrication technologies and the most aggressive circuit design styles yielding the highest clock rates. Given these trends, there will be greatly reduced interest in future special-purpose neurocomputers.

In attempting to optimize microprocessors for these multimedia codes, microprocessor architects will face many of the same challenges that confronted neurocomputer architects. Perhaps the greatest limitation on performance of highly data-parallel codes is sustainable memory bandwidth. Sustaining high bandwidth to off-chip memory requires both high raw memory bandwidth and the ability to tolerate long memory latencies by overlapping many concurrent memory requests. New off-chip memory architectures and packaging techniques will help improve raw memory bandwidths, but significant improvements in on-chip processor architecture will be required to provide sufficient parallelism to tolerate large off-chip memory latencies. The current multimedia extensions provide only very limited data parallelism of four or eight elements at a time. It is likely that future designs will exploit much longer vectors to increase the level of parallelism supported without incurring additional instruction bandwidth costs. In addition, although current microprocessor multimedia extensions have no support for scatter/gather operations, it is likely that these will eventually be added to accelerate the large set of applications that rely on sparse matrix calculations.

A promising future direction is to integrate processor and main memory together on the same die, as in the Berkeley IRAM project (Kozyrakis et al., 1997). The IRAM project is placing a vector processor similar to T0 on the same die as a large DRAM-based main memory. The vector processor is a simple hardware scheme for controlling a large degree of parallelism, while the on-chip memory both reduces latencies and dramatically increases available memory bandwidths. The vector unit provides fast scatter/gather operations from multiple on-chip memory banks. The combination should provide high sustained performance at low cost for data-parallel codes, including both dense and sparse ANN algorithms.

# Prosthetics, Motor Control

*Gerald E. Loeb and Ning Lan*

## Introduction

This article deals with the subset of neural prosthetic interfaces that employ electrical stimulation to alter the function of motor systems, either directly or indirectly. The general biophysical considerations and technology are described in PROSTHETICS, NEURAL (q.v.).

## Clinical Applications

### *Therapeutic Electrical Stimulation*

Therapeutic electrical stimulation (TES) is an electrically produced exercise in which the beneficial effect occurs primarily off-line as a result of trophic effects on muscles and perhaps the central nervous system (CNS). One simple example is periodic exercise of the shoulder muscles to prevent disuse atrophy after a stroke (Faghri et al., 1994), which otherwise often results in chronically painful subluxation of the joint. TES effects have also been used to reduce spasticity following spinal cord injury (Stefanovska et al., 1989), presumably by downregulating the gain of hyperactive spinal reflex circuits. TES systems are relatively simple to implement because the patient chooses when and where to administer the treatment and does not require any immediate effects from the stimulation. Stimulation programs are usually devised by the caregiver, but some parameters may be adjusted manually by the patient during self-treatment sessions.

### *Neuromodulatory Stimulation*

Neuromodulatory stimulation (NMS) involves preprogrammed stimulation that directly triggers or modulates a function without ongoing control or feedback from the patient. Perhaps the oldest clinically successful neural prosthesis is phrenic nerve pacing to provide respiration in patients with central hypoventilation (Glenn and Phelps, 1985). More recently, sacral nerve stimulation has been used successfully to empty the bladder (Brindley and Rushton, 1990) and to reduce detrusor spasticity in patients with urge incontinence (Dijkema et al., 1993). NMS systems must be portable and reliable, but they function mostly autonomously.

### *Functional Electrical Stimulation*

Functional electrical stimulation (FES) involves precisely controlled muscle contractions that produce specific movements required by the patient to perform a task. Much motor prosthetic research has been aimed toward permitting paraplegic patients to walk, a high-risk, high-energy activity that requires sophisticated interactions among the patient's immediate intentions, the pattern of stimulation applied to multiple muscles, and the ongoing movement elicited in the limbs. There have been some laboratory demonstrations of relatively complex but still crude systems that permit slow locomotor progress, but none is yet available clinically. The WalkAide is an FDA-approved (but not widely available) prosthesis that uses transcutaneous stimulation of the peroneal nerve to correct foot drop (Wieler et al., 1999). Research emphasis has shifted to FES-assisted grasp in quadriplegic patients, using residual motor function in the proximal and contralateral limb to control stimulation of finger muscles (Prochazka et al., 1997; Smith et al., 1998; Figure 1). Most of the subsystems described in the next section are in development to improve on-line control of FES.

## Subsystems

### *Muscle Stimulation*

Most research has been performed with skin surface electrodes, percutaneous wire electrodes, and implanted multichannel stimulators (Figure 1). The development of advanced stimulation techniques that require less extensive surgery (e.g., intramuscular BIONs, Figure 2; Loeb et al., 2001) promises to improve the practicality of FES systems that require specific and reliable control of large numbers of individual muscles. Electrical activation of muscles by any route does not replicate the natural orderly recruitment of different types of muscle fibers, which gives rise to the high efficiency and fatigue resistance of normal force production. However, artificially stimulated muscles gradually undergo fiber-type conversions as a result of trophic effects that improve their aerobic capacity (Peckham, Mortimer, and Van der Meulen, 1973).

Active muscle has complex intrinsic mechanical properties that complicate attempts to develop feedforward control strategies based on predicting joint torques and movements. Muscle force depends nonlinearly on the number and frequency of firing of recruited muscle units and on the length and velocity of the muscle fibers. Many muscles have substantial amounts of series-elastic connective tissue (tendon and aponeurosis), which means that the length and velocity of the muscle fibers depend, in turn, on the amount of stretch that they produce in that connective tissue, as well as on the trajectory of the limb. While difficult to model mathematically, these complexities appear to play an important role in stabilizing the limb during rapid perturbations (Brown and Loeb, 2000) and in storing and releasing energy to improve the efficiency of cyclical movements such as walking. Many muscles cross more than one joint, further complicating their effects on the overall trajectory of movements.

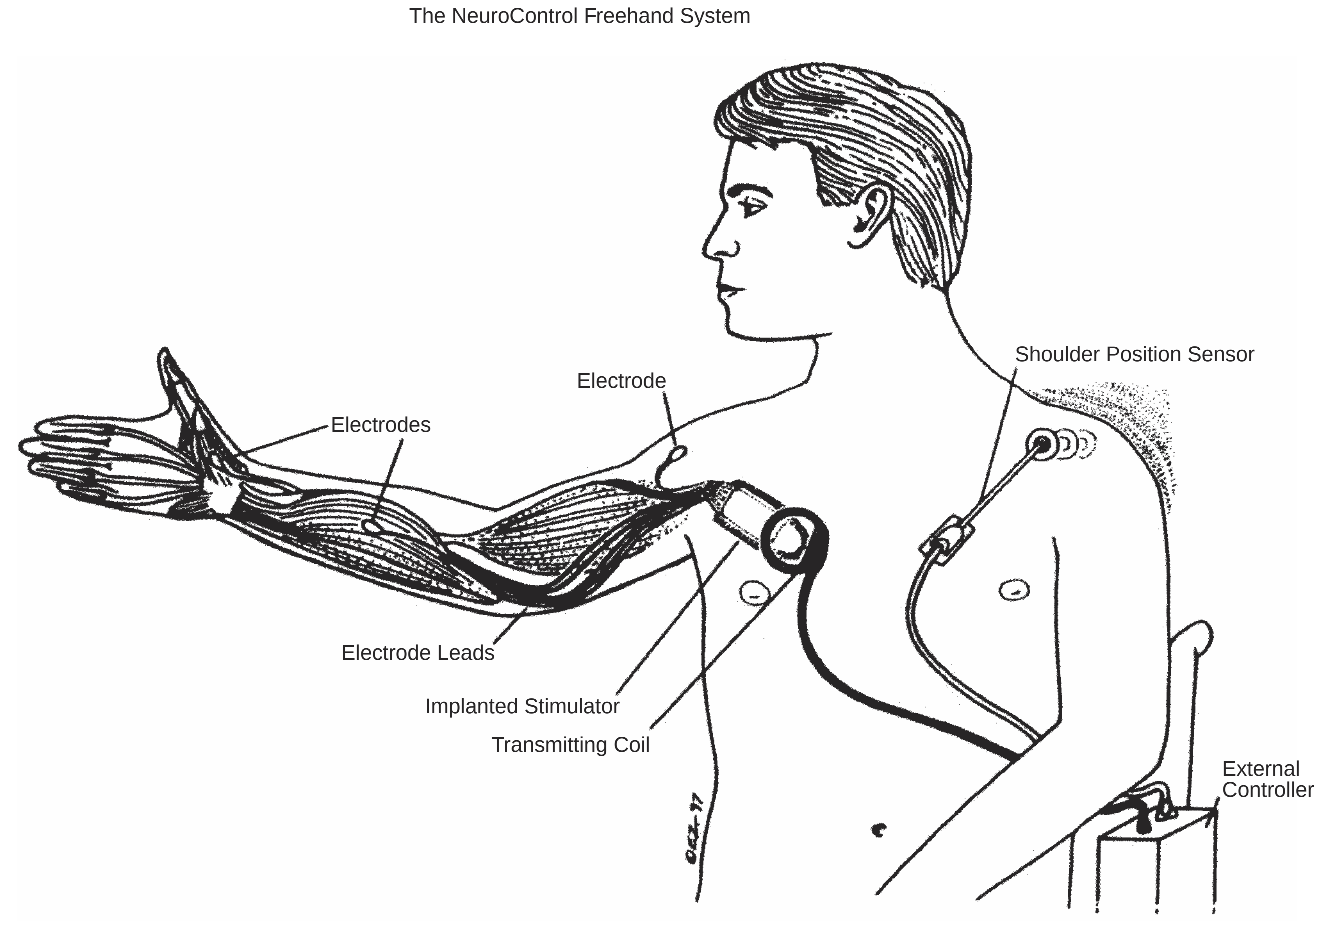

**Figure 1.** Freehand multichannel implanted stimulation system, approved by the U.S. Food and Drug Administration for control of grasp in spinal cord–injured patients. Voluntary shoulder motion detected by the external sensor triggers a stimulation control program that is transmitted to the implanted stimulator and routed to epimysial electrodes implanted near the nerve entry zones of various muscles operating the wrist and digits. (From Smith et al., 1998; photograph courtesy of the manufacturer, NeuroControl Corp., Cleveland, Ohio.)

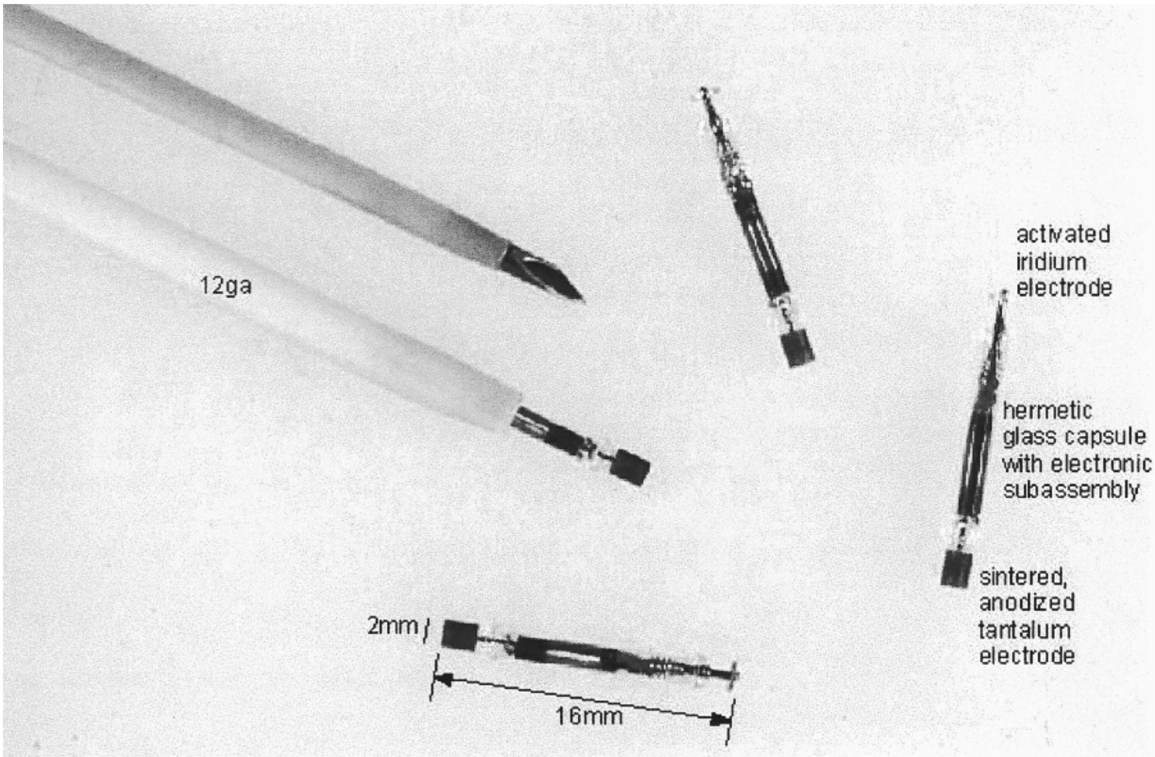

**Figure 2.** BION injectable microstimulators, now in clinical trials of TES to prevent shoulder subluxation due to muscle atrophy following stroke. Each implant (2 mm diameter × 16 mm long) receives power and digital command signals from an amplitude-modulated 2 MHz magnetic field created by an externally worn controller and transmitter coil. Each command specifies the address of one BION, the stimulus current (0.2–30 mA, in 30 steps), and the pulse width (4–514 $\mu$s, in 512 steps).

### *Sensory Feedback*

In biological sensorimotor control, an order of magnitude more neural information comes from intramuscular proprioceptors (muscle spindle and tendon organ afferents) than goes out to control motor units. When this information is absent, both animals and humans have a great deal of difficulty making stable and accurate movements. For tasks requiring manipulation of objects, information from cutaneous mechanoreceptors is even more important. Most rehabilitation therapists believe that an insensate hand is actually less useful than a paralyzed hand.

There are three general approaches to providing sensory feedback signals to implement biological-like control systems:

- Recording the proprioceptive and cutaneous signals that are still largely present in the peripheral nerves and dorsal root ganglia of patients with upper motor lesions. Microelectrode arrays have been implanted long term into these structures in animals (Loeb, Bak, and Duysens, 1977), but the technology is not yet robust enough for clinical use. Nerve cuff electrodes can record the aggregate activity of the large-diameter fibers in peripheral nerves, which can be useful in nerves with fairly homogeneous populations of afferents such as those innervating the digits (Haugland et al., 1999).
- Affixing various electromechanical sensors to the surface of the skin or to worn components of the prosthetic system, such as braces and gloves. While useful as research tools, such external appliances generally result in unacceptable problems related to mechanical maintenance, donning time, and physical appearance.
- Implanting artificial sensors into the sites where they are needed. In addition to the design problems inherent in protecting electromechanical sensors from body fluids, such systems also require electrical leads or wireless communication to handle data and power requirements from large numbers of distributed transducers.

### *Sensorimotor Regulation*

It has long been known that biological systems use a form of servocontrol. Mechanical perturbations sensed by mechanoreceptors give rise to specific reflex responses that tend to stabilize posture and force in the limb (e.g., the stretch reflex). More recently, spinal neurophysiologists have made substantial progress in unraveling the complexities of the spinal interneuronal circuitry and its role in coordinating descending commands with continuous sensory feedback.

The peripheral motor control system is substantially different in its organization from the servocontrollers used in robots. Spinal interneurons receive convergent input from many different modalities and origins of proprioceptive and cutaneous afferents, and they tend to project directly and indirectly to motor neurons controlling many different muscles and joints. Furthermore, most of the descending command signals from the brain that control limb movements terminate on these interneurons rather than directly on motor neurons. This has three important implications for the design of biological control systems (the ramifications for FES control remain unclear):

- The effects of command signals are essentially continuously modulated by the background activity from somatosensory afferents converging on the spinal interneurons.

- The brain can achieve a particular pattern of muscle activation via many different programs of interneuronal activation and inhibition, with each program resulting in potentially different patterns of reflex responses to perturbations.
- Descending pathways appear to be organized to produce various synergies of muscle recruitment and derecruitment rather than specific control of individual muscles.

FES control systems are starting to employ state-dependent logic to switch among different regulatory algorithms as different phases of the movement are detected from patterns in the signals from sensors (Kostov et al., 1995).

### *Control Systems*

Controllers convert a given volitional command signal into a set of time-varying outputs from which the instantaneous intensities of muscle stimulation can be computed. Robotic engineering approaches that are based on complete knowledge of the sensorimotor plant have proved difficult to apply to the many degrees of freedom to be controlled and the number and complexity of the muscles to be stimulated for an FES task. An alternative approach may be to duplicate the adaptive control strategies of the CNS, which tends to perform much better in the low-precision but unpredictable demands of most activities of daily living. Biological sensorimotor systems appear to be organized in a hierarchical manner (Loeb, Brown, and Cheng, 1999), in which each layer of information processing plays a distinctive and important role in achieving goals with reasonable accuracy, stability, and energy efficiency. It remains to be elucidated how a motor goal is translated into a pattern of muscle activation through this hierarchical process, and what the organizing principles behind the formation of motor programs are. Given a sufficiently rich set of sensory feedback and informative commands, it may be possible to create interneuron-like networks for sensorimotor regulation and to use neural networks to learn how to control them to achieve similar goals for FES. For this strategy to be acceptable clinically, however, it will have to minimize the sort of trial-and-error sensorimotor learning that occupies so much of an infant's first few years of life.

### *Command Signals*

Command signals convey the intent of the user to the control system of the prosthetic device. The control system senses and interprets the user's intent and computes an appropriate pattern of muscle stimulation. The controllers of all current FES systems and motorized artificial limbs obtain command signals from the myoelectrical activity or mechanical motion produced by those muscles that the subject can still control voluntarily. There is a general paradox in prosthetic motor control, however: the higher the level of the injury, the more degrees of freedom the prosthetic system must control, but the fewer the sources of voluntary command signals. For FES control of grasp, contralateral shoulder motion and residual wrist movement have been used to provide relatively simple commands (Smith et al., 1998). Subjects are able to produce reasonably high information rates on one channel by modulating rapidly among several distinguishable positions, probably because these muscles are still equipped with proprioceptive feedback. Other command sources, such as EMG and voice, tend to be slower and/or less precise. It remains to be seen whether systems can be designed to command the multiple simultaneous degrees of freedom involved in tasks such as coordinated reach and grasp.

An alternative approach to sensing residual voluntary muscle activity is to record command signals directly from the CNS above the level of the lesion. Attempts to record "brainwaves" via EEG and gross electrocortical electrodes have produced only very low data rates (McFarland, McCane, and Wolpaw, 1998), probably because they reflect the aggregate activity of millions of neurons carrying very different signals simultaneously. Chronic unit recording techniques have been used for many years as a research tool to understand the role of the sensorimotor cortex in controlling natural motor behaviors; technologies feasible for clinical use are starting to emerge (Rousche and Normann, 1998). Limited functional use of such signals has been demonstrated in animals (Chapin et al., 1999) but the ultimate potential is likely to depend on the representation of complex movement in the brain, a subject that is still hotly debated by neurophysiologists. For example, it has been variously proposed that the primary motor cortex (Brodman's area 4) contains a representation of the desired position in space of the hand, the angles of the joints required to achieve a desired posture, the amount of force required from the individual muscles, and the states of the spinal interneurons. These have very different implications for the design of a controller required to respond to and interpret such command signals.

## Conclusions

At one extreme, motor prostheses require only very simple exercise of one or a few muscles. At the other extreme, they require sophisticated bidirectional interfaces with the patient and on-line solution of problems in motor coordination that are normally solved by complex and poorly understood circuitry in the brain and spinal cord. FES applications provide particularly interesting challenges to our theoretical understanding of the normal roles of muscles, proprioceptors, spinal reflex pathways, and trajectory planning by the brain. They have also sparked attempts to reconcile traditional engineering approaches for the control of robotic manipulators with the very different but still obscure strategies for adaptive sensorimotor control in living organisms.

## Introduction

This article provides an overview of the physical components that tend to be common to all neural prosthetic systems. It emphasizes the biophysical factors that constrain the sophistication of those interfaces. Specific applications to neural prosthetic systems for sensory replacement and motor control are covered in PROSTHETICS, SENSORY SYSTEMS (q.v.) and PROSTHETICS, MOTOR CONTROL (q.v.), respectively. Electrical stimulation of the nervous system is also being used to treat other disorders; examples include spinal cord stimulation to control pain and basal ganglia stimulation to control parkinsonian dyskinesias.

## Electroneural Interfaces

Two types of physical system are known to be capable of real-time information processing: electronic circuits, in which information is carried by the flow of electrons in metal conductors, and neural circuits, in which information is carried by ions in water. Much contemporary research in computational neurobiology is concerned with discovering or exploiting common principles of information processing in these two systems. Thus, it is natural that real-time interfaces between these systems have been developed so that electronic instrumentation can be used to study neural systems. Neural prosthetics are clinical applications of neural control interfaces whereby information may be exchanged between neural and electronic circuits. Their technology to date has been derived largely from cardiac pacemakers, which themselves have evolved from the fixed-rate, single-channel stimulators of the 1950s to become programmable and adaptive systems equipped with sensors and sophisticated data processing.

In principle, information could be transferred into and out of the nervous system by any of several means, including chemical, magnetic, optical, and ultrasonic. In practice, neural prostheses require temporospatial resolution and physical portability, which have only been achieved with the types of electrical signals that are familiar to most electrophysiologists. Thus, the future of neural prosthetics depends heavily on the well-understood biophysical properties of excitable membranes and on the development of technology that can approach physical limits that are readily predictable from those properties.

In addition to the obvious goal of restoring function to patients with disabilities, the field of neural prosthetics offers important opportunities for pure research:

- The clinical and commercial value of neural prostheses justifies the development of technology that is also useful in basic research.
- The implantation of sophisticated neural control interfaces in sentient observers creates unique opportunities for a new class of psychophysical research into neural computation.
- The development of functional replacement parts for the nervous system forces researchers to examine and test theories of neural computing more rigorously than they might do otherwise.
- The development of neural prosthetic controllers that can deal successfully with the exigencies of daily life will almost certainly require advancement of principles and methods for neural networks and other forms of adaptive control.

### *Stimulation*

Most neural prosthetic devices operate by injecting electrical current into the extracellular fluids surrounding excitable neurons in order to elicit action potentials in those neurons. Action potentials so elicited are indistinguishable from those that arise through the natural mechanisms of sensory transduction or synaptic input. When these action potentials arrive at their destinations, the receiving cells respond to and interpret the signals as if they arose from naturally occurring neural activity. Thus, the goal of the neural prosthetic device is to recreate the temporospatial pattern of activity that would have occurred normally during the particular function that is being replaced or augmented prosthetically (see PROSTHETICS, SENSORY SYSTEMS, for a discussion of these factors in cochlear implants).

*Biophysics.* Topologically, a neuron in its resting state is essentially a charged spherical capacitor with elongated deformations comprising its axon and dendrites. The cell membrane is the dielectric, the ionic solutions on either side of the membrane constitute the plates, and differences in the concentrations of ions on each side generate the charging potential of about −70 mV (inside versus outside). In order to generate an action potential, the membrane capacitance must be discharged by about 15 mV in a small region. This results in a brief sequence of openings and closings of sodium and potassium channels in the membrane, which results in the flow of the action current. The action current depolarizes and then repolarizes adjacent regions of the cell membrane, giving rise to the propagating wave of activity known as an action potential or spike.

The process of evoking an action potential through extracellular stimulation is somewhat counterintuitive. In order to depolarize a capacitor, it is necessary to pass charge across the dielectric, i.e., into the cell body. However, neither the source nor the sink electrode of the stimulator is actually inside the cell. Instead, the stimulator creates a voltage gradient in the tissues surrounding the target cell. This gradient induces charge to flow across the cell membrane by capacitive conductance in response to the rate of change of the voltage gradient, i.e., *dV/dt*. The amount and extent of the depolarization so produced depend on the intensity and time course of the pulse of stimulation current, its propagation through the various conductances in the tissues through which it diffuses, and the physical dimensions and consequent electrical properties of the excitable target cell (Ranck, 1975).

The most important physical dimension of highly elongated neurons is their diameter, which affects the ratio of membrane surface area (which determines capacitance) to axonal cross-sectional area (which determines resistance to current spread inside the cell). The presence, thickness, and disposition of myelin are also important because myelin greatly reduces the capacitance that must be discharged in order to reach threshold depolarization. It should also be remembered that electrical current must form a complete circuit, so that any capacitive stimulation current that enters a cell at one point, depolarizing its cell membrane locally, must be balanced by equal current leaving the cell and causing some degree of local hyperpolarization in other regions.

In order to predict accurately the effects of stimulating a complex structure such as a part of the cerebral cortex or a muscle with embedded sensory and motor axons, it is necessary to have a great deal of quantitative information about the neural architecture and the disposition of the stimulating electrodes. There are some useful rules of thumb, however, that cover most of the important phenomena:

- The most important consequence of a stimulation pulse is the steepness of the extracellular field gradient that it produces in the vicinity of the target neurons. Small electrodes positioned close to excitable processes are most effective.
- The important stimulus variable is the charge of a pulse, which is current times duration. Voltage is not important, as most of the voltage tends to be dissipated across the metal-electrolyte interface (see below) rather than contributing to the voltage gradient in the tissue surrounding the neurons.
- Stimulation pulses are most efficient when they have a duration that is somewhat shorter than the membrane time constant of the target cells, which is usually on the order of 100–200 $\mu$s for myelinated axons and 500–1,000 $\mu$s for unmyelinated axons and cell bodies.
- The first recruited elements tend to be the largest, most elongated, and most myelinated elements, namely large-diameter myelinated axons and large cell bodies attached to myelinated axons.
- Most body tissues (including bone and scar tissue) are sufficiently conductive that they tend, in aggregate, to act as volume conductors in which stimulus current density steadily decreases with distance from the electrode.
- Stimulation electrodes must be used in pairs (source and sink), but each contact tends to function as an independent monopolar electrode unless the two contacts are positioned closer together than to the target neurons.

*Electrochemistry.* The rise of safe and effective neural prosthetic devices over the past 30 years is a consequence of the gradual elucidation of the electrochemical processes involved in converting electrical current from flow of electrons in a metal conductor to flow of ions in an aqueous one. In order for this to occur without cumulative deterioration of the electrodes or damage to the tissues, it is necessary that this be accomplished by entirely reversible chemical reactions. The typical reactions of electrolysis result in irreversible breakdown of water molecules into gases and acid or alkali solutions and shifts of the neutral valence of metals into positive-valence oxides with very different electrical, chemical, and biotoxic properties (reviewed by Loeb, McHardy, and Kelliher, 1982).

The most obvious fully reversible reaction is the charging and discharging of the capacitance between the metal electrode and the body fluids. Because the irreversible reactions of electrolysis all have minimal working voltages that must be exceeded before they occur (usually about ±0.8 VDC), stimulating current can be passed into and out of the electrode safely as long as capacitive charging never reaches these working voltages. Thus, repeated brief pulses of electrical current can be applied safely, as long as an equal and opposite amount of charge flows in the opposite direction between each stimulating pulse.

The amount of charge that can be passed by this double-layer charging depends on the capacitance of this interface, which depends on the surface area of the electrode and the thickness of the effective dielectric boundary of the interface. A metal that forms little or no surface oxide, such as platinum, has a dielectric boundary thickness that depends on the thermodynamics of molecules bouncing off its surface. Metals that form stable nonconductive oxides, such as tantalum, can be anodized to build up their oxide thickness, reducing the capacitance but providing a barrier to inadvertent electrolytic reactions (Guyton and Hambrecht, 1974) and permitting them to sustain much higher voltages during stimulation pulses. Other reversible reactions available on some metal surfaces include absorption and desorption of hydrogen and oxygen. Iridium provides the highest charge density limit (about 3 mC/cm$^2$) of any biocompatible electrode material because it can be "activated" by growing a multilayer surface oxide that is electrically conductive and porous to ions (Robblee, Lefko, and Brummer, 1983). Iridium exhibits a range of stable positive valences from about +3 to +4.8, so that each atom in the oxide layer can absorb or release about two electrons, with concomitant release or absorption of two hydroxyl ions.

Electrochemical considerations are particularly important to attempts to extend neural prosthetic technology to provide denser multichannel interfaces with the nervous system. In order to provide more independent channels of stimulation in a given neural pathway, it is necessary to make the electrodes smaller and position them closer to their target neurons (Loeb, Peck, and Martyniuk, 1995). Such a microelectrode produces sufficient current density to activate local neurons selectively, while minimizing the spread of stimulation current to adjacent sites under the control of other microelectrodes. Unfortunately, the surface area of such electrodes tends to decrease faster than the amount of charge required to activate local neurons, pushing electrode materials to their safe charge density limits.

### *Recording*

Electrophysiological recordings of interest to the control of neural prosthetics range from the potentials generated by large populations of cells (such as those measured in EEG and EMG) to the action potentials generated by individual neurons. All of these signals are small-amplitude AC signals (typically less than 1 mV) that must be detected against a background of interfering signals from other bioelectrical sources and various sources of noise. In most parts of the central and peripheral nervous systems, the activity of adjacent neurons is often quite distinctive, making it necessary to record and distinguish the action potentials of single units to use them as command and control signals. This has been accomplished for brief periods of time in many research applications, but techniques remain to be developed for stable, long-term recordings from human patients.

The action potentials generated by individual neurons are produced by action currents of 1–10 nA lasting 0.2–2 ms, depending on the size and myelination of the cell. As in the case of the currents produced by electrical stimulation, the current density and the resulting potential gradient in the surrounding tissues drop rapidly with distance from the current source (Rall, 1962). Microelectrodes usually must be within 100 $\mu$m of a neuron to record a usable action potential. In order to be positioned that close to a neuron, such a microelectrode must be physically small, with a small surface area. For a metal microelectrode, double-layer charging of the metal-electrolyte interface provides the mechanism for converting a biopotential from ion fluxes in water to electron motion in a metal conductor. The small surface area of the exposed metal surface provides only a small capacitance, resulting in a relatively high impedance in the frequency band of the action potential (typically 100–1,000 kΩ at 0.5–5 kHz). The resistivity of the saline in the immediate vicinity of the microelectrode also presents a substantial impedance. High impedance is associated with high thermal noise, which adds to and obscures any biopotentials to be recorded.

Usually microelectrodes pick up signals from several adjacent neurons, which may need to be discriminated based on small differences in their waveforms. Even relatively low noise levels may degrade the reliability of such discrimination. Small movements of the microelectrode with respect to the neurons are likely to distort the relative amplitude and shape of the single unit potentials or change the sampled population entirely.

## Systems Hardware

### *Power and Data Management*

In order to improve the sophistication and capabilities of neural prosthetic interfaces, larger numbers of stimulating and recording channels must be positioned closer to their neural targets. This raises the problem of how to transmit more data to and from arrays of small electrodes located in delicate neural tissues.

One approach is to combine many electrodes into an array that includes active electronic processing so that a large number of separate signals can be multiplexed onto one data connection (Najafi, Ji, and Wise, 1990). Stimulation pulses are usually relatively brief (~100 $\mu$s) compared to their interpulse intervals (~10–100 ms), making it possible for a single stimulus channel to be multiplexed among many electrodes. Bioelectrical potentials are more difficult to multiplex because they usually have high concurrent bandwidths (1–10 kHz) on each channel, resulting in very high aggregate sampling rates.

Any active circuitry for multiplexing or demultiplexing requires DC power. Electrical leads and connectors carrying DC voltages are particularly difficult to insulate because even tiny amounts of saline leakage result in electrolytic corrosion (see below). The very low power consumption of some integrated circuit technologies has led to interest in the wireless transmission of power. Radio-frequency (RF) inductive coupling is now used routinely in cochlear implants and has been developed for injectable muscle stimulators (Troyk and Schwan, 1992). Infrared transmission and photoelectric conversion may also be possible over short distances.

### *Packaging*

Active microelectronic circuitry is generally contained within a hermetic enclosure to protect it from moisture. This adds greatly to the physical bulk of the circuitry, particularly if large numbers of input-output channels must be routed through feedthroughs and connectors incorporated into the package. The design of the package and the selection of hermetic materials (metals, ceramics, and glasses) are likely to be further complicated by the need to transmit RF or infrared energy to power and control the electronics. Embedding in epoxy, silicone, and other nonhermetic polymers was commonplace in the early cardiac pacemaker industry, but it is difficult to perform reliably on complex circuits. There is much interest in passivating monolithic integrated circuits so that they can be implanted directly into the nervous system with few or no attached leads.

Nonhermetic encapsulation and passivation depends on adhesion of the coating material to the substrate electronic components rather than impermeability. Water in the vapor phase tends to diffuse through all polymeric materials, but it does not cause electronic problems until it condenses onto the circuitry itself. Once condensation occurs, the water vapor forms an ionic solution by dissolving surface contaminants or the materials themselves. This solution represents an osmotic attractant, pulling additional water vapor out of the surrounding polymer and pressurizing itself so that it dissects along the surface, eventually bridging electrical conductors and resulting in corrosion and circuit failure. Condensation on hydrophilic surfaces can be prevented only if there are no voids and there is sufficient adhesive force between the encapsulant and all substrate materials. Even trace surface contaminants tend to interfere with adhesion, which usually depends on electrostatic bonding (Donaldson, 1987).

An alternative approach to chemical adhesion for certain geometries is to use hydrostatic pressure. This has proved useful in preventing electrical shorting from condensed water within connectors that must be opened and closed in the body. The encapsulant is pressurized mechanically as the connector is closed so that its hydrostatic pressure exceeds the maximal osmotic pressure of salt solutions (typically 200–250 psi) (Loeb et al., 1983).

## Conclusions

Serious attempts to build functional neural prostheses have been under way for about 35 years. Progress has been limited because it depended on concurrent developments in microelectronic and biomaterial technologies as well as on advances in understanding the neurophysiology of the functions to be restored. Once these thresholds have been passed for a given application (e.g., cochlear implants for the deaf; see PROSTHETICS, SENSORY SYSTEMS), dramatic functional restoration has been achieved, although the development of these complex and highly regulated medical devices remains much slower than that of comparable consumer electronics. As the armamentarium of applicable technology and basic neurophysiology enlarges, there should be a steady acceleration in the clinical application of neural prostheses.

## Introduction

This article concerns sensory prostheses, in which information is collected by electronic sensors and delivered directly to the nervous system by electrical stimulation of pathways in or leading to the parts of the brain that normally process a given sensory modality. In principle, all of the senses could be replaced or even augmented by such technology. In practice, only some sensory modalities seem amenable to currently available approaches; the status for each sense is summarized below:

- Hearing—widespread clinical success with the use of cochlear implants over the past decade.
- Vision—long-standing goal, with a recent resurgence in preclinical research plus some pilot human experiments.
- Touch—some clinical research on peripheral restoration in conjunction with functional electrical stimulation (FES; see PROSTHETICS, MOTOR CONTROL).
- Proprioception—little research under way, despite eventual importance to FES.
- Balance—some theoretical potential and early-stage analysis of feasibility.
- Smell—some theoretical interest because of the clinical significance of anosmia in the elderly, but hampered by the complexity of the natural senses and the unavailability of prosthetic sensors.
- Taste—no research under way; little clinical interest.

The general problem in constructing and implementing sensory prostheses is to understand and emulate the relevant parts of the neural code used by normal sense organs to encode and transmit sensory information to the brain. In practice, this means identifying a surgically accessible site through which to apply a complex temporospatial pattern of electrical stimulation. The general biophysical and electronic considerations can be found in PROSTHETICS, NEURAL. This article describes current research on auditory and visual prostheses.

## Cochlear Prostheses

### Current Technology

Cochlear prostheses use direct electrical stimulation of auditory nerve cells to bypass absent or defective hair cells that normally transduce acoustic vibrations into neural activity. They are the most sophisticated and the most successful neural prostheses to date, and they are still evolving. The currently available devices generally use multicontact electrodes inserted into the scala tympani of the cochlea so that they can differentially activate auditory neurons that normally encode different pitches of sound (for a historical review, see Loeb, 1990). A much smaller number of patients with bilateral degeneration of the auditory nerve have been treated with modest success by stimulation of the cochlear nucleus in the brainstem. In all currently available systems, an external, wearable control unit (Figure 1) determines a pattern of electrical stimulation in which the stimulus amplitude in each channel depends on the spectral content in the acoustic input and a previously stored map of auditory sensations that can be elicited by electrical stimulation of each channel in that patient. Many algorithms have been developed over the years, employing both analog and pulsatile electrical waveforms delivered sequentially and/or simultaneously to fixed or dynamically changing channels.

Clinical results with cochlear implants have improved steadily, to the point that they are the treatment of choice for most cases of severe to profound sensorineural hearing loss in both adults and children. Most patients with adult-onset deafness are devastated by the loss of social interactions and find it difficult to develop alternatives such as lip-reading and sign language. Cochlear implants provide essentially immediate restoration of awareness of sound in all patients and functional levels of speech recognition in the majority, suggesting that the goal of replicating the salient natural encoding of sound has been achieved in most but not all patients (see below).

For prelinguistically deafened children, the trend is to implant a cochlear prosthesis at an early age, generally under 6 and increasingly under 2 years old. Young children appear to benefit from the increased plasticity of the young nervous system and the ability to participate in conventional verbal educational programs (Svirsky et al., 2001). In general, they acquire language skills at the same rate as normal children, but they remain delayed by the preimplantation period. Individuals who have received no acoustic stimulation in the first few years of life appear to lose much of their ability to learn to process such information by adolescence (Busby et al., 1991), consistent with the notion of "critical periods" in the training of biological neural networks.

### Current Research

*Improved temporospatial representations of speech sounds.* The replacement of 10,000 independent hair cell transducers with 8 to 20 sources of stimulation current necessarily results in distortions of both the temporal and spatial patterns of neural activity received by the brain. The spatial problem is further aggravated by the tendency of stimulus currents to spread radially from their source in the volume-conductive tissues of the cochlea, resulting in "cross-talk," whereby a stimulus targeted to one spatial subgroup of spiral ganglion cells exerts modulatory effects on distant subgroups that are the target of another stimulation channel. The extent of this problem has been appreciated relatively recently through both clini-

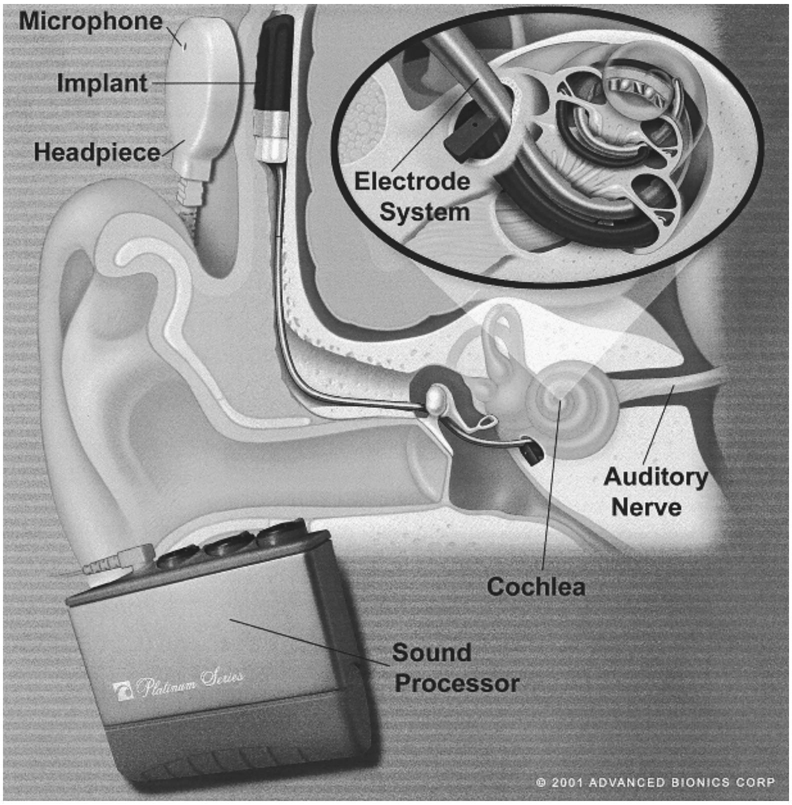

**Figure 1.** Clarion cochlear prosthesis showing external (left foreground) and implanted (right) components. The implanted components include a 16-contact intracochlear electrode (wedged into the spiral shape of the first one-and-a-half turns of the scala tympani by the dark blue positioner; see insert) and hermetically encased electronics (labeled implant: 25 mm wide by 6 mm thick). The external sound processor contains patient-operated controls, a rechargeable battery, a microprocessor, and a digital signal processor, and connects to a headpiece with a microphone and the antenna that transmits power and data to the implant. Acoustic signals from the microphone are filtered and converted into 8 to 16 channels of stimulus waveforms; these are delivered by the electrode contacts to recruit tonotopically arranged subsets of the spiral ganglion cells that comprise the auditory nerve. (Photograph courtesy of the manufacturer, Advanced Bionics Corp., Valencia, Calif.)

cal studies (Lawson et al., 1996) and computer modeling (Frijns, Briaire, and Grote, 2001). It is particularly severe for apical (low-frequency) sites. This has led to renewed development and testing of novel cochlear electrode arrays intended to position the contacts closer to the target spiral ganglion cells and reduce spread of stimulation currents.

The temporal distortions are more complex and their significance and amelioration less obvious. As the strength of an electrical stimulus is increased to represent increasing loudness, it recruits more and more auditory neurons, as would occur with an acoustic stimulus, but the electrically evoked activity tends to be much more highly synchronized. This results in a form of “beating” or “aliasing” among the repetition rates of the stimulation pulses (typically 400–800 pps), the modulation bandwidths of the acoustic information (typically 100–400 Hz), and the relative refractory periods of auditory neurons (probably 1–3 ms, corresponding to 300–1,000 Hz). The effect is most severe for low-frequency (apical) percepts, which are normally decoded from both temporal and spatial cues in the neural activity. It appears to be possible and useful to break up such beating by employing stimulation pulse rates that are far higher than those that can be followed by individual neurons (e.g., 1,500 up to 5,000 pps). This reduces beating and aliasing and results in a more randomized temporospatial representation, which many patients find to be subjectively less annoying and functionally more useful (Wilson et al., in press).

*Combined electrical and acoustic stimulation in patients with residual hearing.* There are many more patients with severe than with profound hearing loss, and most of these tend to have preferential preservation of low-frequency (apical) acoustic perception. This is the band in which cochlear implants tend to produce the greatest spatial and temporal distortions (see above). Clinical testing in a limited number of such subjects suggests that it is usually possible to preserve acoustic hearing apical to an electrode array that has been inserted shallowly into the scala tympani. The simultaneous presentation of amplified low-frequency acoustic information together with a multichannel electrical representation of the higher frequencies produces substantial improvements in performance, particularly for complex tasks such as perception of speech in highly noisy environments (Wilson et al., in press).

*Bilateral cochlear implants.* Individuals with normal hearing use binaural cues to distinguish desirable signals from noise sources that are located at different positions. Differences in relative loudness and arrival time at the two ears are decoded in the auditory brainstem so that the cognitive centers of the cortex can focus on spectral information from a single source. At least some of the few patients who have received cochlear implants in both ears have experienced substantial improvements in speech perception in noisy environments (Wilson et al., in press). This has motivated additional research on methods to synchronize the stimulation of the corresponding channels in the two ears, which might lead to performance that would warrant the additional expense and invasiveness of two cochlear implants.

*Psychophysical correlates of performance variability.* The development and testing of cochlear implants has been plagued by large variability of results among patients with no distinguishing characteristics. This complicates the design and interpretation of studies comparing the performance of different devices and speech-processing strategies. It also makes it difficult to justify implantation in the many patients whose residual hearing provides function comparable to that obtained by the poorest implant recipients. Enhanced psychophysical tests enabled by more flexible stimulation systems have started to identify neurophysiological correlates of cochlear implant performance (Wilson et al., in press). This bodes well for the development of speech-processing strategies to overcome these individual limitations and to fit them to the appropriate patients.

*Fully implanted systems.* Cochlear implants have been following a development track similar to that of hearing aids, their technological predecessors. Both started with relatively large and power-hungry circuitry that had to be worn on the body, including large, heavy, rechargeable batteries. Both used improvements in low-power integrated circuitry and battery technologies to miniaturize the sound-processing systems so they could be worn behind the ear (or even in the ear canal, in the case of hearing aids). Because one component of a cochlear prosthetic system must be surgically implanted, an obvious goal is to eliminate the external components entirely. This poses three major challenges that seem likely to be overcome within the next 2–3 years:

- The power consumed by the stimulation pulses themselves is substantial in a high-speed, multichannel implant, necessitating the development of high-performance batteries that can be recharged rapidly and frequently by inductive coupling of RF energy applied outside the body. More efficient electrodes closer to the spiral ganglion cells should also help.
- The microphone in present cochlear implant systems is usually located with the external headpiece that transmits power and data to the implanted electrodes. Novel technologies are in development for an implanted microphone that will function electrically and acoustically in a surgically suitable site.
- The dynamic range of electrical stimulation (from perceptual threshold to uncomfortably loud) is very narrow compared with that of acoustic hearing (6–20 dB versus 100 dB). Speech processors employ sophisticated digital algorithms for dynamic gain control and stimulus intensity mapping, but many patients find it necessary to make frequent adjustments to the manual loudness control on their externally worn speech processors. An alternative strategy is to have the implant monitor the electromyographic activity associated with the stapedius reflex and use it to make automatic adjustments of stimulation intensity. This is a protective reflex that comes on when the brain perceives the sound to be uncomfortably loud; it is intact in most cochlear implant recipients.

## Visual Prostheses

As in the early days of auditory prostheses, there is not yet any general agreement on the most promising site to apply electrical stimulation to the visual pathways. Sites that have been considered include subretinal (microelectronic array of photocells between the retina and the sclera), epiretinal (thin film electrode array on the vitreous surface of the retina), optic nerve (nerve cuff electrode), optic radiations (probes with multiple contacts inserted stereotactically), surface of striate cortex (arrays of contacts on the pial surface), and striate intracortical (see below). The obvious difference between auditory and visual prostheses is that auditory information requires a small number of channels with high data rates while the visual system requires a large number of channels with low data rates. This would seem to favor the two sites described below, which offer large, fairly flat surfaces on which to deploy retinotopically mapped electrode arrays.

### *Cortical Approach*

Attempts to provide useful visual sensations in the blind by direct electrical stimulation of visual cerebral cortex began in 1966 (Brindley and Lewin, 1968). The initial devices used arrays of small electrodes (about 1 mm diameter) on the pial surface. Relatively high stimulus currents (about 1 mA for a 200 $\mu$s pulse) were required to produce sensations of light called phosphenes. Because of current spread by volume conduction, such stimulation presented to a single electrode presumably recruits neurons scattered over many adjacent cortical columns, but the surround inhibitory mechanisms actually result in a surprisingly small, well-formed dot of light. This seems to suggest that a complete, if coarse-grained, picture could be built up from a sufficient number of such phosphenes. The problem is that the processes responsible for the focusing operate quite slowly, so that stimulus trains presented concurrently but interleaved between even two such sites produce unpredictable, nonlinear interactions (Girvin, 1988). A useful image will require hundreds, if not thousands, of independently controllable phosphenes.

More recently, intracortical microelectrodes have been employed successfully to create similar phosphenes with stimulus currents (5–20 $\mu$A) that would tend to recruit only a few neurons within the immediately vicinity of the electrode tip (Bak et al., 1990). When two sites spaced less than a millimeter apart are stimulated concurrently, their phosphenes seem to combine and fuse in a predictable and desirable manner. Silicon fabrication (Wise and Najafi, 1991; Normann et al., 1996) may make it feasible to build dense arrays of contacts and associated electronic circuitry that are safe to implant and operate continuously for long periods of time.

### *Retinal Approach*

Recent improvements in low-power integrated circuitry and intraocular surgical techniques have sparked interest in the possibility of placing an array of microelectrodes on the inner retinal surface. This approach requires viable retinal ganglion cells, so it is limited to blindness caused by photoreceptor degeneration, such as retinitis pigmentosa and macular degeneration.

Human research to date has employed intraoperative probes and small electrode arrays to determine suitable stimulation parameters and the percepts that they evoke. Data are inconclusive because of the severe limitations on intraoperative experiments and because of uncertainties about the positioning of the electrodes and the condition of the retinal circuitry. The following is a tentative interpretation of the biophysics of retinal stimulation and their implications for the design of a functional visual prosthesis.

In the intact retina, photoreceptors maintain a polarization level that maximizes sensitivity to incident photons, which results in changes in the release of transmitter and in the background spontaneous activity of bipolar and ganglion cells. Even tiny transretinal currents in the $\mu$A range can change the bias levels of these photoreceptors, resulting in perceptions of light and dark phosphenes. In the absence of photoreceptors, electrical stimulation pulses must produce sufficiently intense voltage gradients to depolarize neurons from the resting potential to the threshold for the propagation of action potentials. Retinal neurons are relatively small and unmyelinated, so they would be expected to have high thresholds and long membrane time constants. The output axons of retinal ganglion cells are the largest structures and lie on the vitreous surface of the retina, immediately under the stimulating electrodes, so they would be expected to have the lowest thresholds. However, the axons at a given location originate from a wedge-shaped sector of the retina, so their activation would be expected to produce elongated and overlapping phosphenes. Bipolar cells are more localized and tend to be preserved in most retinopathies, but their electrical thresholds are unclear. Because bipolar cells have longer membrane time constants than ganglion cells (1–2 ms versus 0.5 ms), they can be activated selectively by long-duration pulses (Greenberg et al., 1999). However, such stimulation applied to a large array may result in cross-talk between channels and unacceptable levels of power dissipation.

## Information Processing

The introduction of information directly into the CNS, bypassing the natural sensory encoding, raises interesting questions about how that information will be interpreted by the CNS.

### *Temporal Patterning*

Classical neurophysiology is grounded in the notion that the output of each individual neuron represents an independent channel in which the mean spike rate encodes unidimensional information. There have been various theories regarding the encoding and decoding of information in the fine temporal details of activity patterns in ensembles of neurons. One theory of pitch perception held that the acoustic frequency information encoded in the phase-locked activity of auditory afferents could be decoded by cross-correlation of delayed and undelayed versions of this signal. However, patients reported pitch sensations that were dominated by place of electrical stimulation rather than frequency for stimulation rates above about 500 Hz (Eddington et al., 1978). Electrical stimulation of the visual cortex would seem to offer a powerful technique to test current theories regarding the significance of widespread synchronization among neurons responding to a single object in a complex scene.

### *Neuronal Plasticity*

There have been dramatic demonstrations of remapping of both sensory maps and motor representations in primary cortex in response to various surgical, electrical, and behavioral modifications of cortical input (Merzenich and Grajski, 1990). Abrupt or gradual loss of signals from failing sense organs is likely to induce various reorganizations of the ascending pathways, as well as the general atrophy that has been noted. The use of electrical stimulation to restore sensory information inevitably results in somewhat unphysiological temporospatial patterns of neural activity that are likely to induce further reorganizations. For example, recent evidence suggests that the tendency of cochlear implants to produce a better representation of high (basal) versus low (apical) acoustic frequencies may result in a remapping of the central representations and consequent improvements in speech perception (Svirsky et al., 2001). Because of the complex precortical processing of auditory information, the locus of such plasticity will be difficult to identify. Similar experiments in the much simpler visual system have the potential to provide important insights into cortical information processing.

## Conclusions

The growing clinical application of neural prosthetics should provide a major catalyst for the expansion of basic knowledge about the nervous system. The devices themselves provide unique opportunities for psychophysical testing of current theories of neural computing and immediate incentives for improving those theories when their limitations are revealed. The technology that is being developed to build these prostheses has considerable spin-off potential as neurophysiological research tools. Conversely, the nervous system embodies tried and proven solutions to computational problems that have resisted conventional algorithmic approaches of robotics and artificial intelligence. It is difficult to imagine a more appropriate application of electronic neural networks than in the repair of the biological systems that have inspired them.

# Pursuit Eye Movements

*Richard J. Krauzlis and Leland S. Stone*

## Introduction

When viewing objects, primates use a combination of saccadic and pursuit eye movements to stabilize the retinal image of the object of regard within the high-acuity region near the fovea. Although these movements involve widespread regions of the nervous system, they mix seamlessly in normal behavior. Saccades are discrete movements that quickly direct the eyes toward a visual target, thereby translating the image of the target from an eccentric retinal location to the fovea. In contrast, pursuit is a continuous movement that slowly rotates the eyes to compensate for the motion of the visual target, minimizing blur that can compromise visual acuity. Whereas other mammalian species can generate smooth optokinetic eye movements—which track the motion of the entire visual surround—only primates can smoothly pursue a single small element within a complex visual scene, regardless of any extraneous motion on the retina. This difference likely reflects the greater ability of primates to segment the visual scene, to identify individual visual objects, and to select targets of interest.

## Basic Features of Pursuit Behavior

The basic features of pursuit can be illustrated by considering the *ramp paradigm*, in which a target initially at rest moves at a constant speed (Figures 1*A* and 1*B*). Pursuit is often interrupted by initial "catch-up" saccades, because the delay in the eye movement response makes the eye lag behind the target. However, if the onset of target motion is accompanied by a position step in the opposite direction, pursuit can be elicited without any catch-up saccades (Rashbass, 1961). The eye movement records obtained with this paradigm can be divided roughly into four phases (Figure 1*B*). During the latent phase (1), the target is moving, but the eyes have not yet begun to move. During the initiation of pursuit (2), eye speed increases at a nearly constant rate related to the constant image motion experienced during the latent phase. This is followed by a transition phase (3), as eye speed continues to increase and often overshoots target speed slightly. During sustained pursuit (4), eye speed settles to a steady-state value that often oscillates around a value near target speed.

The ramp paradigm illustrates several features of the pursuit system. The first feature is that, as Rashbass (1961) demonstrated, the pursuit response is dominated by target motion; pursuit rotates the eyes in the direction of target motion, even if this is away from the current position of the target. Although subordinate to motion, position offsets can also contribute to the visual drive for pursuit (Pola and Wyatt, 1979).

A second feature is that, because the retina is part of the eye, there is a reciprocal relationship between the motion of the target's retinal image and the motion of the eyes. During the latent phase, the retinal *image speed* (the difference between target and eye speeds) is equal to target speed. Afterward, image speed decreases and then oscillates near zero during sustained pursuit. Pursuit therefore acts like a negative feedback system; its eye-movement output tends to reduce its visual motion input.

A third feature is the relatively long delay (~100 ms) associated with sensory and motor processing. Combined with negative feedback, this delay tends to make the system unstable; in fact, under certain conditions, pursuit can exhibit large-amplitude oscillations. To compensate for this inherent problem, pursuit uses predictive mechanisms. For example, pursuit can maintain a constant speed in the absence of visual motion, perhaps by retaining an *eye velocity memory*. Visual motion is therefore an indicator of how eye speed should change and is correlated with future *eye acceleration* (compare Figures 1*C* and 1*D*; see also Lisberger et al., 1981).

A fourth feature is that pursuit provides a steadily changing *muscle force* to produce a constant-speed eye movement (Figure 1*E*). The required changes in muscle force are a function of eye position in the orbit and can be approximated by taking the mathematical integral of eye speed. This integration process, believed to be common to all eye movements, is accomplished by an *oculomotor integrator* contained within the brainstem.

A fifth feature is that pursuit largely compensates for the mechanical effects on movement dynamics caused by the eye "plant": the collective term for the inertial mass of the eye and the viscoelastic properties of the eye muscles. As indicated by the initial offset between muscle force and eye position, the applied force begins with an additional boost to overcome the sluggish dynamics of the eye (Robinson, 1965). Without this initial extra force, it would take three to four times longer for pursuit eye speed to match target speed. Pursuit therefore provides an eye movement command that is neurally filtered to compensate for the dynamics of the eye plant.

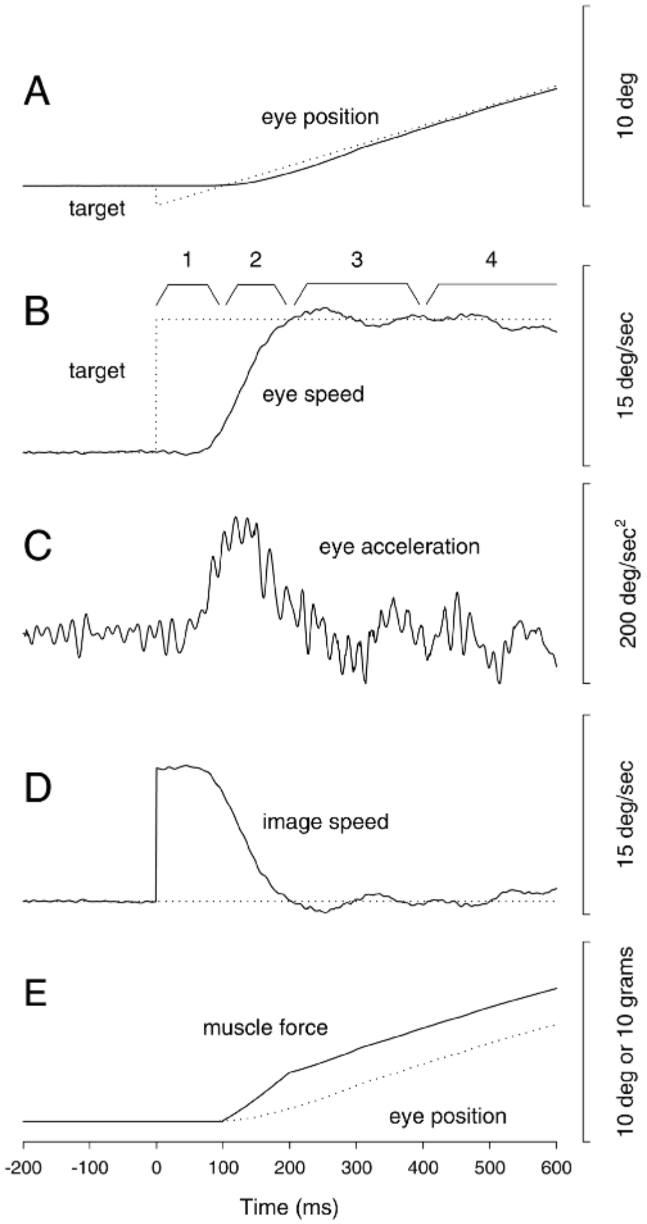

**Figure 1.** Basic features of pursuit are illustrated with the ramp paradigm. The target jumps to an eccentric position (step) and moves at a constant speed of 10°/s (ramp) that is matched by the human's smooth eye movement after a few hundred milliseconds.

## Pursuit as a Negative Feedback System

Pursuit was originally viewed as a negative feedback velocity-servo system, driven primarily by retinal image motion error signals and sustained by an internal positive feedback loop to enhance performance (Figure 2*A*). The contribution of several neural sites to pursuit can be understood within this framework. Areas within the extrastriate cortex that are specialized for processing visual motion, such as the middle temporal area (MT) and the medial superior temporal area (MST), are the major source of the visual-motion information used to guide pursuit (Dursteler and Wurtz, 1988). These cortical regions provide outputs to motor regions in the brainstem and cerebellum that form the motor commands for pursuit. In these subcortical pathways for pursuit, there are reciprocal connections between the ventral paraflocculus of the cerebellum and its target nuclei in the brainstem. This anatomical loop has been suggested to form an eye-command feedback circuit that implements the *velocity memory* for pursuit (Stone and Lisberger, 1990). Purkinje cells in the ventral paraflocculus discharge during pursuit even when there is no image motion on the retina. This discharge, if updated by visual error information from extrastriate cortical areas ($\Delta\dot{E}_d$), could continuously provide a command to change the current eye speed ($\dot{E}_c$). Although appealing because of its simplicity, there is now abundant evidence that the simple control strategy outlined in Figure 2*A* cannot account for some of the known physiological and behavioral features of the pursuit system.

## Gain Control in the Pursuit System

Contradicting the essentially linear control strategy outlined previously, there is abundant evidence that the pursuit system displays major nonlinear behaviors. One such nonlinearity is demonstrated by the dramatic changes in efficacy of visual stimuli with behavioral context. For example, it has been shown that rapid displacements of a target can cause a smooth eye acceleration if they are imposed during pursuit of a moving target, but not if they are imposed during fixation of a stationary target. Models of pursuit have simulated these nonlinear effects by including a variable gain element (Krauzlis and Lisberger, 1994). The observation that steady-state eye speed can exceed target speed requires that the proposed variable gain element affect not only the sensitivity to the visual inputs driving the initiation of pursuit, but also the signals maintaining steady-state eye speed.

The behavioral effects of altering activity at different neural sites (Table 1) have helped identify the location of a gain element in the pursuit pathways. Electrical stimulation applied within area MST or the pons can produce changes in smooth eye speed, but only if applied when the monkey is already engaged in pursuit, suggesting that these structures probably lie upstream of a variable gain element. In contrast, stimulation of the ventral paraflocculus elicits smooth eye movements even during fixation, consistent with the proximity of this structure to the final motor pathways for pursuit and its likely placement downstream of the gain element. Finally, microstimulation of the Superior Colliculus (SC) or the pursuit area within the Frontal Eye Fields (FEF) modifies pursuit speed, suggesting that these areas might directly influence a variable gain element (Basso, Krauzlis, and Wurtz, 2000; Tanaka and Lisberger, 2001).

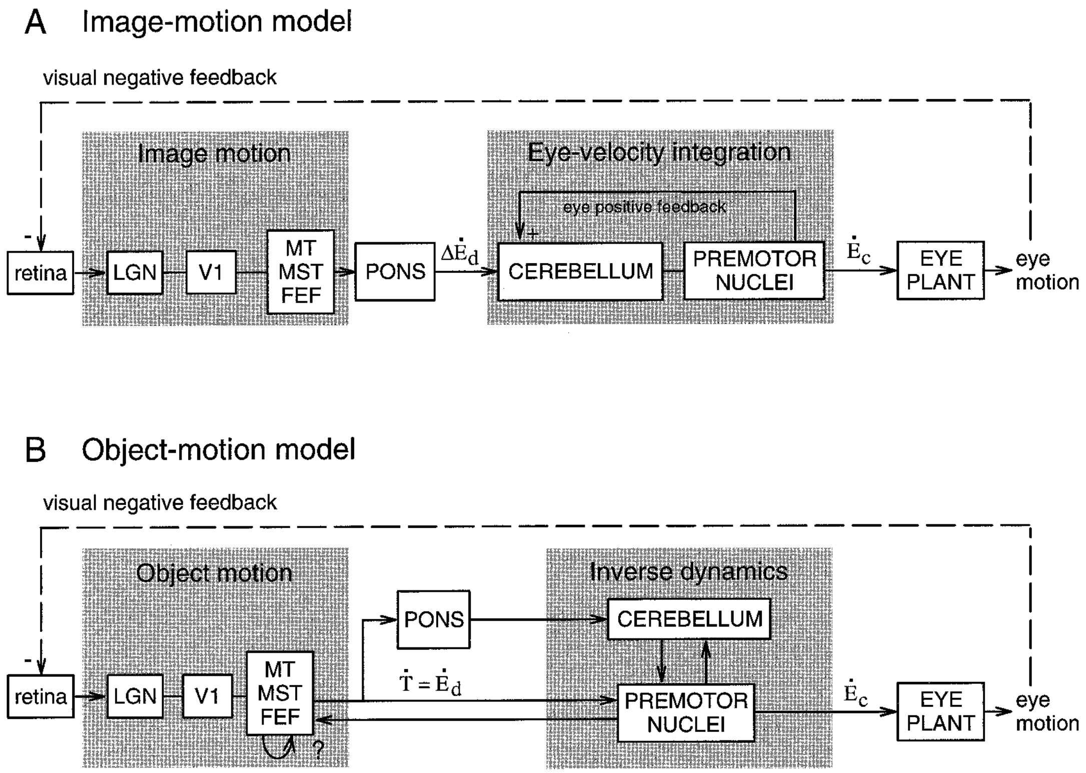

**Figure 2.** Two models of pursuit that relate system functions to physiology. (*A*) The "image-motion model" assumes that the cortex provides an image-motion signal encoding pursuit error. The subcortical pathways integrate the descending visual error signals or correction commands ($\Delta\dot{E}_d$) to generate a command for smooth eye movement ($\dot{E}_c$). (*B*) The "object-motion model" assumes that the cortex provides a combined visual and extra-retinal signal encoding the target object's motion. The cerebellar loop transforms this object-motion signal ($\dot{T}$) or desired eye motion signal ($\dot{E}_d$) into a plant compensated eye-velocity command ($\dot{E}_c$), whereas the brainstem provides the required neural integration to generate the eye-position command.

**Table 1.** Summary of Physiological Studies

| Structure | A. Lesions | B. Microstimulation | C. Neuronal recording |
|---|---|---|---|
| 1. V1 | Retinotopic deficits in saccades and pursuit | | |
| 2. Extrafoveal MT | Retinotopic deficits in the initiation of pursuit | | Visual responses tuned for direction/speed of small stimuli |
| 3. Foveal MT | Retinotopic deficits in initiating pursuit; directional deficits for ipsiversive sustained pursuit | Ipsiversive eye acceleration if applied during sustained pursuit | Visual responses tuned for direction/speed of small stimuli |
| 4. MST | Deficits in initiating pursuit; directional deficits for ipsiversive sustained pursuit | Ipsiversive eye acceleration if applied during sustained pursuit | Visual responses to small- and large-field motion; extraretinal responses during sustained pursuit |
| 5. 7a, VIP | | | Visual responses to stimulus motion; extraretinal responses |
| 6. FEF | Deficits in sustained and predictive or anticipatory pursuit | Eye acceleration, often ipsiversive | Visual responses to stimulus motion; responses during pursuit |
| 7. Rostral SC | | Contraversive saccades, contraversive eye acceleration if applied during pursuit | Visual responses to stimulus position; responses during fixation, pursuit and saccades |
| 8. DLPN | Deficits in initiating pursuit; deficits for ipsiversive sustained pursuit | Ipsiversive eye acceleration if applied during sustained pursuit | Visual responses best for moving large stimuli; extraretinal responses |
| 9. DMPN, NRTP | Deficits in pursuit | | Visual responses to large-field motion |
| 10. NOT | Deficits in ipsiversive pursuit | Ipsiversive eye acceleration | Visual responses to large-field motion |
| 11. LTN | | | Visual responses to large-field motion |
| 12. Ventral paraflocculus | Deficits in pursuit | Ipsiversive eye acceleration | Responses to eye and head velocity; transient responses during pursuit initiation and changes in eye speed |
| 13. Oculomotor vermis | Deficits in pursuit | Ipsiversive saccades if applied during fixation, ipsiversive eye acceleration or saccades if applied during pursuit | Responses to eye and head velocity; passive visual responses |
| 14. VN, FN, NPH | Deficits in pursuit and saccades | | |

Abbreviations: V1, primary visual cortex; MT, middle temporal area; MST, medial superior temporal area; VIP, ventral intraparietal area; FEF, frontal eye fields; DLPN, dorsolateral pontine nucleus; DMPN, dorsomedial pontine nucleus; NRTP, nucleus reticularis tegmenti pontis; NOT, nucleus of the optic tract; LTN, lateral terminal nucleus; VN, vestibular nucleus; FN, fastigial nucleus; NPH, nucleus prepositus hypoglossi; SC, superior colliculus.

## The Role of the Cerebellum: Velocity Memory or Plant Compensation?

The command signal provided by the central nervous system compensates for the lagging dynamics of the eye plant (Figure 1); this compensation appears to be included in the output signal of the ventral paraflocculus of the cerebellum. One line of evidence has shown that the time-varying profiles of individual Purkinje cell firing rates can be replicated by a weighted average of eye position, eye velocity, and eye acceleration (Shidara et al., 1993). The fits provided by this model suggest that the output of the ventral paraflocculus could represent an inverse dynamic signal. In a more direct test, it has been shown that when the average Purkinje cell output is provided as the input to a model of eye mechanics, the output matches the observed time course of eye velocity (Krauzlis, 2000). These results demonstrate that neural circuits through the ventral paraflocculus are capable of providing the necessary dynamic compensation for the mechanical properties of the eyeball and surrounding orbital tissues.

The evidence in favor of plant compensation suggests an alternative functional role for the brainstem-cerebellar loop. Rather than forming a velocity memory for pursuit, this circuit may be responsible for ensuring that the movement of the eyes matches that of the target as specified by descending signals (i.e., by converting $\dot{E}_d$ to $\dot{E}_c$ in Figure 2*B*). This interpretation is consistent with evidence that information about image and eye motion already appears to be combined within cortical areas such as MST, thereby obviating the need to combine them downstream. In fact, the sustained output of MST neurons during perfect steady-state pursuit in the absence of visual motion (Newsome, Wurtz, and Komatsu, 1988) casts doubt on the original interpretation of the similar finding within the ventral paraflocculus (Stone and Lisberger, 1990), which reinforced the view of pursuit shown in Figure 2*A*. More explicitly, if the cerebellar input from MST is not reduced to zero during perfect steady-state pursuit, then the sustained activity observed at the level of the cerebellum may simply reflect this sustained descending input, rather the presence of eye-velocity feedback from brainstem structures.

Additional advantages of the plant-compensation view are that it generalizes to other motor systems and simplifies the overall control strategy. All motor systems must contend with the mechanical properties of the body part they control. Rather than attempting to tailor individual sensory signals appropriately for each body part or movement type, the strategy of plant compensation makes it possible for the same input signal to control multiple body parts synergistically—the same object-motion signal could be used in several different ways, allowing one's eyes or one's pointed finger to simultaneously track the same object. This generalization is consistent with the fact that local circuits throughout the cerebellum are quite uniform, suggesting that they are indeed performing a single consistent process across the body for motor control in general.

## The Role of the Cerebral Cortex: Retinal Motion or Object Motion?

The pursuit behaviors that led to the development of the view in Figure 2*A* were mostly studied with small spots moving over a featureless background. However, one of the distinguishing features of pursuit, as compared to phylogenetically older smooth eye-movement systems, is that, by performing a global analysis of the visual scene, it can track complex objects over textured backgrounds—even when those objects are only partially visible. Experiments using more complex visual stimuli suggest that the descending cortical signal driving pursuit is not a 2D *image motion* signal that relays ongoing eye-movement errors ($\Delta\dot{E}_d$ in Figure 2*A*), but rather a 3D *object motion* signal that relays the current estimate of the target's trajectory ($\dot{T}$ in Figure 2*B*), or in motor terms, the desired eye trajectory ($\dot{E}_d$ in Figure 2*B*). For example, more than two decades ago, Steinbach (1976) provided qualitative evidence that humans can pursue the horizontal motion of a wagon wheel defined only by the cycloidal motion of a few illuminated points along its circumference. More recently, it has been shown that humans can pursue the motion of partially occluded line-figure objects (Stone, Beutter, and Lorenceau, 2000). These stimuli were designed such that the object's motion could only be recovered by selectively grouping its local component line segments (i.e., deciding which pieces belong together) and performing a global motion-integration (i.e., combining the disparate local motions to compute a single object-motion vector). Furthermore, when the static luminance of such line-figure stimuli is altered to induce a percept of independent line segments, rather than of a single moving object, pursuit can no longer accurately follow the object despite the identical image motion. These parallel effects on both motion perception and pursuit cannot be accounted for by any linear system, so future models of both perception and pursuit must contend with this inherently nonlinear processing. They will also have to incorporate the fact that the visual signals driving pursuit are time-varying, initially reflecting image motion and converging towards object motion only after a few hundred milliseconds (Pack and Born, 2001). Finally, the close relationship between smooth eye movement and 3D perception is further supported by the findings that humans can generate smooth vergence eye movements in response to the kinetic depth effect, i.e., perceived motion in depth from global motion integration in the absence of disparity (Ringach, Hawken, and Shapley, 1996). These results imply that the sustained steady-state pursuit previously attributed to an *eye-velocity memory* within a brainstem-cerebellar loop, might actually result from an *object-motion memory* within the cortex, most probably in area MST, derived either from local cortical circuits or ascending feedback from brainstem oculomotor structures (question mark in Figure 2*B*). Modulation of this object motion signal by nonvisual factors could account for the frequently observed effects of attention and cognitive expectations on pursuit movements (e.g., Kowler, 1989; Barnes, 1993).

Another component of the analysis required for pursuit in real world conditions is the selection of the visual target from within the visible scene. The presence of a moving distractor stimulus can alter the latency or direction of pursuit made to a target stimulus. Although similar effects have been observed with microstimulation of area MT, single-unit studies of MT neurons in selection tasks have produced variable and often only small effects (Ferrera and Lisberger, 1997), suggesting that the process of target selection occurs elsewhere. The role of target selection in pursuit has a close affinity to the idea of a variable gain element described previously—both putative mechanisms regulate how sensory information accesses the motor pathways for pursuit. Given that the SC and the FEF are involved in saccade target selection, it is tempting to postulate that these areas play a similar role in pursuit (Krauzlis and Dill, 2002).

## Pursuit and Saccades: Separate Motor Systems or Coordinated Motor Outputs?

Pursuit and saccades have been viewed as functionally and anatomically distinct eye movement systems, but recent studies have begun to question this assumption. The pursuit-related areas of the cerebral cortex are not restricted to those processing visual motion, but can also be found adjoining each of the saccade-related eye fields; these pursuit and saccade areas have overlapping connections with several subcortical structures. Accordingly, several regions in the brainstem that have been traditionally considered part of the saccadic system now appear to be involved in pursuit as well (Krauzlis and Stone, 1999). Recent single-unit and microstimulation studies show that the SC is involved in the programming of pursuit, in addition to its well-known role in the control of saccades, perhaps by processing target signals that are common to the two types of movements (Krauzlis and Dill, 2002; Basso, Krauzlis, and Wurtz, 2000). The firing rate of some saccade-related "burst" neurons is related to eye speed during pursuit, as well as during saccades (Missal et al., 2000). These new findings suggest the presence of direct pathways through the brainstem for the control of pursuit, in addition to the established pathways through the cerebellum. As we learn more about these alternate pathways, the organization of the pursuit system may more nearly resemble that of the saccade system, consisting of direct pathways from the cerebral cortex to the brainstem and pre-motor nuclei, with a critical but less direct pathway involving the cerebellum.

## Discussion

This brief review has outlined in broad strokes old and new frameworks for understanding the sensorimotor processing and control strategy of the pursuit eye-movement system. Control theory models and experiments using small-spot stimuli have helped frame some of the basic organizational principles of the pursuit system. However, the fundamentally linear models that have resulted from this approach cannot account for more recent behavioral and physiological data obtained under more realistic visual stimulus conditions. The growing evidence that inherently nonlinear processes such as image segmentation, selective motion integration, target identification and selection, prediction, and even cognitive and attentional factors play essential roles in pursuit, highlights the critical need for new pursuit models to transcend traditional linear or quasi-linear system control theory. Moreover, the growing evidence of interactions between the pursuit and saccade systems raise basic questions about the overall control strategy employed during tracking eye movements. The operation of pursuit is clearly not limited to the narrow goal of minimizing retinal image motion, but—together with saccadic eye movements—has the broader goal of acquiring and using visual information about real objects in the 3D world to guide motor behavior.

# Q-Learning for Robots

*Claude F. Touzet*

## Introduction

Robot learning is a challenging—and somewhat unique—research domain. If a robot behavior is defined as a mapping between situations that occurred in the real world and actions to be accomplished, then the supervised learning of a robot behavior requires a set of *representative* examples (situation, desired action). In order to be able to gather such a learning base, the human operator must have a deep understanding of the robot-world interaction (i.e., a model). However, in many application domains, such models cannot be obtained, either because detailed knowledge of the robot's world is unavailable (e.g., spatial or underwater exploration, nuclear or toxic waste management), or because it would be too costly. In this context, the *automatic* synthesis of a representative learning base is an important issue. It can be sought using reinforcement learning techniques—in particular, Q-learning, which does not require a model of the robot-world interaction. Compared to supervised learning, Q-learning examples are triplets (situation, action, $Q$ value), where the $Q$ value is the *utility* of executing the action in the situation. A supervised learning base is obtained through the selection by the human operator of the triplets with the highest utility. Robot Learning avoids human operator involvement: an important step toward automatic learning.

Because it allows the synthesis of behaviors despite the absence of a robot-world interaction model, Q-learning (Watkins and Dayan, 1992) has become one of the most used learning algorithms for autonomous robotics. Although the convergence theorem does not apply to the robotics domain (due to the limited number of situation-action pairs that can be explored during the lifetime of robot batteries), heuristically adapted Q-learning has proved successful in applications such as obstacle avoidance, wall following, go-to-the-nest, etc. This is mostly due to *neural-based* implementations, such as multilayer perceptrons trained with backpropagation, or self-organizing maps. Such implementations provide an efficient generalization, i.e., fast learning, and designate the critic—the reinforcement function definition—as the real issue. The articles Reinforcement Learning and Reinforcement Learning in Motor Control provide background information on reinforcement learning. Kaelbling, Littman, and Moore (1996), Sutton and Barto (1998) and Wiering, Salustowicz, and Schmidhuber (1999) are three other sources of information. For more detailed treatments, the reader should consult Touzet (1997).

## Q-Learning

Figure 1 shows a functional decomposition of Q-learning. Three different functions are involved: *evaluation, memorization,* and *updating.* Using the information stored in the robot memory, the current situation is evaluated to select the *best* action to accomplish (i.e., the most reward-promising action). This proposition is modified to allow exploration of the situation-action space. The new situation, entered as a consequence of the execution of the action, is qualified by the reinforcement function. Its qualitative criterion (reinforcement) is used by the updating algorithm to adjust the $Q$ values in the following way:

$$Q(s, a)_{\text{new}} = Q(s, a)_{\text{old}} + \beta(r + \gamma \cdot \text{Max}(Q(s', a)) - Q(s, a)_{\text{old}}) \quad (1)$$

where $s$ is the situation, $a$ is the action, $r$ is the reinforcement, and $s'$ represents all situations that can be reached from $s$. $\beta$ and $\gamma$ are positive coefficients less than 1.

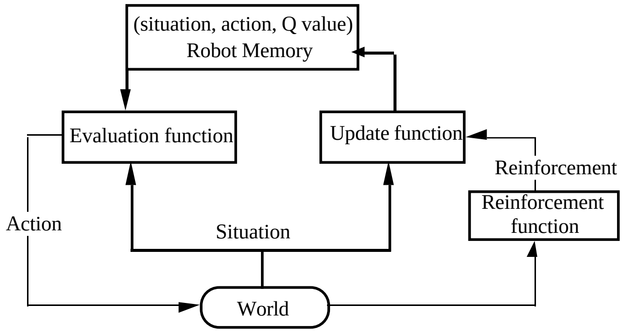

**Figure 1.** Q-learning method functional decomposition. In response to the present situation, an action is proposed by the robot memory. This action is the one that has the best probability of reward (relatively to the robot memory). However, this proposition may be modified by the evaluation function to allow an extensive exploration of the situation-action space. After the execution of the action by the robot in the real world, a reinforcement function provides a reinforcement value. This value—a simple qualitative criterion (e.g., +1, 1, or 0)—is used by the updating algorithm to adjust the utility value associated with the situation-action pair.

### *Convergence*

Recent developments in the theory of reinforcement learning have allowed proof of asymptotic convergence. These proofs rely on several assumptions that do *not* apply to robots facing real-world tasks. In particular, the asymptotic convergence requires a discrete coding of the situation-action pairs (look-up table storage) and requires attempting every action for every situation an infinite number of times. A robot is a mechanical device that needs at least a few hundred microseconds to execute any action. Therefore, because robot battery life typically lasts less than 10 hours, only a few thousand situation-actions can be visited during a given experiment. This is an extremely small number when compared to the potential number of situation-action pairs (e.g., $10^{26}$ for the Khepera miniature mobile robot (basic module with eight IR sensors and two wheels), today the most common research robot). Thus, generalization between similar situation-action pairs is *mandatory.*

## Generalization

Improvements emphasizing generalization have been proposed by Mahadevan and Connell (1992) who used weighted Hamming distance to generalize between similar situations. This simple method is limited to *syntactic* situation criteria (i.e., it is dependent on the coding of the situations). A second method, proposed by the same authors, adds the action into the syntactic criteria, using clusters to generalize across similar situation-action sets. One of the problems is that the clusters must be handpicked.

## Neural Q-Learning

Neural implementations offer a *compact* representation (i.e., limited memory requirement) and good generalization performance (as demonstrated by numerous connectionist applications). The memorization function uses the weight set of the neural network: the memory size required by the system to store the knowledge is defined, a priori, by the number of connections in the network. It is independent of the number of explored situation-action pairs. The proposed action is the processing result of the situation by the network, plus the addition of a random component for the exploration. The update function uses the weight modification algorithm to store the utility values computed by the Q-learning rule (1).

The ideal neural implementation would provide, in a given situation, the best action to undertake and its associated $Q$ value. However, training of such a network requires the definition of an error on the output layer, i.e., knowledge of the best action to undertake in every situation. Such knowledge can be inferred if there are only two different possible actions for the robot, as in the cart pole balancing problem. However, in the general case, the number of actions is larger. Lin (1993)—who proposed the first multilayer perceptron implementation of the Q-learning (Q-Con)—uses as many perceptrons as there are actions, each network output coding for the utility of accomplishing this action in the current situation. Therefore, only one Q-Con network is updated at every time step, and generalization between networks (i.e., actions) is impossible. Other multilayer perceptron implementations have been proposed (Ackley and Littman, 1991; Touzet, 1997), but they do not yet solve the output error definition problem.

### *Q-Kohon*

*Unsupervised* learning models—such as Self-Organizing Feature Maps (q.v.), Radial Basis Function Networks (q.v.), and Adaptive Resonance Theory (ART; q.v.)—do not require an error definition for updating their weight values. Q-Kohon, a Kohonen map implementation of the Q-learning, is a method of state grouping involving syntactic similarity and locality (McCallum, 1995). Each neuron codes a particular triplet (situation, action, $Q$ value); therefore the number of neurons equals the number of stored associations. The neighborhood property of the self-organizing map accounts for the generalization across similar situation-action pairs.

Q-Kohon uses the self-organizing map as an *associative memory.* This associative memory stores triplets. Part of a triplet is used to probe the self-organizing map in search of the corresponding information. Here, situation and $Q$ value are used to find the action: the best action to undertake in a world situation is given by the neuron that has the minimal distance to the input situation and to a $Q$ value of value $+1$. The selected neuron corresponds to a triplet (situation, action, $Q$). It is this particular action that should offer the best reward in the world situation. To update the $Q$ value, equation (1) requires the maximum Q value of the new entered situation. This is easily obtained by probing the map with the new situation and a $Q$ value of value $+1$. The selected neuron $Q$ value will be the maximum possible value.

A nice side effect of using clustering techniques to implement the Q-learning is that the learned behavior can be interpreted by looking (see Self-Organizing Feature Maps) at the network weights (something extremely difficult with multilayer implementations). Also, because the neurons of the self-organizing map approximate the probability density function of the inputs, one can predict that if a correct behavior is learned, all neurons will code positive $Q$ values. This is most useful to determine when a correct behavior has been learned. This last fact results in the *optimization* of the stored knowledge.

### *Comparisons*

Experiments aimed at comparing various implementations of the Q-learning in a task of synthesizing an *obstacle avoidance behavior* for the miniature robot Khepera (Touzet, 1997) demonstrate that neural Q-learning implementations require a lot less memory and less learning examples, and learn faster (Table 1). The Q-Kohon implementation also exhibits the best behavior after learning, i.e., less negative reinforcements received than all the other implementations.

**Table 1.** Comparison of Various Implementation.

| | Q-learning | +Hamming | +Clustering | Q-Comp | Q-Kohon |
|---|---|---|---|---|---|
| Time length | 55 mn | 25 mn | 30 mn | 8 mn | 2 mn |
| # iterations | 7500 | 3500 | 4000 | 2000 | 500 |
| Memory size | 6400 | 6400 | 1.6 $10^6$ | 56 | 176 |

The learning time is the time in seconds needed to synthesize an obstacle avoidance behavior. It reflects the number of real world experiments required. The number of learning iterations is the number of updates to the memory (look-up table or neural network). The memory size is the number of floats required to store the information.

## Reinforcement Function Design

The reinforcement function quality is intrinsically limited by the expert's abilities. When a reinforcement learning experiment does not converge, it is impossible to know if this is due to the fact that the experiment was too short and more examples are needed, or if the intrinsic nature of the reinforcement function forbids convergence. Today, reinforcement learning researchers use a slow and painful *trial-and-error* approach to define the reinforcement function. In the meantime, efforts have been devoted to find ways to automatically define such functions. Santos and Touzet (1999) have proposed an Update Parameter Algorithm (UPA) to automatically adjust the threshold values: $\theta_+$ and $\theta_-$ within a particular definition of the reinforcement function:

$$RF(s_1, \ldots, s_u) = \begin{cases} +1 & \text{if } g_1(s_1, \ldots, s_u) > \theta_+ \\ -1 & \text{if } g_2(s_1, \ldots, s_u) < \theta_- \\ 0 & \text{otherwise} \end{cases} \qquad (2)$$

where $(s_1, \ldots, s_u)$ is the output readings of the sensors, $g_1(\,)$ and $g_2(\,)$ are any functions linking the sensor data to the rewards.

The resulting effect is to *optimize* the exploration part of the learning phase by achieving and maintaining predefined ratios of positive and negative rewards. If there is no positive reward, the evaluation function built during the learning phase will have “0” as a maximum value and the policy cannot select effective actions. If there is no negative reward, the robot can remain in a dead-end situation forever. If there is no null reward, the evaluation function will be noncontinuous at the frontier between positive and negative situation-action pairs.

A dynamic version of UPA (Santos and Touzet, 1999) updates the threshold values during the learning phase—exploration and exploitation (to take into account the improvement of the robot policy). It allows behavior performance improvements without the need of some sort of external supervisor, capable of ranking situations by difficulty and of choosing tasks of increasing difficulty. (Dorigo and Colombetti, 1998). Santos et al. have been able to synthesize a wall-following behavior by using reinforcement learning (Figure 2), demonstrating support for reinforcement function design techniques.

## Discussion

Q-learning is one of the most used (reinforcement) learning technique for behavior-based robots (see REACTIVE ROBOTIC SYSTEMS). Neural-based Q-learning implementations provide compactness and generalizability. Clustering-based neural methods, such as Q-Kohon, allow drastic reduction of the learning time and number of examples required. Their efficiency puts forward the definition of the reinforcement function as a major issue.

Another major issue involves the ability to overcome the exponentially growing number of required learning examples that comes with target behaviors of greater complexity. Battery lifetime seems to impose a definite limit, and researchers tend to promote knowledge incorporation as a speed-up mechanism. The goal is to bias the exploration toward “rewarding” part of the search space—at the expense of *tabula rasa* methods. The drawback is that new—unforeseen—solutions *cannot* be discovered.

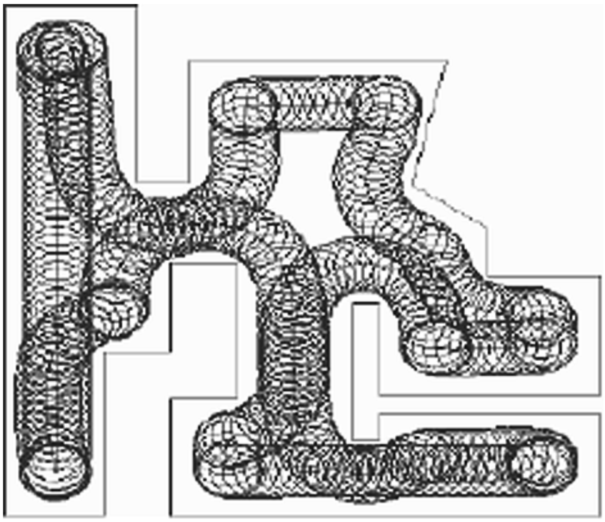

**Figure 2.** The trace of the miniature Khepera robot after the synthesis of a wall following behavior using a RBF implementation of the Q-learning and Dynamic-UPA in a new environment. Only about 2000 learning iterations are needed.

*Lazy learning* (Aha, 1997), also called instance-based learning, provides a way to add samples without implying bias. In a lazy learning approach, computation of the inputs is delayed until the necessity arises. Lazy learning samples the situation-action space, storing the succession of events in memory and, when needed, probes the associative memory for the best move. The sampling process stores the successive situation-action pairs generated by a random action selection policy. The exploration phase is done only once, stored, and used later by all future experiments. The probing of the memory involves complicated computations: clustering, pattern matching, and so forth.

By storing situation-action pairs, a lazy memory builds a nonexplicit model of the situation transition function, that is used as a bias to leverage the model-free following learning phase (i.e., Q-learning). Sheppard and Salzberg (1997) propose to mix lazy learning and reinforcement learning, probing the memory with the reinforcement function. Their objective is to provide a method for predicting the rewards for some state-action pairs without explicitly generating them. They call their algorithm *lazy Q-learning.* For the current real-world situation, a situation matcher locates all the states in the memory that are within a given distance. If the situation matcher has failed to find any nearby situations, the action comparator selects an action at random. Otherwise, the action comparator examines the expected rewards associated with each of these situations and selects the action with the highest expected reward. This action is then executed, resulting in a new situation. There is a fixed probability of generating a random action, regardless of the outcome of the situation matcher. New situation-action pairs are added to the memory, along with their $Q$ values computed in the classical way. Among similar situation-action pairs in the memory, an update of the stored $Q$ values is made. There is a limit to the generalizability of this lazy memory because the $Q$ values associated with the situation-action pairs only apply for a particular application.

Learning is not restricted to single robots. Learning in *cooperative robotics* is intriguing: this would be a way to program a set of robots without having to explicitly model their interactions with the world—including the other team members—to achieve cooperation. To achieve this goal, mechanisms that relay the *unique* information associated with the team behavior (reinforcement value) to the individual robots have to be found (see Parker, Touzet, and Fernandez, 2001). Results from the multi-agent research community cannot be applied since they are usually symbolic methods, where robot Q-learning requires a sub-symbolic approach.

Despite all the efforts and success around Q-learning, several drawbacks are associated with supervised and reinforcement learning when it comes to real applications. First, the time needed to achieve the synthesis of any behavior is *prohibitive,* and determining good initial approximations that reduce wasted exploration is not recommended, since it may forbid the finding of unsuspected solutions. Second, the robot behavior during the learning phase is—by definition—bad, and it may even be *dangerous.* To put constraints that preclude dangerous moves implies that there exists a complete model of the robot-world interactions (which by definition does not exist). Third, except within the lazy learning approach, a new behavior implies a *new* learning phase. What is needed is a learning that instantaneously synthesizes any behavior, and which leads to improvement in performance resulting from the mere repetition of this behavior (for a first step in this direction see Touzet, 1999).

# Radial Basis Function Networks

*David Lowe*

## Introduction

The radial basis function (RBF) network is conceptually a very simple yet intrinsically powerful network structure. Recent reviews of the RBF approach from a mathematical perspective of function interpolation can be found in Buhmann (2000), from a perspective of regularization and connections to support vectors machines in Evgeniou, Pontil, and Poggio (2000; see also SUPPORT VECTOR MACHINES), and in relation to ideas in statistical analysis in Lowe (1999).

We can motivate the basic idea of the RBF network and reveal its difference from the multilayer perceptron by considering Figure 1. This figure conceptually illustrates a simple classification example in which the distribution of data points exhibits a simple clustering. There are primarily two ways to separate these clusters. One is by segregating the space into polygonal cells. The straight lines in the figure illustrate this decomposition of the pattern space into regions, as would be obtained by a simple multilayer perceptron, where the lines represent the class boundaries. An alternative is to describe the clusters of data themselves as if they were generated according to an underlying probability density function, modeled here in the figure by elliptical distributions. Thus, one method concentrates on class boundaries and the other focuses on regions where the data density is highest. These are complementary approaches, with respective disadvantages and advantages. The latter alternative is the RBF approach.

The RBF constructs global approximations to functions using combinations of basis functions centered on weight vectors (Figure 2), whereas a multilayer perceptron constructs an architecture out of separating hyperplanes. These weight vectors could be actual data points in the training set, as they are in the basic interpolation model of RBF networks, or they could be chosen according to a utility function, such as a clustering criterion, in density modeling, or a separation criterion, as in support vector machines and regularization. An extra distinction is that the RBF employs a distance function to convert the vector input pattern into a scalar at the hidden layer, as opposed to a vector dot product such as is used in the multilayer perceptron. The network's strength derives from a rich interpretational foundation because it lies at the confluence of a variety of established scientific disciplines. Thus, although the original motivation of this particular network structure was in terms of function approximation techniques (Broomhead and Lowe, 1988; Powell, 1992), the network may be derived on the basis of statistical pattern processing theory (Lowe, 1999), regression and

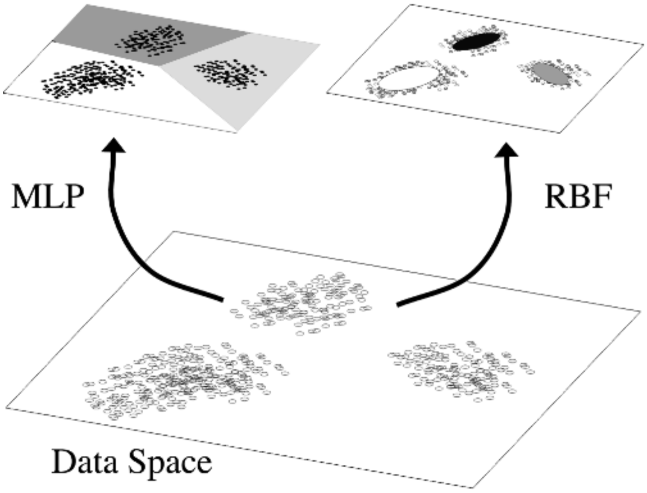

**Figure 1.** Dissection of pattern space by clusters and hyperplanes. The multilayer perceptron (MLP) exploits the logistic nonlinearity to create combinations of hyperplanes to dissect pattern space into separable regions. Subsequent layers combine these regions to allow the formation of nonconvex class boundaries. The radial basis function (RBF) dissects pattern space by modeling *clusters* of data directly and so is more concerned with data distributions.

regularization (Evgeniou et al., 2000), biological pattern formation (Logothetis, Pauls, and Poggio, 1995), mapping in the presence of noisy data and, more recently, in terms of kriging approximations (Wan and Bone, 1997) and kernel methods, particularly support vector machines (see SUPPORT VECTOR MACHINES). However, in addition to exhibiting a range of useful theoretical properties, the RBF network structure is above all a practical construct, as it may be applied efficiently to problem domains in discrimination (such as speaker verification), time series prediction (such as economic modeling), and feature extraction or even topographic mapping problem domains (such as encoding the sensory space of an artificial nose in chemical vapor analysis). Some studies have even suggested that RBF topology developed in nature as an evolutionary functional counterpart to object views for vision, where the basis functions correspond to cell aggregates tuned to particular views of familiar objects (Logothetis et al., 1995). This idea supports Edelman's "chorus of prototypes" and is reflected in the approach adopted in Moody and Darken (1989) using locally tuned processing units, although understanding of the biology in this area is presently insufficient to support generalizations.

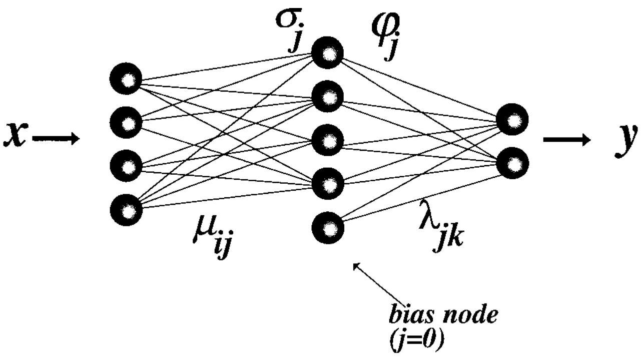

**Figure 2.** The basic radial basis function structure. A nonlinear basis function $\phi_j(\ldots)$ is centered on each hidden node weight vector $\boldsymbol{\mu}$, which also has a (possibly) adaptable "range of influence" $\sigma_j$. The output of the hidden node $j$, $h_j$ is given as a *radial* function of the distance between each pattern vector and each hidden node weight vector, $h_j = \phi_j(\|\mathbf{x} - \boldsymbol{\mu}_j\|/\sigma_j)$. This is the main difference from a multilayer perceptron. The network outputs are evaluated by a traditional scalar product between the vector of hidden node outputs and the weight vector attached to output node $k$, as $o_k = \mathbf{h}.\lambda_k$.

## The Basic RBF Structure

The RBF is a single-hidden-layer feedforward network with linear output transfer functions and nonlinear transfer functions, $\phi_j(\ldots)$, on the hidden layer nodes. Many types of nonlinearities may be used. There is also typically a bias on each output node. The primary adjustable parameters (see Figure 2) are the final layer weights, $\{\lambda_{jk}\}$, connecting the $j$th hidden node to the $k$th output node. There are also weights $\{\mu_{ij}\}$ connecting the $i$th input node with the $j$th hidden node, and occasionally a "smoothing" factor matrix, $\{\Sigma_j\}$. It often helps to think of the weights $\{\mu_{ij}\}$ as representing "prototypes" of patterns in the input space, either as cluster centers or as pattern exemplars that are in some sense representative of the distribution of input patterns. Similarly, the weights $\{\Sigma_j\}$ that govern the regularization of the network (after the model order complexity of the number of basis functions) are sometimes considered to represent the range of influence of these prototypes (though this intuition can break down for some of the nonlocal basis functions that can be employed).

The mathematical embodiment of the RBF takes the following form. The $k$th component of the output vector $\boldsymbol{y}_p$ corresponding to the $p$th input pattern $\boldsymbol{x}_p$ is expressed as

$$[\boldsymbol{y}(\boldsymbol{x}_p)]_k = \sum_{j=0}^{h} \lambda_{jk}\phi_j\left(\|\boldsymbol{x}_p - \boldsymbol{\mu}_j\|; \sum_j\right) \tag{1}$$

where $\phi_j(\ldots)$ denotes the nonlinear transfer function of hidden node $j$, ($\phi_0(\ldots) \equiv 1$ is the bias node), and the possible dependence on a smoothing matrix is left explicit. The most common example of the smoothing factor is in the use of a general Gaussian transfer function, i.e., $\phi(z) \approx \exp -[\mathbf{z}^T\Sigma^{-1}\mathbf{z}]$. Since the general expression is an analytic function of the variables corresponding to the basis function positions and smoothing factors, it is possible to adapt them by a full nonlinear least squares process if required (Moody and Darken, 1989). This is usually not necessary. As can be seen from Equation 1, the main difference from a multilayer perceptron is that the output of the hidden node $j$, $h_j$ is given as a *radial* function of the distance between each pattern vector and each hidden node weight vector (or prototype), $h_j^{RBF} = \phi_j(\|\boldsymbol{x} - \boldsymbol{\mu}_j\|)$, rather than as a scalar product, $h_j^{MLP} = \phi_j(\boldsymbol{x} \cdot \boldsymbol{\mu}_j)$.

One of the advantages of the RBF is that the first-layer weights $\{\boldsymbol{\mu}_j, \Sigma_j; j = 1, \ldots h\}$ may often be determined or specified by a judicious use of prior knowledge, or adapted by simple techniques. Early work (Broomhead and Lowe, 1988) found it sufficient to position the basis functions at data points sampled randomly according to the distribution of the data. This ensured that network resources were concentrated in regions of higher data density. Another early technique (Moody and Darken, 1989) was to position the centers of the basis functions according to a $K$-means clustering process on the data points, and then set the smoothing parameters of the assumed Gaussian basis functions to be the average distance between cluster centers. Over the past decade, many variations on these themes have been introduced that employ some form of prior knowledge expressed as a utility function, which the choice of prototypes should try to optimize. Therefore, once the weights associated with the first layer have been specified, the major problem in training an RBF network is focused on determining the final layer weights. Since the RBF network is typically employed to perform a *supervised* discrimination or prediction task, such as time series forecasting, this training usually takes the form of optimizing a cost function requiring the outputs of the network to somehow closely approximate a set of known target values. It is common to attempt to minimize a standard residual sum-of-squares cost function, although other cost functions may be employed. Because this is a linear optimization process (the parameters $\{\lambda_{jk}\}$ occur linearly when minimizing the residual sum-squared-error measure), the RBF is computationally more attractive in applications than a multilayer perceptron, even though they are both computationally universal architectures (Park and Sandberg, 1991).

## RBFs for Classification

One of the more common uses for an RBF network is as a semiparametric classification model capable of modeling nonlinear boundaries between clusters. This problem can be analyzed statistically and may be motivated from the perspective of kernel-based density estimation (Tråvén, 1991). Here we outline how the RBF architecture emerges from this statistical perspective, although historically it first emerged from interpolation theory.

In classification, we are primarily interested in the posterior, $p(c|\boldsymbol{x})$, the probability that class $c$ is present given the observation $\boldsymbol{x}$. However, it is easier to model other related aspects of the data, such as the unconditional distribution of the data, $p(\boldsymbol{x})$, and the likelihood of the data, $p(\boldsymbol{x}|c)$, which is the probability that the data were generated given that the data came from a specific class $c$. We can then recreate the posterior from these quantities according to Bayes's theorem, $p(c_i|\boldsymbol{x}) = p(c_i)p(\boldsymbol{x}|c_i)/p(\boldsymbol{x})$. The distribution of the data is modeled as if it were generated by a mixture distribution, i.e., a linear combination of parameterized states or of basis functions such as Gaussians. Since individual data clusters for each class are not likely to be approximated by a single Gaussian distribution, we need several basis functions per cluster. We assume that the likelihood and the unconditional distribution can both be modeled by the same set of distributions, $q(\boldsymbol{x}|s)$, but with different mixing coefficients, i.e., $p(\boldsymbol{x}) = \Sigma_s \hat{p}(s)q(\boldsymbol{x}|s)$ and $p(\boldsymbol{x}|c_i) = \Sigma_s\, p(s; i)q(\boldsymbol{x}|s)$. Then the quantity we are interested in $p(c_i|\boldsymbol{x}) = p(c_i)p(\boldsymbol{x}|c_i)/p(\boldsymbol{x})$ is given by

$$p(c_i|\boldsymbol{x}) = \sum_s \frac{p(c_i)p(s;\, i)}{\hat{p}(s)} \frac{\hat{p}(s)q(\boldsymbol{x}|s)}{\sum_{s'} \hat{p}(s')q(\boldsymbol{x}|s')} \equiv \sum_j \lambda_{ij}\phi(\boldsymbol{x}|j)$$

where $\lambda_{ij} = p(c_i)p(\,j;\, i)/\hat{p}(\,j)$ relates the overall significance of state $j$ to class $i$, and $\phi(\boldsymbol{x}|j)$ is a normalized basis function, $\hat{p}(\,j)q(\boldsymbol{x}|j)/\Sigma_j\hat{p}(\,j)q(\boldsymbol{x}|j)$.

This gives an RBF architecture. For a total of $h$ functions used to approximate the likelihood and the unconditional density, there are $h$ hidden nodes corresponding to the normalized basis functions, and the final layer weights relate the significance of the hidden nodes to the $c$ output class nodes, providing the class-conditional information. Of course, the positions and possibly also the ranges of influence of each of these basis functions need to be specified or adapted to allow an adequate model of each data cluster. This can be achieved by unsupervised clustering techniques.

In this manner, the RBF is an ideal network for use in classification problems. Note that the architecture of RBF networks for density estimation is more general than was indicated in the discussion of motivation. In particular, it is not essential that each basis function itself should be a probability density function.

## RBFs for Prediction

In the previous section, the RBF was motivated by a statistical interpretation of data distributions. In that case, the underlying generator of the data (the probability density function) was sampled stochastically. However, the original formulation of the RBF network was developed in order to produce a deterministic mapping of data by exploiting links with traditional function approximation. This approach attempted to introduce the notion that the training of neural networks could be described as curve fitting. Hence, "generalization" consequently has a natural interpretation as interpolating along this fitting surface.

The basic idea was as follows. Assume that we have a set of input/output pairs of input/target patterns representing data from an unknown but smooth surface in $\mathbb{R}^n \times \mathbb{R}^c$. As a simple example, consider a set of $(x, y)$ pairs generated according to $y = x^2$. In this approach, the problem is to choose a function $\boldsymbol{y} : \mathbb{R}^n \to \mathbb{R}^c$, which satisfies the interpolation conditions $\boldsymbol{y}(\boldsymbol{x}_p) = \boldsymbol{t}_p$, $p = 1, 2, \ldots, P$. This is *strict* interpolation, in which the function is constrained to pass through all the known data points. The strategy in interpolation theory was to construct a linear function space spanned by a set of nonorthogonal basis functions that depended on the positions of the known data points. The radial basis function expansion mapping to one dimension was originally expressed as $y(\boldsymbol{x}) = \Sigma_{j=1}^{P}\lambda_j\phi(\|\boldsymbol{x} - \boldsymbol{x}_j\|)$. By using the interpolation conditions, the fitting parameters $\lambda$ may be determined by matrix inverse methods. The approach was generalized to higher-dimensional mappings, to incorporate bias terms, and to account for the fact that strict interpolation is not a good strategy for real-world noisy data, leading to the feedforward neural network topology already discussed.

In the case of the simple $y = x^2$ example mentioned above, the inputs are $x$ values, the targets are specific $y$ values, and the RBF network is constructed so as to produce a fitting surface to the parabola $y = x^2$, which is a surface in $\mathbb{R}^1 \times \mathbb{R}^1 = \mathbb{R}^2$. Note that this is curve fitting to the *parabola* in the product space, not the data samples themselves. This parabola may be interpreted as the *generator* of the observed data, as locations on the parabola "produce" or "generate" the $(x, y)$ input/output pairs. As long as the generator of the data is smooth and nonlinear, we should be able to arbitrarily closely approximate it with an RBF network. This explains why networks can be successful in predicting deterministically chaotic time series: although the time series themselves may exhibit apparent randomness, the underlying map that produces the samples is itself usually very smooth.

## Miscellaneous Topics

Many topics related to RBF networks cannot be addressed in detail here. Among them are the issues of how many centers to use, what types of nonlinearities may be employed, Bayesian approaches to choosing the smoothing parameters, how to optimize the various weights, how to assist generalization through regularization, and how to determine confidence intervals. A few of these topics are briefly discussed below.

### *Choice of Kernel Function*

The theory of statistical density estimation produces many recommended bounded kernels that may or may not be density functions themselves. Examples of $\phi(z)$ are the Epanechnikov ($3/4[1 - z^2/5]/\sqrt{5}$ for $|z| < \sqrt{5}$, and 0 otherwise), the triangular ($1 - |z|$ for $|z| < 1$ and 0 otherwise), and of course the Gaussian. From interpolation theory the following choices are common: cubic ($z^3$), thin-plate spline ($z^2 \log z$), inverse multiquadric ($[z^2 + c^2]^{-1/2}$), multiquadric ($[z^2 + c^2]^{1/2}$), and again the Gaussian. Note that these functions do not have finite support, and indeed, some of the choices are *unbounded* functions, contrary to intuition and common belief that network basis functions are localized. However, despite this unbounded nature, it is correct that the parameters of the network may be chosen such that $y(x) \to 0$ as $x \to \infty$ so that the network as a whole achieves a localized response, even if the individual basis functions do not.

### *Regularization*

Various schemes have emerged to discourage overfitting of the training data points. Such options include (1) choosing a small set of initial centers and adapting the positions and spreads to best describe the data in some sense; (2) regularization—having a center located at each data point, but adding a smoothing term that is an effective constraint on the possible weight values, the magnitude of this extra term governing the amount of smoothing applied to the fitting surface (see Generalization and Regularization in Nonlinear Learning Systems); (3) selecting centers over a subset of the data points in the training set incrementally to maximize the descriptive power of the data variance obtained by adding each new basis function; and (4) Bayesian approaches of using the evidence to estimate the hyperparameters and weights. Because of its importance, we outline the regularization approach. Extensive and useful reviews of this approach, along with further references, can be found in Haykin (1999) and Evgeniou et al. (2000).

In regularization we wish to interpolate a finite data set using an approximation $\boldsymbol{y}(\boldsymbol{x})$. Of all possible approximators, we wish to choose the one that minimizes the augmented functional

$$H[y] = \sum_{p=1}^{P} (t_p - y(\boldsymbol{x}_p))^2 + \eta \|\hat{O}y\|^2$$

where $\hat{O}$ is an operator such as $\partial/\partial\boldsymbol{x}$, which is a mathematical embodiment of our prior knowledge on desired smoothness constraints. For example, this particular choice of operator gives an extra component to the overall cost function that represents curvature of the resulting map (it is an approximation to the expected Hessian or matrix of second derivatives of the map). So, high curvature solutions will incur a higher penalty than lower curvature solutions. Overall, then, there will be an interplay between the desire to produce a very-low-curvature RBF mapping and the desire to produce a surface that exactly passes through each data point. This latter objective usually requires very high curvature surfaces, since there will be random noise on the data points. $\eta$ is the regularization parameter that embodies the degree to which the constraint should dominate the data. Interestingly (Lowe, 1999), the functional that formally minimizes $H[y]$ takes the form of an RBF, i.e., $y(\boldsymbol{x}) = \sum_{p=1}^{P} \lambda_p G^{\dagger}(\boldsymbol{x}, \boldsymbol{x}_p)$. Here, $G^{\dagger}(\boldsymbol{x}, \boldsymbol{x}_p)$ denotes a Green function that is a solution of an equation determined by the regularization operator. If the operator $\hat{O}^{\dagger}\hat{O}$ is rotationally and translationally invariant, then the Green function is only a function of the radial differences of its arguments, i.e., $G(\|\boldsymbol{x} - \boldsymbol{x}_p\|)$. Thus, once again the form of the RBF may be derived, but this time from the perspective of preventing overfitting by regularization. In this case the form of the basis function is determined by the type of smoothness constraint we have imposed. As in the previous interpolation case, the weighting coefficients, $\lambda_p$, may be determined by the solution of a linear equation. Again, strictly speaking, this approach requires a center or basis function located at each data point, and overfitting is avoided by imposing the smoothing constraint. However, in practice the number of centers may also be chosen to vary, in which case these precise mathematical relationships no longer hold.

## Discussion

This article has discussed the motivation and application of the radial basis function network from a variety of perspectives. We have chosen to concentrate on contrasting a statistical pattern processing perspective with a function approximation perspective. However, both perspectives have the common philosophical basis that the aim of the network is to approximate the underlying structure that generated the observed data, rather than the data itself. This is also how a multilayer perceptron operates. However, the RBF was introduced to make this link with curve fitting and interpolation explicit.

The RBF may be employed in classification tasks, time series prediction, and both unordered and topographic feature extraction. Because of its computational tractability, the RBF has been applied to many diverse real-world problems, and there is some evidence that its structure may have similarities to biological aspects of vision processing. But above all, its strength and utility derive from its simplicity and from a close relationship with other areas of signal and pattern processing and other neural network architectures. These connections and interpretations are still being uncovered, as recent work on support vector machines (see Support Vector Machines), Gaussian processes, and kriging has demonstrated.

# Rate Coding and Signal Processing

*Fabrizio Gabbiani*

## Introduction

In the peripheral and central nervous system, many neurons encode information and pass it on to other neurons by generating irregular sequences of short voltage pulses, typically less than 1 ms in duration, called action potentials. The shape of these action potentials, or spikes, is usually quite stereotyped over the course of time. The sequence of spike occurrence times generated by the cell, often called the *spike train*, is therefore thought to carry most of the information that a neuron communicates to its targets. When studying how sensory information might be encoded in neuronal spike trains, one is faced with the fact that spike trains are often quite variable under seemingly identical stimulation conditions (Figure 1). Is this variability simply noise, perhaps due to uncontrolled changes in the state of some internal variable, or does it carry information about the stimulus? Answering this question in a particular case would require a thorough knowledge of the biophysical mechanisms of spike generation and of stimulus coding—knowledge that is out of reach at present.

Although no universal definition exists, the term *rate coding* is applied in situations where the precise timing of spikes is not thought to play a significant role in carrying sensory information. Rate codes have been identified in many sensory systems and are probably the best understood means by which neurons encode information. In many cases, rate codes have been shown to play an important role in determining behavioral responses of animals.

Rate coding comes in two flavors: mean firing rate codes and instantaneous firing rate codes. The sensory information conveyed by these two types of codes can be studied rigorously by applying classical methods of statistical signal processing borrowed from the engineering literature. In the next two sections, we will show how these methods can be carried over to the analysis of neuronal spike trains. Before turning to more general examples in the third section, we will illustrate them in the case of electrical field amplitude–sensitive neurons of weakly electric fishes. These animals possess an unusual sense for the electrical properties of their environment that is favorable to computational investigations (see ELECTROLOCATION).

Rate coding is not the only mean by which neurons convey information. In weakly electric fishes and in other auditory-like sensory systems, the role played by spike timing information is well documented (see ELECTROLOCATION and ECHOLOCATION: COCHLEOTOPIC AND COMPUTATIONAL MAPS). Two articles address the issue of spike timing in cortical circuits (SYNFIRE CHAINS; SYNCHRONIZATION, BINDING AND EXPECTANCY). Finally, the role of rate coding in the context of neuronal populations is examined in POPULATION CODES (q.v.) and MOTOR CORTEX (q.v.), CODING AND DECODING OF DIRECTIONAL OPERATIONS (q.v.).

## Mean Firing Rate Coding

An increase in firing rate is typically the most conspicuous change recorded from sensory neurons in response to external stimuli. It is therefore natural to ask how well the spike count observed in a single trial from such a cell can predict the presence of the stimulus. Let us take the example of a neuron having a mean spontaneous rate $\bar{\lambda}_0 = 30$ spk/s that fires at a rate of $\bar{\lambda}_s = 50$ spk/s under stimulus presentation (Figure 1*B*). We will first assume for simplicity that spikes are generated completely independently of each other (i.e., following a Poisson process) and thus do not carry any additional information beyond their mean rate of occurrence.

Figure 2*A* illustrates the distribution of spike counts observed during a 200 ms window in the baseline and stimulus condition for this model neuron. The overlap between these two distributions indicates that guessing the presence of the stimulus from the spike count observed in a single trial will lead to a significant fraction of errors. A simple method to decide between the two alternatives "stimulus present" or "no stimulus" consists in choosing a threshold number of spikes, $k_{\text{thres}}$, and classifying the observed responses, $n$, as baseline activity or stimulus-induced activity according to whether the threshold is exceeded or not:

$$\begin{aligned} n < k_{\text{thres}} &\Rightarrow \text{baseline activity} \\ n > k_{\text{thres}} &\Rightarrow \text{stimulus present} \end{aligned} \qquad (1)$$

This decision strategy leads to two types of errors. On the one hand, we might call for the stimulus to be present in a trial during which spontaneous activity was unusually high. This type of error is called a false alarm. On the other hand, we might confuse an unusually low stimulus response with spontaneous activity, an error called a false miss. Clearly, the proportion of false alarms to false misses depends on the choice of the threshold $k_{\text{thres}}$: high (low) threshold values correspond to low (high) probabilities of false alarms with higher (lower) fractions of false misses. It is customary to characterize the performance of this detection algorithm by varying the threshold from low to high values and plotting the probability of correct detection, $p_D$ (i.e., 1 minus the probability of false

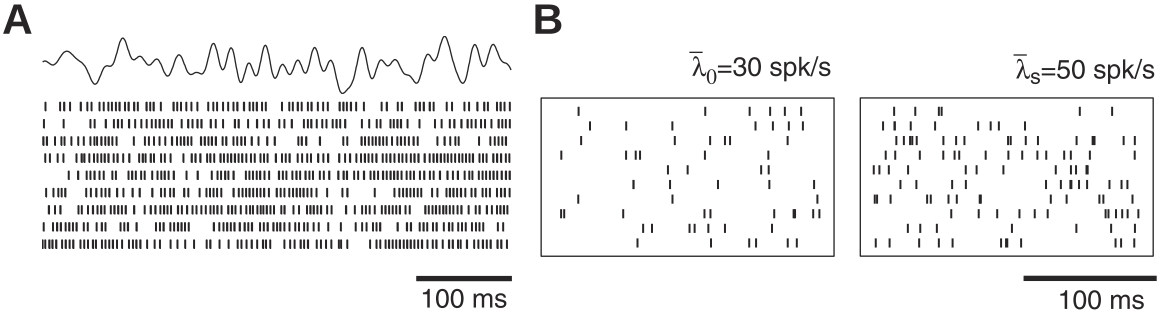

**Figure 1.** *A*, Nine spike trains recorded from an amplitude-sensitive afferent in the weakly electric fish *Eigenmannia* in response to repeated presentations of the same random electrical field amplitude modulation (shown on top). (Adapted from Kreiman et al., 2000.) *B*, Ten spike trains (200 ms long) obtained from a Poisson process with mean firing rate $\bar{\lambda}_0 = 30$ spk/s (spontaneous rate, left) and $\bar{\lambda}_s = 50$ spk/s (stimulus-induced rate, right).

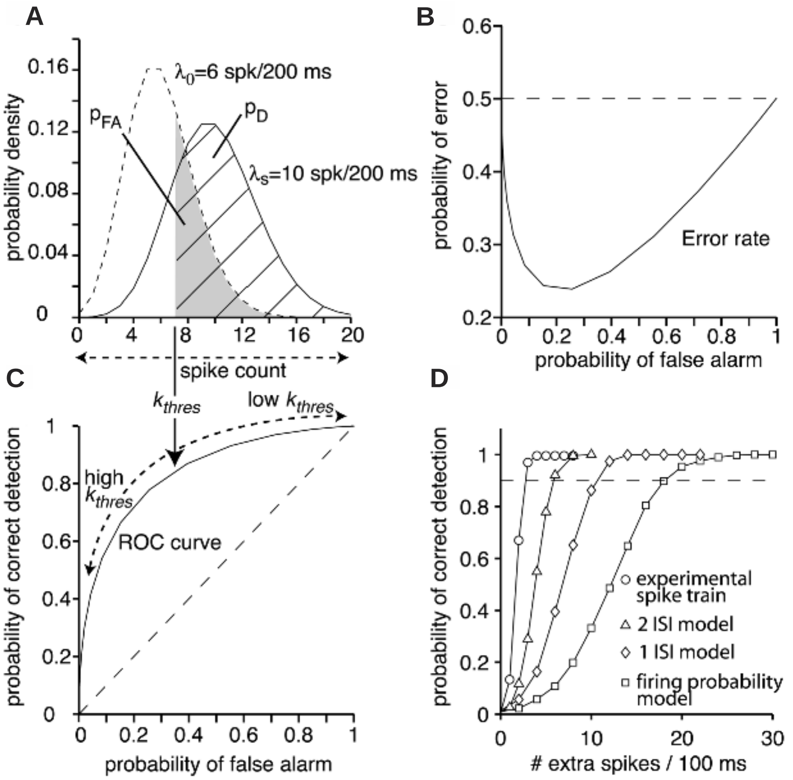

**Figure 2.** *A*, Probability distributions of the spike count observed in a 200 ms window for the two Poisson processes illustrated in Figure 1*B*. Choosing a threshold number of spikes ($k_{thres}$) to discriminate between the presence or absence of the stimulus leads to errors because of the overlap of the distributions. The probability of false alarm ($p_{FA}$) and of correct detection ($p_D$) are illustrated by the gray and hatched areas, respectively. *B*, Plot of $p_D$ versus $p_{FA}$, called an ROC curve. Different thresholds will correspond to different values of $p_D$ and $p_{FA}$ (dashed double arrows in *A* and *B*). *C*, Overall probability of error (see Equation 2), computed from the ROC curve in *B*. *D*, Probability of correct detection obtained from the spike trains of an amplitude-sensitive afferent neuron as a function of the number of spikes above spontaneous activity generated by the cell (circles). Note that the cell can discriminate with more than 90% accuracy increases of three spikes or more, corresponding to a 1% increase in firing rate. Different models that take into account only the mean firing rate (squares), the mean firing rate and the interspike interval distribution (diamonds), or in addition the joint properties of successive intervals (triangles) are unable to match the experimental performance. (Adapted from Ratnam and Nelson, 2000.)

misses), as a function of the probability of false alarms, $p_{FA}$ (i.e., 1 minus the probability of correct rejections; Figure 2*B*).

This curve is called the receiver operating characteristic (ROC) curve of the detection algorithm (a term originating from early applications to radar observations). The dashed diagonal line $p_D = p_{FA}$ corresponds to chance performance (i.e., independent of the threshold, $k_{\text{thres}}$, the probability, $p_D$, of correctly detecting the stimulus is as good as the probability, $p_{FA}$, of incorrectly mistaking spontaneous activity with stimulus-induced activity). Thus, the higher the ROC curve lies above the diagonal, the better the performance of our detection algorithm and, in the limit of perfect performance, $p_D = 1$ over the entire interval $0 \leq p_{FA} \leq 1$.

From the ROC curve, one can obtain the values of $p_{FA}$ and $p_D(p_{FA})$ that minimize the overall probability of stimulus detection error (comprising both false alarms and false misses). If the stimulus is presented on average in one-half of the trials, the error rate is given, for a fixed value of $p_{FA}$, by

$$\varepsilon(p_{FA}) = ½\, p_{FA} + ½\, (1 - p_D(p_{FA})) \qquad (2)$$

The minimum of $\varepsilon(p_{FA})$ as a function of $p_{FA}$ can be easily found by numerical methods (see Figure 2*C*). The corresponding threshold $k_{\text{thres}}$ may then be obtained from $p_{FA}(k_{\text{thres}})$. Thus, in our example the minimal error rate $\varepsilon = 0.24$ is achieved for $p_{FA} = 0.26$, corresponding to a detection threshold $k_{\text{thres}}$ of 8.5 spk/s.

One important question remains: Given the simplicity of this algorithm, could it be outperformed by a more sophisticated one? Remarkably, this is not the case: under fairly general assumptions, the threshold condition of Equation 1 is equivalent to a similar condition on the likelihood ratio, $l(n) = p_s(n)/p_0(n)$, where $p_s(\cdot)$ and $p_0(\cdot)$ are the probability distributions of the spike count in the presence and absence of the stimulus, respectively (Figure 2*A*). The likelihood ratio is a quantity central to signal detection theory, and this equivalence shows that, for a fixed value of $p_{FA}$, no other algorithm taking into account only the probability distributions of Figure 2*A* can outperform the threshold test. Thus, the ROC curve defines the performance of an ideal observer of the mean rate code, having complete access to $p_0(\cdot)$ and $p_s(\cdot)$. Whether neurons or neuronal networks in the brain adopt similar algorithms to read out information about the external world remains an open question.

The performance of the ideal observer algorithm will be affected by at least two additional factors, the first being the length of the time window over which spikes are registered. Longer windows typically lead to better performance by averaging out the noise component of the spike rate that causes deviations from the mean. In the case of the Poisson process discussed above, for a fixed mean firing rate $\bar{\lambda}$, the mean number of spikes observed in a time window $T$ is given by $\bar{n} = \bar{\lambda}T$, whereas the standard deviation is $\sigma = \sqrt{\bar{\lambda}T}$. Thus, $\bar{n}/\sigma \propto \sqrt{T}$, and the signal grows as $\sqrt{T}$ with respect to noise over the course of time. Currently, the time interval that is relevant for behavioral responses often is only weakly constrained by experimental observations.

The second factor is the regularity of the spike train or, in other words, the amount of noise that is present to start with. While many neurons in cortical areas have highly variable responses resembling those obtained from Poisson processes, other neurons can be much more regular. In the weakly electric fish *Apteronotus*, for example, the spike trains of primary sensory afferent neurons sensitive to amplitude modulations of the electrical field have a variability that is almost an order of magnitude smaller than that expected from a Poisson spike train on behaviorally relevant time scales (Ratnam and Nelson, 2000). These neurons are thought to encode information necessary for the detection of small prey, such as the water fleas on which the fish feeds. Computer simulations, behavioral observations, and electrophysiological recordings suggest that the firing rate of these cells will increase by only a few spikes per second during the 200 ms needed to detect the prey. An ROC analysis reveals that increases of 2–3 spk/s above baseline activity can be detected with greater than 90% accuracy even if the probability of a false alarm is very low, 0.1% (Figure 2*D*). Such low false alarm rates ($p_{FA} \leq 0.001$) are constrained from behavioral observations showing that fishes almost never strike a nonexistent prey. As illustrated in Figure 2*D*, three spike trains of models designed to reproduce the short-term variability of the experimental spike trains cannot reproduce these results. The first model (squares) reproduces only the mean firing rate of the afferents, while the second and third models also reproduce the interspike interval distribution (diamonds) or the joint statistical distribution of two successive interspike intervals (triangles), respectively. The regularity and statistical structure of the spike trains over at least three firing cycles is therefore responsible for this unusually low detection threshold.

## Instantaneous Rate Coding

Stimuli that vary on a fast time scale—comparable to the 200 ms observation window introduced in the last section—cannot be encoded by the mean spike count alone. Such stimuli are ubiquitous in the sensory environment of many animals. Motion of an object or self-motion, for example, result in rapid changes in light intensity across the visual field. Sound stimuli used for communication or localization correspond to rapidly varying changes in air pressure. In the case of weakly electric fishes considered in the last section, time-varying electrical field amplitude modulations occur as the fish moves through an electrically dense environment in water.

Such time-varying stimuli could be encoded by time-varying changes in the instantaneous firing rate of a neuron, even if the precise timing of spikes does not play an essential role in the process (Gabbiani and Koch, 1999). Consider, for example, the Poisson spike train model of the previous section with a spontaneous rate $\bar{\lambda} = 30$ spk/s. We assume that changes in the instantaneous firing rate from its mean value, $\bar{\lambda}$, are caused by changes of the stimulus, $s(t)$, from its mean value, $\bar{s}$,

$$\lambda(t) = \alpha(s(t) - \bar{s}) + \bar{\lambda} \tag{3}$$

The constant $\alpha$ is a conversion factor between stimulus and firing rate, and $\lambda(t)$ is assumed to be positive. In the following discussion the stimulus will usually be assumed to have zero mean, i.e., $\bar{s} = 0$.

How much information does such a spike train convey about the stimulus? Using an approach analogous to that introduced in the last section, this question can be addressed by presenting a random stimulus $s(t)$ and estimating it from the spike train (Figure 3*A*). Because $s(t)$ varies randomly in time, the estimate $s_{\text{est}}(t)$ will also have to vary in time to track $s(t)$. Thus, this estimation problem is more complex than the detection problem considered in the last section. It is customary to minimize the root mean square error between the stimulus and its estimate,

$$\varepsilon = \langle (s(t) - s_{\text{est}}(t))^2 \rangle^{1/2} \tag{4}$$

where the average is taken over the stimulus presentation interval (Figure 3*A*). It is much more difficult to find an optimal estimate $s_{\text{est}}(t)$ from the spike train than it is to find an optimal classification strategy based on the spike count. A simplification is therefore

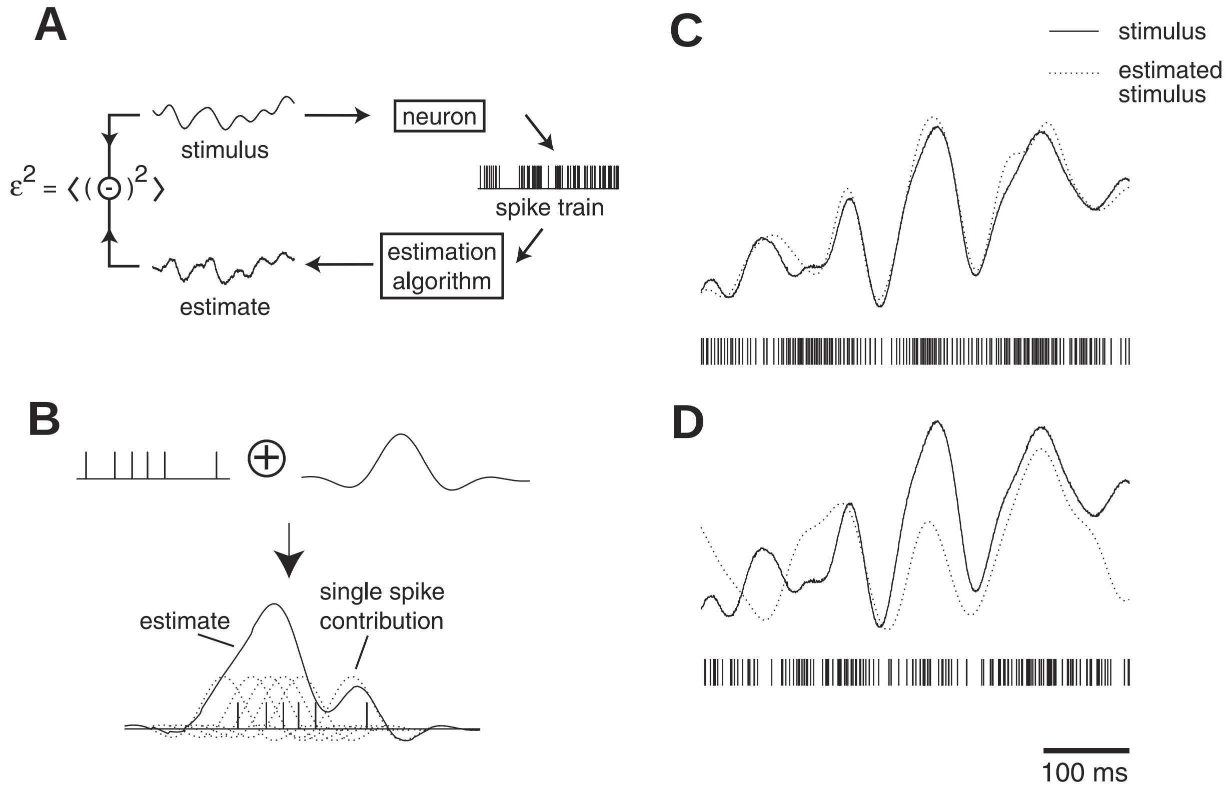

**Figure 3.** *A*, Stimulus estimation is performed using a linear algorithm (see *B*) that is based on a comparison of the stimulus and its estimate aimed at minimizing the mean square error between the two (Equation 4). *B*, The linear algorithm consists in taking a spike train (left) and placing a waveform (right) around each spike. Linear superposition of these waveforms (bottom) yields the estimate. The waveform is chosen to minimize the mean square error between stimulus and estimate (see *A*). *C*, Estimation of a random amplitude modulation from the spike train of an amplitude sensitive afferent neuron in *Eigenmannia* (mean firing rate 314 spk/s). *D*, Same stimulus estimated from a Poisson spike train encoding the stimulus according to Equation 3 at the same mean firing rate as in *C*.

made by looking only at estimates obtained from linear superpositions of a waveform, $h(t)$, around each spike. If $r(t) = \Sigma_i \delta(t - t_i)$ is a sum of delta functions representing the sequence of spikes at times $\{t_i\}$, the estimated stimulus is assumed to be of the form

$$\begin{aligned} s_{\text{est}}(h, t) &= \int h(t - t_0) r(t_0) dt_0 - \bar{r} \int h(t_0) dt_0 \\ &= \sum_i h(t - t_i) - \bar{r} \int h(t_0) dt_0 \end{aligned} \tag{5}$$

where $\bar{r}$ is the mean firing rate of the cell and the second term ensures that $s_{\text{est}}(t)$ has zero mean value, as was assumed for $s(t)$ (Figure 3*B*). Under this assumption, the optimal waveform, $h(t)$, minimizing the root mean square error in Equation 4 can be obtained by standard statistical and Fourier transform techniques. The minimum value obtained for the root mean square error, $\varepsilon$, is usually normalized by the stimulus standard deviation, $\sigma$, which corresponds to chance guessing (i.e., to the error obtained in Equation 4 when $s_{\text{est}}(t) = \bar{s} = 0$). Figure 3*C* illustrates the result of this estimation procedure using the spike train of an amplitude-sensitive afferent obtained in response to a random electrical field amplitude modulation in a second species of weakly electric fishes, *Eigenmannia*. From the spike train, the amplitude modulation could be estimated with an error $\varepsilon/\sigma = 0.17$. Equivalently, our ideal linear observer could reproduce 83% of the stimulus standard deviation using a single spike train.

In contrast, estimation of the same stimulus using a spike train generated using a Poisson process and Equation 3 is considerably less accurate (only 25% of the stimulus standard deviation is recovered; Figure 3*D*), because a Poisson process is more variable than the spiking of *Eigenmannia* afferents (Kreiman et al., 2000). Thus, as in the signal detection case, spike train variability plays an important role in stimulus estimation. Other factors that play a significant role in the encoding capacity of the instantaneous firing rate are the contrast of the stimulus (or its standard deviation $\sigma$; typically, higher contrasts result in larger firing rate modulations and thus better encoding), the mean firing rate of the cell (higher mean firing rates lead to a finer temporal sampling of the stimulus), and the cutoff frequency of the stimulus (accurate encoding is possible only when temporal stimulus frequencies are well below the mean firing rate of the cell).

The assumption relating spike train and stimulus estimate by a linear transform embodied in Equation 5 works very well in practice when the encoding of the stimulus by the spike train can be described by equations analogous to Equation 3. This result can be justified theoretically (Gabbiani and Koch, 1999). In contrast, no systematic studies have been carried out on the effect of nonlinear relations between stimulus and firing rate; only a few scattered examples have been examined (Gabbiani and Koch, 1999; Haag and Borst, 1998).

## Rate Coding in Neural Systems

Instantaneous and mean firing rate codes have been extensively characterized in a variety of different neuronal systems. In the following discussion, we will highlight a few directions of investigation and some open questions relevant to the subject.

Starting in the late 1940s, signal detection methods have been applied to characterize the information conveyed by neuronal spike trains, along the lines prescribed earlier in this article (see Parker and Newsome, 1998). The investigation of neuronal signals carried by optic nerve fibers of the horseshoe crab *Limulus* was one of the earliest examples of work on this topic (see Parker and Newsome, 1998). Over the next 30 years, signal detection methods were extended to the activity of sensory neurons in the early auditory, somatosensory, and visual pathways of vertebrates. The variability of retinal ganglion cell spike trains, for example, has been extensively investigated in an attempt to explain its impact on the encoding reliability of visual signals (Parker and Newsome, 1998).

More recently, signal detection methods have been applied to neurons in cerebral cortical areas (visual and somatosensory, for instance) of monkeys trained to perform discrimination tasks. In some cases, the reliability of neuronal firing could be compared to the behavioral accuracy of the animal performing the task. These results, together with analyses of variability and correlation across cells, have led to neural models of signal encoding that can account for the animal's behavior (see Parker and Newsome, 1998). The neural mechanisms underlying behavioral selection in those discrimination tasks, however, remain difficult to test experimentally.

In the cockroach, directional escape responses to wind stimuli are thought to rely on the mean firing rate of 14 giant interneurons (GIs). Several models that could in principle explain escape behaviors on the basis of the mean firing rate of GIs have been tested by directly manipulating them through current injections (Levi and Camhi, 2000). The results of these experiments suggest that a directional average of the GIs' mean firing rate is the most accurate description of the behavior. Mean firing rate codes across population of neurons have also been shown to play similar roles in vertebrate neurons, in the generation of visual saccades in the superior colliculus of monkeys, and in the generation of limb movements in motor cortical areas (Sparks, Kristan, and Shaw, 1997).

Given that in the engineering literature signal estimation is usually considered a close relative of signal detection (Poor, 1994), it is perhaps surprising that it has been applied to neural spike trains only within the past 10 years. Estimation of time-varying stimuli along the lines developed earlier in this article has shown that single spike trains of sensory neurons can accurately convey information about time-varying stimuli, although the results are usually less spectacular than those shown in Figure 3*B* (Borst and Theunissen, 1999). At present, these methods have been applied mainly to invertebrate and lower vertebrate preparations. Mechanisms of encoding across multiple neurons and their relation to behavior have received little attention so far (but see Stanley, Li, and Dan, 1999).

In contrast, instantaneous firing rate codes have been extensively studied by characterizing how stimulus attributes are encoded in the instantaneous firing rate of neurons through generalizations of Equation 3. Such models are particularly well developed for the early visual pathways of mammals, from the retina to early visual cortical areas (Dayan and Abbott, 2001).

## Discussion

Mean and instantaneous firing rate codes are undoubtedly the best documented and best understood way by which neurons transmit information. Several other codes have also been studied, among them the mechanisms of coincidence detection in auditory processing (Pena and Konishi, 2001). More elaborate coding schemes are likely to be found, particularly across populations of neurons, although the highly sophisticated codes at the heart of information theory seem unlikely to find a place in describing the signaling repertoire of sensory and motor neurons.

One question that has long intriguied neuroscientists is whether the spike train variability usually observed in neurons using rate coding also carries further sensory information (Bullock, 1970). This question is difficult to answer rigorously. In the case of the cockroach, the pattern of spikes in GIs does not appear to play a role in determining escape behaviors (Liebenthal, Uhlmann, and Camhi, 1994). On the other hand, it has been suggested that in electric fishes, coincidence detection could be used to integrate the information conveyed by the amplitude-sensitive receptors described in this article and in Berman and Maler (1999). Thus, neurons might use a combination of different codes simultaneously at different levels of a neuronal circuit.

# Reaching Movements: Implications for Computational Models

*Paul Cisek and John F. Kalaska*

## Introduction

Computational models are playing an increasingly important role in the study of biological motor control. In the first edition of this *Handbook*, the article on reaching movements (Kalaska, 1995) reviewed a range of computational models of visually guided movements and discussed their implications for cerebral cortical mechanisms of motor control. Here, we take the opposite approach. We discuss a number of issues that are emerging from neurophysiological studies of motor control and their implications for model development. We present these issues and implications as a set of challenges for computational models that hope to meet the demands of both functional competence and biological plausibility.

## Planning Movement

Much of the theoretical background for computational models of the motor control system comes from engineering. Engineering practice usually solves a problem by breaking it down into a set of subproblems, each solved by a dedicated and distinct module. For example, a central distinction that motor control models inherit from engineering is that between planning and execution (Figure 1*A*). However, while this distinction may appear obvious from a robotics perspective because it is implied by the statement of the problem of control, it is not necessarily the most appropriate description for the organization of the biological motor system.

Neurophysiological evidence does not support a rigid separation between planning and execution at either the single-cell level or the population level (Kalaska, Sergio, and Cisek, 1998). Neurons that become active during movement preparation are distributed throughout the premotor and motor regions as well as in parietal regions, and those same cortical areas exhibit movement-related activity during execution. Motor imaging studies show that many of the same cortical areas are activated whether the subject is actually performing a movement or merely imagining it. Furthermore, even during execution of the movement itself, extensive representations of higher-order movement parameters and "early" sensorimotor transformations can be seen, especially in areas outside of primary motor cortex (Shen and Alexander, 1997a, b; Wise et al., 1997). Finally, correlates of both motor planning and execution processes can often be found in the activity of single cells, whose association with motor output changes in time from more abstract aspects of the task to more limb movement–related parameters (Crammond and Kalaska, 2000; Shen & Alexander, 1997a, b), as if single cells tended to shift functionally from the planning to the execution boxes of traditional models.

The functional distinctions most useful in understanding the organization of the biological motor control system may not be those that have proved most useful for traditional engineering methods. The general organization of the motor control system may in fact not resemble the serial input-to-output hierarchy of traditional models (Figure 1*A*) but instead may consist of parallel systems for *action specification* and *action selection* (Kalaska et al., 1998) (Figure 1*B*). Action specification includes all mechanisms involved in the computation of the parameters of motor actions. For a reaching movement, this begins with the processing of sensory information defining parameters such as distance to target and required grip size, and continues even during movement execution with on-line modification of the hand trajectory and joint torques. Because it continues even during movement itself, action specification incorporates processes that are often separated into the planning and execution stages of many computational models. Action selection includes all the mechanisms that choose between the various actions that are possible at a given moment. For a reaching movement, it encompasses such processes as attentional mechanisms that orient the eyes toward potential targets and select the ones most relevant at a given moment, cognitive mechanisms which decide the most appropriate response based on prior reinforcement, and

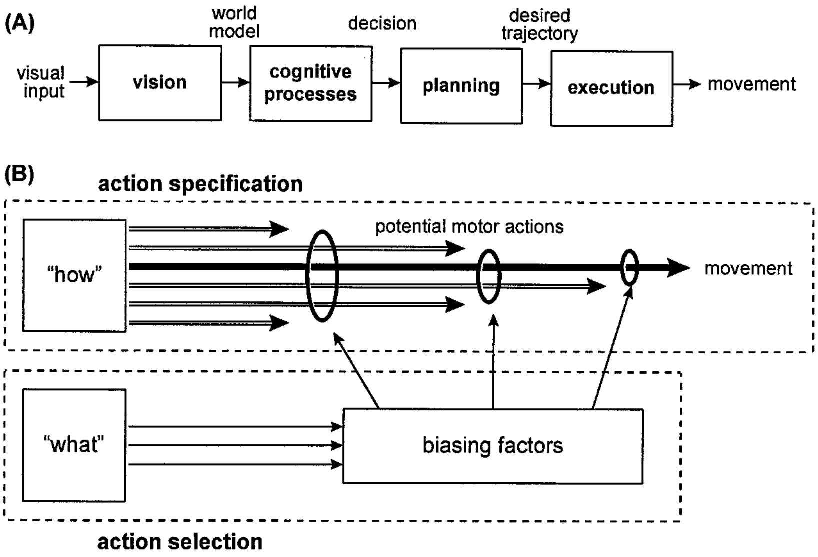

**Figure 1.** *A*, The traditional "sequential processing" model of visually guided behavior. In this model, visual input is used to construct a model of the world that is used to make decisions. After decisions are made, a desired trajectory is generated and executed. *B*, Schematic representation of the "specification and selection" architecture for visually guided behavior. Under this view, visual information has two different roles: specifying the parameters of potential motor actions, and defining criteria that bias competition among those potential actions until a single action is selected. These biasing factors include attention, behavioral relevance, prior reinforcement, required effort, behavioral context, learned associations, motivations, long-term behavioral objectives, desired outcomes, and any other factor that influences action selection. The processes of specification and selection occur in parallel and continue even during overt movement. A striking feature of this architecture is the absence of a central model of the visual world.

even mechanisms that abort or switch ongoing actions if the need arises.

The processes of selection and specification need not occur in a serial order but can instead both operate in parallel. Several potential motor actions may begin to be specified by the available sensory information through parallel sensorimotor transformations, allowing multiple responses to be "primed" for action (Cisek and Kalaska, 2002). At the same time, selection mechanisms using information on object identity and the organism's objectives influence attentional and decision-making mechanisms, which select out the action most appropriate at the time. While the selected action is performed, other alternatives may not be discarded but instead may be maintained and updated in case the need arises to switch the course of action. Such a parallel architecture allows the flexibility of behavior required by the changing demands of a natural environment. This perspective argues against computational models with a strict sequential hierarchical structure and supports models that emphasize dynamic interactions between different brain regions.

Because the tasks of action specification and action selection impose different demands on the processing of sensory information, they likely involve at least partially independent neuronal systems. Action specification requires information about the spatial relationships between body segments and objects in the environment with which the organism is interacting. In contrast, action selection emphasizes information about the nature and identity of external objects in order to evaluate the possible consequences of acting on these objects. These differing demands correspond well to the differing properties of the dorsal and ventral visual streams (Milner and Goodale, 1995), suggesting that these sensory systems evolved initially to serve the needs of the motor system, not to generate an internal representation of the world.

The general architecture of action specification and selection has much in common with Arbib's Schema Theory (q.v.). According to schema theory, visual information activates perceptual mechanisms ("perceptual schemas"), such as object localization and size recognition, that provide the information required to prepare specific action-oriented mechanisms ("motor schemas"), such as hand transport and hand preshaping, which are selected and released for execution according to learned contextual clues. Instead of a serial decomposition of action into planning and execution modules, schema theory suggests that behavior consists of the interplay between different parallel perception-action schemas that the organism applies when interacting with its environment.

## Trajectory Generation

Another consequence of assuming separate planning and execution systems is the assumption that there must exist a representation of the motor plan that links them together. Different theories subscribe to this assumption to different degrees. For example, some theories propose that the motor plan takes the form of a representation of the complete time sequence of states that the execution system will pass through, a "desired trajectory" that is prespecified before movement begins. This is particularly important for explicit optimization models, which must know about the final states of movement before adjusting parameters of the intermediate states (see Optimization Principles in Motor Control).

To date, however, there has been no compelling neurophysiological evidence for an explicit representation of desired trajectories prior to the execution phase of motor tasks. One simple way to assess trajectory preplanning is to compare activity between instructed-delay tasks in which complete information about the metrics of an upcoming movement is presented prior to the instruction to initiate movement ("Go signal"), and reaction-time tasks in which the metrics are specified at the same time as the Go signal. One expects that during instructed-delay tasks, preplanning can take place as soon as movement metrics are specified, and need not be recapitulated after the Go signal. Although some of the predicted "neural savings" can be seen, especially in premotor cortex, most of the movement-related activity in premotor and primary motor cortex is relatively unaltered by the prior information, suggesting that most of the spatiotemporal details of the trajectory are generated dynamically as the movement unfolds (Crammond and Kalaska, 2000).

This is supported by another study (Shen and Alexander, 1997a, b), which dissociated the direction of limb movement and the direction of visual feedback guiding action (cursor motion on a screen). It was found that most of the activity in premotor and primary motor cortex during the delay period reflected the direction of cursor motion, and that a representation of the direction of limb motion became prominent only after the Go signal. This implies that only a relatively abstract representation of motor output is preplanned, even during well-practiced behaviors, whereas limb-specific signals are expressed at the time of movement. This implication does not contradict the possibility that certain high-level aspects of complex movements such as via points or sequence elements can be preplanned (see SEQUENCE LEARNING).

One might also question the concept of preplanned trajectories from an evolutionary perspective. It is unlikely that very primitive creatures preplanned and optimized the details of their actions before executing them. Instead, they generated movement on-line, adjusting movement details based on information fed back in real time. This kind of solution can produce acceptable results for many kinds of movements without requiring complex internal models of the dynamics of the controlled object. With a closed-loop system, the dynamics of the controlled object directly participate in the modification of the time course of the control signals. It is likely that such a simple strategy set the ancestral foundation for motor control.

Indeed, recent evidence suggests that movements are fine-tuned and adjusted using on-line sensory information during the movement itself. When a target of a reaching movement unexpectedly jumps during the course of the reach, subjects adjust automatically, even when the jump is not consciously perceived (Desmurget et al., 1999). Such on-line correction processes appear to involve the parietal cortex (Milner and Goodale, 1995; Desmurget et al., 1999) and are presumed to operate at all times during natural movements. In fact, without on-line correction, most normal activity would be very inaccurate because the world around us is always changing. For example, one could never catch a baseball by preplanning one's position and glove placement only when the ball is first hit or thrown. Instead, constant adjustments are necessary as the ball approaches, with the subject using sensory information about the ball's motion as well as feedback about the subject's own movements.

Nevertheless, the ability of the motor system to adjust movements on-line does not imply that it operates purely in the closed-loop manner of a standard feedback controller. That would not be possible with the conduction delays inherent in the system. To compensate for such delays, the motor system is able to learn specific movement contexts and to predict the state of the system when performing in each context (see SENSORIMOTOR LEARNING). For example, the system may learn an internal "forward model" that predicts, for a given movement context, what the outcome of a particular set of motor commands will be. With such a forward model, compensation for an expected perturbation can occur even before the perturbation causes any overt movement errors. As the system becomes more and more familiar with a given movement context, its dynamics will converge on the production of those commands that minimize the errors most relevant for the given task. However, although the resulting trajectory may be described as optimal (with respect to some criterion such as end-point error), this optimization arises slowly over a series of repeated action-perception cycles. It does not occur before movement begins through the explicit optimization of a desired trajectory. Instead, trajectories are produced during movement through the interplay of dynamics involving overt feedback and forward models, and it is the set of parameters implicitly defining these dynamics that is optimized during learning over many repeated movements.

## Temporal Features of Cortical Activity

Many motor control models are described in terms of abstract computational elements whose activity over time does not clearly correspond to any of the neural activity profiles observed in the nervous system. However, the temporal features of cell activities in movement-related cortical areas should be very informative about the evaluation and modification of motor control models.

Neural activities in primary motor cortex exhibit a variety of complex shapes that appear to be importantly related to the kinematic and kinetic requirements of the task at hand (Kalaska et al., 1989; Fetz, 1992; Sergio and Kalaska, 1998). Since even the cells that project directly to spinal motor neurons exhibit complex temporal response profiles that do not explicitly code the ensuing EMG, it is clear that the descending command is not simple. These studies demonstrate that many details of the time-varying aspects of movement are already evident at the cortical level and thus are not all computed at the spinal cord, despite the elegance of proposed schemes for doing so (see EQUILIBRIUM POINT HYPOTHESIS).

These various temporal response profiles must certainly be informative for computational models. For example, area 4 cells exhibit several different kinds of response profiles, including phasic, tonic, and phasic-tonic responses (Kalaska et al., 1989; Fetz, 1992). The phasic-tonic cells are the most load sensitive of these and are most often found in the deeper layers from which the pyramidal tract projection originates. They form the largest proportion of corticomotor-neuronal (CM) cells that directly project to spinal motor neurons (Fetz, 1992). Their temporal response pattern is clearly related to the dynamical requirements of different tasks (Sergio and Kalaska, 1998). In contrast, phasic cells tend to show much less load sensitivity, are more often found in superficial layers, and are almost never CM cells. There are also important differences between the activities of cortical neurons in different regions and different layers, as well as during different movement contexts. For example, cells in parietal area 5 exhibit much less sensitivity to loads than do cells in primary motor cortex, especially at the population level (Kalaska et al., 1990).

Such observations led Bullock, Cisek, and Grossberg (1998) to outline a circuit model that incorporates neural elements whose activity resembles these observed temporal patterns. According to this model, the load-sensitive phasic-tonic cells in area 4 assemble a descending command by integrating a directional signal from phasic cells and combining it with launching and braking pulses. Area 5 tonic cells combine a load-sensitive corollary discharge signal from area 4 and a load-sensitive feedback from stretch receptors to yield a load-insensitive position representation. In the model, interactions between area 4 and area 5 cells result in the on-line generation of reaching trajectories. By assigning specific functional roles to observed cell profiles, such models make specific predictions that can be tested in future neurophysiological experiments.

## Overlapping Polymodal Gradients

Motor control models usually consist of discrete functional modules, with specific computational roles assigned to specific elements. However, a striking feature of cortical neurophysiology, at least in the motor system, is the absence of well-delineated borders separating populations of cells with different functional properties. Instead, one observes gradual transitions in cell properties as one moves across the cortical surface.

Within a local area, cells do not neatly partition into separate classes or "types," but rather form a complex continuum exhibiting different mixtures of properties (Caminiti, Ferraina, and Battaglia-Mayer, 1998). As we move along the cortical surface, the mixture of cell properties changes gradually. Moving medially or laterally in the motor cortex, we find cells whose activity relates to different body parts. Moving rostrally from the central sulcus over the precentral gyrus, we find progressively more phasic and less load-sensitive cells and more correlation with abstract task information than with the details of movement kinematics or dynamics. In the postcentral gyrus, there is a reciprocal gradient of progressively less movement-related and more preparation-related activity as we move caudally along area 5 and into the deep intraparietal sulcus. These opposing gradients in pre- and postcentral areas are paralleled by a connectivity pattern, with neurophysiologically similar regions across the central sulcus being reciprocally connected. As already mentioned, gradual transitions are also observed in the time domain, with cell properties changing during the course of a movement trial.

In addition to smooth gradients of changing cell properties, some movement-related cortical areas also exhibit a great deal of polymodality. For example, in premotor and posterior parietal areas, cells are found that are sensitive to a variety of sensory and motor information. Cells respond to different degrees to salient retinal inputs, especially to objects and motion in the region of space near the monkey, and are modulated by direction of gaze, direction of attention, direction of intended movement, limb configuration, and cutaneous contact, among other factors (Caminiti et al., 1998). Modeling studies suggest that these combinations of signals converging on single cells are appropriate to effect a sensorimotor coordinate transformation. However, neurophysiological studies routinely fail to find a significant population of cells whose activity explicitly encodes the output of that transformation in a unique coordinate system. Instead, the output may be implicitly embedded in the distributed pattern of activity across the population, and extracted by appropriate decoding mechanisms (Pouget and Sejnowski, 1997). This diversity of polymodal properties indicates that computational models based on strict engineering principles and homogeneous coordinate systems (for instance, inverse differential kinematics from instantaneous hand velocity to instantaneous rates of change of muscle lengths) may have some heuristic value but do not capture the true nature of cerebral cortical motor control processes.

A model being developed by Yves Burnod and colleagues (Burnod et al., 1999) takes on the challenge of addressing the distributed nature of movement-related information in the cerebral cortex. In their framework, learned associations between combinations of sensory information (such as target position, gaze direction, and current limb configuration) and motor commands (such as gaze shifts or arm movements) are retrieved by “match” units, and the combination defining the movement that is most appropriate to the given task is selected by “condition” units on the basis of prior reinforcement. These match and condition units are distributed throughout the cortex in a continuum reflecting the possible combinations of information necessary to guide movement in various contexts. Thus, the model suggests that the overlapping gradients of polymodal activities in frontal and parietal regions are not merely a biological nuisance masking the true functional decomposition of motor control but are instead the basis of the motor system’s strategy for flexibly integrating information for the demands of different tasks.

## Discussion

Models that attempt both to solve interesting computational problems and to explain biological data face many challenges. These challenges come from diverse directions, including constraints imposed by the laws of physics, neurophysiological data, psychophysics, the evolution and development of the nervous system, and the impressive flexibility and adaptability of movement. The best way for progress to be made in such an endeavor is through a combined modeling and empirical approach. Models should be viewed as stepping stones in such a process, complementary to the experiments that they help to guide and that in turn help to modify and refine the models.

# Reactive Robotic Systems

*Ronald C. Arkin*

## Introduction

Reactive systems are a relatively recent development in robotics that has redirected artificial intelligence (AI) research. This new approach grew out of a dissatisfaction with existing methods for producing intelligent robotic response and a growing awareness of the importance of studying biological systems as a basis for constructing intelligent behavior. Reactive robots are often referred to as behavior-based robots: they are instructed to perform through the activation of a collection of low-level primitive behaviors. Complex physical behavior emerges through the interaction of the behavioral set and the complexities of the environment in which the robot finds itself, resulting in more rapid and flexible responses than are attainable through traditional methods of robotic control.

Some of the hallmark characteristics of purely reactive robotic systems include (Arkin, 1998):

1. *Behaviors are the basic building blocks*. A behavior in these systems is often a simple sensorimotor circuit, where sensory activity consists of providing necessary information to support low-level reactive motor response, such as avoiding obstacles, escaping from predators, being attracted to goals, etc.
2. *Abstract representational knowledge is avoided*. Creating and maintaining accurate representations of the world is a time-consuming error-prone process. Purely reactive systems do not maintain world models, instead reacting directly to the stimuli the world presents. This is particularly useful in highly dynamic and hazardous worlds, where the environment is unpredictable and potentially hostile.
3. *Animal models of behavior are often used as a basis for these systems*. Models from neuroscience, cognitive psychology, and ethology are used to capture the nature of the behaviors that are necessary for a robot's safe interaction with a hostile world.
4. *Demonstrable robotic results have been achieved*. These techniques have been applied to a wide range of robots, including six-legged walking robots, pipe-crawling robots, military robots, entertainment robots such as Sony's AIBO, mobile manipulators, dextrous hands, and entire herds of mobile robots. Because these systems are highly modular, they can be constructed incrementally from the bottom up by adding new behaviors to an existing repertoire. From an engineering perspective, this property is quite desirable, as it facilitates the growth and application of existing software and hardware systems to new domains.

Even more recently, hybrid reactive/deliberative robotic architectures have emerged that combine aspects of more traditional AI symbolic methods and their use of abstract representational knowledge with the responsiveness, robustness, and flexibility of purely reactive systems. Both purely reactive and hybrid architectures are discussed in this article.

## Biological Basis for Reactive Robotic Systems

Many of the designers of reactive systems look to biology as a source of models for use in robots. Although these efforts are quite diverse, ranging from traditionally engineered systems to those dedicated to faithfully replicating biological behavior, this article reports on a few exemplars that have affected reactive and hybrid system design.

*Action-oriented perception.* Neuroscientists and psychologists, especially in the cognitive and ecological communities, have provided models for the relationships between perceptual activities and behaviors required for a particular task. One excellent example is presented in Arbib (1972). His model of action-oriented perception shows that what an agent needs to perceive is based on its need to act. This is a primary guiding principle in the design of reactive robots. The traditional computer vision community often views perception as a disembodied perceiver that interprets images without consideration for what the knowing agent needs to do. In contrast, the strong coupling between action and perception is one of the hallmarks of purely reactive robotic systems. Neisser has further developed these ideas in the context of cognitive psychology (see Arkin, 1998, for a review of those aspects relevant to robotic systems).

*Ethological studies.* A pressing question for reactive robotic system designers is just what behaviors are necessary or sufficient for a particular task and environment. Many of these researchers have turned to ethological studies as a source for behaviors that are relevant in certain circumstances. Specific models used in reactive robotic systems have been quite varied, including bird flocking, ant foraging, fish schooling, and cockroach escape, among others. One example involving toad detour behavior (Arbib and House, 1987) provided motivation and justification for the use of vector fields in reactive schema-based robot navigation (Arkin, 1998).

*Coexistence of parallel planning and execution systems (hybrid systems).* Norman and Shallice (1986) have modeled the coexistence of two distinct systems concerned with controlling human behavior. One system models "automatic" behavior and is closely aligned with reactive systems. This system handles automatic action execution without awareness, starts without attention, and consists of independent parallel activity threads (schemas). The second system controls "willed" behavior and expresses an interface between deliberate conscious control and the automatic system.

While purely reactive robotic systems are compatible with the modeled automatic system (e.g., Brooks, 1986), most hybrid robotic systems (e.g., Arkin, 1990; Gat, 1992) incorporate both willed (deliberative) and automatic (reactive) components in a manner somewhat consistent with the above model.

One problem confronting the reactive robotic systems designer is that much of the data reported by biological scientists is often presented statistically. Although this approach may be useful within the context of their home disciplines, it is important for process models to be constructed whenever possible to facilitate the adoption of this work into intelligent robotic systems (see NEUROETHOLOGY, COMPUTATIONAL).

## Purely Reactive Robotic Systems

Reactive robotic systems originated in the cybernetic movement of the 1940s. Grey Walter (1953) developed an electronic "tortoise" capable of moving about the world, avoiding perceived threats and attracted to certain goals. Of special interest was the inclusion of changing goals regarding the robot's recharging station. When power was low, the tortoise was attracted to and docked with the recharger. When sufficient energy was acquired, it lost its "appetite" (charger attraction) and was repelled by it. There was no use of abstract representational constructs as later found in traditional AI; perception directly controlled motor action. Simple behaviors were created: head toward weak light, back away from strong light, and turn-and-push to avoid obstacles.

Braitenberg (1984) revived interest in this class of creatures. Using simple analog circuitry, he demonstrated that "creatures" could be built that manifested behaviors comparable to those found in animals, such as cowardice, aggression, love, exploration, and logic. These thought experiments in "synthetic psychology" showed that seemingly complex behavior could result from a collection of simple sensorimotor transformations.

Brooks (1986) was an early leader of the purely reactive robotic paradigm. His group pursued this approach with the development of subsumption architecture. He articulated the departure from classical AI and broke away from the sense-plan-act paradigm that dominated AI in the 1970–1980s as typified by robots like Shakey that used resolution theorem proving as its primary reasoning mechanism. This new position brought into question the role of representational knowledge in AI altogether. The subsumption architecture was biologically motivated only in the behaviorist sense, as it produced overt results that resembled the behaviors of certain insect systems but was unconcerned for the underlying biological mechanisms that produced them.

At about the same time that subsumption architecture appeared, other researchers were interested in pursuing parallels in biological and mechanical systems. A sort of cybernetics revival occurred. Studies produced by ethologists, neuroscientists, and others provided models that were used within reactive robotic systems. These researchers' goals varied. For example, Arkin (1990) exploited these models for the purpose of constructing intelligent robotic systems, using interacting schemas as a basis for reactive robotic control systems design (see SCHEMA THEORY). Beer, alternatively, used robotic systems to demonstrate the fidelity of neuroscientific models (see LOCOMOTION, INVERTEBRATE). Significant conferences now exist dedicated to animal and computational systems relationships; an example is the conference whose proceedings are regularly published as *Simulation of Adaptive Behavior: From Animals to Animats*, by MIT press.

Figure 1 presents a simple reactive control system example. A robot controlled by this system wanders around avoiding collisions until it finds a path, which it then follows until it locates its goal. It consists of four behaviors: *avoid-obstacle* prevents the robot from colliding with anything; *wander-about* ensures movement in the absence of goal or path attraction; *stay-on-path* guides the robot down a hall or road to find the goal near the path's end; and *move-to-goal* attracts the robot to the final goal. The perceptual strategies for each behavior are also depicted. The behavior coordination mechanism can be of several forms. Arbitration or action-selection mechanisms are typically found in subsumption-style architectures where only one behavior is active at any given time. This action-selection mechanism can be complex, involving extensive connections between behaviors for inhibition/suppression. The schematic representation of this mechanism is greatly simplified in this figure. Other coordinators may involve blending, as in schema-based reactive control systems, where all active behaviors contribute somewhat to the overall coordinated motion. Even combinations of different coordination mechanisms can be used to compose intelligent robotic behavior.

## Hybrid Reactive/Deliberative Robotic Systems

Hybrid architectures permit reconfiguration of reactive control systems based on available world knowledge, adding considerable flexibility over purely reactive systems. Dynamically reconfiguring the control system based on deliberation (reasoning over world models) is an important addition to the overall competence of general-purpose robots.

It should be recognized that purely reactive robotic systems are not appropriate for every robotic application. In situations where the world can be accurately modeled, where there is restricted uncertainty, and where there exists some guarantee of virtually no change in the world during execution (such as an engineered assembly workcell), deliberative methods are often preferred, since a plan can most likely be effectively carried out. In the real world, in which biological agents function, these prerequisites for purely deliberative planners do not exist. If roboticists hope to have their machines functioning in the same environments that we do, methods like reactive control are required. Many feel that hybrid systems capable of incorporating both deliberative reasoning and reactive execution are needed to deliver the full potential of robotic systems.

Arkin was among the first to advocate the use of both deliberative (hierarchical) and reactive (schema-based) control systems within the Autonomous Robot Architecture. Incorporating a traditional planner that could reason over a flexible and modular reactive control system, specific robotic configurations could be constructed that integrated behavioral, perceptual, and a priori environmental knowledge (Arkin, 1990). This system was tested on a wide range of applications, both indoors and outdoors.

Gat (1992) proposed a three-level hybrid system (Atlantis) incorporating a Lisp-based deliberator, a sequencer that handled failures of the reactive system, and a reactive controller. This system was fielded and tested successfully on Mars rover prototypes.

## Perception and Reactivity

A fundamental guiding principle for purely reactive systems is that perceptual activities should always be viewed on the basis of motor needs (i.e., a *need-to-know basis*). A large body of mainstream computer vision research is concerned with the abstract task of image understanding, which usually is considered independently of a particular agent's needs. Proponents of purely reactive control advocate that perception serves motor action, and that image interpretation algorithms must take this into account. Sensing strategies should be constructed that take advantage of the knowledge of underlying behavioral requirements. This eliminates the need to construct global representations of the world, an activity avoided in purely reactive robotic systems. By creating perceptual algorithms that extract only relevant information and that exploit expectations of what is necessary and sufficient to be perceived, efficient sensor processing is a natural consequence.

Hybrid approaches, nonetheless, are more consistent with the views of neuroscientists (e.g., Mishkin, Ungerleider, and Macko

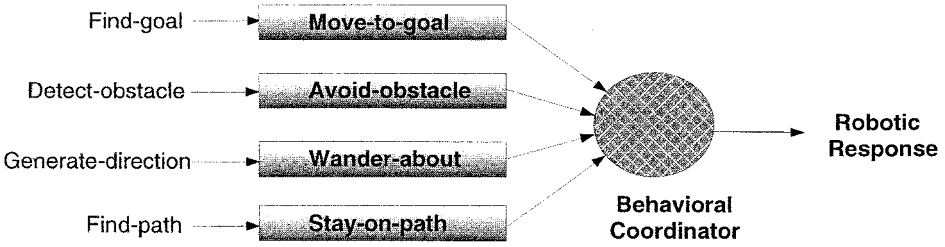

**Figure 1.** Example of a reactive control system.

1983) on *what* + *where* visual systems that account for the maintenance of spatial relationships in a more than purely reactive manner (see VISUAL SCENE PERCEPTION).

There are three ways in which reactive systems can utilize perceptual information: perceptual channeling (sensor fission), action-oriented sensor fusion, and perceptual sequencing. Perceptual channeling is straightforward: a motor behavior requires a particular stimulus for it to be invoked, so a single sensor system is created. A simple sensorimotor circuit results. There are numerous examples (e.g., Maes, 1990; Brooks, 1991).

Action-oriented sensor fusion (Arkin, 1993) permits the construction of representations (percepts) that are local to individual behaviors. Restricting the representation to the requirements of a particular behavior provides the benefits of reactive control while permitting more than one sensor to provide input, resulting in increased robustness.

Sometimes fixed action patterns require varying stimuli to support them over separations in time and space. As a behavioral response unfolds, it may be modulated by different sensors or different views of the world. Perceptual sequencing supports the coordination of multiple perceptual algorithms over time in support of a single behavioral activity. Perceptual algorithms are phased in and out, based on the needs of the agent and the environmental context in which it is situated.

## Discussion

Space prevents an extensive survey of the wide range of reactive robotic systems; the reader is referred to Maes (1990), Brooks (1991), Mataric (1992), Efken and Shaw (1993), and Arkin (1998) for additional information and alternative perspectives. These methods have gained dramatically in popularity and utility since the mid-1980s and are being applied to robotic systems throughout the world.

Hybrid reactive/deliberative architectures have been created to address several of the potential shortcomings of purely reactive systems. They permit the incorporation of world knowledge and the construction of global representations, yet preserve the strength of reactive execution and responsiveness to environmental change.

## Introduction

A skilled reader can recognize many thousands of printed words, each in a fraction of a second, with no noticeable effort. A child who is developmentally dyslexic does not easily acquire this skill. For a dyslexic child, recognizing a printed word as a particular word can be effortful to the point of frustration. Dyslexia may plague an otherwise bright and articulate child, and the fact of dyslexia illustrates how recognition of printed words as words is the crux of reading. Reading is not exclusively the recognition of printed words, but it is word recognition that sets reading apart from natural language. In effect, to become a reader is to master this special skill (Perfetti, 1985). A vast empirical literature concerns word recognition, and most "neural" networks of reading are models of word recognition.

One tool with which to diagnose dyslexia is a naming task that presents individual *pseudoword spellings*, such as "glurp," to be read aloud. A dyslexic child may have great difficulty with this task, and success in this nonword task is generally correlated with word reading skill. Trouble decoding the pronunciations of letter strings is a symptom of the most common form of dyslexia (Pennington, 1991). In this form, dyslexia is a specific problem in translating words' spellings into their phonology (roughly, their sounds or pronunciations). And the key to word recognition would seem to lie in the derivation of phonology from words' printed forms.

All written languages have systematic relationships between words' printed and spoken forms (Mattingly, 1992), so perhaps word recognition includes an analytic letter-by-letter process that translates spelling into phonology. This possibility has preoccupied reading scientists for over 100 years. Nevertheless, word recognition is not simply analytic. Evidence that supports an analytic hypothesis has always existed side by side with evidence that word recognition is synthetic (or holistic). The consequent synthetic/analytic debate defined reading theory throughout the twentieth century, and it provides the organizing theme for this article.

## Early Reading Research

Nineteenth century studies introduced almost all topics of current reading research (Rayner and Pollatsek, 1989). A key early finding from eye-movement studies was that readers' eyes make a series of jumps in moving across a line of text, pausing for about a quarter of a second when fixated. Discrete eye movements implied the *fixation* (recognition) of individual printed words in natural reading. Another key development was the invention of the t-scope (or tachistoscope). A t-scope can flash individual words for a few milliseconds at a time, well within the range of fixation times observed in eye movements.

More recent t-scope studies, in the second half of the twentieth century, perpetuated the synthetic/analytic debate. Ulric Neisser's seminal book *Cognitive Psychology* (1967) includes a review of this debate concerning word recognition. For example, pseudoword spellings, such as "glurp," that obey the letter-to-sound pronounceability patterns of English are more easily recognized and recalled than are random strings of letters. The advantage for pronounceable letter strings suggests an analytic process. A more contemporary finding, however, indicates that word recognition could be synthetic. Words that are flashed for a fraction of a second (and then replaced by a "pattern mask" of letter features) are more accurately reported than are their component letters presented individually under the same extreme conditions, a phenomenon known as the *word superiority effect*.

## Dual-Route Theories

Dual-route theories emerged in the 1970s with the advent of cognitive psychology. As the name implies, traditional dual-route theories were an ad hoc resolution of the synthetic/analytic debate. Both options were included as separate processing modules (mechanisms). Early dual-route theories were important in this regard because they moved past a contentious theoretical debate that could not be resolved empirically.

The two modules of dual-route theories accomplish word recognition in two different ways. Skilled readers reading frequently encountered words rely on a fast, synthetic, lexical module to translate a visual representation into an entry in the lexicon, the mind's dictionary. The speed of access to dictionary entries in the lexical module is determined by the relative frequency with which a word appears in print. Word frequency is estimated by counting the occurrence of each word (per million words) in large samples of text. Higher-frequency words are more readily available in the lexicon. (Different dual-route theories propose different frequency-sensitive mechanisms.)

By contrast, novice readers and skilled readers who encounter a novel word recognize words via a slow, analytic, sublexical module. At the heart of the sublexical module are rules to translate minimum units of spelling (graphemes) into minimum units of phonology (phonemes). A combination of phonemes may guide assembly of pronunciation for completely novel letter strings, such as "glurp," or may achieve lexical access when the unfamiliar spelling translates into the phonology of a familiar word. Access to a lexical entry allows access, in turn, to lexical representations of words' pronunciations and conventional meanings, as one would find in a dictionary. (Different dual-route theories propose different representations and translation procedures.)

## Word Naming

Word naming experiments measure the time required to pronounce individually presented words. At one time, dual-process theories provided a sufficient account of results from naming experiments, with skilled readers as participants. Low-frequency regular words, such as "mint," that obey sublexical grapheme-phoneme correspondence rules are named faster than low-frequency exception words, such as "pint," that entail exceptions to the rules. No regularity effect was found to high-frequency words. Hence, naming of low-frequency words is accomplished by the sublexical module, but naming of all other words is accomplished by the lexical module. Eventually, however, this categorical regular/exception distinction was contradicted. New studies found graded effects of semiregular relationships between spelling and phonology, not simply the regular versus exception distinction predicted by traditional dual-route theories. For instance, although both "wave" and "wade" obey the grapheme-phoneme rules, the existence of "have," an exception "neighbor" to "wave," induces slower naming times to "wave" itself.

## Lexical Decision

Word recognition is also studied by using the *lexical decision task*. Lexical decision experiments measure the time required to indicate that an individually presented word is a word (with catch trials that present pseudoword spellings). Previously, lexical decision time did not appear to be affected by regularity, only by relative frequency. High-frequency words are recognized faster than low-frequency words. Regularity effects arise in the sublexical module, and frequency effects arise in the lexical module. Hence, recognition for lexical decisions appeared to rely on the lexical module, exclusively. New studies contradicted this hypothesis, however. Key findings were subcategories of exception words, such as "weird" or "choir," called *strange words*, that produced slow and error-prone performance, reliably worse performance than that to ordinary exception words such as "pint." These findings, like the graded-regularity effects in naming experiments, contradict the categorical regularity distinction of dual-route theories.

## Patient Studies

At one time, dual-process theories also provided a reasonable account of neuropsychological findings. Lexical and sublexical modules were corroborated in the patterns of naming errors, described in case studies of brain-damaged individuals. For example, surface dyslexics incorrectly regularize exception words ("pint" is pronounced to rhyme with "mint") but correctly name regular words. Regularized pronunciations of exception words dissociate the sublexical module (the source of regularization errors) from the damaged or absent lexical module (the source of correct pronunciations). Alternatively, deep dyslexics produce visual errors ("bush" is pronounced as "brush") and semantic errors ("bush" is pronounced as "tree"). These errors were attributed to a dissociated but damaged lexical module.

Evidence from patient studies proved to be problematic, however. No general agreement emerged concerning which patients' deficits actually counted as dissociated components of word recognition. All of the patient case studies that concerned reading were challenged by competing theorists, who claimed that they did not actually dissociate synthetic versus analytic components or that they simply did not pertain to reading (Van Orden, Pennington, and Stone, 2001). More recent brain-imaging studies appear to have arrived at a similar impasse. No general agreement has emerged in the brain-imaging literature that uniformly implicates specific brain regions in a large sample of reading tasks. Indeed, small differences in reading tasks and experimental methods appear to implicate different brain regions in what appear, intuitively, to be very similar reading acts.

## Additive Factors Method

As we have noted, dual-process theories emerged in the 1970s, when cognitive psychology was predominantly concerned with information processing. Within that framework, the mind was conceived as an information-processing device that could be described in a way much like a flowchart of information processing in a computer program. Simon (1973) described how complex systems, such as cognitive systems, could be partly decomposed if the system's components interact approximately linearly. If interactions (exchanges) between components are linear in their effect, then the components can be identified even if their internal dynamics are nonlinear. Cognitive components thus described work as a chain of single causes—a metaphorical extension of domino causality. Push the first domino in a chain of standing dominoes, and each will fall in its turn.

The previous theoretical rationale coincided with a methodological tool to individuate cognitive components: the *additive factors method*, proposed by Sternberg (1969). Factorial experiments allow simultaneous manipulations of candidate variables that may influence distinct hypothetical components. The main effects of two or more manipulations are additive if they add up to the total behavioral effect. In this idealization, separate experimental manipulations selectively influence (e.g., slow) the falling times of separate "dominoes."Alternatively, when nonadditive interaction effects are observed, manipulations do not satisfy the assumption of selective influence and influence (at least) one component in common. Thus, to Sternberg's lasting credit, his method included an empirical failure point: ubiquitous nonadditive interaction effects.

Additive main effects are rarely observed in reading experiments. It is not possible to manipulate all factors simultaneously in one experiment, but it is possible to trace chains of nonadditive interactions across published experiments that preclude the assignment of any factors to distinct components. For example, factorial manipulations of word frequency and regularity yield nonadditive interaction effects. This raises the question of whether the respective effects actually arise from separate synthetic and analytic processes.

## Parallel Distributed Processing Models

Parallel distributed processing (PDP) models allowed a new position in the debate, because they did not require distinct synthetic and analytic processes (Seidenberg, 1995). PDP models are connectionist models in which constraints (connection weights) determine the activation values of nodes. Nodes represent words' spellings, pronunciations, or meanings, and patterns of response times are simulated in a model's *error term* (the difference between a model's pronunciation, for example, and an ideal correct pattern of pronunciation-node activation). A learning algorithm shapes a matrix of connection weights to reflect statistical relationships among node representations. This is referred to as statistical or *covariant learning*. PDP models introduced covariant learning algorithms to a broad audience of cognitive scientists. PDP models were equally important as existence proofs, which advanced the synthetic/analytic question. Covariant learning may reflect, in a single process, both subword (analytic) and whole-word (synthetic) covariation, as we illustrate next.

Distinctions in the relationships among English spellings and pronunciations, at a variety of scales, may all be construed as statistical relationships. Covariant learning tracks all scales of covariation, simultaneously, in the connection weights of a PDP model (Plaut et al., 1996). For example, consonant spellings and pronunciations are more reliably correlated than vowel spellings and pronunciations, and in both cases, there are statistically dominant and subordinate relationships. "Regular" words, comprising dominant relationships, are named more quickly than "exception" words that include subordinate relationships. Likewise, spelling bodies (e.g., the spelling pattern "-uck" in "duck") and pronunciation rimes (e.g., pronunciation /uk/ in /duk/) are invariantly correlated; but some other body-rime relationships are dominant though less strongly correlated ("-int" pronounced as in "mint"); and still other body-rimes are subordinate and only weakly correlated ("-int" pronounced as in "pint"). This rank order is corroborated in naming times; words like "duck" are named faster than words like "mint," and words like "mint" are named faster than words like "pint" (all other things being equal). Finally, a word's relative frequency estimates the strength of the relationship between the word's (whole-word) spelling and pronunciation; high-frequency words are named faster than low-frequency words.

As the examples illustrate, the outcome of covariant learning will be determined by the pattern of statistical relationships in a *training set*—the sample of words used to train the model. Each training set entails a sample of constraints (relationships between spelling, phonology, and meaning) from the body of constraints in a literate culture, and covariant learning attunes the network to the sampled constraints. Thus, implicit in the training set is a description of the cultural artifact—a particular language's pattern of relationships—that is crucial for cognitive theory. Jared (1997) used this implication of PDP models to derive a nonintuitive empirical test. Careful attention to statistical relationships among the spellings and pronunciations of high-frequency words predicted a statistical advantage for high-frequency words with invariant body-rime relationships. Jared subsequently corroborated this prediction—a previously unobserved "regularity" effect in naming for high-frequency words. However, no such effect was observed in a lexical decision experiment.

Hybrid, partially recurrent, connectionist models moved the PDP approach further in the direction of fully recurrent, iterative, "neural" network models. In a hybrid model, the output of nonrecurrent (strictly feedforward) portions of a PDP network sets the initial conditions in a recurrent subnetwork that includes feedback connections. The recurrent portion behaves as an attractor network, tuned to fixed points that correspond to word pronunciations (for example), and pronunciation times are simulated in the number of iterations before the network reaches a "stable" attractor.

Partly "damaged" hybrid networks simulated the bizarre semantic and visual errors of deep dyslexic patients as well as the regularization errors of surface dyslexics. Simulated lesions have been implemented in several ways, including (a) random cutting of some connections between nodes, (b) random changes in connection weights, and (c) random selection of nodes whose values are fixed at zero. The various patterns of dyslexic patient's naming errors have been mimicked by using one or combinations of these simulated lesions.

## Iterative Network Models

Hybrid feedforward PDP models were actually proposed as a first step toward fully recurrent, iterative networks. Iterative networks are attractor networks simulated as nonlinear iterative maps. A nonlinear iterative map may approximate solutions of a system of nonlinear differential equations. Thus, iterative network models, as dynamical systems, invoke the most sophisticated mathematical framework available to scientists (Farmer, 1990). An iterative map takes its output at one time step as input on the next time step until a stable pattern of node activity emerges—an attractor state. A stable attractor state corresponds to an iterative model's naming response.

Iterative network models may include covariant learning algorithms that reflect relationships that map from patterns of spelling to pronunciations and from pronunciations to spelling patterns (and meanings). Invariant, bidirectional relationships correspond to stable attractors in the network, which extends the previous view of statistical relationships among spellings and pronunciations. Some consonants have invariant bidirectional relationships with their pronunciations. For example, the grapheme B at the beginning of a word is always pronounced /b/, and the /b/ pronunciation is always spelled B. Likewise, some spelling-body pronunciation-rime relationships are invariant (e.g., "-uck" and /uk/, as in "duck," always co-occur). And most words have a bidirectional invariant relationship between their particular whole-word spelling and their particular pronunciation. As we noted, invariant bidirectional relationships correspond to stable attractor states in an iterative network. By contrast, ambiguous spelling-pronunciation relationships correspond to multiple, mutually inconsistent *multistable*, or more precisely *metastable*, attractor states in an iterative network.

Empirical studies of nonlinear systems typically focus on their less stable behavioral regimes, because very stable regimes reveal less of system dynamics. Pioneering studies have examined how ambiguous relationships between spelling and pronunciation affect empirical patterns in naming performance. By definition, the relationship between spelling and phonology is ambiguous if more than one reliable pronunciation is elicited by the same spelling. For example, a homograph, such as "wind," has two legitimate pronunciations and is thus an ambiguous spelling. In the case of "wind," its "regular" pronunciation (to rhyme with "pinned") is produced faster than its "exception" pronunciation (to rhyme with "find"). Thus, the dynamics of word naming must unfold in a way that respects this ordering.

Kawamoto and Zemblidge (1992) simulated homograph naming using an iterative network. Relationships (connections) among letter, phoneme, and semantic node families were recurrent (including both feedforward and feedback connections) and excitatory, but within each node family, recurrent connections were (predominantly) inhibitory. The multistable unfolding of homograph pronunciations was simulated as a transcritical bifurcation. In a transcritical bifurcation, for example, the two possible pronunciations of "wind" exchange stability at a bifurcation point. That is, initial dynamics unfold in favor of one potential solution, but over successive iterations, additional constraints (which may unfold on a slower time scale) begin to favor an alternative solution. In the case of "wind," the faster "regular" pronunciation reflected a strong local attractor between letter and phoneme nodes. However, coherent interactive activation among phoneme and semantic nodes slowly emerged to favor the "exception" pronunciation. The bifurcation point occurred when the balance of constraints switched to favor the "exception" pronunciation. At the bifurcation point, the "regular" pronunciation (attractor) exchanged stability with the "exception" pronunciation.

## Discussion

The previous simulation of ambiguous homograph pronunciations as bifurcation phenomena illustrates how nonlinear dynamical systems theory has been applied to reading performance. However, empirical methods that are appropriate to nonlinear analysis are not widely applied. In large part, connectionism has inherited the empirical methods of information-processing psychology. However, statistical analyses that assume the general linear model and theories to be implemented as strongly nonlinear dynamical systems may be incompatible because they entail different notions of causality.

Previously, we discussed how the factorial logic of additive factors method assumes a one-way, domino-effect notion of causality. In contrast, bifurcation phenomena entail *circular causality*. Circular causality requires a strategic (not morphological) reduction of system behavior, due to emergent properties. In a strategic reduction, generic emergent properties may be found at multiple levels of systems, but emergent properties at "higher" levels do not reduce to causal properties of "lower" levels.

Plausible nonlinear models allow that it may not be productive, for scientific purposes, to view word recognition (or reading) as a component process, but linear methods are directed at the discovery of component processes. Moreover, the results of a vast linear analysis actually raise the question of whether a distinct process of word recognition may be distinguished. All reading tasks would seem to include word recognition, but they do not yield any converging pattern of word recognition effects.

Consider the word frequency effect in the lexical decision task, for example. The same set of words that produce a large word frequency effect in the lexical decision task may produce a reduced, or statistically unreliable, word frequency effect in naming (or other tasks). Within the lexical decision task itself, it is possible to modulate the word frequency effect by making the non-words more or less word-like (and, in turn, modulate nonadditive interaction effects among word frequency, regularity, and other variables). Across languages, Hebrew produces a larger word frequency (familiarity) effect than English, and English produces a larger effect than Serbo-Croatian (which tracks the analytic transparency of their print-to-sound relationships—less transparent equals larger frequency effect).

All empirical phenomena of word recognition appear to be conditioned by task, task demands, and reference language (Frost and Katz, 1992; Lukatela and Turvey, 1998). These nonadditive interactions allow the question of whether "word recognition effects" may be attributed to a distinct process of word recognition. Consider the previous examples together, within the guidelines of additive factors logic. Word recognition factors cannot be individuated from each other, and they cannot be individuated from the context of their occurrence (task, task demands, and language). Because additivity of task effects or language effects is never observed, we lack evidence that may individuate word recognition.

Despite these problems, most theorists, including connectionist theorists, share the intuition that a distinct separable component of word recognition may yet exist. We speculate, however, that the intuition persists because most cognitive theorists were trained exclusively in linear methods. If we are correct, then rigorous tests of iterative network models await a reliable logic of nonlinear analysis that is consistent with nonlinear dynamical systems theory and appropriate to reading performance. Thus, the historical question of analytic versus synthetic processes with which we began is replaced by the question of linear versus nonlinear dynamics—a question motivated in part by the success of nonlinear iterative network models.

# Recurrent Networks: Learning Algorithms

*Kenji Doya*

## Introduction

The backpropagation algorithm for feedforward networks (Figure 1*A*) has been successfully applied to a wide range of problems, from neuroscience to consumer electronics (see BACKPROPAGATION: GENERAL PRINCIPLES). However, what can be implemented by a feedforward network is just a static mapping of the input vectors. The human brain, however, is not a stateless input-output system but a high-dimensional nonlinear dynamical system. In order to model dynamical functions of the brain, or to design a machine that performs as well as a brain does, it is essential to utilize a system that is capable of storing internal states and implementing complex dynamics.

This is why learning algorithms for *recurrent neural networks* (Figure 1*B*), which have feedback connections and time delays, have been studied with enthusiasm. In a recurrent network, the state of the system can be encoded in the activity pattern of the units and a wide variety of dynamical behaviors can be programmed by the connection weights.

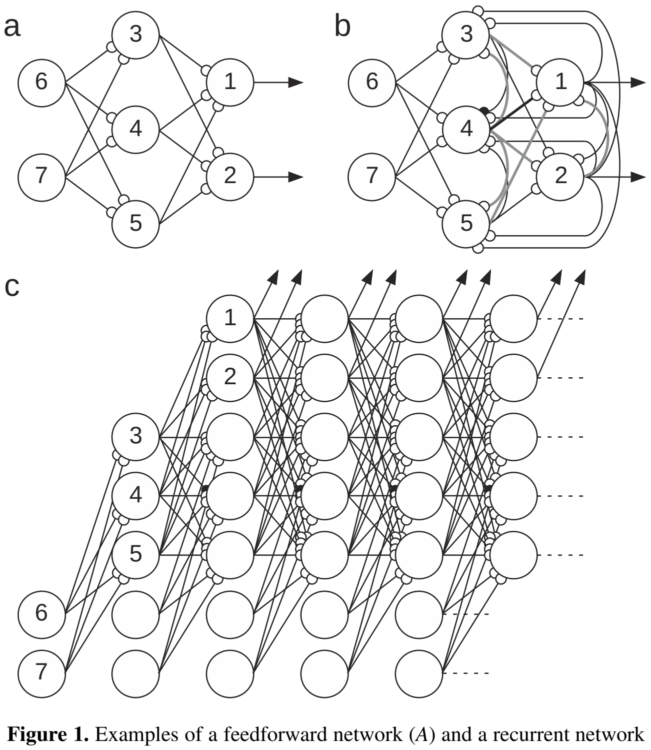

**Figure 1.** Examples of a feedforward network (*A*) and a recurrent network (*B*), where units 1 and 2 are output units; units 3, 4, and 5 are hidden units; and units 6 and 7 are input units. The multistep operation of a recurrent network (*B*) can be unrolled as a multilayer feedforward network (*C*).

A popular subclass of recurrent networks is those with symmetric connection weights. In this case, the network dynamics is guaranteed to converge to a minimum of "energy" function (see ENERGY FUNCTIONALS FOR NEURAL NETWORKS and COMPUTING WITH ATTRACTORS). Typical examples are associative memory networks (see ASSOCIATIVE NETWORKS), optimization networks (see OPTIMIZATION, NEURAL), and WINNER-TAKE-ALL NETWORKS (q.v.).

However, steady-state solutions are only a limited portion of the capabilities of recurrent networks. A recurrent network can serve as a sequence recognition system (see LANGUAGE PROCESSING) or as a sequential pattern generator (see MOTOR PATTERN GENERATION and SEQUENCE LEARNING). More generally, it is capable of transforming an input sequence into some other output sequence (see TEMPORAL PATTERN PROCESSING). It can be used as a nonlinear filter (see KALMAN FILTERING: NEURAL IMPLICATIONS), a nonlinear controller (see IDENTIFICATION AND CONTROL), or a finite-state machine (see LANGUAGE PROCESSING).

This article reviews the learning algorithms for training recurrent networks. There are three major frameworks of learning: *supervised learning*, based on the output error signal, *reinforcement learning*, based on the scalar reward signal, and *unsupervised learning*, based on the statistical feature of the input signal. Our main focus will be on supervised learning algorithms for recurrent networks. We also provide a brief overview of reinforcement and unsupervised learning algorithms.

## Supervised Learning Algorithms

The problem setup of supervised learning in recurrent networks is similar to the case of feedforward networks: a network is given a desired output for an input. An error function is defined and its gradient with respect to the weights is derived. However, the major difference is that the input and output are not static vectors but *time sequences*.

For example, in the recurrent network shown in Figure 1*B*, units 1 and 2 are output units; units 3, 4, and 5 are hidden units; and units 6 and 7 are input units. A small change of a connection weight, say $w_{43}$ (shown as black dot), affects the output units, say unit 1, not only through the direct connection from unit 4 to 1 (thick black line), but also through indirect connections, through units 2, 3, and 5 (thick gray lines), and through infinitely many multistep paths with multiple delays. It makes exact calculation of output error gradient rather complex.

One simple strategy is to neglect all the indirect paths. In this case, although the network state evolves according to the recurrent network, as in Figure 1*B*, a simple backpropagation algorithm is applied by regarding it as a feedforward network, as in Figure 1*A*. Such coarse approximation methods turned out to be effective in work on language acquisition using *simple recurrent networks* that have recurrent connections between hidden units (see LANGUAGE PROCESSING).

There are two basic ways to calculate the exact gradient of the output with respect to the weights: forward methods and backward methods. Forward methods estimate the effects of a small change in a weight on the network state trajectory in the form of a linear dynamical equation system. This can be calculated concurrently with the network dynamic, and thus is useful for on-line learning. A drawback is the amount of computation needed to update a set of dynamical equations for each weight.

Backward methods estimate the causes of the output error backward in time. In discrete-time case, this method is realized by "unrolling" the multistep evolution of the network state as a multilayer feedforward network, as in Figure 1*C*, and applying the standard backpropagation algorithm (Rumelhart, Hinton, and Williams, 1986). In continuous-time cases it is done by running a set of "adjoint systems" backward in time. Although the method requires asynchronous operation, with the evolution and storage of the state trajectory done first and the error gradient calculation done afterwards, the amount of computation is much less than in the forward methods (see Pearlmutter, 1995, for a comprehensive review). In the following sections, we formulate these algorithms for both discrete-time and continuous-time models, and then discuss technical problems in using them.

## Discrete-Time Model

We will start with a discrete-time recurrent network with $n$ units and $m$ inputs. We denote the state of the $i$th unit by $y_i$ and the connection weights from the $j$th to the $i$th unit by $w_{ij}$. Both external inputs $u_j$ and recurrent inputs $y_j$ are represented as $z_j$ for convenience:

$$y_i(t+1) = f\left(\sum_{j=1}^{n+m} w_{ij} z_j(t)\right) \quad (i = 1, \ldots, n)$$

$$z_j(t) = \begin{cases} y_j(t), & j \le n \\ u_{j-n}, & j > n \end{cases} \qquad (1)$$

The output nonlinearity $f(\,)$ is usually a squashing function, such as $f(x) = 1/(1 + e^{-x})$ and $f(x) = \tanh x$, whose derivatives are conveniently given by $f'(x) = f(x)(1 - f(x))$ and $f'(x) = 1 - f(x)^2$, respectively. We can introduce a bias parameter by assuming that one of the inputs $u_j$ is constant.

The goal of learning is to set the parameters $w_{ij}$ so that the output trajectory $(y_1(t), \ldots, y_n(t))$ follows a desired trajectory $(d_1(t), \ldots, d_n(t))(t = 1, \ldots, T)$ with a given initial state $(y_1(0), \ldots, y_n(0))$ and an input sequence $(u_1(t), \ldots, u_m(t))(t = 0, \ldots, T - 1)$. We define the error function

$$E = \sum_{t=1}^{T} \sum_{i=1}^{n} \mu_i(t)\ \tfrac{1}{2}\ (y_i(t) - d_i(t))^2 \qquad (2)$$

and perform gradient descent on $E$ with respect to the weights $w_{ij}$. The masking function $\mu_i(t)$ specifies which components of the trajectory are to be supervised at what time. In a typical case, $\mu_i(t) \equiv 1$ for output units and $\mu_i(t) \equiv 0$ for hidden units. When only the end point of the trajectory is specified, $\mu_i(T) = 1$ and $\mu_i(t) = 0$ for $t < T$.

### *Real-Time Recurrent Learning*

The effect of weight change on the network dynamics can be seen by simply differentiating the network dynamics equation (Equation 1) by a weight $w_{kl}$ (Williams and Zipser, 1989).

$$\frac{\partial y_i(t+1)}{\partial w_{kl}} = f'(x_i(t))\left[\sum_{j=1}^{n} w_{ij} \frac{\partial y_j(t)}{\partial w_{kl}} + \delta_{ik} z_l(t)\right] \quad (i = 1, \ldots, n) \qquad (3)$$

where $x_i(t) = \Sigma_{j=1}^{n+m} w_{ij} z_j(t)$ is the net input to the unit and $\delta_{ik}$ is Kronecker's delta ($\delta_{ik} = 1$ if $i = k$ and otherwise 0). The term $\delta_{ik} z_l(t)$ represents an *explicit* effect of the weight $w_{kl}$ on the unit $k$, and the term $\Sigma_{j=1}^{n} w_{ij}(\partial y_j(t)/\partial w_{kl})$ represents an *implicit* effect on all the units because of network dynamics.

Equation 3 for each unit $i = 1, \ldots, n$ constitutes an $n$-dimensional linear dynamical system (with time-varying coefficients), where $((\partial y_1/\partial w_{kl}), \ldots, (\partial y_n/\partial w_{kl}))$ is taken as a dynamical variable. Since the initial state $y_i(0)$ of the network is independent of the connection weights, the appropriate initial condition for Equation 3 is

$$\frac{\partial y_i(0)}{\partial w_{kl}} = 0 \quad (i = 1, \ldots, n)$$

Thus, we can compute $\partial y_i(t)/\partial w_{kl}$ *forward in time* by iterating Equation 3 simultaneously with the network dynamics (Equation 1). From this solution, we can calculate the error gradient as follows:

$$\frac{\partial E}{\partial w_{kl}} = \sum_{t=1}^{T} \sum_{i=1}^{n} \mu_i(t)(y_i(t) - d_i(t)) \frac{\partial y_i(t)}{\partial w_{kl}} \qquad (4)$$

A standard *batch* gradient descent algorithm is to accumulate the error gradient by Equation 4 and update each weight $w_{kl}$ by

$$w_{kl} := w_{kl} - \varepsilon \frac{\partial E}{\partial w_{kl}} \qquad (5)$$

where $\varepsilon > 0$ is a learning rate parameter.

An alternative update scheme is the gradient descent of *current* output error $\Sigma_{i=1}(\tfrac{1}{2})\mu_i(t)(y_i(t) - d_i(t))^2$ at each time step, namely,

$$w_{kl}(t+1) = w_{kl}(t) - \varepsilon \sum_{i=1}^{n} \mu_i(t)(y_i(t) - d_i(t)) \frac{\partial y_i(t)}{\partial w_{kl}} \qquad (6)$$

Note that we assumed that $w_{kl}$ is a constant, not a dynamical variable, in deriving Equation 3, so we have to keep the learning rate $\varepsilon$ small enough. However, this on-line update scheme was shown to be effective on a number of temporal learning tasks (Williams and Zipser, 1989), and it is often called *real-time recurrent learning*.

A drawback to this error gradient calculation forward in time is that we have to solve an $n$-dimensional system (Equation 3) for each of the weights $w_{kl}(k = 1, \ldots, n;\ l = 1, \ldots, n + m)$. It requires $O(n^3)$ memories and $O(n^4)$ computations.

### *Backpropagation Through Time*

Another learning algorithm for a discrete-time model can be derived by "unfolding" a recurrent network into a multilayer network (Figure 1*C*) (Rumelhart et al., 1986). In this scheme, $T$-step iteration of a recurrent network is regarded as one sweep of operation in a $T$-layered feedforward network with identical connection weights $w_{ij}$ between successive layers. The error gradient can be derived in the same way as in the standard backpropagation, except that the output errors are not only given in the last layer but added in each layer:

$$\frac{\partial E}{\partial y_i(t)} = \sum_{j=1}^{n} \frac{\partial E}{\partial y_j(t+1)} f'(x_j(t)) w_{ji} + \mu_i(t)(y_i(t) - d_i(t)) \quad (i = 1, \ldots, n) \qquad (7)$$

Since the error $E$ is independent of the state at $t > T$, the boundary condition for Equation 7 is given at the final time step as

$$\frac{\partial E}{\partial y_i(T + 1)} = 0 \quad (i = 1, \dots, n)$$

Thus, the learning equation (Equation 7) can be iterated *backward in time* from $t = T$ to 1.

From the solution $\partial E/\partial y_i$, the error gradients are given by

$$\frac{\partial E}{\partial w_{ij}} = \sum_{t=1}^{T} \frac{\partial E}{\partial y_i(t)} f'(x_i(t - 1))z_j(t - 1) \tag{8}$$

and the weights are updated in a batch using Equation 5.

The advantage of this algorithm is that we have to solve only one $n$-dimensional system, Equation 7, for adjusting all the weights. Therefore, only $O(n^2)$ computations are required. However, since the learning equation, Equation 7, has to be solved *backward* in time, we cannot update the weights on-line, and we have to store the history of the network state $y_i(t)$ ($i = 1, \dots, n$; $t = 1, \dots T$), which requires $O(nT)$ memories.

## Continuous-Time Model

A continuous-time model is a natural choice for modeling systems that are governed by differential equations. Time constants of continuous-time models are convenient parameters for setting local memory spans for individual units. They can also be adjusted by learning, as discussed later.

Slightly different versions of continuous-time models have been studied. Here, we focus on the following model (Pearlmutter, 1989),

$$\tau_i \dot{y}_i(t) = -y_i(t) + f\left(\sum_{j=1}^{n+m} w_{ij} z_j(t)\right) \quad (i, = 1, \dots, n)$$

$$z_j(t) = \begin{cases} y_j(t), & j \le n \\ u_{j-n}, & j > n \end{cases} \tag{9}$$

However, similar derivations apply to other models as well (Doya and Yoshizawa, 1989).

We define an error integral

$$E = \int_0^T \sum_{i=1}^{n} \mu_i(t)\ ½\ (y_i(t) - d_i(t))^2 dt \tag{10}$$

and derive a gradient descent algorithm for minimizing $E$ for a desired trajectory $(d_1(t), \dots, d_n(t))(0 \le t \le T)$ with a given initial state $(y_1(0), \dots, y_n(0))$ and an input sequence $(u_1(t), \dots, u_m(t))$.

### *Variation Method*

The effect of a change in a weight $w_{kl}$ on the state $y_i(t)$ can be estimated by differentiating Equation 9, the network dynamics equation, as follows:

$$\tau_i \frac{d}{dt}\left(\frac{\partial y_i}{\partial w_{kl}}\right) = -\frac{\partial y_i}{\partial w_{kl}} + f'(x_i(t))\left[\sum_{j=1}^{n} w_{ij} \frac{\partial y_j}{\partial w_{kl}} + \delta_{ik} z_l(t)\right] \quad (i = 1, \dots, n) \tag{11}$$

This forms an $n$-dimensional linear differential equation system with the state variable $((\partial y_1/\partial w_{kl}), \dots, (\partial y_n/\partial w_{kl}))$ and is called a *variation system* of the network dynamics equation, Equation 9. The initial condition for this system is given by

$$\frac{\partial y_i(0)}{\partial w_{kl}} = 0 \quad (i = 1, \dots, n)$$

because the initial state of the network is independent of the weights. We can numerically integrate Equation 11 forward in time concurrently with the network dynamics in Equation 9.

From the solution $(\partial y_i(t)/\partial w_{kl})(0 \le t \le T)$, the error gradient is given by

$$\frac{\partial E}{\partial w_{ij}} = \int_0^T \sum_{i=1}^{n} \mu_i(t)(y_i(t) - d_i(t)) \frac{\partial y_i(t)}{\partial w_{kl}}\, dt \tag{12}$$

We can use either the batch update scheme (Equation 5) at the end of a sequence, or the on-line update scheme

$$\dot{w}_{kl} = -\varepsilon \sum_{i=1}^{n} \mu_i(t)(y_i(t) - d_i(t)) \frac{\partial y_i(t)}{\partial w_{kl}} \tag{13}$$

with sufficiently small learning rate $\varepsilon > 0$.

The error gradient for a time constant $\tau_k$ is given by the following variation equation:

$$\tau_i \frac{d}{dt}\left(\frac{\partial y_i}{\partial \tau_k}\right) = -\frac{\partial y_i}{\partial \tau_k} + f'(x_i(t))\left[\sum_{j=1}^{n} w_{ij} \frac{\partial y_j}{\partial \tau_k} - \delta_{ik}\dot{y}_k(t)\right] \quad (i = 1, \dots, n) \tag{14}$$

### *Adjoint Method*

The backward algorithm for a continuous-time model can be derived in several ways, for example, by finite difference approximation (Pearlmutter, 1989). Here we derive the algorithm as an "adjoint" system of the forward learning equation, Equation 11.

A pair of $n$-dimensional linear systems

$$\dot{\boldsymbol{p}} = A(t)\boldsymbol{p} + \boldsymbol{b}(t) \quad \text{and} \quad \dot{\boldsymbol{q}} = -A^*(t)\boldsymbol{q} - \boldsymbol{c}(t)$$

are called *adjoint* to each other, where $A^*$ denotes the transpose of matrix $A$. A useful property of adjoint systems is that their solutions satisfy the following *Green's equality*:

$$\int_0^T \boldsymbol{q}(t) \cdot \boldsymbol{b}(t)dt - \int_0^T \boldsymbol{c}(t) \cdot \boldsymbol{p}(t)dt = \boldsymbol{q}(T) \cdot \boldsymbol{p}(T) - \boldsymbol{q}(0) \cdot \boldsymbol{p}(0)$$

We can actually compose an adjoint system of the variation equation, Equation 11,

$$\dot{q}_i = \frac{q_i(t)}{\tau_i} - \sum_{j=1}^{n} \frac{f'(x_j(t))}{\tau_j} w_{ji} q_j(t) - \mu_i(t)(y_i(t) - d_i(t)) \tag{15}$$

where we put $p_i = (\partial y_i/\partial w_{kl})$, $A_{ij}(t) = (f'(x_i(t))/\tau_i)w_{ij} - (\delta_{ij}/\tau_i)$, $b_i(t) = (f'(x_i(t))/\tau_i)\delta_{ik} y_l(t)$, and $c_i(t) = \mu_i(t)(y_i(t) - d_i(t))$. With the boundary conditions $p_i(0) = (\partial y_i(0)/\partial w_{kl}) = 0$ and $q_i(T) = 0$, Green's equality becomes

$$\int_0^T \sum_{i=1}^{n} q_i(t) \frac{f'(x_i(t))}{\tau_i} \delta_{ik} y_l(t)dt = \int_0^T \sum_{i=1}^{n} \mu_i(t)(y_i(t) - d_i(t)) \frac{\partial y_i}{\partial w_{kl}}\, dt \tag{16}$$

Note that the right-hand side is identical to the error gradient (Equation 12). Thus, we have an alternative form of the error gradient

$$\frac{\partial E}{\partial w_{kl}} = \int_0^T q_k(t) \frac{f'(x_k(t))}{\tau_k} z_l(t)dt \tag{17}$$

Similarly, the error gradient for a time constant is given by

$$\frac{\partial E}{\partial \tau_k} = \int_0^T q_k(t) \frac{f'(x_k(t))}{\tau_k} (-\dot{y}_k(t))dt \tag{18}$$

As in the discrete-time case, we first run the network dynamics (Equation 9) forward in time and then run the adjoint system (Equation 15) backward in time with the terminal condition $q_i(T) = 0$. The weights are updated in batch by Equation 5.

## Technical Remarks

### *Forward or Backward?*

The forward algorithms require $O(n^4)$ computations. Therefore, it is not suitable for a fully connected network with tens or hundreds of units. However, for a small-sized network or a network with only local connections, on-line weight update can be an advantage.

In order to allow on-line weight update with the efficiency of the backward algorithm, a truncated version of the backpropagation-through-time algorithm has been proposed (Schmidhuber, 1992)

### *Teacher Forcing*

The so-called teacher forcing technique has been shown to be helpful, especially in training a network into an autonomous dynamical system (Doya and Yoshizawa, 1989; Williams and Zipser, 1989). In this scheme, the desired output $d_i(t)$ is used to drive the network dynamics in place of the feedback of its actual output $y_i(t)$.

The reasons for needing teacher forcing are:

- The state of the network is assigned to the desired one of the many attractor domains.
- In learning oscillatory patterns, unless the phase of the network output is synchronized to the teacher signal, there will be an apparently large error (Doya and Yoshizawa, 1989).
- It will avoid a local minimum solution of static output at the mean value of the dynamic teacher signal (Williams and Zipser, 1989).
- The linearized equation for a limit cycle trajectory is not asymptotically stable if the system is running autonomously (Doya, 1992).

One problem with this technique is that the trajectory learned with teacher forcing may not be stable when the network is run autonomously after learning. Several heuristics have been proposed for enhancing the stability of the nonforced trajectory:

*Noisy forcing*: Add some noise to the forcing input.

*Partial forcing*: Use a mixed input $z_i(t) = y_i(t) + \alpha(d_i(t) - y_i(t))$ with $0 < \alpha < 1$ and decrease the forcing rate $\alpha$ with the progress of learning.

*Part-time forcing*: Turn on forcing to synchronize the network to the teacher, and then turn off forcing to train the autonomous trajectory.

### *Bifurcation Boundaries*

In many learning tasks, the goal is not only to replicate particular sample trajectories but to reconstruct some *attractors* in the state space, such as fixed points, limit cycles, and chaotic attractors.

For example, when a network is trained as a finite-state machine, it must have distinct attractors in order to represent discrete states. As another example, when a network is trained as a periodic oscillator, it must have a limit cycle attractor. When we gradually change network parameters, we expect that the shape and location of the attractors will change continuously. However, that is not always true. At some points in the parameter space, attractors can emerge, disappear, or change their stability. Such a phenomenon is known as *bifurcation* in nonlinear systems theory (see Dynamics and Bifurcation in Neural Nets and Canonical Neural Models).

With some kinds of bifurcation, such as saddle-node bifurcation, the state of the network changes drastically. Even if the equilibrium or the trajectory persists, the linearized equations that are used for gradient computation can lose asymptotic stability. Accordingly, when the network goes through a bifurcation point, the solution of the learning equation can grow rapidly, and the gradient descent algorithm can be unstable (Doya, 1992).

Although this might sound like a rare, pathetic situation, bifurcation is actually an inevitable step in many learning tasks (Doya, 1992). If the connection weights $w_{ij}$ are initialized with small random values, the network dynamics has a single global attractor point. In order to have multiple attractor domains or a limit cycle, the network must go through some bifurcation boundary. Conversely, until the network goes through an appropriate bifurcation, even a simple memory task can be very difficult, owing to exponential decay of the error gradient.

### *Incremental Training*

It has been reported that gradual increase in the complexity of training examples is critical for successfully training a network as a finite-state machine (see Language Acquisition). A possible reason for this is that a network can acquire memory mechanisms only gradually, by going through bifurcation boundaries. If we impose examples that require many internal states with a long time delay from the beginning, we might simply mess up the network. This problem of the developmental capability of recurrent networks needs further examination.

## Discussion

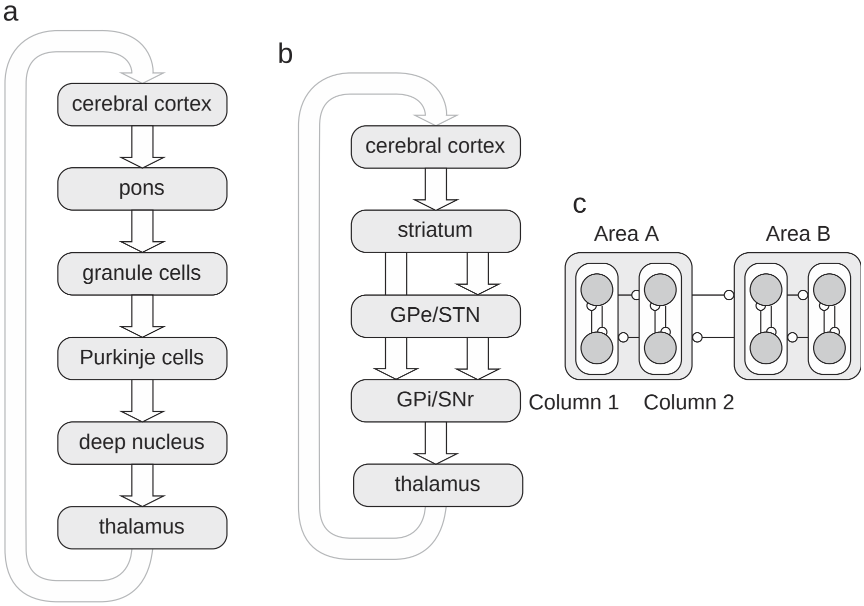
A fully connected recurrent neural network is potentially a very powerful system for temporal information processing. Based on the universal approximation theorem for three-layered networks (see Universal Approximators), it has been shown that a recurrent network can, with enough units, approximate any dynamical system (Funahashi and Nakamura, 1993). It has also been shown that a recurrent neural network, with its analog-valued computation, can have super-Turing computational power (see Neural Automata and Analog Computational Complexity). However, these theories do not guarantee that such a network can be readily realized by error gradient descent learning.

As already mentioned, the error gradient can decay or expand exponentially in time, which makes gradient descent more difficult than in the case of feedforward networks. Convergence of learning depends critically on the choice of network topology, initial weights, and the choice of training samples. These are some of the reasons why networks with specialized architectures have been crafted for specific problems, for example, networks with tapped delay-lines or local recurrent loops.

In a recent study of grammar learning (see Language Processing), recurrent neural networks were successfully trained to predict strings from context-free and context-sensitive languages (Rodriguez, 2001). In these examples, fractal structures in the network state space were utilized to approximate multiple "counters," which are necessary for processing complex grammatical structures such as palindromes. Interesting findings in such studies were that recurrent networks can generalize in terms of the depth of embedding.

Bayesian approaches have recently been applied to the learning of dynamics in recurrent networks (see Bayesian Methods and Neural Networks; Bayesian Networks; Graphical Models). A recurrent network can be trained by the method of extended Kalman filtering, which has properties similar to the RTRL algorithm with teacher forcing (Williams, 1992). EM methods for estimating the states of the hidden units and the weight parameters have been formulated (Ghahramani and Hinton, 2000). This seems to be a theoretically more sound way of nonlinear dynamical system estimation. However, since EM is essentially a local optimization process, whether this new wave of modeling methods can escape from the issue of bifurcation remains to be seen. Many recent approaches to temporal sequence processing are reviewed in Sun (2001) and other articles in the same book.

**Figure 2.** Network architectures of the cerebellum (*A*), the basal ganglia (*B*), and the cerebral cortex (*C*).



### *Biologically Inspired Learning Methods*

It has been suggested that the network architectures of the cerebellum, the basal ganglia, and the cerebral cortex are specialized for different frameworks of learning, namely, the cerebellum for supervised learning, the basal ganglia for reinforcement learning, and cerebral cortex for unsupervised learning (Doya, 1999). The circuits of the cerebellum (Figure 2*A*) and the basal ganglia (Figure 2*B*) have roughly feedforward structures. While learning in the cerebellum is characterized by specific error signals carried by the climbing fibers to the Purkinje cells, learning in the basal ganglia is characterized by the reward signal broadcasted by the dopaminergic input to the striatum (see CEREBELLUM AND MOTOR CONTROL and BASAL GANGLIA). They both form long recurrent loops starting from and ending in the cerebral cortex. The circuit of the cerebral cortex is characterized by massive recurrent connections, within and between functional columns, and between cortical areas (Figure 2*C*). Learning in the cerebral cortex is characterized by Hebbian learning (see CORTICAL HEBBIAN MODULES). Since the cerebral cortex embodies the most successful application of recurrent networks, both within the cortex and in the corticocerebellar and cortico–basal ganglia recurrent loops, it is natural to try to draw insights from the cortical network architecture.

The combination of recurrent excitation and lateral inhibition can implement a winner-take-all mechanism (see WINNER-TAKE-ALL NETWORKS). In combination with Hebbian plasticity and certain regulatory mechanisms, self-organization of feature detectors can be achieved (see SELF-ORGANIZATION AND THE BRAIN; COMPETITIVE LEARNING; HEBBIAN LEARNING AND NEURONAL REGULATION). This basic framework is shared by recent studies of receptive field formation and INDEPENDENT COMPONENT ANALYSIS (q.v.), which combine bottom-up Hebbian plasticity with lateral or top-down anti-Hebbian plasticity (see PATTERN FORMATION, NEURAL; INDEPENDENT COMPONENT ANALYSIS; UNSUPERVISED LEARNING WITH GLOBAL OBJECTIVE FUNCTIONS).

The Boltzmann Machine (see SIMULATED ANNEALING AND BOLTZMANN MACHINES) with its wake and sleep modes, is another basic model of cortical processing. Its extension to layered recurrent networks, the Helmholtz machine, is capable of extracting the hidden structure of sensory data and reproducing the data by top-down processing (see HELMHOLTZ MACHINES AND SLEEP-WAKE LEARNING).

One of the main open issues in REINFORCEMENT LEARNING (q.v.) is how to learn a good behavior when the environmental states are not perfectly observable (see IDENTIFICATION AND CONTROL). In such a case, the agent should store a certain “belief state” and update it according to the model of the environment. Actions are chosen according to the predicted future reward based on the belief state. Such complex operations could be implemented in the corticocerebellar and corticobasal ganglia loops, with the cerebral cortex representing the belief state, the cerebellum implementing the internal model of the environment, and the basal ganglia predicting the future reward. Better understanding of the corticocerebellar–basal ganglia system may give some clue for designing an adaptive agent under uncertainty.

## Introduction

Dynamic recurrent network models can provide invaluable tools to help systems neurophysiologists understand the neural mechanisms mediating behavior. They can help overcome the limitations of biological experiments, which typically provide limited samples of the system, such as anatomical structures and their connections, the effects of lesions on behavior, or the activity of single neurons in behaving animals. The missing element required to synthesize these pieces can be provided by neural network models of the complete system. New algorithms make it possible to derive networks that simulate dynamic sensorimotor behavior and incorporate anatomically appropriate recurrent connectivity. The resulting networks determine the remaining free parameters based on examples of the behavior itself.

Training procedures initially developed for feedforward networks have been extended to dynamic recurrent networks, which differ from other modeling approaches in three key properties. First, the units are *dynamic*, meaning they can exhibit time-varying activity that can represent the mean firing rates of single or multiple neurons, membrane potentials, or some relevant time-varying stimulus or motor parameter. Second, the networks can have *recurrent* connectivity, including feedback and cross-connections. Third, the network connections required to simulate a particular dynamic behavior can be derived from examples of the behavior by *gradient descent* methods, such as backpropagated error correction. The resulting models provide complete neural network solutions of the behavior, insofar as they determine all the connections and activations of the units that simulate the behavior.

Neural networks that emulate particular dynamic behaviors basically transform spatiotemporal inputs into appropriate spatiotemporal outputs. These networks are usually comprised of interconnected "sigmoidal" units (units whose outputs are sigmoidal functions of their inputs); this mimics a biological neuron's property of saturating at maximal rates for large inputs and decreasing to zero for low inputs.

To illustrate the training procedure, Figure 1 shows a representative network of such units, with input and output patterns that simulate a target-tracking task. Four input units carry signals representing the step changes in target locations; eight output patterns represent the firing rates of motor units in monkeys tracking such targets. To train the network, the synaptic weights between units are initially assigned randomly and the output response of the network is determined. The difference between network output patterns N(t) and the desired target output activations T(t) is the error E(t). The backpropagation algorithm calculates the weight changes that would reduce this error, and therefore implements a "gradient descent" of the error as a function of the weights (Figure 1, inset). The process of presenting input patterns and changing the weights to reduce the remaining error is iterated until the network converges on a solution with minimal error. Various training methods for recurrent networks are presented in Williams and Zipser (1989) (see also Recurrent Networks: Learning Algorithms). It should be recognized that backpropagation is not a model for biological learning, simply an effective method of obtaining a solution. Biologically plausible learning algorithms will also find the same solutions, but usually take longer (Mazzoni, Andersen, and Jordan, 1991; see also Reinforcement Learning in Motor Control).

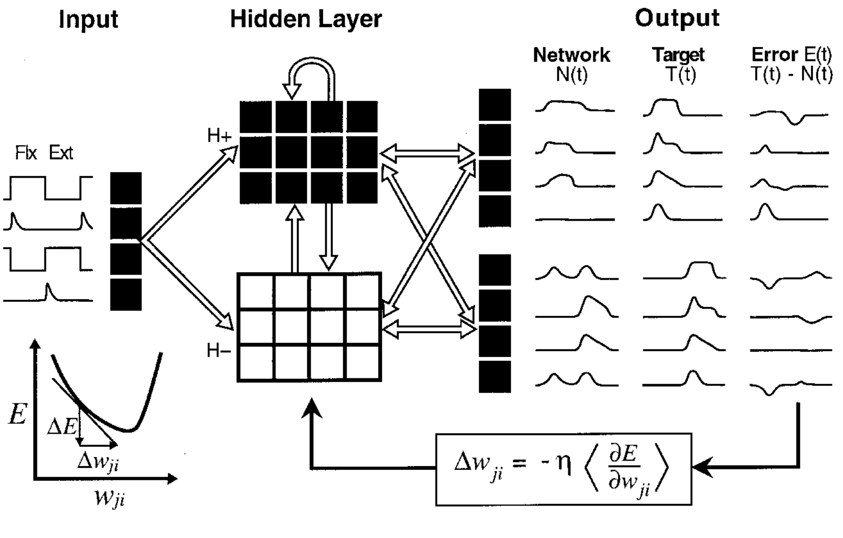

**Figure 1.** Typical network architecture and training procedure used with dynamic recurrent networks. This network simulates the step-tracking task. The network input consists of four representations of the step target position and target change; the output represents the firing patterns of eight representative motor units in flexor and extensor muscles. The intervening hidden units consist of excitatory and inhibitory groups, with distributed connections indicated by the open arrows. Network training proceeds by calculating the difference between the network output [N(t)] and the desired target activations [T(t)], and changing the connection weights in such a way as to reduce the error [E(t)]. Inset at lower left illustrates the error as a function of one weight, and how the gradient of this function is used to determine the appropriate weight change.

Other algorithms, such as genetic algorithms (see LOCOMOTION, VERTEBRATE) or random weight perturbations (Arnold and Robinson, 1991), can also be applied when the unit input-output functions are not differentiable.

## Applications

The applications of these dynamic recurrent networks fall into three general categories:

1. *Pattern recognition* applications involve sorting of spatiotemporal input patterns into discrete categories. A set of input units receiving time-varying signals can represent a spatiotemporal pattern, and the output codes the appropriate categories.

2. *Pattern generation* networks produce temporal patterns in one or more output units, either autonomously or under the control of a gating input. These include oscillating networks (Williams and Zipser, 1989) and simulations of central pattern generators (Tsung, Cottrell, and Selverston, 1990; Rowat and Selverston, 1993; Lansner, Kotaleski, and Grillner, 1998; see also ACTIVITY-DEPENDENT REGULATION OF NEURONAL CONDUCTANCES).

3. *Pattern transformation* networks convert spatiotemporal input patterns into spatiotemporal outputs. Examples include simulations of the leech withdrawal reflex (Lockery and Sejnowski, 1992), step target tracking in the primate (Fetz, 1993), the vestibulo-ocular reflex (Arnold and Robinson, 1991; Lisberger and Sejnowski, 1992) and short-term memory tasks (Zipser, 1991; Moody et al., 1998). Recurrent networks can also simulate analytical transforms such as integration and differentiation of input signals (Munro, Shupe, and Fetz, 1994).

### *Oscillating Networks*

Among the many examples of autonomously generated periodic motor activity to be found in biological systems are locomotion, mastication, and respiration. The neural circuitry underlying cyclic periodic movements has been called a *central pattern generator* (CPG). Williams and Zipser (1989) first trained dynamic recurrent networks to generate oscillatory activity with various frequencies. The smallest circuit that sustained quasi-sinusoidal oscillations consisted of two interconnected sigmoidal units.

Tsung et al. (1990) trained a network with the connectivity and sign constraints of neurons in the lobster gastric mill circuit to simulate their oscillatory activity. This network replicated the correct phase relations of the biological interneurons. If its activity was perturbed, the network reverted to the original pattern, indicating that the weights found by the learning algorithm represented a strong limit cycle attractor. Dynamic recurrent networks simulating the oscillatory activity of the gastric mill circuit have shown remarkably robust abilities to mimic the observed patterns (Rowat and Selverston, 1993; see also ACTIVITY-DEPENDENT REGULATION OF NEURONAL CONDUCTANCES).

### *Primate Target Tracking*

We used dynamic networks to simulate the neural circuitry controlling forelimb muscles of the primate. In monkeys performing a step-tracking task, physiological experiments documented the discharge patterns and output connections of task-related neurons. Premotoneural (PreM) cells were identified by postspike facilitation of target muscle activity in spike-triggered averages of EMG. During alternating wrist movements, the response patterns of different PreM cells—corticomotorneuronal (CM), rubromotorneuronal (RM), dorsal root afferents, and PreM interneurons—as well as of single motor units (MU) of agonist muscles fall into specific classes (Fetz et al., 1989). All groups include cells that exhibit phasic-tonic, tonic, or phasic discharge, as well as cells with unique firing properties. Many MUs show decrementing discharge through the static hold period. Some RM cells fire during both flexion and extension, and some are unmodulated with the task.

To investigate the function of these diverse cells and to determine what other types of discharge patterns might be required to transform a step signal to the observed output of motor neurons, we derived dynamic networks that generated as outputs the average firing rates of motor units recorded in monkeys performing a step-tracking task (Figure 1). Changes in target position are represented by step inputs to the network and/or by brief transient bursts at the onset of target changes. The input signals are transformed to eight output patterns by intervening hidden units consisting of interconnected excitatory and inhibitory units.

The activation patterns and connection matrix of units in such networks are illustrated elsewhere (Fetz, 1993). In these simulations the network solutions have features that resemble biological situations but that were not explicitly incorporated: (1) Divergent connections of hidden units to different co-activated motor units are representative of divergent outputs of physiological PreM neurons (Fetz et al., 1989). (2) Some hidden units have counterintuitive discharge patterns also seen in biological neurons, e.g., bidirectional and sustained activity. (3) Different network simulations with the same architecture but initialized with different weights often converged on different solutions, comparable to the diversity of neural relations seen in biological networks

A useful heuristic feature of these networks is the ability to quickly probe their operation with manipulations (Fetz, 1993). The contributions of hidden units can be tested by making selective *lesions* and analyzing the behavior of the remaining network. The output effects of a given unit can also be tested by delivering a simulated *stimulus* and analyzing the propagated network response. Because of changing activation levels, the effect of a stimulus depends on the time it is delivered, as is also observed in physiological experiments. These networks can also be trained to scale their responses, that is, to generate output activation patterns proportional to the size of the input. Their ability to generalize can be quickly tested by presenting different inputs.

To generate more realistic models of the primate motor system, the same approach has been used with networks incorporating additional biological features (Maier, Shupe, and Fetz, 1993): (1) the connectivity of central and segmental neurons was included with appropriate conduction delays; (2) the known activity of some central units was required to be part of the solution; and (3) in addition to the active target-tracking task, the network was required to simulate reflex responses to peripheral perturbations of the limb. The resulting networks can generate both types of behaviors and have more realistic properties. Some complex activity patterns seen in PreM neurons of monkeys, such as bidirectional responses of RM cells, also appear in the networks. Even some apparently paradoxical relations seen in monkeys, such as PreM units that covary with muscles that they inhibit, appear in networks and make contributions that are understandable in terms of other units: their activity subtracts out inappropriate components of bidirectional activity patterns. Thus, network simulations have proved useful in elucidating the function of many puzzling features of biological networks.

In contrast to such simulations of a specific neuronal system, others have modeled the representation of reaching movements, as described in REACHING MOVEMENTS: IMPLICATIONS FOR CONNECTIONIST MODELS.

### *Short-Term Memory Tasks*

Neural mechanisms of short-term memory have been investigated in many experiments by recording cortical cell activity in animals performing instructed delay tasks. A common type of instructed delay task involves the requirement to remember the value of a particular stimulus. Zipser (1991) trained recurrent networks to simulate short-term memory of an analog value during the delay; the resulting network implements a sample-and-hold function. The network has two inputs: an analog signal representing the stimulus value to be remembered and a gate signal specifying the times to take samples. The network output is the value of the analog input at the time of the previous gate. During the delay between gate signals, the activity of many hidden units resembles the response patterns of cortical neurons recorded in monkeys performing comparable instructed delay tasks. The activity patterns of hidden units, like those of cortical neurons, fall into three main classes: sustained activation proportional to the remembered analog value, often with a decay or rise; transient modulation during the gate signal; and combinations of the two. The network simulations allow the function of the patterns observed in the animal to be interpreted in terms of their possible role in the memory task.

We investigated such short-term memory networks to further analyze their operation. To elucidate the underlying computational algorithm, we constrained units to have either excitatory or inhibitory output weights, and reduced the network to the minimal essential network. A larger network was initially trained, then reduced by (1) combining units with similar responses and connections into one equivalent unit and (2) eliminating units with negligible activation or weak connections, then (3) retraining the smaller networks to perform the same operation. A reduced network performing the sample-and-hold function (Figure 2) consists of three excitatory and one inhibitory unit. The two inputs are the sample gate signal (S) and the analog variable (A); the output (O) is the value of A at the last sample gate. This reduced version reveals a computational algorithm that exploits the nonlinear sigmoidal input-output function of the units. The first excitatory unit (SA) carries a transient signal proportional to the value of A at the time of the gate. This signal is derived by clipping the sum of the analog and gating inputs with a negative bias, as shown by the input weights to SA in the first column. This input sample is then fed to two excitatory units (M1 and M2) that maintain their activity by reciprocal connections and also feed their summed activity to the output (M1 and M2 could also be replaced by a single self-connected M unit). The inhibitory unit (SM) carries a transient signal proportional to the previous value of A. Its value is derived from a clipped sum of the gate S and the previous values held in M1 and M2. The function of SM is to subtract the previously held value from the integrating hidden units and from the output. Thus, the network uses nonlinearity and integration to yield the appropriate remembered value.

More sophisticated recurrent networks have been derived that perform delayed matching-to-sample tasks (Moody et al., 1998). These networks identified test stimuli presented at the location of a previous sample and ignored intervening distractor stimuli. In reduced networks, the hidden units performed either storage or comparator functions. Another form of spatial memory is involved in making delayed saccades to remembered targets. This function can be simulated in networks whose inputs represent visual targets in space and eye position, and whose hidden units have recurrent connections. The outputs can represent either motor error (Xing and Andersen, 2000) or stored locations in retinal and head-centered coordinates that remain stable in the face of intervening saccades (Mitchell and Zipser, 2001).

## *Neural Integration*

In biological motor systems, neural integrators have been postulated to transform transient commands into sustained activity and to mediate the vestibulo-ocular reflex (VOR) (see Vestibulo-Ocular Reflex). Arnold and Robinson (1991) modeled the VOR integrator with a recurrent network whose connections resembled those of the vestibulo-ocular system. Two input signals represented the reciprocal responses of opposed vestibular afferents to head movement; these connected to four interneurons that were interconnected to each other and to motor neurons. Since vestibular afferents carry tonic activity in the absence of head movement, the integrator had to be configured so as to integrate only deviations from baseline, but not the baseline activity itself. The authors used units with intrinsically sustained activity with decay and a nondifferentiable rectifying input-output characteristic. To train the networks, they tweaked individual weights, and used the effect on the error to update the weights. Integration was performed through positive recurrent connections between the interneurons. The networks could mimic physiological responses to lesions and postsaccadic drift.

Lisberger and Sejnowski (1992) used dynamic networks to investigate mechanisms of learning in the vestibulo-ocular system. The network was constructed to include many anatomical and physiological constraints, including pathways through the cerebellar flocculus, with appropriate delays. The two inputs to the network, head velocity and target velocity, were converted to a single output: eye velocity. The network was initially trained to simulate three behaviors: smooth pursuit of a moving visual target, the VOR to head movement, and suppression of the VOR (when head and target move together). Then the network was required to change the gain of the VOR (as occurs after wearing magnifying or minifying goggles) and also to maintain accurate smooth pursuit visual

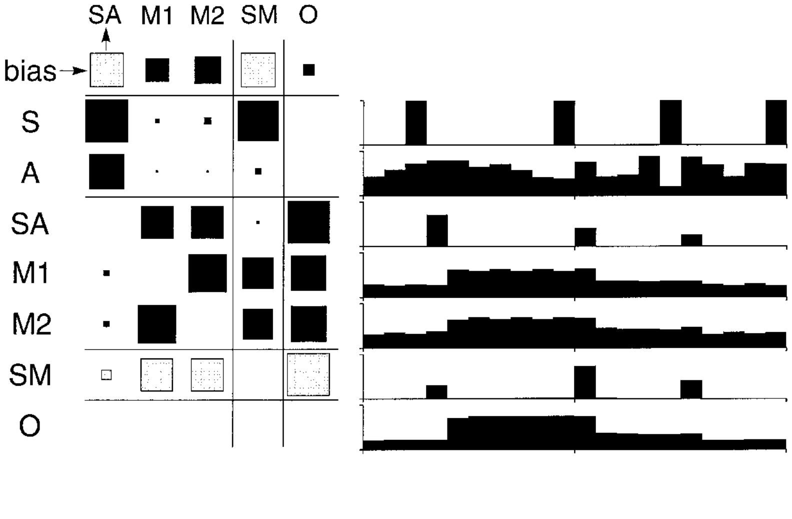

**Figure 2.** Reduced network performing a sample-and-hold function, simulating short-term memory. The units are indicated by abbreviations and representative activation patterns at right. The weights are indicated by squares (black = excitatory; gray = inhibitory) proportional to the connection from row unit to column unit (e.g., arrows). The two inputs are the sample signal (S) and a random analog value (A); the output (O) is the sustained value of the last sampled analog value.

tracking. Performing these functions required changes in the connection weights at both of two specific sites: the vestibular input to the flocculus and to the brainstem neurons controlling oculomotor neurons. This study exemplifies the insights gained from a biologically constrained dynamic model that can incorporate the time course of neural activity observed under different behavioral conditions, and shows the power of such simulations to reveal novel network mechanisms.

## Discussion

The unique insights provided by neural network simulations assures their continued use in elucidating the operations of neural systems. The basic limitation of conventional physiological and antomical data is that they provide a selective sample of a complex system, leaving a gap between particular glimpses of neural activity or anatomical structure and the behavior of the overall system. This gap is usually bridged by intuitive inferences, often based on selective interpretations of the data (Fetz, 1992). A more objective approach would be to derive neural network models that simulate the behavior. These models can incorporate the observed responses of units and can help explain the functional meaning of neural patterns. Thus, integrative neurophysiologists can profitably use a combination of unit recording and neural modeling to elucidate network mechanisms. To the extent that models can incorporate anatomical and physiological constraints, they can provide plausible explanations of the biological neural mechanisms mediating behavior.

# Reinforcement Learning

*Andrew G. Barto*

## Introduction

The term *reinforcement* comes from studies of animal learning in experimental psychology, where it refers to the occurrence of an event, in the proper relation to a response, that tends to increase the probability that the response will occur again in the same situation. Although not used by psychologists, the expression *reinforcement learning* has been widely adopted by theorists in artificial intelligence and engineering to refer to learning tasks and algorithms based on this principle of reinforcement. The simplest reinforcement learning methods use the commonsense idea that if an action is followed by a satisfactory state of affairs, or an improvement in the state of affairs, then the tendency to produce that action is strengthened, i.e., reinforced. The ideas of reinforcement learning have been present in engineering for many decades (e.g., Mendel and McClaren, 1970) and in artificial intelligence since its earliest days (Turing, 1950; Minsky, 1954, 1961; Samuel, 1959). It is only relatively recently, however, that the development and application of reinforcement learning methods have occupied a significant number of researchers in these fields. Fueling this interest are two basic challenges: (1) designing autonomous robotic agents that can operate under uncertainty in complex dynamic environments, and (2) finding useful approximate solutions to very-large-scale dynamic decision-making problems.

Reinforcement learning is usually formulated as an *optimization problem* with the objective of finding a strategy for producing actions that is optimal, or best, in some well-defined way. In practice, however, it is usually more important for a reinforcement learning system to continue to improve than it is for it to actually achieve optimal behavior. Reinforcement learning differs from the more commonly studied paradigm of supervised learning, or "learning with a teacher," in significant ways that we discuss in the course of this article. It also differs significantly from various forms of unsupervised learning. The article Reinforcement Learnining in Motor Control (q.v.) contains additional information. For a more detailed introductory treatment, the reader should consult Sutton and Barto (1998); for a more in-depth mathematical treatment, the reader should consult Bertsekas and Tsitsiklis (1996).

## The Reinforcement Learning Problem

Think of an agent interacting with its environment over a potentially infinite sequence of discrete-time steps $t = 1, 2, 3, \ldots$. At each time step $t$, the reinforcement learning agent receives some representation of the environment's current *state*, $s_t \in S$, where $S$ is the set of possible states, and on that basis executes an *action*, $a_t \in A(s_t)$, where $A(s_t)$ is the set of actions that can be executed in state $s_t$. One time step later, the agent receives a *reward*, $r_{t+1}$, a real number, and finds itself facing a new state, $s_{t+1} \in S$ (Figure 1). The reward and new state are influenced not only by the agent's action, they are also influenced by the state, $s_t$, in which the action was taken, and they can depend on random factors as well. Throughout this article we assume that $S$ and $A(s)$, $s \in S$, are finite sets, but extension to infinite sets is possible, as is extension to continuous-time formulations.

The rule the agent uses to select actions is called its *policy*. It is a function, often denoted $\pi$, that for each state assigns a probability to each possible action: for all $s \in S$ and all $a \in A(s)$, $\pi(s, a)$ is the probability that the agent executes $a$ when in state $s$. While interacting with its environment, a reinforcement learning agent adjusts its policy based on its accumulating experience to try to improve the the amount of reward it receives over time. More specifically, it tries to maximize the *return* it receives after each time step. The most commonly studied type of return is the *discounted return*. If $r_{t+1}$, $r_{t+2}$, $r_{t+3}, \ldots$, denotes the sequence of rewards received after time step $t$, then the discounted return for step $t$ is

$$\sum_{k=0}^{\infty} \gamma^k r_{t+k+1} \tag{1}$$

where $\gamma \in [0, 1)$ is the *discount factor*. A reinforcement learning agent adjusts its policy to try to maximize the expected value of this quantity for all $t \geq 0$.

The discount factor determines the present value of future rewards. If $\gamma = 0$, the agent is only concerned with maximizing immediate rewards: its objective would be to learn how to act at each time step $t$ so as maximize only $r_{t+1}$. But in general, acting to maximize immediate reward can reduce access to future rewards, so that a longer-term return may actually be reduced. As $\gamma$ approaches one, the objective takes future rewards into account more strongly: the agent becomes more far-sighted. Discounting is used because it is mathematically the simplest way to deal with cases in which the agent and environment can interact for an unbounded number of time steps. In many problems only finite numbers of steps can ever happen in each learning trial, so that $\gamma$ can be set to one. These are called *episodic* problems. Other definitions of return have been extensively studied as well.

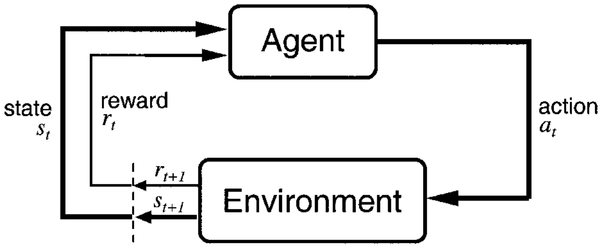

**Figure 1.** A reinforcement learning model. A reinforcement learning agent and its environment interact over a sequence of discrete-time steps. The *actions* are the choices made by the agent, the *states* provide the agent's basis for making the choices, and the *rewards* are the basis for evaluating these choices. (From Sutton, R. S., and Barto, A. G., 1998, *Reinforcement Learning*: *An Introduction*, Cambridge, MA: MIT Press.)

This model of the reinforcement learning problem is based on the theory of *Markov decision processes* (MDPs), which has been extensively developed in decision theory and stochastic control (see, e.g., Bertsekas, 1987). An MDP has the property that the environment satisfies the Markov property, which means that environment state at any time step $t > 0$ provides the same information about what will happen next as would the entire history of the process up to step $t$. A full specification of an MDP includes the probabilistic details of how state transitions and rewards are influenced by states and actions, i.e., a full probabilistic model of the environment and how it is influenced by the agent's actions. The objective is to compute an *optimal policy*, i.e., a policy that maximizes the expected return from each state. In theory, this can be done using any of several stochastic dynamic programming algorithms, although their computational complexity makes them impractical for large-scale problems.

Reinforcement learning has much in common with this traditional study of MDPs, but it emphasizes approximating optimal behavior during on-line behavior instead of computating optimal policies off-line on the basis of known probabilistic models. In particular, the objective in reinforcement learning is actually not to compute an optimal policy; it is instead to allow the agent to receive as much reward as possible during its behavior. This does not always require a policy that is optimal for all possible states, since the agent may not visit all of these states while it is behaving.

Following are some key observations about the reinforcement learning problem:

1. *Uncertainty* plays a central role in reinforcement learning. The agent's environment and its own behavior can be subject to random fluctuations, so that the outcomes of decisions cannot be known beforehand with complete certainty. An accurate probabilistic model of the these uncertainties may or may not be available to the agent.
2. The reward input to the agent can be any scalar signal evaluating the agent's behavior. It might indicate just success when a goal state is reached or just failure while not reaching a goal state; or it might provide moment-by-moment evaluations of ongoing behavior (as, for example, in giving the amount of energy currently being consumed while a task is being accomplished). Moreover, multiple evaluation criteria can be combined in various ways to form the scalar reward signal (for example, via a weighted sum).
3. An important difficulty faced by a reinforcement learning system is the *credit-assignment problem* (Minsky, 1961): How do you distribute credit for success among the many decisions that may have been involved in producing it? (see also Reinforcement Learning in Motor Control).
4. A reinforcement learning system often has to forgo immediate reward in order to obtain more reward later or over the long run. This kind of "sacrificing" behavior arises because the agent's actions influence not only each reward input but also the environment's state transitions. An action may be preferred because it sets the stage for a large reward later rather than for its immediate reward.
5. The reward signal does not directly tell the agent what action is best; it only evaluates the action taken. A reward input also does not directly tell the agent how to change its actions. These are key features distinguishing reinforcement learning from supervised learning, and we discuss them further below.
6. Reinforcement learning algorithms are *selectional* processes. There must be *variety* in the action-generation process so that

the consequences of alternative actions can be compared to select the best. Behavioral variety is called *exploration*; it is often generated through randomness, but it need not be.

7. Reinforcement learning involves a conflict between *exploitation* and *exploration*. In deciding which action to take, the agent has to balance two conflicting objectives: it has to exploit what it has already learned to obtain high rewards, and it has to behave in new ways—explore—to learn more. Because these needs ordinarily conflict, reinforcement learning systems have to somehow balance them. In control engineering, this is known as the conflict between control and identification.
8. Some researchers think of reinforcement learning as a form of supervised learning (because the reward input is a kind of supervision), and others think of it as a form of unsupervised learning (because the reward input is not like the label of an example). There is some truth to each of these views, but reinforcement learning is really different from both. A key distinguishing feature is the presence in reinforcement learning of the conflict between exploitation and exploration. This is absent from supervised and unsupervised learning unless the learning system is also engaged in influencing which training examples it sees.

## Value Functions

The most commonly studied reinforcement learning algorithms are based on estimating *value functions*, which are scalar functions of states, or of state-action pairs, that tell how good it is for the agent to be in a state, or to take an action in a state. The notion of "how good" is the return expected to accumulate over the future, which is well-defined if the Markov property holds and the agent's policy is specified.

If the agent uses policy $\pi$, then the state value function $V^\pi$ gives the *value*, $V^\pi(s)$, of each $s \in S$, which is the return expected to accumulate over the time period after visiting $s$, assuming that actions are chosen according to $\pi$. For the discounted return defined by Equation 1, the value of state $s$ is

$$V^\pi(s) = E_\pi\left[\sum_{k=0}^{\infty} \gamma^k r_{t+k+1} \middle| s_t = s\right]$$

where $E_\pi$ is the expected value given that policy $\pi$ is followed. A state's *optimal value*, $V^*(s)$, is the return expected after visiting $s$, assuming that actions are chosen optimally; i.e., it is the largest expected return possible after visiting $s$.

Similarly, the *action value* of taking action $a$ in state $s$ under a policy $\pi$, denoted $Q^\pi(s, a)$, is the expected return starting from $s$, taking the action $a$, and thereafter following policy $\pi$:

$$Q^\pi(s, a) = E_\pi\left[\sum_{k=0}^{\infty} \gamma^k r_{t+k+1} \middle| s_t = s, a_t = a\right]$$

The *optimal action value* of taking action $a$ in state $s$, denoted $Q^*(s, a)$, is the expected return starting from $s$, taking the action $a$, and thereafter following an optimal policy.

Value functions are useful because of several properties of MDPs. If $V^*$ is known, optimal policies can be found by looking ahead only one time step. That is, if $s_t$ is the state at step $t$, then an optimal action is any $a \in A(s_t)$ that maximizes the expected value of $r_{t+1} + \gamma V^*(s_{t+1})$. Thus, given $V^*$ and an accurate model of the immediate effects on the environment of all of the actions, acting optimally does not require deep look-ahead because $V^*$ summarizes the effects of future behavior. If $Q^*$ is known, then finding optimal actions is even easier. An optimal action at step $t$ is any action that maximizes $Q^*(s_t, a)$. In this case, it is not necessary to look ahead one step, so that no model is needed of the effect of actions on the environment. This is what makes reinforcement learning algorithms that use action-value functions a popular choice in many applications. Any such one-step-ahead maximizing action for a state value function, or a maximizing action for an action value function, is called a *greedy* action with respect to that function.

Value functions that depend on a policy, that is, $V^\pi$ and $Q^\pi$, are useful for improving behavior because of the *policy improvement property*. Suppose the agent is deciding which action to execute in a state. It could pick an action using its current policy, $\pi$, or it could select some other action. If it picks an action that is greedy with respect to $V^\pi$, and otherwise follows $\pi$, then its performance is guaranteed to be at least as good as it would have been under $\pi$, and possibly better. This fact is the basis of the policy improvement, or policy iteration, dynamic programming algorithm, and it motivates many reinforcement learning algorithms, as we explain below.

A fundamental property of value functions is that they satisfy particular consistency conditions if the Markov property holds. For any policy $\pi$ and any state $s$, the following is true (for the discounted return case):

$$\begin{aligned} V^\pi(s) &= E_\pi\left[\sum_{k=0}^{\infty} \gamma^k r_{t+k+1} \middle| s_t = s\right] \\ &= E_\pi\left[r_{t+1} + \gamma \sum_{k=0}^{\infty} \gamma^k r_{t+k+2} \middle| s_t = s\right] \\ &= E_\pi\ [r_{t+1} + \gamma V^\pi(s_{t+1}) | s_t = s] \end{aligned} \tag{2}$$

An analogous consistency condition holds for values of $Q^\pi$. Similarly, $V^*$ satisfies the following equation for all $s \in S$:

$$V^*(s) = \max_a E[r_{t+1} + \gamma V^*(s_{t+1}) | s_t = s, a_t = a]$$

and $Q^*$ satisfies

$$Q^*(s, a) = E[r_{t+1} + \gamma \max_{a'} Q^*(s_{t+1}, a') | s_t = s, a_t = a]$$

for all pairs $(s, a)$, $s \in S$, $a \in A(s)$.

If a model is available giving the probabilistic details of how the environment responds to actions, then these equations (or, more precisely, these *sets* of equations) are completely specified and can in principle be solved using one of a variety of methods for solving systems of linear equations (to obtain $V^\pi$ or $Q^\pi$) or nonlinear equations (to obtain $V^*$ or $Q^*$). These are often called *Bellman equations*, after Richard Bellman, who introduced the term *dynamic programming* to refer to a collection of solution methods (Bellman, 1957). There are many books that explain dynamic programming (e.g., Bertsekas, 1987).

Solving Bellman equations is therefore one route to finding optimal policies. Unfortunately, in many problems of interest one does not have the complete Markov model of the environment needed to fully define the Bellman equations, or the state set may be so large that it is not computationally feasible to exactly solve the Bellman equations. Unless some special additional structure can be exploited, one has to settle for approximate solutions.

## Reinforcement Learning Based on Value Functions

Value functions are used in several different ways in reinforcement learning. One approach uses the *actor-critic architecture*, which maintains a representation of both a value function and a policy (Figure 2). To select actions, an agent using this architecture consults its current policy, represented by the *actor* component. The policy might be represented by a lookup table, by an artificial neural network, with its input coding the current state and its output coding the action to be taken, or by some other means. To evaluate the action just taken, the *critic* component is consulted, which

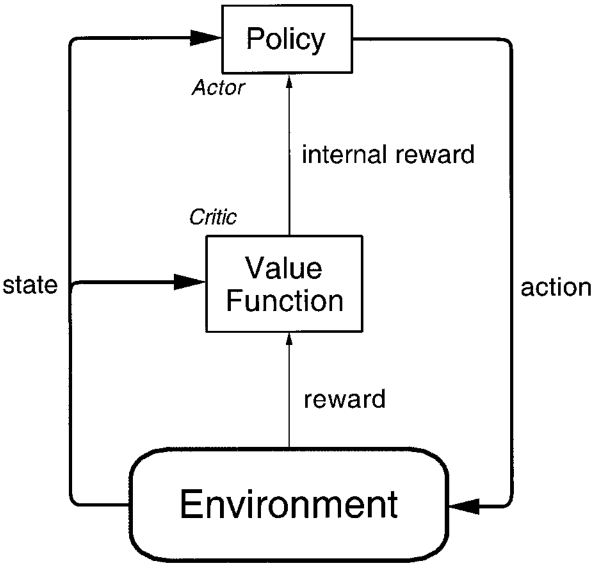

**Figure 2.** Actor-critic architecture. The *critic* provides an internal reward signal to an *actor*, which learns a policy for interacting with the environment.

maintains an estimate of the value function of the current policy. The action is considered to be "good" ("bad") to the extent that it leads to a next state with a value higher (lower) than that of $s$, both state values being estimated by the critic. Upon receiving this evaluation, the actor updates the policy by making a good action more likely to be selected on revisiting $s$, or a bad action less likely, thus implementing a version of Edward Thorndike's famous Law of Effect (Thorndike, 1911). The critic component then updates its value function estimate using a temporal difference learning algorithm of the kind described below.

Barto, Sutton, and Anderson (1983) used this architecture for learning to balance a simulated pole mounted on a cart. Their perspective was that the critic provides an internal reinforcement signal—changes in estimated values—that provides *immediate* action evaluations, even though the goal is to maximize reward over the long term. To the extent that the critic's value estimates are correct given the actor's current policy, the actor actually learns to increase the total amount of future reinforcement. This method thus relies on the policy improvement property. Although not a fail-safe approach from a theoretical perspective, it is often successful in improving the agent's behavior.

Another type of reinforcement learning algorithm that uses value functions maintains an estimate of the current policy's value function but does not keep an explicit representation of the current policy. Instead, it selects actions solely by consulting its current value function estimate. At each time step, the agent selects an action that is either greedy with respect to its current estimate of the value function or is an exploratory action chosen on some other basis (see below). If state values are being estimated, finding a greedy action requires projecting ahead one step using an environment model; if action values are being estimated, no look-ahead is required, as explained above. Like actor-critic methods, this approach also relies on the policy improvement property, but since there is no separate policy representation and no separate policy update rule, it is more closely related to various dynamic programming algorithms and is therefore somewhat easier to understand.

## Estimating Value Functions

The simplest method for estimating the value function of the current policy while the agent is behaving is to average an ensemble of returns actually observed. For example, if an agent follows policy $\pi$ and maintains, for each state $s$ encountered, an average of the actual returns that have followed that state, then the averages will converge to $V^\pi(s)$ as the number of times that state is encountered approaches infinity. If separate averages are kept for each action, $a$, taken in a state, then these averages will similarly converge to the action values, $Q^\pi(s, a)$. This is easiest to do in episodic problems, where return is accumulated over finite numbers of time steps. Methods like this are sometimes called *simple Monte Carlo* value estimation methods.

Another class of value estimation methods are called *temporal difference* (TD) algorithms (Sutton, 1988). The most basic TD algorithm, called *tabular TD(0)*, estimates $V^\pi$ while the agent is behaving according to $\pi$ and is applicable when the state set is small enough to store the state values in a lookup table with a separate entry for the value of each state. Suppose the agent is in state $s$, executes action $a$, and then observes the resulting reward $r$ and the next state $s'$. TD(0) updates the current estimate of the value of state $s$, $V(s)$, using the following update:

$$V(s) \leftarrow V(s) + \alpha[r + \gamma V(s') - V(s)] \tag{3}$$

where $\alpha$ is a positive step-size parameter. TD algorithms are based on the consistency condition expressed by the Bellman equations. This TD algorithm is designed to move the term $r + \gamma V(s') - V(s)$, called the *TD error*, toward zero for every state. If the expected TD error could be made to equal zero for every state, then the corresponding Bellman equation (Equation 2) would be satisfied. An update of this general form is often called a *backup* because the value of a state is moved toward the current value of a successor state, plus any reward that is received on the transition.

This algorithm converges to the correct state values under certain conditions (Sutton, 1988). This and other TD algorithms have been extended to include *eligibility traces*, which allow values to be backed up over more than one time step. When so extended, these are called TD($\lambda$) algorithms, where $\lambda$ is a parameter determining the temporal characteristics of the backups: $\lambda$ ranges from zero (no eligibility traces as above) to one (resulting in a simple Monte Carlo method). Forms of this TD algorithm are also known as *adaptive critic algorithms*.

Another TD algorithm, known as *Q-learning*, was proposed by Watkins in 1989 (see Sutton and Barto, 1998). This algorithm directly estimates $Q^*$ without relying on the policy improvement property. Its tabular form works as follows. Suppose the agent is in state $s$, executes action $a$, and then observes the resulting reward $r$ and the next state $s'$. The Q-learning algorithm updates the action value estimate, $Q(s, a)$, of the pair $(s, a)$ using the following backup:

$$Q(s, a) \leftarrow Q(s, a) + \alpha[r + \gamma \max_{a'} Q(s', a') - Q(s, a)] \tag{4}$$

where $\alpha$ is a positive step-size parameter. If $\alpha$ decreases appropriately with time and each state-action pair is visited infinitely often in the limit, then this algorithm converges to $Q^*(s, a)$ for all $s \in S$ and $a \in A(s)$ with probability one. Unless it is known that the environment is deterministic, the "infinitely often" requirement is necessary for this kind of strong convergence of any method that is based, as this one is, on sampling environment state transitions and rewards. Letting the agent sometimes select actions randomly from a uniform distribution is one simple way to help the agent maintain enough variety in its behavior to try to satisfy this condition. Otherwise, the agent executes actions that are greedy with respect to its current estimate of $Q^*$.

Closely related to Q-learning is the *Sarsa* algorithm. Suppose the agent is in state $s$, executes action $a$, observes reward $r$ and the next state $s'$, and then executes action $a'$. Then the Sarsa update is

$$Q(s, a) \leftarrow Q(s, a) + \alpha[r + \gamma Q(s', a') - Q(s, a)]$$

which is the same as the Q-learning update (Equation 4) except that instead of taking the maximum over the actions available in $s'$, it uses the action, $a'$, which was actually executed. (This requirement of $s$, $a$, $r$, $s'$, $a'$ is what accounts for the algorithm's name.) Notice that if actions are always greedy with respect to the current estimate of $Q^*$, then Sarsa is the same as Q-learning. Despite this similarity, Sarsa and Q-learning have somewhat different properties (see Sutton and Barto, 1998). Whereas Q-learning converges to $Q^*$ independently of the agent's behavior (as long as the conditions for convergence are satisfied), Sarsa converges to an action value function that is optimal given the agent's mode of exploration. Like the TD algorithm for state values described above, both Q-learning and Sarsa can be extended to include eligibility traces.

TD algorithms are closely related to dynamic programming algorithms, which also use backup operations derived from Bellman equations. There are two main differences. First, a dynamic programming backup computes the expected value of successor states using the state-transition distribution of the MDP, whereas a TD backup uses a sample from this distribution. (TD backups are sometimes called *sample backups*, in contrast to the *full backups* of dynamic programming.) A second difference is that dynamic programming uses multiple exhaustive "sweeps" of the MDP's state set, whereas TD algorithms operate on states as they occur in actual or simulated experiences. These differences make it possible to use TD algorithms on problems for which it is not feasible to use dynamic programming.

### *Function Approximation*

Instead of storing the estimated values of states or state-action pairs in lookup tables, it is possible to represent them more compactly. This is an important feature of reinforcement learning because it enables its use for problems whose state sets are too large to allow explicit representation of each value estimate, and hence too large for textbook dynamic programming algorithms to be feasible. Very large state sets often arise due to combinatorial explosions in representing states that are configurations of discrete objects. They also arise when multidimensional continuous spaces are discretized (prompting Bellman to coin the familiar phrase, "the curse of dimensionality"). For example, the game of backgammon, to which reinforcement learning has been applied with striking success (Tesauro, 1992), has more than $10^{20}$ states.

Any of the TD backup rules described above can be used to derive an update rule for a parameterized function approximation method of the type developed for supervised learning. Many reinforcement learning applications have used multilayer artificial neural networks and error backpropagation (see BACKPROPAGATION: GENERAL PRINCIPLES). To do this requires representing states or state-action pairs as feature vectors. Training examples are extracted from the agent's behavioral trajectory. For example, suppose one approximated the value of any state $s$ by a function of a feature vector $\vec{\phi}(s)$ and parameter vector $\vec{\theta}$: $V(s) = f(\vec{\phi}(s), \vec{\theta})$. Then the agent's experience of observing state $s$, followed by reward $r$ and successor state $s'$, would yield the training example consisting of input vector $\vec{\phi}(s)$ and the target output $r + \gamma f(\vec{\phi}(s'), \vec{\theta}_t)$. A gradient-descent update of $\vec{\theta}$ derived from Equation 7 is

$$\vec{\theta}_{t+1} = \vec{\theta}_t + \alpha[r + \gamma f(\vec{\theta}(s'), \vec{\theta}_t) - f(\vec{\phi}(s), \vec{\theta}_t)]\nabla_{\vec{\theta}_t} f(\vec{\phi}(s), \vec{\theta}_t)$$

Notice that unlike the case in supervised learning, the target output also depends on the parameter vector. This complicates the behavior and analysis of this type of learning rule. Convergence results have been derived for TD($\lambda$) algorithms in the case of function approximators that are linear in $\vec{\theta}$, and counterexamples to convergence have been presented for Q-learning (see Sutton and Barto, 1998, and Bertsekas and Tsitsiklis, 1996, for discussions of these results). Despite a shortage of theoretical guarantees, many reinforcement learning systems using nonlinear function approximators have demonstrated good performance, and much current research is examining these issues.

### *Exploration*

Reinforcement learning agents have to explore: they have to sometimes select actions that appear to be suboptimal according to their current state of knowledge (e.g., current value and/or policy estimates). Otherwise, behavior can become irretrievably suboptimal as the knowledge base comes to reflect only limited experiences. Balancing exploration with the exploitation of current knowledge is a subtle problem that has been extensively studied. In principle, it is possible to optimally balance exploration and exploitation by solving an MDP whose states are *belief states* that summarize the agent's entire history of observations and actions. But this approach is not feasible for most tasks of interest.

Several simple heuristic exploration methods are usually used in applications of reinforcement learning. In the simplest, the agent selects *$\varepsilon$-greedy* actions. This means that with probability $1 - \varepsilon$, the agent exploits its current knowledge by selecting a greedy action, that is, an action that is optimal given its current value estimates, and with probability $\varepsilon$, it selects an action at random, uniformly, independently of its of its current value estimates. Somewhat more complicated is the *softmax* method, which selects actions according to a Boltzmann distribution based on the current action values. This gives actions with higher estimated values higher probabilities of being selected, with a "temperature" parameter determining how much an action's estimated value influences its selection probability. More sophisticated methods monitor the degree of certainty involved in action choices and direct exploration accordingly. How to design methods for balancing exploration and exploitation that are practical, effective, and amenable to theoretical treatment is an important research area.

## Direct Policy Search

Not all reinforcement learning methods use value functions. It is possible to search directly in the space of policies. For example, the amount of reward that a policy yields can be estimated by running the policy for some number of time steps, possibly repeating many times from different initial states. This provides an evaluation of the entire policy that can be used to direct the search in policy space. The success of the approach usually depends on suitably parameterizing policies by vectors of real numbers so that the search can be conducted in parameter space using any of a large number of optimization algorithms. Some of these algorithms require estimates of the gradient of the policy evaluation with respect to the parameters, which can also be extracted from sample policy executions.

If the agent-environment interaction is approximately Markov, TD methods can take advantage of local consistency conditions to obtain state-localized information about how to improve a policy. On the other hand, direct policy search does not depend on the Markov property and so can be used when state information is not close to being available. Direct policy search methods also do not require the use of function approximation methods to represent value functions. Offsetting these advantages of direct policy search methods, however, is the more coarse form of credit assignment that is possible and the difficulty of efficiently evaluating entire policies. Which type of method is to be recommended is highly problem dependent. The actor-critic architecture can be considered to combine aspects of value function and direct policy search algorithms, and there is considerable interest in this hybrid approach.

## Using Environment Models

Algorithms like Q-learning and Sarsa do not need a model of the agent's environment. They can learn from the agent's actual experience as the agent behaves in the real world. However, many reinforcement learning systems do take advantage of environment models. For example, algorithms like Q-learning and Sarsa are often applied to experience generated as the agent interacts with a simulation of its environment. This not only allows much faster learning (since simulations can run much faster than real time), it eliminates the potential of catastrophic consequences that can occur in some domains when a learning system is given control over a real system.

Sutton and Barto (1998) called models that can support learning from simulations *sample models*. In contrast, stochastic dynamic programming algorithms need *distribution models*, which explicitly represent the environment's state-transition and reward probabilities. Since sample models can sometimes be much easier to construct than distribution models, their ability to form policies through simulation is an important advantage of reinforcement learning methods for some applications. It is also easy to devise algorithms that learn from both real and simulated experience. Other reinforcement learning algorithms take advantage of distribution models by using full, instead of sample, backups, while still applying backups to states encountered along simulated or actual behavioral trajectories. This approach makes each backup more informative than a sample backup but avoids the exhaustive sweeping of dynamic programming.

Determining a policy from an environment model, either a distribution or a sample model, is a form of *planning*. Reinforcement learning algorithms that use models are not clearly distinct from some types of planning algorithms. Their main distinguishing characteristic is probably that they often do not fully complete a planning process before committing to actions. The planning process is extended over time, with knowledge in the form of a value function and/or a policy accumulating as behavior continues. Model-based reinforcement learning is closely related to *decision-theoretic planning* in artificial intelligence, which also makes use of the MDP formalism.

## Elaborations and Extensions

Among the many topics being addressed by current reinforcement learning research are (1) extending theoretical results to include parameterized function approximation methods; (2) understanding how exploratory behavior is best introduced and controlled; (3) learning under conditions in which the environment state cannot be fully observed (related to the theory of partially observable MDPs, or POMDPs); (4) exploiting the structure present when states and/or actions are represented as vectors giving the values of descriptive variables (formalized in terms of *factored* or *structured* MDPs); and (5) introducing various forms of abstraction such as temporally extended actions and hierarchy (which rely strongly on the theory of semi-Markov decision processes, or SMDPs). Finally, researchers are studying the relationship of computational reinforcement learning theories to brain reward mechanisms. Strong parallels exsit between TD learning and the activity of dopamine neurons (Schultz, 1998; see also Dopamine, Roles of).

# Reinforcement Learning in Motor Control

*Andrew G. Barto*

## Introduction

How do we learn motor skills such as reaching, walking, swimming, or riding a bicycle? There is a large literature on motor skill acquisition that is full of controversies (for an introduction to human motor control, see Schmidt and Lee, 1999), but there is general agreement that motor learning requires the learner, human or not, to receive response-produced feedback through various senses providing information about performance. Careful consideration of the nature of the feedback used in learning is important for understanding the role of reinforcement learning in motor control (see Reinforcement Learning). One function of feedback is to guide the performance of movements. This is the kind of feedback with which we are familiar from control theory, where it is the basis of servocontrol, although its role in guiding animal movement is more complex. Another function of feedback is to provide information useful for improving *subsequent* movement. Feedback having this function has been called *learning feedback*. Note that this functional distinction between feedback for control and feedback for learning does not mean that the signals or channels serving these functions need to be different.

## Learning Feedback

When motor skills are acquired without the help of an explicit teacher or trainer, learning feedback must consist of information automatically generated by the movement and its consequences on the environment. This has been called *intrinsic feedback* (Schmidt and Lee, 1999). The "feel" of a successfully completed movement and the sight of a basketball going through the hoop are examples of intrinsic learning feedback. A teacher or trainer can augment intrinsic feedback by providing *extrinsic feedback* (Schmidt and Lee, 1999) consisting of extra information added for training purposes, such as a buzzer indicating that a movement was on target, a word of praise or encouragement, or an indication that a certain kind of error was made.

Most research in the fields of machine learning and artificial neural networks has focused on the learning paradigm called *supervised learning*, which emphasizes the role of training information in the form of desired, or "target," network responses for a set of training inputs (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION). However, motor learning is more complex than supervised learning, even when it involves extrinsic feedback provided by a trainer. For example, a trainer can tell or show us what to do, explicitly guide our movements, give us hints on how to deal with difficult parts of a skill, tell us when we have improved or done badly, etc. The aspect of real training that corresponds most closely to the supervised learning paradigm is the trainer's role in telling or showing the learner what to do, or explicitly guiding his or her movements. These activities provide standards of correctness that the learner can try to match as closely as possible by reducing the error between his or her behavior and the standard. Supervised learning can also be relevant to motor learning when there is no trainer, because intrinsic feedback can be used to learn various kinds of *models* that are useful for motor control. Kawato (1999) and Desmurget and Grafton (2000) discuss some of the uses of models in motor control.

In contrast to supervised learning, *reinforcement learning* emphasizes learning feedback that *evaluates* the learner's performance without providing standards of correctness in the form of behavioral targets (see REINFORCEMENT LEARNING). Although the most obvious evaluative feedback is extrinsic feedback provided by a trainer, most evaluative feedback is probably intrinsic, being derived by the learner from sensations generated by a movement and its consequences on the environment: the kinesthetic and tactile feel of a successful grasp or the swish of a basketball through the hoop. Evaluative feedback is often called *reinforcement* feedback (and it need not involve pleasure or pain). A reinforcement learning system has to actively try alternatives, compare the resulting evaluations, and use some kind of selection mechanism to guide behavior toward the better alternatives. This basic idea follows Thorndike's classical law of effect (Thorndike, 1911) and is commonly called learning by trial and error (not to be confused with error-correction, or supervised, learning).

The great Russian physiologist Nikolai Bernstein discussed the role of trial-and-error learning in motor control in his classic 1967 book (Bernstein, 1967). He distinguished his view from the concept of random undirected search, which he attributed to the behaviorists. According to Bernstein, the process must be an active search involving "gradient extrapolation" by probabilistic sampling so that each attempt is informed by previously acquired information about "how and where the next step must be taken." This is very much in accord with modern concepts of reinforcement learning, where randomness is often used to generate behavioral variety, but action selections are strongly constrained by evaluations of earlier experience (see REINFORCEMENT LEARNING). To Bernstein, this kind of search was important for motor behavior, especially for movements requiring high levels of coordination. Another motor control theorist, Jack Adams, provided an interesting discussion of the role of the law of effect in motor control in a 1978 article (Adams, 1978). Although he called into question some of the details of Thorndike's theories, he affirmed the importance of reinforcement learning in motor control.

Motor learning involves feedback carrying many different kinds of information. Consequently, it is incorrect to view motor learning strictly in terms of supervised, reinforcement, or any other learning paradigms that have been formulated for theoretical study. Aspects of all of these paradigms play interlocking roles, with their relative importance undoubtedly varying with the type of task as well as the developmental stage. However, reinforcement learning may be an essential component of motor learning simply because evaluative feedback is more easily obtained than many other kinds of learning feedback.

## Learning from Consequences

To illustrate how reinforcement learning applies to motor learning, we first discuss it within the general context of control. Then we describe several special cases related to motor control. Figure 1, panel *A*, is a variation of the classical control system diagram. A controller provides control signals to a controlled system. The behavior of the controlled system is influenced by disturbances, and feedback from the controlled system to the controller provides information on which the control signals can depend. Commands to the controller specify aspects of the control task's objective.

In Figure 1, panel *B*, the control loop is augmented with another feedback loop that provides learning feedback to the controller. In accordance with common practice in reinforcement learning, a

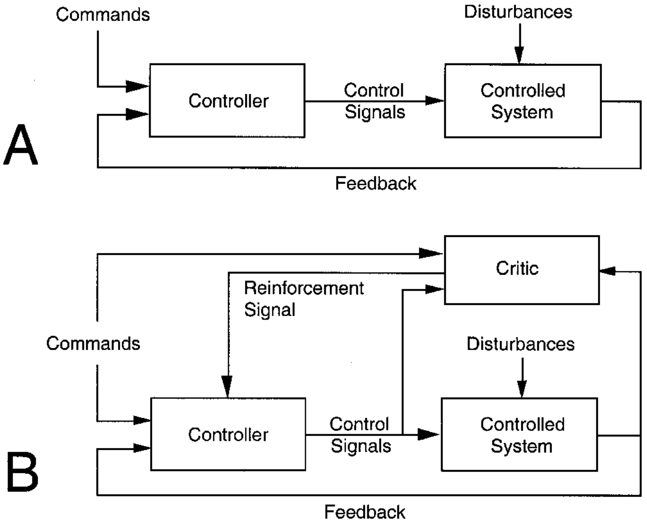

**Figure 1.** *A*, A basic control loop. A controller provides control signals to a controlled system, whose behavior is influenced by disturbances. Feedback from the controlled system to the controller provides information on which the control signals can depend. Commands to the controller specify aspects of the control task's objective. *B*, A control system with learning feedback. A *critic* provides the controller with a reinforcement signal evaluating its success in achieving the control objectives.

*critic* is included that generates evaluative learning feedback on the basis of observing the control signals and their consequences on the behavior of the controlled system. The critic also needs to know the command to the controller because its evaluations must be different depending on what the controller should be trying to do. The critic is an abstraction of whatever process supplies evaluative learning feedback, both intrinsic and extrinsic, to the learning system. It is often said that the critic provides a *reinforcement signal* to the learning system. In most artificial reinforcement learning systems, the critic's output at any time is a number that scores the controller's behavior: the higher the number, the better the behavior. Assume for a moment that the behavior being scored is the immediately preceding unit of behavior. (We discuss what a unit of behavior might be, as well as more complex temporal relationships, in later sections.) For this process to work, there must be some *variability* in the controller's behavior so that the critic can evaluate many alternatives. A learning mechanism can then adjust the controller's behavior so that it tends toward behavior that is favored by the critic.

A learning rule particularly suited to reinforcement learning control systems implemented as artificial neural networks was developed by Gullapalli (1990) in the form of what he called a Stochastic Real-Valued (SRV) unit. An SRV unit's output is produced by adding a random number to the weighted sum of the components of its input pattern. The random number is drawn from a zero-mean Gaussian distribution. This random component provides the unit with the variability necessary for it to "explore" its activity space. When the reinforcement signal indicates that something good happened just after the unit emitted a particular output value in the presence of some input pattern, the unit's weights are adjusted to move the activation in the direction in which it was perturbed by the random number. This has the effect of increasing the probability that future outputs generated for that input pattern (and similar input patterns) will be closer to the output value just emitted. If the reinforcement signal indicates that something bad happened, the weights are adjusted to move future output values away from the value just emitted. Another part of the SRV learning rule decreases the variance of the Gaussian distribution as learning proceeds. This decreases the variability of the unit's behavior, with the goal of making it eventually stick (i.e., become deterministic) at the best output value for each input pattern. Using this learning rule, an SRV unit learns to produce the best output in response to each input pattern (given appropriate assumptions). Unlike more familiar supervised learning units, it is never given target outputs; it has to discover what outputs are best through an active exploration process.

## Overcoming the Distal Error Problem

As a simple illustration of how reinforcement learning can be useful in motor learning, consider the problem of learning to reach to specific points in space starting from a variety of initial hand positions. Lipitkas et al. (1993) proposed a particularly straightforward method (although not as a model of the human learning process, which is much more complex). Their controller is an artificial neural network receiving inputs coding the initial spatial location and the desired, or target, spatial location of the hand (ignoring hand orientation). The six outputs of the network provide parameters to a torque generator that generates time-varying signals for driving the joint actuators of a dynamic arm model (Figure 2). The time-varying signals are parameterized by six numbers determining characteristics of their wave-like shapes (e.g., giving the magnitudes and relative timing of the half-waves). During each movement, the controller operates in open-loop mode, generating the torque time functions without the aid of sensory feedback. The problem for the network is to learn a function associating each pair of hand starting and target positions with the values of the six torque-generator parameters that will accomplish the movement.

A straightforward application of supervised learning is not possible here because the required training examples are not available: it is not known what parameters will work for any pair of starting and target positions (except possibly the trivial cases in which the starting position is already the target position, but these are not useful as training examples). This is an instance of what has been called the *distal error problem* (Jordan and Rumelhart, 1992) for supervised learning. This problem is present whenever the standard of correctness required for supervised learning is available in a coordinate system that is different from the one in which the learning system's activity must be specified for learning. In the case of learning how to move the hand from a starting position to a target position, the standard of correctness is the target position, but what must be learned is the control signals to the joint actuators, that is, to the muscles. The hand position error is distal to the output of the controller that has to be learned. Although a non-zero distal error vector indicates that the controller made an error, it does not tell the controller how it should change its output in order to reduce the error.

The distal error problem can be solved by using a model of the controller's influence on the arm's movement (possibly learned via supervised learning) to translate distal error vectors into error vectors required for supervised learning (Jordan and Rumelhart, 1992). Another approach is to learn an inverse model of the controller's influence on the arm's movement (Jordan and Rumelhart, 1992; Kawato, 1999). Reinforcement learning offers another way to overcome the distal error problem because it does not need learning feedback in the form of error vectors. Continuing with the reaching example, Lipitkas et al. (1993) defined a reinforcement signal that attains a maximum value of 1 if the hand reaches the desired position and stops there. The signal decreases, depending on the distance between the hand's final position and the target position and on its tangential velocity as it passes the target position. The reinforcement signal could include other criteria of successful move-

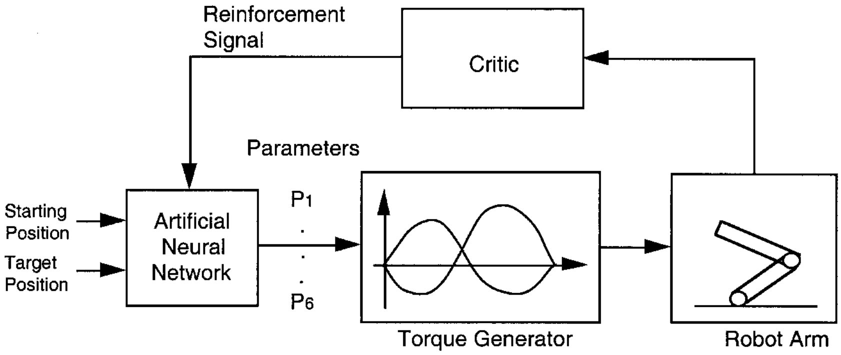

**Figure 2.** Block diagram of a reinforcement learning controller of an arm. Given inputs coding the starting and target positions of the hand, the network controller learns to provide correct parameters to a torque generator that generates, in open-loop mode, time-varying torque signals to the arm. The reinforcement signal evaluates the success of each movement after its completion. (Modified from Lipitkas et al., 1993, Figure 1.)

ments as well. With inputs coding starting and target hand positions, the network employs SRV units to generate six parameter values using its current weights. The torque generator generates a movement using these parameter values. When the movement is completed, it is scored by the reinforcement signal, and the network's weights are changed according to Gullapalli's SRV learning rule. After a few thousand movements with different starting and target hand positions, the system could move with reasonable accuracy for new pairs of starting and target positions as well as for the pairs on which it was trained. This amount of practice is required because the system effectively has to search the six-dimensional parameter space for each starting and target position. A more complicated example of reinforcement learning using SRV units is the work on biped walking by Benbrahim and Franklin (1997).

The relative advantages and disadvantages of supervised and reinforcement learning approaches to the distal error problem have been discussed by many researchers. It is clear that reinforcement learning approaches are simpler, but reinforcement learning is usually slower in terms of the amount of experience required for learning. This is true because reinforcement learning methods extract less information from each experience than do the model-based supervised approaches. However, in some problems it is easier to learn the right actions than it is to model their effects on a complicated process. Reinforcement learning methods are also more plausible from the perspective of neuroscience (see below), while the backpropagation process often used by supervised approaches is more difficult to reconcile with what we know about neural mechanisms. In practical terms, which approach is more advantageous will depend on aspects of the specific problem being considered.

## Collective Behavior

Another property of reinforcement learning that might be relevant to motor control is the ability of a "team" of reinforcement learning systems to learn to cooperate so that the team as a whole improves performance. Here is an example presented in a 1965 lecture by the cybernetician Mikhail Tsetlin (Tsetlin, 1973), a pioneer in the study of simple reinforcement learning systems called learning automata. He presented the basic idea as follows in terms of human players (the so-called Goore game). Suppose there is a referee and some number of players. The referee can see the players, but the players cannot see one another. At the sound of a buzzer, each player is to raise one or two fingers. The referee determines what percentage of players raised one finger, then pays each player a fixed amount with a probability that depends only on this percentage (and is the same for each player). The process repeats each time the buzzer sounds. It turns out that for any number of players each implementing a sufficiently competent reinforcement learning rule, eventually each player will settle on raising either one or two fingers, so that the percentage of those raising one finger is (with probability close to 1) a local maximum of whatever payoff function the referee uses. This occurs with no direct communication among the players and no agreements of any kind among them.

It is possible to extend this result to one in which the referee provides payments based not just on the percentage of players raising one finger, but on *any function whatsoever* of the pattern of players' fingers. One can see how this is an instance of the problem of learning with a distal teacher, with the added complication that the payoff, or reinforcement signal, to each player is extremely noisy due to the noise introduced by the actions of the other players (in addition to the referee's probabilistic payoff method).

Tsetlin speculated that the recruitment of motor units can be reduced to this type of problem. Here, the problem would be to activate the right number of motor units to obtain a pull of a given force. The referee corresponds to a process that evaluates the results of the collective behavior of the entire pool of motor units on the resulting force. The collective behavior of reinforcement learning systems has been studied by many researchers (e.g., Narendra and Thathachar, 1989; Barto, 1985), although no modern work following up Tsetlin's suggestion about motor unit recruitment appears to exist.

## Credit Assignment Problems

The challenge of reinforcement learning is often summed up as various kinds of *credit assignment* problems. A scalar evaluation of a complex mechanism's behavior does not indicate which of its many action components, both internal and external, were responsible for the evaluation. This makes it difficult to determine which of these components deserve the credit (or the blame) for the evaluation. This problem is sometimes referred to as the *structural* credit assignment problem: How is credit assigned to the internal workings of a complex structure? One approach is to assign credit equally to *all* the components, so that, through a process of averaging over many variations of the behavior, the components that are key in producing laudable behavior end up gaining the most strength, while inappropriate components are weakened. This is the general approach illustrated above by the Goore game.

The fact that reinforcement learning can work under these circumstances makes neural implementation quite plausible. A single reinforcement signal uniformly *broadcasted* to all the sites of learning, either neurons or individual synapses, is consistent with anatomical and physiological evidence showing the existence of diffusely projecting neural pathways by which neuromodulatory chemicals can be widely and nonspecifically distributed. It has been suggested that some of these pathways may play a rule in reward-mediated learning. A specific hypothesis is that dopamine mediates synaptic enhancement in the corticostriatal pathway in the manner of a broadcasted reinforcement signal (see Dopamine, Roles of). This may be one of the ways in which reinforcement learning is implemented for motor control.

Another aspect of the credit assignment problem occurs when the temporal relationship between a system's behavior and evaluations of that behavior is not as simple as assumed above. How can reinforcement learning work when the learner's behavior is temporally extended and evaluations occur at varying and unpredictable times? Under these more realistic conditions, it is not always clear what elements of behavior are being evaluated. This has been called the *temporal* credit assignment problem. It is especially relevant in motor control because movements extend over time and evaluative feedback may become available only after the end of a movement. An approach to this problem that is receiving considerable attention is the use of methods by which the critic itself can learn to provide useful evaluative feedback immediately after the evaluated event. According to this approach, reinforcement learning is not only the process of improving behavior according to given evaluative feedback; it also includes learning how to improve the evaluative feedback itself. The strong parallels between algorithms for adapting evaluative feedback (temporal difference methods; see Reinforcement Learning) and the properties of dopamine-producing neurons in the brain (see Dopamine, Roles of) make it plausible that the brain uses similar methods for dealing with the temporal credit assignment problem.

The modern view of reinforcement learning developed by machine learning researchers uses the framework of stochastic optimal control to study the temporal credit assignment problem (see Reinforcement Learning). From this perspective, reinforcement learning algorithms are methods for approximating solutions to complex stochastic optimal control problems via relatively simple mechanistic learning rules. Because optimality principles have played significant roles in theories of motor control (Engelbrecht, 2001), and because stochasticity may be an important element of motor control (Harris, 1998), the modern theory of reinforcement may prove to be of great utility in extending our understanding of motor learning.

## Discussion

As this article has emphasized, motor learning is too complex to be viewed strictly in terms of either supervised learning or reinforcement learning. Feedback used in motor learning ranges from specific standards of correctness to nonspecific evaluative information, and many learning mechanisms with differing characteristics probably interact to produce the motor learning capabilities of animals. However, reinforcement learning principles may be indispensable for motor learning because they seem necessary for improving motor performance when the standards of correctness required by supervised learning are not available.

# Respiratory Rhythm Generation

*Richard J. A. Wilson, John E. Lewis, and John E. Remmers*

## Introduction

After several decades of intense debate, fueled by exciting experimental advance, a number of fundamental issues regarding the neuronal mechanisms that synthesize normal breathing (eupnea) remain unresolved. This article examines recent data and evaluates insights from modeling studies. We begin by discussing potential neuronal components of the respiratory rhythmogenic network and then assess current models of the respiratory oscillator in the context of the mechanisms of rhythmogenesis.

The apparent simplicity and reliability of breathing are enticing to the experimenter and modeler alike. During inspiration, activity in the phrenic nerve contracts the diaphragm, sucking air into the lungs. During expiration, passive recoil of the lungs, diaphragm, and ribs almost suffices for stale air expulsion. However, a closer look reveals a fascinating and complex behavior involving recruitment of many muscles (facial, upper airway, thoracic, abdominal, postural), modulation from many different sources (mechanosensory, chemosensory, descending), and coordination with many other behaviors (e.g., swallowing, locomotion).

In light of this complexity, perhaps one of the most remarkable ideas to arise in the field over the last decade is that only a small kernel of brainstem neurons (perhaps as few as 1,200) are responsible for the rudimentary respiratory rhythm (Gray et al., 2001). This idea originated from studies in vitro. If this idea is correct, then in vivo these neurons should meet *all* the following criteria: (1) have activity correlated with breathing, (2) be necessary for breathing (i.e., breathing is abolished if they are functionally ablated), and (3) be sufficient for breathing (functionally defined as capable of accelerating breathing when stimulated). Unfortunately, demonstrating all but the last criterion experimentally has proved to be very difficult, as reviewed below.

## Possible Components of Rhythm Generator

### Correlation

Respiratory neurons are generally defined by and categorized in relation to inspiratory phrenic discharge. At least six categories have been identified (e.g., Richter, Ballanyi, and Schwarzacher, 1992): pre-inspiratory (PreI), early inspiratory (EI), throughout inspiratory (I), late inspiratory (LateI), post-inspiratory (PostI), and expiratory (E2). These categories are found across different species and, some claim, experimental preparations. Note, however, that while the phrenic discharge during eupnea consists of augmenting bursts, phrenic activity changes dramatically during other behaviors such as hiccuping, coughing, and gasping. For unambiguous identification of eupneic respiratory neurons therefore, the *pattern* of the phrenic discharge must be considered.

Correlation is but one of the three criteria that should be applied before a neuron can be given a functional definition. A neuron that fires in relation to the eupneic rhythm could conceivably be more important (i.e., necessary) for some other behavior. Furthermore, despite the presence of several categories of respiratory neurons, the generation of the eupneic rhythm may require but a subset of the types found.

Further details of the data discussed below may be found in the papers by Ballanyi, Onimaru, and Homma (1999); St. Jacques and St. John (1999); and St. John, (1996). Further information on models is given by Smith et al. (2000).

### *Sufficiency and Necessity*

The brainstem alone can produce the respiratory rhythm. Rhythmic augmenting bursts in cranial nerves, a characteristic of eupnea, continues in vagotomized animals after transections at the midcollicular level and at the obex. Several regions in the brainstem cause acceleration of respiratory rhythm when stimulated (i.e., are sufficient). Two of these areas in the medulla, the pre-Bötzinger complex (preBötC) and the pre-inspiratory region have received particularly intense study.

The preBötC is situated rostral to the ventral respiratory group and ventral to the nucleus ambiguous (Rekling and Feldman, 1998). Gray et al. (2001) determined that the preBötC can be defined anatomically according to the distribution of Substance P receptors. The pre-inspiratory region lies just rostral and ventral to the preBötC (see Ballanyi, Onimaru, and Homma, 1999).

The preBötC contains the complete suite of respiratory neurons, and several groups have shown it to be necessary for eupnea. Ramirez et al. showed that in anesthetized, artificially ventilated, vagotomized cats, irreversible inactivation of this region with tetrodotoxin caused the cessation of the eupneic motor pattern but not anoxia-induced gasping. Gray et al. (2001) demonstrated that in awake rats, four to five days after injection of poison-conjugated Substance P into the preBötC, blood gases and breathing were abnormal, with ablated cells concentrated in, though not limited to, the preBötC.

Other in vivo experiments have generated contrasting results. Huang et al. have reported that lesioning both preBötC and pre-inspiratory regions of anesthetized, artificially ventilated, vagotomized neonatal rats with kainic acid had no effect on eupnea but eliminated anoxia-induced gasping. Lucid histological boundaries of the preBötC have been identified only recently. Therefore, discrepant results between lesion studies may reflect ablations in different regions. While this explanation may explain why some studies failed to eliminate eupnea following ablation of sites in the ventral medulla, in other studies, the lesions seem too extensive to have spared the preBötC. St. Jacques and St. John (1999) found that massive kainic acid injections (whether ipsilateral or bilateral) in the vicinity of the preBötC eliminate eupnea but only transiently. Gasping, however, was permanently abolished. While these results support the importance of the preBötC for eupnea, they also suggest that it may not be necessary, at least in the strictest sense, and that sites other than the preBötC can produce the eupneic rhythm. Where might these sites be?

One candidate is the pre-inspiratory area. This area contains large numbers of neurons that begin firing before inspiration (e.g., PreI and PostI) and, when stimulated with single shocks, can reset the respiratory rhythm. In addition, brainstem areas rostral to the medulla (i.e., in the pons) may also be necessary for eupnea. The pons also contains large numbers of respiratory neurons and may have an inherent rhythm-generating capability (St. John, 1996). It is possible that this pontine rhythm generator may interact with that in the medulla to generate breathing. Indeed, transecting the brainstem at the pontine-medulla level causes profound changes in phrenic nerve activity, to a pattern that is no longer eupneic and therefore could be produced by a different brainstem circuit (see St. John, 1996).

In summary, there is mounting evidence that the preBötC plays an important role in respiratory rhythmogenesis (Rekling and Feldman, 1998). However, we are of the opinion that the preBötC might not act alone to produce the respiratory rhythm: other areas, most notably the pons, may also be necessary for eupnea. Slices containing the preBötC complex are capable of producing rhythmic activity. However, elevated extracellular [$K^+$] is usually required, and some argue that the rhythm produced is more gasp-like than eupneic (St. John, 1996). The ability to generate a rhythm when isolated from other neuronal structures does not dictate that the preBötC is solely responsible for the eupneic rhythm in the intact animal. In our thinking, we allow for the possibility that sites other than the preBötC may be necessary and that rhythmogenesis may be distributed.

## Mechanism of Rhythm Generation

Despite the difficulty of localizing categorically the necessary and sufficient components responsible for the eupneic rhythm, models have been proposed for the mechanism by which the rhythm is generated. These models fall into two distinct groups: (a) *hybrid-pacemaker models*, in which the basic rhythm is generated by the endogenous pacemaker-like membrane properties of a small subset of respiratory neurons (Figure 1*A*), and (b) *network models*, in which the rhythm is generated by synaptic interactions within a large network (Figure 1*B*). These models are based largely on different data, obtained from in vitro and in vivo experiments, respectively.

### *Hybrid-Pacemaker Models*

These models predict that the basic rhythm stems from a small population of respiratory neurons. These neurons, when synaptically isolated, burst as a result of inherent membrane properties (e.g., Ramirez and Richter, 1996; Reckling and Feldman, 1998; Smith et al., 2000). In these models, synaptic interactions between respiratory neurons are not necessary for rhythmogenesis per se but function primarily to elaborate, shape, and transmit the basic rhythm to generate the eupneic motor pattern.

Evidence that some respiratory neurons have pacemaker-like membrane properties arises mainly from in vitro neonatal preparations. For example, I and PostI neurons in the pre-inspiratory area of the in vitro neonatal rat brainstem-spinal cord preparation retained rhythmic bursts of action potentials after blocking inhibitory synaptic transmission either with GABA and glycine antagonists

or by bathing the preparation in a low $Cl^-$ solution (Ballanyi et al., 1999). Similarly, in the transverse slice preparation from the neonatal rat, rhythmic bursts persisted in I and E2 preBötC neurons despite blocking of chemical synaptic connections with low $Ca^{2+}$ (Johnson et al., 1994).

These important experiments suggest that some respiratory neurons have endogenous bursting properties, at least under certain conditions. However, Johnson et al. (1994) identified a third class of cell whose activity was transformed from tonic to bursts when exposed to low $Ca^{2+}$. This illustrates the difficulty of ascertaining the normal properties of neurons when they are examined outside their usual ionic and synaptic realms. In this light, one should note that the in vitro neonatal rat brainstem-spinal cord preparation has an anoxic, acidic (pH ~6.5) core that compromises synaptic inhibition and produces a gasp-like motor pattern (see St. John, 1996). One should also note that the preBötC in the in vitro slice preparation has lost many synaptic inputs and usually requires elevated $[K^+]$ for rhythmogenesis. Therefore, bursting cells in vitro may operate at membrane potentials that are not normally encountered. Whether endogenous bursting drives eupnea in vivo will be an important question for future research.

The hybrid-pacemaker model was first implemented by using conductance-based Hodgkin-Huxley-type model neurons, each with up to nine ionic conductances (see Smith et al., 2000). The early simulations consisted of a kernel of endogenous bursting neurons, which fired during the inspiratory phase. Burst initiation was determined largely by a subthreshold activating persistent $Na^+$ conductance ($I_{Na(p)}$), whereas a persistent $K^+$ conductance was critical for burst termination. These neurons provided drive to both inhibitory interneurons and premotor neurons. Interactions between interneurons and premotor neurons form the basis of the pattern-forming network, appropriately phasing the motor output. It should be emphasized that feedback from the inhibitory interneurons onto the endogenous bursters, while not necessary for eupneic rhythmogenesis per se, nonetheless makes an important contribution to the eupneic rhythmogenesis by both controlling baseline membrane potential (which influences burst frequency) and facilitating burst termination. Increasingly elaborate hybrid pacemaker-type simulations are now being used. Although the voltage clamp data to support the use and magnitude of specific conductances are extremely sparse, these second-generation simulations benefit from recent work to characterize the voltage-dependent behavior of preBötC neurons. They also involve much larger numbers of neurons to account for heterogeneous cellular properties within given neuronal populations. As such, the output of these simulations is becoming increasingly realistic, but more important, they are now being used to formulate experimentally testable hypotheses about how rhythmicity in vitro is generated (Del Negro et al., 2001). With the third generation of models, we can look forward to simulation of (1) conductances based on voltage clamp data from preBötC neurons, (2) electrical synaptic connections, and (3) effects of neuronal modulation.

A different approach to using conductance-based modeling is to use more abstract components, which make the analysis of dynamic behavior more tractable. For example, Matsugu, Duffin, and Poon (1998) considering a minimal respiratory network consisting of two mutually inhibitory elements (representing I and E neurons) that were driven by different periodic inputs (representing "pacemaker" neurons). By varying the nature of the coupling between elements, the authors found that 1:1 entrainment to the "pacemaker" required a number of specific conditions. The simplified nature of this model, while allowing a rigorous analysis, does not allow an easy transfer of these predictions to practical experimental tests. However, an important aspect of this study is that it aimed specifically at evaluating the class of hybrid-pacemaker model in the context of respiratory rhythmogenesis.

### *Network Models*

By far the most common feature of neuronal networks that generate rhythmic output is the presence of cells with mutually inhibitory synaptic connections. Such networks have an inherent tendency to generate rhythmic outputs without the need for cells with endogenous bursting properties. The network models for respiratory rhythm generation can be thought of as an elaboration on this basic theme (Figure 1*B*). These models have been constructed by analyzing the activity and phase of synaptic inputs of various types of respiratory neurons (see Richter et al., 1992). The data necessary to construct these models come from cross-correlation and spike-triggered averaging from single-unit recordings largely from in vivo preparations.

Data supporting inhibitory synaptic interactions in rhythmogenesis include the following:

1. Reduced $Cl^-$ solutions caused cessation of eupneic bursts in an adult arterially perfused rodent preparation (Hayashi and Lipski, 1992).
2. GABA and glycine antagonists injected bilaterally into the preBötC of the in vivo cat abolished eupnea (Pierrefiche et al., 1998).

These data are consistent with a role for phasic inhibition in rhythmogenesis. However, these manipulations may have had direct effects on membrane potential and/or removed tonic inhibition, either of which could silence pacemaker neurons.

Paton and Richter (1995), using both in vivo and in vitro preparations, showed comparable results blocking inhibitory synaptic transmission in postnatal animals. However, in neonates, they found that blocking inhibitory synaptic transmission did not eliminate rhythmic motor output, in line with previous results from experiments on neonates (e.g., Ballanyi et al., 1999; Johnson et al., 1994). The authors conclude that inhibitory synaptic connections are necessary for respiratory rhythmogenesis, but only in postnatal (>15 days) animals. Others have found no dependence of rhythmicity on postnatal age (Ramirez in Ramirez and Richter, 1996). These dichotomous results might be explained by the fact that the preparations used by Paton and Richter included the pons. Some have argued that a late-developing pontine input negates the bursting properties of pacemaker neurons, making inhibitory connections in the ventral medulla necessary for eupneic rhythmogenesis (Pierrefiche et al., 1998).

These data have motivated a number of modeling efforts. Early network models took the view that each population of respiratory neurons could be considered as a homogenous group, often described with a few simple equations, with connections between populations as the underlying mechanism of rhythmogenesis (Lewis, 1995). More recent simulations have used individual conductance-based model neurons. In one study, by balancing the relative contributions of six different channels, two different types of neurons were modeled. The first type shows an "adapting" response to synaptic excitation (resembling Early I, PostI), while the second type exhibits a "ramping" response to release from inhibition (resembling I, Late I, E2). Modeling demonstrated that the ratio of high- and low-threshold $Ca^{2+}$ channels was the principle factor in determining type. The greater the high-threshold $Ca^{2+}$ conductance, the more likely the neuron would have an adaptive firing pattern. This prediction remains to be tested experimentally. Using these two types of "canonical" neurons, the authors then constructed a network consisting of seven cells representing seven classes of respiratory neurons—those described in the classification of Richter et al. (1992) plus an additional class of expiratory neuron. The model also includes inputs from pulmonary stretch receptors. The authors used various network configurations (based on experimental data) to show how intrinsic membrane properties interact with synaptic (network) properties to control the firing patterns of individual neurons as well as the dynamics involved in changing between inspiratory and expiratory phases.

## Discussion: A Hybrid-Pacemaker or a Network-Based Rhythm Generator?

We have outlined experimental data from two types of preparations that lead to very different predictions about the mechanisms of respiratory rhythmogenesis. In vivo data point to the importance of network interactions in generating the basic rhythm, whereas results from in vitro experiments indicate the importance of endogenous bursting neurons. Most recent modeling studies retain this polarity, concentrating on one or the other data set, resulting in models in which rhythmogenesis is either pacemaker driven or network driven. By providing a quantitative framework, these modeling studies have been invaluable in helping to understand the cellular basis of each of these mechanisms. In listing the assumptions they require to make the models, they also illustrate the need for more voltage clamp data from respiratory neurons.

An important use of modeling in the future will likely be to determine how to distinguish experimentally between pacemaker-driven and network-driven rhythmogenesis. Rybak, St. John, and Paton (2001) recently published a study demonstrating the possibility of using models in this way. Using a conductance-based pacemaker model as a starting point, they shifted the voltage dependence of $I_{\mathrm{Na(p)}}$ by $-9$ mV (which they considered more physiological) and added a transient $\mathrm{K}^+$ current ($I_{\mathrm{kA}}$). These modifications did not affect the model neuron's ability to burst under the simulated conditions of elevated extracellular $\mathrm{K}^+$ (9 mM) used in vitro. However, when $[\mathrm{K}^+]$ was reduced toward levels closer to those in vivo (6 mM), the model neuron lost its ability to generate spontaneous bursts, owing to suppression of $I_{\mathrm{Na(p)}}$ by $I_{\mathrm{kA}}$. Furthermore, simulations suggested that bursting was disrupted by phasic synaptic inhibition. The authors suggest that rhythmogenesis in vitro represents a "switching" from a network-driven mechanism. They speculate that in vivo, the $I_{\mathrm{Na(p)}}$ in conditional pacemakers is suppressed, but in vitro, the $I_{\mathrm{Na(p)}}$ is released from suppression, owing to higher extracellular $[\mathrm{K}^+]$ and the loss of synaptic inhibition. The authors tested this hypothesis in an artificially perfused preparation by blocking $I_{\mathrm{kA}}$ (using 4-AP), reducing inhibitory synaptic transmission (with a low dose of strychnine), and elevating extracellular $\mathrm{K}^+$ (10 mM). The eupneic bursts were transformed to gasp-like events similar to those produced by in vitro preparations. While the details of Rybak et al.'s model are likely to be debated and the effects of their experimental manipulations should be scrutinized, the elegance of this study demonstrates the true potential of modeling and its growing importance in the study of respiratory rhythm generation.

# Retina

*Robert G. Smith*

## Introduction

At the most basic level, the retina transduces spatial and temporal variations in light intensity and transmits them to the brain. However, instead of directly coding intensity, the retina transforms visual signals in a multitude of ways to code properties of the visual world such as contrast, color, and motion. This article develops a conceptual theory to explain why the retina codes visual signals and how the structure of the retina is related to its coding function.

The vertebrate retina reliably responds to light contrast as low as 1% (Shapley and Enroth-Cugell, 1984). Yet as the delicate visual signal is amplified in its passage through the retina, the biological limitations of neural processing add distortion and noise. The ease with which we see fine details in the presence of such biological limitations suggests that one function of retinal circuitry is to maintain the signal's quality by removing redundant signals (Laughlin, 1994). This hypothesis predicts that much of the retina's signal coding and structural detail is derived from the need to optimally amplify the signal and eliminate noise.

## Structure

### Layers and Cell Classes

The retina is a thin (100–200 $\mu$m) tissue at the rear surface of the eye consisting of three layers of neurons and glial cells (Figure 1) (see Dowling, 1987; Sterling, 1997; Rodieck, 1998). Neurons in the *outer nuclear layer* (ONL) are exclusively photoreceptors. The *inner nuclear layer* (INL) (i.e., the middle layer) contains the cell bodies of horizontal cells (H), bipolar cells (B), and amacrine cells (A). Between these two layers lies the *outer plexiform layer* (OPL), in which bipolar and horizontal cells extend dendritic processes laterally to receive synaptic contacts from photoreceptors. The innermost cell layer, called the *ganglion cell layer* (GCL), contains cell bodies of ganglion cells and amacrine cells. Between the INL and GCL lies the *inner plexiform layer* (IPL), where bipolar, amacrine, and ganglion cells are synaptically connected. Ganglion cells send their output to the brain through axons that lie on the inner surface of the retina.

### Cell Types: Specificity in Form and Function

Each class of neuron described above comprises several cell types, and overall the retina comprises several dozen (Sterling, 1997; Rodieck, 1998). A cell type is defined by a distinctive morphology, distribution, synaptic connection pattern, physiology, and/or immunocytochemical staining pattern (Rodieck, 1998). That distinct cell types exist suggests that each has a specific function. Although the retina of one species may contain cell types not present in another, the same five retinal cell classes exist in all vertebrate species (Dowling, 1987; Masland, 1988; Sterling, 1997; Rodieck, 1998; Kandel, Schwartz, and Jessel, 2000). Therefore all vertebrates likely share similar neural circuit organization.

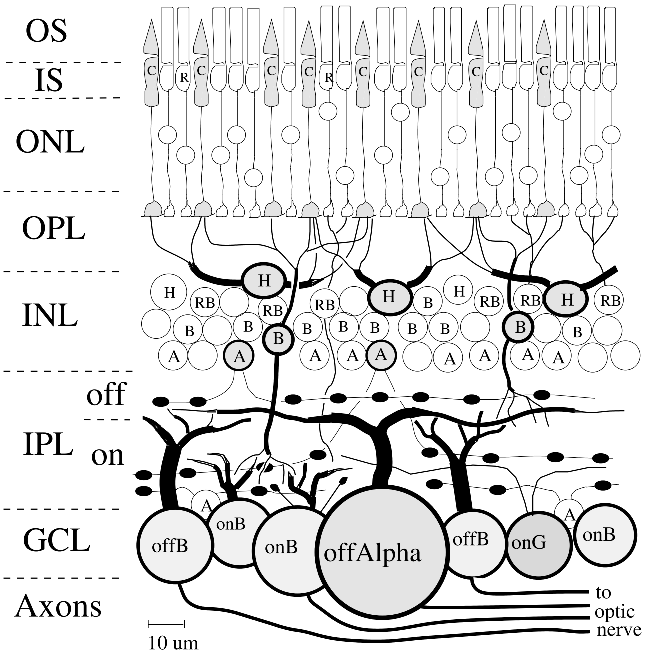

**Figure 1.** Structure of the retina, showing the outer segments (OS), inner segments (IS), outer nuclear layer (ONL), outer plexiform layer (OPL), inner nuclear layer (INL), inner plexiform layer (IPL), ganglion cell layer (GCL), horizontal cells (H), bipolar cells (B), amacrine (A), and rod bipolar (RB) cells.

### Receptive Fields and Connectivity

Neurons of each type are spaced in a regular array across the retina (see Figure 1), so the key to understanding retinal function is to identify the processing strategies of repeating functional circuits or modules (Sterling, 1997). To understand a retinal neuron's physiological function, investigators measure its *receptive field*, the region in space and time over which it responds to light. Receptive fields of retinal neurons consist of a sensitive circular region in visual space, called the *center*, and a larger but weaker antagonistic region concentric with the center, called the *surround* (Rodieck, 1998). These receptive fields are determined by intrinsic and presynaptic mechanisms. For example, a ganglion cell's receptive field shape and properties reflect its morphology and biophysical properties (Kandel et al., 2000), and also the receptive field properties of its presynaptic bipolar and amacrine cells, which in turn originate to some extent in the receptive field properties of photoreceptors and horizontal cells (Dowling, 1987; Sterling, 1997; Rodieck, 1998).

Although receptive field analysis is a powerful method for studying the function of a neural circuit (see Rodieck, 1998; Shapley and Enroth-Cugell, 1984), the origin of a receptive field in a circuit that includes several layers of neurons is difficult to grasp. The difficulty is to separate the effects of cell morphology, synaptic connectivity, and membrane channels on the receptive field (see, e.g., Directional Selectivity). However, by computationally simulating these biophysical details based even on partial knowledge, it is possible to test specific hypotheses about neural circuit connectivity (Teeters and Arbib, 1991; Smith, 1995).

## Functional Circuits

### Photoreceptors and Adaptation

The outer segment (OS) of a vertebrate photoreceptor transduces light via a multistep biochemical cascade (Rodieck, 1998; Kandel et al., 2000) into an electrical signal that is conducted through the photoreceptor's axon to its terminal in the OPL. In response to a flash of light, ion channels close, hyperpolarizing the photoreceptor proportionately over a limited range of stimulus intensity. The advantage of this coding function is that a photoreceptor responds well to low-contrast signals common in the visual world. The disadvantage is that outside this limited range the photoreceptor responds poorly. At lower intensities, the photoreceptor's transduction gain (i.e., proportion of change in its output signal to a change in light) tends to be insufficient, and at higher intensities the photoreceptor's response tends to saturate. To solve such saturation problems, the photoreceptor adjusts its gain in a process called *adaptation*, which in some species can modulate transduction gain by up to 4 log units.

The two classes of photoreceptors, rods and cones (Rodieck, 1998), differ in that rods are sensitive to single photons and are bleached by daylight, but cones are less sensitive and can regenerate their pigment in daylight (photopic intensity range). At twilight (the mesopic intensity range), rods are coupled via gap junctions to neighboring cones, causing the rod signal to pass directly into cones, where it is carried by the lower-gain cone pathway (Rodieck, 1998). At night (scotopic intensity range), a special *rod bipolar* pathway (RB in Figure 1) carries quantal *single-photon* signals, removes dark noise, and adapts over an extra 3 log units of intensity (Sterling, 1997; Rodieck, 1998; Smith and van Rossum, 1998).

### *Outer Plexiform Layer*

The axon terminal of a cone transmits its signal to bipolar cells with a chemical synapse, increasing signal gain at the cost of extra noise and a reduction in the intensity range over which the bipolar cell can respond (Laughlin, 1994). To reduce the tendency of the cone signal to saturate its synapse, the OPL filters the signal (Laughlin, 1994). The filter consists of two components, a spatial low-pass filter constructed from lateral electrical connections (gap junctions) between cones, and a spatiotemporal high-pass filter constructed by horizonal cells. Cone coupling removes uncorrelated noise from the cone's response, and consequently causes cone synaptic release to be more correlated. Although the coupling also causes "neural blur," it is useful to provide an anti-aliasing filter for the next stage of processing in the IPL.

The OPL's high-pass filter is constructed by subtracting a local average from the cone. Horizontal cells, also coupled laterally by gap junctions, sum inputs from many cone terminals and provide negative feedback to each via a feedback synapse. The negative feedback mechanism in some cases is a GABA-ergic synapse (Dowling, 1987; Sterling, 1997), but has also recently been postulated to be a form of electrical feedback. The synaptic structure that performs this function, called a *triad*, has both feedforward and feedback contacts, so it is termed *reciprocal* (Dowling, 1987; Rodieck, 1998). This type of coding has been termed *predictive* (Laughlin, 1994) because the ideal signal to subtract would be a *local average* of signals from neighboring cones (Smith, 1995).

### *Synaptic Function and Noise: Signal-Processing Mechanisms*

The glutamatergic synapse that transmits a cone's signal to bipolar and horizontal cells adds noise originating in the random fluctuation of synaptic vesicle release rate (Sterling, 1997; Kandel et al., 2000). To reduce the amount of noise relative to the signal, vesicles are released at a high rate by a ribbon that functions as a docking site and reservoir for vesicles (Sterling, 1997; Rodieck, 1998; Kandel et al., 2000). The synapse that relays rod signals to rod-bipolar cells in starlight has a special challenge because noise generated by the rod's transduction cascade and synapse would swamp the tiny single-photon signal. A computer simulation suggested the solution (recently verified by in vitro recordings): a nonlinear threshold in the postsynaptic second-messenger system removes the noise (Smith and van Rossum, 1998).

### *IPL: Bipolar and Amacrine Circuits*

The retina contains about 10 types of bipolar cell and more than 20 types of amacrine cell (Kolb, Nelson, and Mariana, 1981; Masland, 1988; Sterling, 1997; Rodieck, 1998). Bipolar cell dendrites arborize in the OPL to receive multiple synaptic contacts from photoreceptors, and their axons terminate in the IPL. Amacrine cells extend their dendrites laterally in the IPL to contact bipolar, amacrine, and ganglion cells.

Bipolar cells respond as photoreceptors do with a voltage proportional to light intensity, but their response range is narrower and they adapt over a wider range of stimuli. Adaptation occurs at the dendritic tip from changes in gain at a second-messenger biochemical cascade, at the membrane by voltage-gated ion channels, or at the axon, where gain of output synapses is regulated in several ways by feedback. Bipolar cells contact ganglion cells with glutamatergic ribbon synapses to allow high release rates and reduce noise. A bipolar cell may contact several ganglion cell types, each with a different characteristic number of synapses, which implies a specific coding of the bipolar signal (Teeters and Arbib, 1991; Sterling, 1997).

### *Function of Amacrine Cells*

Amacrine cells are a diverse group in both morphology (Kolb et al., 1981; Rodieck, 1998) and neurochemistry (Masland, 1988). Many have a large (0.5–2 mm) but sparse dendritic field with very fine dendritic processes (0.2 $\mu$m diameter) that stretch between small swellings, called *varicosities*, where synaptic connections are made (Kolb et al., 1981; Dowling, 1987). Most amacrine cells contain voltage-gated $Na^+$ channels and fire action potentials, which allows them to transmit signals laterally over the extent of their dendritic field (Masland, 1988). Amacrine cells are generally either GABAergic (Rodieck, 1998; Kandel et al., 2000) or glycinergic, which implies that they perform subtractive or shunting control functions. Some, such as the cholinergic "starburst" amacrine, are involved in temporal processing and respond transiently to light (Masland, 1988). Amacrine circuitry is thought to be responsible for accentuating the surround, directional selectivity in ganglion cells (see DIRECTIONAL SELECTIVITY), excitatory transient and peripheral effects, and several types of gain control (Shapley and Enroth-Cugell, 1984; Dowling, 1987; Rodieck, 1998).

Amacrine cells receive synaptic contacts from bipolar cells at a *dyad*, where a bipolar ribbon synapse contacts two postsynaptic neurons, usually ganglion and amacrine cells (Rodieck, 1998). The similarity between the synaptic dyad in the IPL and the triad in the OPL is striking (Rodieck, 1998). Both contain synaptic ribbons, and both include reciprocal feedback from a lateral neuron. The reason may be the identical problem of noise. The reciprocal feedback from an amacrine varicosity to its presynaptic bipolar cell can process the signal, reducing its dynamic range before transmission to ganglion cells (Masland, 1988; Dowling, 1987; Rodieck, 1998).

### *Gap Junction Coupling in Amacrine and Bipolar Cells*

Amacrine and bipolar cells, like many types of neuron in the brain, are widely coupled by gap junctions to their neighbors. Bipolar cell coupling, like cone coupling, correlates neighboring cells' signals to enhance synchronous vesicle release. Since many amacrines fire action potentials, one possibility is that gap junctions allow them to synchronize their firing. But their diversity emphasizes the complexity of retinal circuitry (Masland, 1988; Rodieck, 1998). The AII amacrine cell is small-field and carries rod signals from the rod bipolar to cone bipolars at night (Kolb et al., 1981; Rodieck, 1998). To grasp the function of the AII has been a special challenge because it is coupled by gap junctions to its AII and bipolar cell neighbors, and these two types of electrical coupling are controlled by independently modulated second-messenger systems. The AII also contains voltage-gated $Na^+$ channels and generates action-potential-like transients. These specialized biophysical properties elegantly solve a signal-processing challenge: in starlight, the AII collects single-photon signals from an array of presynaptic rod bipolars, but synaptic noise is collected even when photons are rare. The AII's strategy, therefore, is to reduce noise by electrical coupling with neighbors, and to nonlinearly amplify the single-photon signal with voltage-gated channels (Smith and Vardi, 1995; Sterling, 1997), removing noise and reshaping the signal before passing it on.

## Diversity of Coding

### *Ganglion Cells*

Ganglion cells have exquisite sensitivity to low contrast stimuli over a wide range of light intensity (Kandel et al., 2000). They are specialized into diverse types that code different properties of the visual world (see Directional Selectivity; see also Maturana, Lettvin, and McCulloch, 1960; Kolb et al., 1981; Rodieck, 1998). Some give a tonic response to stationary stimuli (e.g., the X or W cells of cat retina), and others give a more phasic response to signal the presence of flashing or moving stimuli (e.g., the Y cell of cat retina). Many species (lower vertebrates but also mammals) possess ganglion cells with more complex receptive fields; for example, they respond only to small or large moving objects (Maturana et al., 1960; Teeters and Arbib, 1991). In many species color-opponent ganglion cells provide excellent color vision (Dowling, 1987; Rodieck, 1998).

### *Coding by the Spike Generator*

To transmit a signal to the brain, the ganglion cell codes its intracellular voltage (the generator potential) as the firing rate of action potentials along its axon (Kandel et al., 2000). Like synaptic coding, this process is limited by noise and dynamic range, so optimal coding of information is at a premium. The ganglion cell's spike generator, consisting of voltage- and ion-gated channels, traditionally thought to be located in the axon hillock and soma, is responsible for the coding properties. However, ganglion cells have voltage-gated channels in their dendritic membrane, and recently it was shown by simulation that the dendritic tree must contain these channels at sufficient densities to conduct action potentials, for without them the spike rate becomes too high (Fohlmeister and Miller, 1997). Dendritic morphology and slowly activated $K^+$ channels (Kandel et al., 2000) are also involved in shaping the ganglion cell's response. Simulations have also shown that noise in the spike generator causes variability in the spike rate, and that a significant portion of the information available in the ganglion cells' generator potential is lost in the process.

### *IPL: Specific Circuits in Sublayers*

One problem faced by the spike generator is inherent: it cannot respond well to hyperpolarizations below a certain threshold, and just above threshold, spiking is noisy. To cope with this problem, the retina contains two subclasses of ganglion cell, called *on* and *off*, that respond with opposite polarity to a light stimulus. The on cell increases its firing rate to a flash of light and the off cell reduces its firing rate. Responses of on- and off-ganglion cells in many species are symmetric, which allows the retina to code bright and dark objects without much distortion or noise.

To supply on- and off-ganglion cells with appropriate signals, the IPL is organized into on- and off-layers (sublaminae). Two bipolar cell subclasses, on, and off, respond oppositely to glutamate released by cones. Bipolar and amacrine cell types are divided roughly equally between the two layers, although some arborize in both. The on- and off-layers are in turn organized into specific sublayers defined by microcircuits comprising bipolar, amacrine, and ganglion cells, each generating a specific spatiotemporal code (Sterling, 1997).

On-bipolar dendrites contain *metabotropic* receptors that, when bound by glutamate released by a photoreceptor, signal a cytoplasmic second messenger to turn off the synapse's ionic channels (Dowling, 1987; Sterling, 1997; Rodieck, 1998). Thus, an on-bipolar depolarizes when the photoreceptor decreases its glutamate release (i.e., in response to light). An off-bipolar contains ionotropic glutamate receptors that directly open an ion channel and hyperpolarize to light. Each off-bipolar type contains glutamate receptors with different kinetic parameters, which is the first step in generating a specific temporal code. Some bipolar cells code stimulus velocity, direction, or color (Rodieck, 1998; Haverkamp, Moeckel, and Ammermuller, 1999). These specializations increase signal fidelity, which is an advantage for a visual signal that is destined to pass through a noisy channel to the brain.

## Discussion

There are several explanations for the diversity of retinal circuitry. By discarding part of the information it receives, a neuron specializes in coding specific properties of the signal, e.g., contrast, motion, bright, dark, colored light flashes, and so forth. The exact details of the coding scheme are probably related to the ecological niche occupied by the organism. Rod signals, because of their quantal nature, are qualitatively different from cone signals, so there is an advantage to having a separate rod pathway. Such specialization in coding increases the signal/noise ratio and makes better use of the limited dynamic range of neurons, synapses, and the spike train in the ganglion cell axon (Laughlin, 1994). Specialization in coding also simplifies the task of brain circuitry in visual segmentation, which may imply a function for retinal circuit structure but involves later visual processes as well (see Visual Scene Segmentation).

### *Local Processing in Retinal Circuits*

The receptive fields of many retinal neurons, and particularly of ganglion cells, share important properties, among them a center-surround organization, high sensitivity to contrast, and wide-ranging adaptation. To the extent that each retinal circuit amplifies the signal, it adapts to reduce the signal's dynamic range, which implies that the retina's high sensitivity is achieved at the cost of complexity. For example, the net effect of the OPL circuit is to create for the photoreceptor a receptive field with a broad center region and a wide antagonistic surround (Sterling, 1997; Rodieck 1998; Kandel et al., 2000) that adapts temporally and spatially. By removing information about absolute light intensity, the OPL circuit transmits what is left, i.e., information about contrast. In turn, the IPL circuit removes more information about light intensity and contrast, shaping the signal in time to code transients, and accentuating the spatial center-surround receptive field in bipolar and amacrine cells (Dowling, 1987; Rodieck, 1998). This process further regulates the visual signal's gain to improve discrimination of low-contrast objects from noise and to prevent saturation at high contrast (Shapley and Enroth-Cugell, 1984). The result of these operations is that retinal receptive fields change with background intensity to maximize information transfer (Laughlin, 1994), and the consequence of this processing is the familiar center and surround of the ganglion cell. Thus, it appears that circuits along the retinal pathway all contribute to the ganglion cell's receptive field properties for a similar reason: to prevent noise or saturation from degrading the signal (Laughlin, 1994).

The well-known antagonistic center-surround and adaptation properties of the ganglion cell receptive field, therefore, seem driven by the goal of preserving signal quality. To accomplish this, the circuitry of both OPL and IPL increase the receptive field's lateral extent. But the need for high visual acuity mandates that OPL and IPL circuits not extend laterally too far. Thus, the retina is shaped to compensate for biological limitations by a compromise between spatial acuity and accuracy of coding.

### *Testing the Theory*

Although knowledge of the biophysical components of retinal circuitry and its receptive fields is progressing rapidly, such knowledge does not guarantee a useful theory. For example, whole-cell patch recordings allow the biophysical properties and visual responses of bipolar and amacrine cells presynaptic to a ganglion cell to be measured, and these presynaptic responses contribute to the ganglion cell's receptive field. Yet such knowledge alone cannot answer the question of function in design: what function the individual components add to the circuit, and therefore why they exist. The answer can only be derived from synthetic models that integrate details of the retina's neural circuitry with the noise and dynamic range limitations inherent to neurobiology.

Computational modeling promises to help find the answers (Teeters and Arbib, 1991; Smith, 1995; Smith and Vardi, 1995; Fohlmeister and Miller, 1997; Haverkamp et al., 1999). Once the basic signal flow and function in a retinal circuit have been established, simulations can help determine overall strategies, and with information theory can find what biological limitations are most serious to the circuit (Laughlin, 1994). The effect of noise on the retina's performance can be tested by simulating noise from all the sources in the signal pathway, and comparing the resulting signal/noise ratios as a measure of signal quality.

# Robot Arm Control

*Carme Torras*

## Introduction

A robot is a multifunctional and reprogrammable mechanism able to move in a given environment. Three broad classes of robots can be distinguished on the basis of their mobility. *Robot arms* have a fixed base, and their mobility comes from their articulated structure; thus, they operate on a bounded three-dimensional (3D) subspace. *Robot vehicles* move on two-dimensional (2D) surfaces by using wheels or other similar continuous traction elements (see ROBOT NAVIGATION). *Walking robots* are designed to move through rough terrains by using articulated legs. Of course, mixed possibilities also exist, such as robot arms mounted on wheeled vehicles. This article is devoted to robot arms, or manipulators, which we will call simply robots.

Each robot is endowed with a controller that commands its mechanical structure to perform the desired tasks. Controllers are usually *hierarchically* structured from the lowest level of servomotors to the highest levels of trajectory generation and task supervision. The activity taking place at all these levels is conceptually the same: an actual motion (of a single joint, the end-effector, or the entire robot) is made to follow as closely as possible a commanded motion through the use of feedback. The difference lies in the coordinate systems used at each level.

At least four coordinate spaces can be distinguished: the task space (used to specify tasks, possibly in terms of sensor readings), the workspace (six-dimensional Cartesian coordinates defining a position and orientation of the end-effector), the joint space (intrinsic coordinates determining a robot configuration), and the actuator space (in which actual motions are commanded). Because robot control entails transforming a specification in task space into actuator commands, it critically depends on accurate mappings between the various coordinate spaces.

Neural networks have been used to approximate these mappings when they are difficult or impossible to derive analytically (as in the case of flexible or redundant robots, or in tasks entailing sensorimotor coordination) and when, because of environmental changes or robot wear-and-tear, the mappings vary in time and the controller needs to adapt on-line to these variations. This article discusses four such mappings and the neural models used to implement them adaptively.

## Neural Adaptivity in Robot Control

A robot, when moving, can be thought of as realizing a mapping from actuator space to joint space, and to the workspace and task space as well. These mappings are referred to as *forward mappings* and are parameterized by the current state of the robot. In the same general terms, a controller can be viewed as implementing *inverse mappings* in that, given the current state and a desired output (sensory pattern or robot pose), the controller has to generate the appropriate commands to attain that output.

Control strategies often rely on models of the various mappings we have delineated. Forward models are used to provide fast internal feedback in order to prevent instabilities in the control loop. Inverse models lie at the core of feedforward control. The learning of such models by means of neural networks is described in SENSORIMOTOR LEARNING (q.v.), and their use inside robot controllers is discussed in ROBOT LEARNING (q.v.).

For the purposes of the present discussion, let us mention that inverse models can be acquired under four schemes, namely *direct inverse modeling, feedback-error learning, distal supervised learning*, and *reinforcement learning* (see Sensorimotor Learning for details). These schemes can be applied under both supervised and unsupervised (or self-supervised) training modes and through the use of correlational, reinforcement, or error-minimization adaptation procedures (Torras, 1995). This distinction between adaptation procedures is made on the basis of the type of problem information they use (Figure 1).

*Correlational procedures* use no problem information, and their goal is to carry out feature discovery or clustering. In a robot control setting, these procedures are often used to represent a given state space in a compact and topology-preserving manner. Two applications to be described later rely on representations of this type for the robot workspace (see discussion under "Inverse Kinematics") and the space of joint positions, velocities, and accelerations (see "Inverse Dynamics"). The correlational procedures most widely used for robot control are Self-Organizing Feature Maps (q.v.) and Adaptive Resonance Theory (ART) (q.v.).

*Error-minimization procedures* require complete target information in the form of input-output pairs. The goal of using such procedures is to build a mapping from inputs to outputs that generalizes properly. These procedures are the most widely used in applications. Among others, the LMS rule, backpropagation (see Perceptrons, Adalines, and Backpropagation), locally weighted projection regression, and conjugate gradient optimization have been applied to robot control.

*Reinforcement-based procedures* lie between both extremes. They make use only of a reward/penalty signal to build a mapping that maximizes reward (see Reinforcement Learning). These procedures have been applied for learning sensorimotor maps.

## Inverse Kinematics

Inverse kinematics mapping provides joint coordinates as a function of the position and orientation of the robot end-effector, thus relating the workspace to the joint space. The use of neural networks to learn this mapping is of particular interest when a precise model of some joints is lacking or when, because of the conditions of operation of the robot (in space, underwater, etc.), it is hardly possible to recalibrate it.

Feedforward networks using backpropagation have been extensively tested in this context, under both the *direct inverse modeling* and the *distal supervised learning* approaches (Jordan and Rumelhart, 1992), leading to the conclusion that a coarse mapping can be obtained quickly but an accurate representation of the true mapping often is not feasible or is extremely difficult. The reason for this seems to be the *global* effect that every connection weight has on the final approximation obtained (Kröse and van der Smagt, 1993).

A way to avoid this global effect is to use local representations, so that every part of the network is responsible for a small subspace of the total input space. One such representation is the 3D self-organizing feature map (SOM) used by Ritter, Martinetz, and Schulten (1992) to encode the robot workspace. This is combined with the LMS rule to learn the inverse kinematics of a robot arm with 3 degrees of freedom (dof) under a *direct inverse modeling* approach. The inputs to each neuron are the coordinates of the desired end-effector position, and the outputs (after correct learning) are the joint angles and the Jacobian corresponding to that position. Thus, this model provides a discrete encoding of the inverse kinematics mapping augmented by a linear approximation at each sample point that permits interpolating joint angles with higher precision. The network has been shown to self-organize into a reasonable representation of the workspace in about 30,000 learning cycles. This should be taken as an experimental demonstration of the powerful learning capabilities of this model, because the conditions in which it was made to operate are the worst possible ones: no a priori knowledge of the robot kinematics, random weight initialization, and random sampling of the workspace during training.

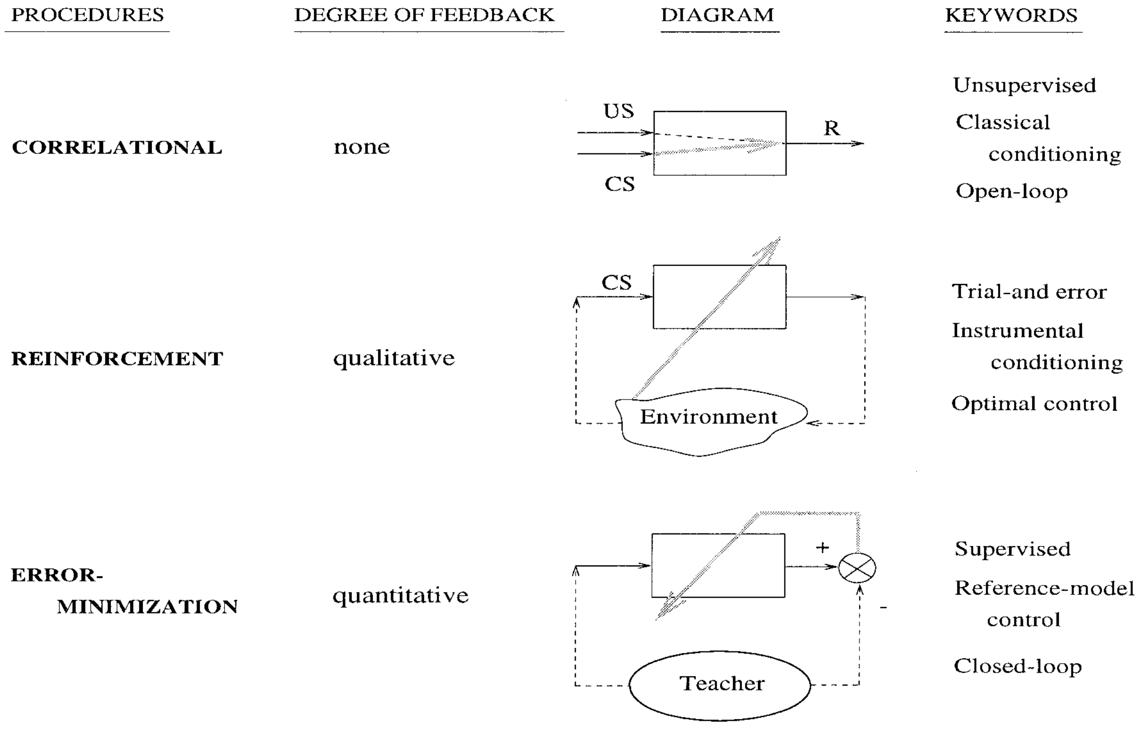

**Figure 1.** Procedures for neural adaptivity. See Torras (1995) for a detailed explanation.

This basic model has been extended in three directions to cope with higher-dof robots. First, a hierarchical version, consisting of a 3D SOM whose nodes each have associated a 2D SOM, was applied to a 5-dof robot. The 3D net encodes the workspace as before, while each 2D subnet approximates the end-effector orientation space at the corresponding position (Ritter et al., 1992).

Ruiz de Angulo and Torras (1997) have adapted this hierarchical model to suit a practical setting. Thus, instead of learning the kinematics from scratch, only the deviations from the nominal kinematics embedded in the original robot controller are learned. This, together with informed initialization and sampling, as well as several modifications in the learning algorithm aimed at improving the cooperation between neurons, led to a speed-up of two orders of magnitude with respect to the original model. Thus, when applied to the self-calibration of a 6-dof robot installed in a space station mockup, 95% of the decalibration was corrected with the first 25 movements, with the percentage rising to 98% after 100 movements. Moreover, other desirable features in stand-alone applications, such as parameter stability, are guaranteed.

The third extension relies on the generalization of SOMs to parameterized SOMs (PSOMs). The idea is to turn the discrete representation into a continuous one by associating a basis function with each neuron, so that a parameterized mapping manifold is obtained. Moreover, PSOMs make no distinction between inputs and outputs, thus encoding bidirectional mappings. Compared with the SOM, the PSOM considerably reduces the number of training samples required to attain a given precision (Walter and Ritter, 1996), allowing the learning of the full inverse kinematics of a 6-dof robot with less than 800 movements.

Recently, the development of humanoid robots has heightened interest in learning inverse kinematics. Because of the many dofs involved, the aim is no longer learning the mapping for the whole workspace but is focused on a specific trajectory. Following the trend of using localized representations, D'Souza, Vijayakumar, and Schaal (2001) have applied a supervised algorithm, locally weighted projection regression, in this context, with promising results (see Robot Learning).

## Inverse Dynamics

When the robot dynamics needs to be taken into account, the control learning problem becomes more involved. An inverse dynamics mapping relating end-effector accelerations to the required joint forces and torques should be considered now.

Because the cerebellum is involved in the production and learning of smooth movements, several cerebellar models have been proposed and applied to control robot arms. The pioneer such model was the Cerebellar Model Articulation Controller (CMAC), developed by Albus in 1975 (see Cerebellum and Motor Control for related material), but today the debate is still open as to what model best captures the functionality of the cerebellum and whether any such model can constitute a practical option to control robots (van der Smagt and Bullock, 1997). A point of agreement is that the cerebellum constructs an inverse dynamics model as it learns. Thus, cerebellar models have been used for this purpose inside robot controllers.

Miller et al. (1990) combined the table look-up facilities provided by CMAC with an error-correction scheme similar to the LMS rule to accomplish the dynamic control of a 5-dof robot. The idea underlying this combination is similar to that of enlarging SOMs with the LMS rule, as described in the preceding section. Here, CMAC is used to represent the state space in a compact and localized manner, as SOMs were used to cover the robot workspace in the preceding section. To teach the robot to follow a given trajectory, successive points along it are supplied to both the neural network and a fixed-gain controller, and then their responses are added up to command the robot. Therefore, the neural network acts as a feedforward component. After each cycle, the actual command given to the robot and its current state are used as an input-output pair to train the neural network, thus following a *direct inverse modeling* approach. As learning progresses, the CMAC network approximates the inverse dynamics mapping, and consequently, the effect of the fixed-gain controller tends to zero. The network converges to a low error (between one and two position encoder units) within ten trials, provided enough weight vectors are used.

The same trajectory learning task as described above was tackled by Miyamoto et al. (1988) using a *feedback-error learning* approach. They used directly as error signal the output of the feedback controller, which can be interpreted as a local linearization of the inverse dynamics mapping if the learning rate is sufficiently small. This error measure is less accurate than that used by Miller et al. (1990) but has the advantage of being directly available in the control loop, thus avoiding the computation of the current state of the robot required in the direct inverse modeling approach. The authors report that, after training the robot to follow a trajectory lasting 6 seconds for 300 trials, the average feedback torque decreased from a few hundred to just a few units, demonstrating that the neural network had taken over control from the fixed-gain controller. Moreover, the mean square error in the joint angles decreased steadily by 1.5 orders of magnitude.

## Force-Motor Mapping

For tasks entailing the achievement of a goal using sensory feedback, even programming in task-space coordinates can be very complex. An example is the insertion of components with small clearance, since devising a detailed force-control strategy that performs correctly in all possible situations, and subject to real-world conditions of uncertainty and noise, is extremely difficult. What is needed to accomplish this type of task is an appropriate *sensorimotor mapping* that relates sensory patterns to actuator commands. A relay through the intermediate workspace and joint space representations may or may not be required (see Limb Geometry, Neural Control).

Gullapalli, Barto, and Grupen (1994) have used an associative reinforcement learning system to learn active compliant control for peg-in-hole insertion using a 6-dof robot (see Reinforcement Learning in Motor Control). The system takes the sensed peg positions and forces, as well as the previous position command, as inputs, and produces a new position command as output. Thus, 18 real values are entered into a network with two hidden layers of backpropagation units, and six real values are produced by its output layer of stochastic reinforcement-learning units. The reinforcement signal depends on the discrepancy between the sensed and the desired position of the peg, with a penalty term being activated whenever the sensed forces on the peg exceed a preset maximum. The training runs start with the peg at a random position and orientation with respect to the hole, and end when either the peg is successfully inserted or 100 time steps have elapsed. Experimental results show that after 150 trials, the robot is consistently able to complete the insertion. Moreover, the time to insertion decreases continuously from 100 to 45 time steps over the subsequent 500 training runs.

## Visuomotor Mappings

Depending on the task to be performed and the camera-robot arrangement, visuomotor mappings take different forms. Thus, in eye-hand coordination, where cameras external to the robot are used to monitor the pose (position and orientation) of its end-effector, a mapping from the camera coordinates of a desired end-effector pose to the joint angles that permit attaining that pose is

**Table 1.** Neuroadaptive Procedures Used to Approximate Several Robot Mappings

| Mapping | Correlational + Error Minimization | Error Minimization | Reinforcement Learning |
|---|---|---|---|
| Inverse kinematics | SOM + LMS (Ritter et al., 1992; Ruiz de Angulo and Torras, 1997)<br>PSOM + LMS (Walter and Ritter, 1996) | BP (Jordan and Rumelhart, 1992; Kröse and van der Smagt, 1993)<br>LWPR (D'Souza et al., 2001) | |
| Inverse dynamics | CMAC + LMS (Miller et al., 1990) | LMS (Miyamoto et al., 1988) | |
| Force-motor | | | RL (Gullapalli et al., 1992) |
| Visuomotor | SOM + LMS (Ritter et al., 1992) | BP (Wells et al., 1996)<br>CG (Schram et al., 1996) | |

Abbreviations: SOM, self-organizing feature map; PSOM, parameterized self-organizing feature map; LMS, least-mean-square algorithm; BP, backpropagation; LWPR, locally weighted projection regression; CMAC, Cerebellar Model Articulation Controller; RL, reinforcement learning; CG, conjugate gradient learning algorithm.

sought. This mapping is closely related to the inverse kinematics one, especially if the camera coordinates of selected points in the end-effector uniquely characterize its pose. Therefore, the same models used to learn inverse kinematics have been applied in this context (Ritter et al., 1992).

A camera mounted on a robot arm is used in tasks such as visual positioning and object tracking. The goal of these tasks is to move the camera so that the image captured matches a given reference pattern. The target is thus no longer a position in space but a desired image pattern, and the desired visuomotor mapping needs to relate offsets with respect to that pattern with appropriate movements to cancel them. In visual positioning, the scene is assumed to be static and the main issue is to attain high precision. Applications include inspection and grasping of parts that cannot be precisely placed (e.g., in underwater or space settings). The aim of object tracking is to maintain a moving object within the field of view, speed being the critical parameter here instead of precision.

The classical way of tackling these tasks consists in defining a set of image features and then deriving an interaction matrix relating 2D shifts of these features in the image to 3D movements of the camera (Samson, LeBorgne, and Espiau, 1990). Note that the visuomotor mapping can be implemented with or without a relay through the workspace, depending on how the movements of the camera are commanded.

In the case of visual positioning, Wells, Venaille, and Torras (1996) have used backpropagation to learn the interaction matrix. The training procedure consists in moving the camera from the reference position to random positions and then using the displacement in image features together with the motion performed as input-output pairs. The system thus follows a *direct inverse modeling* approach. In operation, the robot is commanded to execute the inverse of the motion that the network has associated with the given input. The key option in this work is the use of global image descriptors, which permits avoiding the costly matching of local geometric features in the current and reference images. By using a statistical measure of variable interdependence (the mutual information criterion), sets of global descriptors as variant as possible with each robot dof are selected from a battery of features, including geometric moments, eigenvectors, pose-image covariance vectors, and local feature analysis vectors (Wells and Torras, 1998). The results obtained with a 6-dof robot show that after 10.000 learning cycles, translation and rotation errors are less than 2 mm and 0.1 degrees, respectively.

Concerning object tracking, Schram et al. (1996) have used a feedforward network together with a conjugate gradient learning algorithm to make a camera track a cart moving arbitrarily on a table. A visuomotor mapping relating the current and past visual coordinates of the cart with joint displacements is built on-line as the robot moves. Only 2 robot dofs need to be controlled, and thus the network has two outputs, while several numbers of inputs have been tried. The tracking performance improves as more previous positions of both the cart and the robot are used, attaining an average lag of only 8 mm in the case of seven inputs.

## Discussion

After surveying several robot neurocontrol applications entailing the learning of various mappings (Table 1), we have extracted some guidelines.

In the case of *mappings that can be easily sampled*, it seems sufficient to apply a direct inverse modelling approach combined with an error-minimization learning procedure. Some simple inverse kinematics mappings and visuomotor mappings used for visual positioning have been learned in this way. If *the input space is complex*, then many researchers have resorted to a combination of correlational rules for the efficient coding of that space, with error-minimization procedures to build the appropriate association with the outputs. The use of self-organizing feature maps to encode the robot workspace or the sensor space, as well as the application of CMAC to the coding of the robot dynamics state space, fall into this category. When *the task is specified as a goal to be attained* using sensory feedback, without making explicit the movements necessary to attain it, the only possibility is to resort to reinforcement learning procedures, which depend just on the availability of a measure of success rather than on an error measure.

The number of learning cycles required ranges widely in the applications described, depending on the complexity of the mapping to be learned as well as on the accuracy required. Only ten trials are needed to get a useful mapping in the case of inverse dynamics using CMAC. The explanation is that only a very coarse mapping is needed, since the neural controller is used as a feedforward component in combination with a fixed-gain feedback controller. The number of trials rises to a few hundred in the case of force-motor mappings for insertion of components. One hundred learning cycles suffice to correct the distortions in the inverse kinematics mapping resulting from robot wear-and-tear, while this number rises to nearly 1,000 when the full mapping has to be learned from scratch. And the progression continues, to up to 10,000 trials when the inputs are not spatial coordinates but global descriptors extracted from images. Of course, some of these figures might be considerably lower in the future, especially the last one, if more effcient codings of the input space are found.

# Robot Learning

*Stefan Schaal*

## Introduction

Learning robot control, a subclass of the field of learning control, refers to the process of acquiring a sensorimotor control strategy for a particular movement task and movement system by trial and error. Learning control is usually distinguished from adaptive control in that the learning system is permitted to fail during the process of learning, while adaptive control emphasizes single-trial convergence without failure. Thus, learning control resembles the way that humans and animals acquire new movement strategies, while adaptive control is a special case of learning control that fulfills stringent performance constraints, such as may be needed in life-critical systems such as airplanes and industrial robots.

A key question in learning control is what it is that should be learned. In order to address this issue, it is helpful to assume one of the most general frameworks of learning control as originally developed in the middle of the twentieth century in the fields of optimization theory, optimal control, and in particular dynamic programming (Bellman, 1957; Dyer and McReynolds, 1970). Here, the goal of learning control was formalized as the need to acquire a task-dependent control policy $\pi$ that maps the continuous-valued state vector $\mathbf{x}$ of a control system and its environment, possibly in a time-dependent way, to a continuous-valued control vector $\mathbf{u}$:

$$\mathbf{u} = \pi(\mathbf{x}, \alpha, t) \tag{1}$$

The parameter vector $\alpha$ contains the problem-specific parameters in the policy $\pi$ that need to be adjusted by the learning system. Figure 1 illustrates the generic control diagram of learning a control policy. Since the controlled system can generally be expressed as a nonlinear function

$$\dot{\mathbf{x}} = f(\mathbf{x}, \mathbf{u}) \tag{2}$$

in accordance with standard dynamical systems theory (Strogatz, 1994), the combined system and controller dynamics result in:

$$\dot{\mathbf{x}} = f(\mathbf{x}, \pi(\mathbf{x}, t, \alpha)) \tag{3}$$

Thus, learning control means finding a (usually nonlinear) function $\pi$ that is adequate for a given desired behavior and movement system. This formal viewpoint allows discussing robot learning in terms of the different methods that have been suggested for learning control policies.

## Methods of Learning Robot Control

### Learning the Control Policy Directly

It is possible to learn the control policy $\pi$ directly, i.e., without splitting it into subcomponents, as explained in later sections. For this purpose, the desired behavior needs to be expressed as an optimization criterion $r(t)$ to be optimized over a certain temporal horizon $T$, resulting in a cost function

$$J(\mathbf{x}(t)) = \int_{t=0}^{T} r(\mathbf{x}(s), \mathbf{u}(s))ds$$

or

$$J(\mathbf{x}(t)) = \int_{t=0}^{\infty} \frac{1}{\tau} e^{-(s-t/\tau)} r(\mathbf{x}(s), \mathbf{u}(s))ds \tag{4}$$

The second formulation of Equation 4 illustrates the use of an infinite horizon time window by introducing a discount factor that

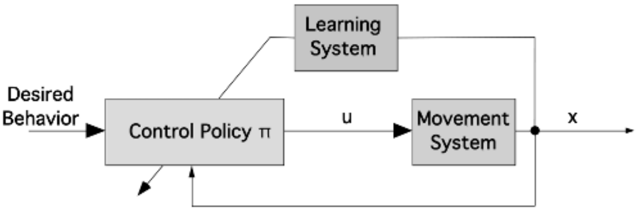

**Figure 1.** Generic control diagram for learning control.

reduces the influence of values of $r(t)$ in the far future. Note that $r(t)$ is usually a function of the state $\mathbf{x}$ and command $\mathbf{u}$ taken in $\mathbf{x}$; i.e., $r(t) = r(\mathbf{x}(t), \mathbf{u}(t))$. Solving such kinds of optimization problems was developed in the framework of dynamic programming (Dyer and McReynolds, 1970) and its recent derivative, reinforcement learning (Sutton and Barto, 1998; see also Reinforcement Learning). For reinforcement learning, $r(t)$ corresponds to the "immediate reward" and $J(\mathbf{x}(t))$ to the "long-term reward." For instance, in the classical task of balancing a pole on a finger, the immediate reward could be $+1$ at every time step at which balancing was successful, and $-1000$ if the pole was dropped; the task goal would be to accumulate maximal long-term reward, equivalent to balancing without dropping.

The policy $\pi$ is acquired with reinforcement learning by, first, learning the optimal function $J(\mathbf{x}(t))$ for every state $\mathbf{x}$, usually by a technique called temporal difference learning (see Reinforcement Learning), and then deducing the policy $\pi$ as the command $\mathbf{u}$ in every state $\mathbf{x}$ that leads to the best future payoff, i.e.,

$$\mathbf{u} = \max_{u'} (r(\mathbf{x}(t), \mathbf{u}'(t)) + J(\mathbf{x}(t + 1)))$$

where

$$\mathbf{x}(t + 1) = \mathbf{x}(t) + f(\mathbf{x}(t), \mathbf{u}'(t))\Delta t \qquad (5)$$

where $\Delta t$ is an arbitrarily chosen constant time step for sampling the system's behavior. Many variations of reinforcement learning exist, including methods that avoid estimating the optimization function $J(\mathbf{x}(t))$ (see Reinforcement Learning).

### *Learning the Control Policy in a Modular Way*

Theoretically, the techniques of reinforcement learning and dynamic programming would be able to solve any robot learning problem that can be formulated as sketched in the previous section. Practically, however, this is not true, since reinforcement learning requires a large amount of exploration of all actions and states for proper convergence of learning as well as appropriate representations for the function $J(\mathbf{x}(t))$. Traditionally, $J(\mathbf{x}(t))$ needs to be represented as a lookup table; that is, for every state $\mathbf{x}$ a specific table cell holds the appropriate value, $J(\mathbf{x}(t))$. For continuous-valued states, discretization of the individual dimensions is needed. For high-dimensional systems, this strategy leads to an explosion of lookup table cells. For example, for a 30-dimensional movement system where each dimension is split into just two cells, an astronomical number of $2^{30}$ cells would be required. Exploring all these cells with a real robot would take forever, and even in computer simulations such problems are not tractable. Newer approaches employ special neural networks for learning and representing $J(\mathbf{x}(t))$ (e.g., Sutton and Barto, 1998), but problems with high-dimensional movement systems remain daunting.

A possible way to reduce the computational complexity of learning a control policy comes from modularizing the policy (Figure 2). Instead of learning the entire policy in one big representation, one could try to learn subpolicies that have reduced complexity and subsequently build the complete policy out of such subpolicies. This approach is also appealing from the viewpoint of learning multiple tasks: some of the subpolicies may be reused in another task, which should strongly facilitate learning new tasks.

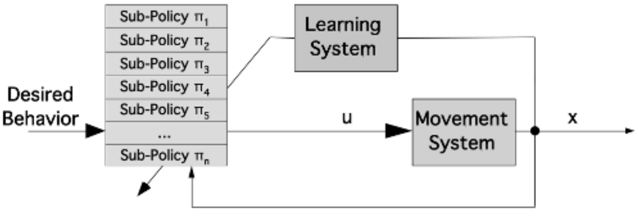

**Figure 2.** Learning control with subpolicies.

Motor control with subpolicies has been explored in various fields under the names of, e.g., schema theory (see Schema Theory), behavior-based robotics (see Reactive Robotic Systems), pattern generators (see Motor Pattern Generation), and movement primitives (Schaal, 1999). Robot learning with such modular control systems, however, is still in its infancy. Reinforcement learning has recently begun to formulate a principled approach to this problem (Sutton, Precup, and Singh, 1999). Another route of investigating modular robot learning comes from formulating subpolicies as nonlinear dynamical systems (Mussa-Ivaldi and Bizzi, 1997; Schaal and Sternad, 1998). However, all this research is still of a preliminary nature and not yet applicable to complex robot learning problems.

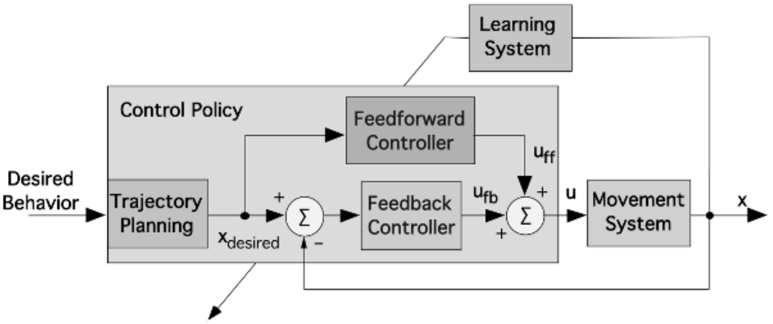
### *Indirect Learning of Control Policies*

The previous sections assumed that motor commands are directly generated based on the information of the state of the world $\mathbf{x}$, i.e., from the policy function $\pi$. For many movement systems, however, such a *direct* control strategy is not advantageous because it fails to reuse modules in the policy that are common across multiple tasks. This view suggests that, in addition to a modularization of motor control and learning in form of a mixture of simpler policies (Figure 2), modularization can also be achieved in terms of a functional structuring within each control policy. A typical example is to organize the control policy into several processing stages, as illustrated in Figure 3 and also discussed as *indirect* control in Motor Control, Biological and Theoretical (q.v.). Most commonly, the policy is decomposed into a planning stage and an execution stage, a strategy that is typical for most robot controllers but also likely to be used in motor control of primates. Planning generates a desired *kinematic* trajectory, i.e., a prescribed way in which the state of the movement system is supposed to change in order to achieve the task goal. Execution transforms the plan into appropriate motor commands.

Separating planning and execution is highly advantageous. For instance, in reaching movements located toward a target, a *direct* approach to robot learning would require learning a new policy for every target location: the desired behavior is to minimize the distance between the hand and the target, and because of the complex dynamics of an arm, different target locations require very different motor commands for reaching. In contrast, an indirect control approach requires learning only the movement execution module, usually in the form of an inverse model (see below). The execution module is valid for any target location. For simplicity, movement plans can be kept the same for every target location, such as a straight line between the target and the starting position of the arm, with a bell-shaped velocity profile. Planning such movement kinematics requires only one-time learning of the robot kinematics model and using standard kinematic planning algorithms (Sciavicco and Siciliano, 1996) that can easily cope with any reachable target location. Thus, after the execution module has been acquired, the problem of reaching is a largely solved, no matter where the target is.

Depending on the task, planning can take place in external kinematic variables (e.g., Cartesian or end-effector space) or in internal kinematic variables (e.g., joint space for a human-like arm). If the planning space does not coincide with the space where motor commands are issued, coordinate transformations are required to map the external motor plan into intrinsic coordinates. This problem is commonly discussed as the inverse kinematics problem of

**Figure 3.** Learning control with functional decomposition.



Robot Arm Control (q.v.), a problem that equally needs to be addressed by biological movement systems.

To transform kinematic plans into motor commands, standard methods from control theory can be employed (e.g., Sciavicco and Siciliano, 1996). Figure 3 illustrates a typical example that uses a feedforward/feedback mechanism, called a *computed torque controller*, that enjoys popularity in both robotic systems and models of biological motor control (Jordan, 1996). The feedback controller is of classical proportional derivative (PD) type, while the feedforward controller contains an inverse dynamics model of the movement system (see Cerebellum and Motor Control).

From the point of robot learning, functional modularity also decomposes the learning problem into several independent learning problems. The modules of the execution stage can be learned with supervised learning techniques (discussed later; see also Cerebellum and Motor Control). For various types of movements, kinematic movement plans can be highly stereotyped, as was described for the reaching example, such that no learning is required for planning. For complex movements such as a tennis serve, planning requires more sophistication, and the same reinforcement learning methods of *direct* control can be applied, the only difference being that the motor commands **u** are replaced with a desired change in trajectory $\dot{\mathbf{x}}_d$. Applying reinforcement learning to kinematic planning is less complex than solving the complete *direct* control problem since the highly nonlinear transformation from kinematic plans to motor commands does not need to be acquired anymore, but how to perform reinforcement learning for high-dimensional movement systems still remains an open research problem.

### *Imitation Learning*

A topic in robot learning that is of increasing interest is *imitation learning.* The idea of imitation learning is intuitively simple: a student watches the performance of a teacher and subsequently uses the demonstrated movement as a seed to start his or her own movement. The ability to learn from imitation has a profound impact on how quickly new skills can be acquired (Schaal, 1999). From the viewpoint of learning theory, imitation can be understood as a method to bias learning toward a particular solution, the teacher's. Motor learning proceeds afterward, as described in the other sections of this article. However, not every representation for motor learning is equally suited to be biased by imitation (Schaal, 1997). For instance, a robot using direct control can hardly profit from a demonstration, as motor commands are not perceivable, but a robot using indirect control could first extract a kinematic plan from the demonstration and then use it for starting its own learning. Imitation thus imposes interesting constraints on the structure of a learning system for motor learning.

## Learning of Motor Control Components

Whether direct or indirect control is employed in a motor learning problem, the core of the learning system usually requires methods of supervised learning of regression problems, called function approximation in the neural network and statistical learning literature. *Function approximation* is concerned with approximating a nonlinear function $\mathbf{y} = f(\mathbf{x})$ from noisy data, drawn according to the data-generating model:

$$\mathbf{y} = f(\mathbf{x}) + \varepsilon \quad \text{where } \mathbf{x} \in \Re^n,\ \mathbf{y} \in \Re^m,\ E\{\varepsilon\} = 0 \qquad (6)$$

i.e., $\mathbf{x}$ is an $n$-dimensional continuous-valued vector, $\mathbf{y}$ is an $m$-dimensional continuous-valued vector, and $\varepsilon$ a zero-mean random "noise" variable. By comparing the generic form of a policy in Equation 1 or a dynamics model in Equation 2 with Equation 6, it is apparent that learning such functions falls into the framework of function approximation.

### *Neural Network Approaches to Function Approximation*

Many different methods of function approximation exist in the literature (see Learning and Statistical Inference). For present purposes, it is sufficient to classify all these algorithms into two categories, spatially localized (*local*) algorithms and spatially nonlocalized (*global*) algorithms. The power of learning in neural networks comes from the nonlinear activation functions that are employed in the hidden units of the neural network. *Global* algorithms use nonlinear activation functions that are not limited to a finite domain in the input space (**x**-space) of the function. The prototypical example is the sigmoid function in Figure 4*A* that outputs a value of roughly one for any input greater than about one. In contrast, *local* algorithms make use of nonlinear activation functions that are different from zero only in a restricted input domain. The Gaussian function in Figure 4*B* exemplifies this class of functions. Even though both local and global algorithms are theoretically capable of approximating arbitrarily complex nonlinear functions, learning speed, convergence, and applicability to high-dimensional learning problems differ significantly between the two (Schaal and Atkeson, 1998).

To understand how global algorithms approximate nonlinear functions, it is helpful to think of them as an octopus whose tentacles stretch out and span the complex surface described by $\mathbf{y} = f(\mathbf{x})$, except that the tentacles exist in an $n$-dimensional space. Global algorithms can work quite well for problems with many input dimensions, since their nonlocal activation function (i.e., their tentacles) can span even huge spaces quite efficiently. But global algorithms usually require very careful training procedures so that the tentacles learn how to stretch appropriately into all directions. In particular, if at some point in training, data are only provided for a restricted area in input space, the tentacles may focus too much on approximating this area and, while doing so, forget maintaining the "tentacle posture" in previously learned areas—a phe-

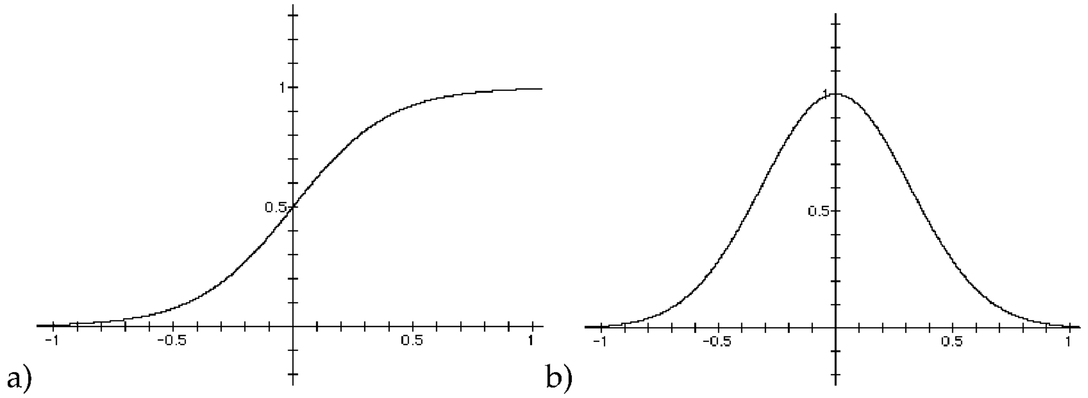


**Figure 4.** Nonlinear activation functions used in neural networks. *A*, The sigmoid function, a spatially global function. *B*, The Gaussian function, a spatially localized function.

nomenon called catastrophic interference (Schaal and Atkeson, 1998). Catastrophic interference is particularly pronounced in incremental learning problems, where training data come point after point and can only be used once for updating the algorithm. Unfortunately, this is the typical scenario in robot learning. Together with the problem of how to select the right number of hidden units (i.e., the right number of tentacles), it becomes quite complicated to train global algorithms for high-dimensional robot learning problems.

In contrast, local learning algorithms have quite different characteristics. The metaphor for local learning is simply that they approximate the complex regression surface with the help of small local patches, for instance locally constant or locally linear functions (Atkeson, Moore, and Schaal, 1997). Problems of how many patches need to be allocated, where to place them, how large they should be in input space, and how to learn them incrementally have largely been solved (Schaal and Atkeson, 1998). The biggest problem of local algorithms is the curse of dimensionality, i.e., the exponential explosion in the number of patches that are needed in high-dimensional input spaces. For instance, assume that we want to divide every input dimension of a function approximation problem into ten local regions. For two input dimensions, this strategy would result in $10^2$ local regions, for three inputs in $10^3$ regions, and for $n$ inputs in $10^n$ regions. Even for only 12 input dimensions, this number reaches the number of neurons in the human brain. The only way to avoid this problem is to make the patches larger, but then the quality of function approximation becomes unacceptably inaccurate. There is theoretically no way out of the curse of dimensionality—but empirically, it turns out not to be a problem. The example demonstrating the curse of dimensionality can be turned around in our favor: How long would it take a robot system to generate all the data points to fill these big spaces? As an example, collecting $10^{12}$ data points at 100 Hz sampling frequency would take more than 300 years of uninterrupted movement! Thus, no actual robot will ever be able to generate enough data to fill these huge spaces. This argument triggers a most important question: What kind of data distributions are actually realized by robotic (or biological) movement systems? Vijayakumar et al. (2002) found that distribution had only about four to six dimensions locally in a robot learning problem that had 21 input dimensions, a finding that was also duplicated in other robot learning domains (Vlassis, Motomura, and Krose, 2002). Local learning can exploit this property by using techniques of local dimensionality reduction and can thus learn efficiently even in very high-dimensional spaces (Vijayakumar et al., 2002). Thus, for the time being, local learning algorithms seem to be better suited for robot learning.

### *Specific Function Approximation Problems in Robot Learning*

Applying function approximation to problems of robot learning requires a few more considerations. The easiest applications are those of straightforward supervised learning, i.e., where a teacher signal $\mathbf{y}$ is directly available for every training point $\mathbf{x}$. For example, learning a dynamics model of the form of Equation 2 usually falls into this category if the inputs $\mathbf{x}$ and $\mathbf{u}$ and the output $\dot{\mathbf{x}}$ can be measured directly from sensors. Many other problems of Robot Arm Control (q.v.) are of a similar nature.

Learning becomes more challenging when instead of the teacher signal only an error signal is provided, and the error signal is just approximate. Assume we have such an error signal $\mathbf{e}$ when the network predicted a particular $\hat{\mathbf{y}}$ for a given input $\mathbf{x}$. From this information, we can create a teacher signal $\mathbf{y} = \hat{\mathbf{y}} + \mathbf{e}$ and train the network with this target. However, if $\mathbf{e}$ was only approximate, $\mathbf{y}$ is not the true target, and later on during learning another (hopefully more accurate) teacher signal may be formed for training the network. Thus, learning proceeds with "moving targets," which is called a nonstationary learning problem. For such learning tasks, neural networks need to have an appropriate amount of plasticity in order to keep on changing until the targets become correct. On the other hand, it is also important that the network converge at some point and average out the noise in the data, i.e., that the network not have too much plasticity. Finding appropriate neural networks that have the right amount of plasticity-stability trade-off is a nontrivial problem, and so far, heuristic solutions dominate the literature.

Nonstationary learning problems are unfortunately quite common in robot learning. Learning the optimization function $J(\mathbf{x}(t))$ in reinforcement learning is one typical example since the temporal difference algorithm (Sutton and Barto, 1998) can only provide approximate errors. Other examples include feedback error learning and learning with distal teachers (Jordan, 1996). Both of these methods address the problem that in learning control, we usually receive errors in only sensory variables, such as positions and velocities, but what is needed to train a control policy is an error in motor commands. Thus, feedback error learning creates an approximate motor command error by using the output of a linear feedback controller as the error signal. Learning with distal teachers accomplishes essentially the same goal, except that it employs a learned forward model to map an error in sensory space to an approximate motor error.

## Applications

While the theoretical development of learning control has progressed significantly in recent years, applications in actual robots have remained rather sparse because of the significant computational burden of most learning algorithms and the real-time constraints of actual robots. Reinforcement learning in actual robots remains largely infeasible, and only few examples exist in simplified setups (e.g., see references in Atkeson et al., 1997; Sutton and Barto, 1998; Schaal, 1999). Learning of internal models for robot control has found increasingly more widespread application owing to significant advances in the computational efficiency of supervised learning algorithms (e.g., see references in Atkeson et al., 1997; Vijayakumar et al., 2002; Vlassis et al., 2002).

## Discussion

Robot learning is a surprisingly complex problem. It needs to address how to learn from (possibly delayed) rewards, how to deal with very high-dimensional learning problems, how to use efficient function approximators, and how to embed all the elements in a control system with real-time and robust performance. A further difference from many other learning tasks is that in robot learning, the training data are generated by the movement system itself. Efficient data generation, i.e., exploration of the world, will result in fast learning, while inefficient exploration can prevent successful learning altogether (see REINFORCEMENT LEARNING). Insofar as very few robots in the world are equipped with learning capabilities, research on robot learning is still in an early stage of development.

# Robot Navigation

*José del R. Millán*

## Introduction

Mobile robots are gradually leaving the laboratories to undertake service tasks ranging from providing surveillance of buildings and supervision of plants, to transporting patients and delivery items, to cleaning houses and guiding people. Independently of the assigned task, the basic capability of a mobile robot is to move to its destination—or sequence of targets—efficiently (e.g., along short trajectories) and safely (i.e., without collisions). *Navigation* refers to the capability of selecting and performing a path from a current position to a desired location. Implicit in this definition is the ability to adapt the goal-oriented behavior to the complexity of the task. If a target location is either visible or identified by a landmark (or sequence of landmarks), a simple stimulus-response strategy can be adopted (REACTIVE ROBOTIC SYSTEMS). However, targets are often neither visible nor identified by any sequence of cues. In this case, for a robot to navigate it must first determine its position with respect to the target. This is the *localization* problem. Finally, to perform more flexible and sophisticated navigation (e.g., planning short cuts), the robot needs a model of the environment encoding the spatial relationships between locations. Acquiring such a model is the *map-building* problem.

Like any other robotic system (ROBOT ARM CONTROL), mobile robots must rely on on-line sensory information to take actions. But, unlike most arm robots, sensory information cannot only be proprioceptive (i.e., an odometry process that gives the robot's coordinates based on internal encoders); it must also provide exteroperception (i.e., information about the external environment). Indeed, odometry alone accumulates errors due to slippage, which will make the robot get lost and crash sooner or later. Mobile robots mainly use three types of sensors to perceive their surroundings, namely tactile sensors that inform about contacts, range sensors (lasers, ultrasounds, or infrareds) that return distances after appropriate transformations, and vision. Given the opposite strengths and weaknesses of the different sensors, an orthogonal issue not covered by this article is that of sensor fusion (SENSOR FUSION).

A common property shared by all types of sensors is their noisy responses. This sensor uncertainty, together with the inaccuracy of the robot's actuators and the unpredictability of real environments, makes the design of mobile robot controllers a difficult task. The complexity of the sensorimotor mapping underlying robot navigation yields two main consequences. First, simulations, though useful, are not enough to reproduce the actual agent-environment interaction. Second, robots must build their control strategies based on their own sensory perceptions of the real world (i.e., *embodiment*). Human-made controllers are, except for simple tasks and environments, inadequate because the designer must anticipate every possible situation the robot might face and must tune the controller's parameters to achieve efficient performance. An alternative is to endow robots with *learning capabilities* in order to acquire autonomously their control system and to adapt their behavior to never-experienced situations (i.e., *generalization*).

Artificial neural networks (ANN) offer a suitable learning framework to model the basis of adaptive behavior. Indeed, their noise robustness and generalization capabilities allow robots to cope with the nature of their interaction with the world and to build appropriate sensorimotor mappings. The next three sections discuss ANN approaches to localization, map building, and navigation.

## Localization

To solve complex navigation tasks, mobile robots must self-localize in the environment by relying on their exteroceptive and proprioceptive sensory inputs. In general, localization calls on *place recognition.* To localize itself, the robot can either simply memorize the sensory perceptions observed during exploration or can learn a more complex representation (map) encoding spatial relationships between experienced local perceptions. How the robot acquires a map is discussed in the next section.

Strictly speaking, only Thrun (1998a,b) uses an ANN for localization. In the remaining approaches, the robot's perception is matched against the model, which has an ANN organization, and its location is derived from that associated to the winning unit. Actually, the robot's perception can be the current sensory reading plus odometry information (Zimmer, 1996), sensory data averaged as the robot moves (Matarić, 1992), or egocentric views obtained from the sensory perceptions (Recce and Harris, 1996).

An alternative is to transform raw sensory data into a more reliable representation through ANN (Thrun, 1998a). In particular, a feedforward ANN is trained through *backpropagation* to generate a local *occupancy grid* from the current sensory perception. Such a grid is a discrete representation of the space around the robot, where each cell has a value that estimates the occupancy probability of the corresponding area of the world. After exploration, the localization algorithm searches for the previously stored grid that best matches the current local map. There are two advantages of using a neural sensor interpretation to build local occupancy grids: the ANN does not assume any noise distribution, and it interprets sensor readings simultaneously. On the other hand, the shortcoming of this approach is its computational cost, as building an *n***n* grid requires *n***n* calls to the ANN.

A totally different approach is to learn what environmental features are the most relevant landmarks for localization. Thrun (1998b) trained a feedforward ANN to optimize a Bayesian measure of probabilistic localization. Training was done on samples collected during an exploration phase in which each sample consisted of a sensory perception and its location. During operation, the robot averaged the ANN response for the *k* nearest neighbor samples to its estimated location. This approach demonstrated its superiority to hand-coded localization methods based on using doors and ceiling lights as landmarks.

## Building

The representations a robot may learn are of two main types, namely *metric* and *topological.* In the former, maps quantitatively reproduce the geometric and spatial features of the environment. This is computationally expensive and vulnerable to errors that affect the metric information. Topological maps are more qualitative and consist of a graph, on which nodes represent perceptually distinct places (landmarks) and arcs indicate spatial relations between them. They are less vulnerable to sensory errors, and enable fast planning since the latter reduces to a simple search process in a graph. However, topological representations rely on the existence of ever-recognizable landmarks.

One of the most popular approaches to building metric maps is based on the use of occupancy grids. Thrun (1998a) trained a feedforward ANN to create a local occupancy grid modeling the space surrounding the robot. Successive local grids generated as the robot explored its environment were then combined to produce an accurate global metric map. Once the global metric map was available, a topological graph could be abstracted off-line. This greatly reduces the cost of planning paths between different locations in the environment. This approach (in conjunction with the localization process discussed before) is implemented in museum tour-guided robots. An alternative is to use the same neural sensor interpretation but only for deriving coarse geometrical features from which to build up on-line a variable-resolution partitioning of the environment (Arleo, Millán, and Floreano, 1999). The environment is discretized in cells of different sizes, with a high resolution only on critical areas (i.e., around obstacles). The resulting map combines geometrical and topological aspects that are learned simultaneously.

Among topological approaches, Matarić's model (1992) builds a sparse graph in which each node represents a unique predefined landmark. Spatial relationships between landmarks are encoded by neighbor links in the graph, which produces a structure isomorphic to the topology of the environment. Disambiguation between similar sensory patterns is done by spreading expectations from the currently active unit to its neighbors (contextual discrimination) or by attaching metric information to the units. Self-organizing organizing feature maps or Kohonen maps (SELF-ORGANIZING FEATURE MAPS) provide an alternative way of acquiring topological maps (Kurz, 1996; Zimmer, 1996). A self-organizing, or *Kohonen,* map clusters the sensory perceptions gathered during the exploration phase of the robot (Kurz, 1996). The dimensionality of the Kohonen map matches the robot's degrees of freedom, either two or three depending on whether or not the robot moves with a constant orientation. As a result, neighboring units in the learned Kohonen map correspond to neighboring areas in the sensory space. The problem is that there is no guarantee that neighbor areas in sensory space are also close in metric space. Still worse, due to the limitations of its sensors a robot may have similar sensory perceptions from two different metric locations. A possible solution is to include odometry information in the self-organizing process (Zimmer, 1996), which presumes a reliable localization process. Another solution is to use the temporal sequence of sensory perceptions and not just the current one. This can be achieved by means of a recurrent Kohonen map. Finally, instead of using a self-organizing map with a fixed structure (dimensionality and number of units), it is also possible to learn the topological map of the environment by means of a *dynamic self-organizing map.* This method adds a new unit whenever the current sensory perception is sufficiently different from any existing unit (Millán, 1997; Zimmer, 1996), or is using statistical measures (Zimmer, 1996). In this kind of network the topology of the environment is kept in the links between units. It is worth noting that the ADAPTIVE RESONANCE THEORY (q.v.) can yield quantizations of the environment similar to a dynamic self-organizing map, but the resulting map does not exhibit topological relationships between the units.

Map learning systems engineered so far are not as robust, flexible, and adaptable as biological spatial learning solutions. Neurophysiological findings suggest that the spatial memory of mammals is supported by location-sensitive neurons (*place cells*) in the *Hippocampus* (see HIPPOCAMPUS: SPATIAL MODELS). Recent research in robot navigation has moved toward biologically inspired approaches to developing autonomous systems that mimic mammalian spatial learning capabilities. For example, Recce and Harris (1996) put forward a map-building model that ascribes the spatial memory function to the hippocampus. The authors assume that a place cell in the robot's hippocampus memorizes a complete egocentric map of the environment. This is a strong requirement for both robots and animals, especially if operating in middle- and large-scale environments. Arleo and Gerstner (2000) propose a hippocampal model in which unsupervised *Hebbian* learning is applied to acquire a spatial map incrementally and on-line. The representation consists of a population of localized overlapping place fields that provide a stable coarse space code. The robot establishes place fields by extracting spatiotemporal properties of the environment from visual inputs and solves visual ambiguities by taking into account proprioceptive self-motion signals.

### *Navigation*

If the robot has acquired (or is given) a topological map, then whenever it is requested to navigate to a given destination it simply searches for an optimal route in the graph and uses elemental *behaviors* to move from one node to the next along that route. However, building and maintaining consistent global maps of the environment is far from being a trivial problem, since noisy sensory data may introduce errors into the maps. Also, unless the robot is equipped with good exploration strategies, it may fail to model the whole environment and topological relationships. For example, most map building approaches rely on a wall-following (and obstacle avoidance) behavior that prevents the robot from visiting open or cluttered areas. Thus, while in operation, the robot will never take shortcuts. Alternatively, the robot can directly use behaviors to reach its destination without resorting to any map. In this section we discuss how the necessary behaviors can be learned by means of ANN.

A behavior is a set of perception-action rules that provide the robot with a given functionality such as obstacle avoidance (REACTIVE ROBOTIC SYSTEMS). Perception-action mappings can be learned off-line from representative training sets, mainly through *supervised* techniques (Pomerleau, 1993; Sharkey, 1998). Pomerleau's system (1993) is a paradigmatic example of the potentiality of the supervised approach. He trained a feedforward ANN to drive a car in a variety of roads. Training data were gathered by observing a human expert driving the vehicle. In particular, inputs corresponded to images of the road in front of the car and desired outputs corresponded to the driver's steering direction. After learning, the ANN controller made the vehicle follow the road by keeping it in the center of the lane.

Instead of requiring a human for data collection, an alternative is to use a preprogrammed controller as an initial teacher. Sharkey (1998) made feedforward ANN learn from an initial behavior-based controller to approach a target while avoiding obstacles. The final neural controller, obtained through a bootstrapping process, performed better than the original controller did. Nevertheless, the resulting network also inherited limitations of the initial controller. This illustrates one of the fundamental limitations of supervised learning and leads to the necessity of *autonomous* robot learning.

Autonomous robots must train themselves on-line in order to cope with weak and incomplete training examples. REINFORCEMENT LEARNING (q.v.) is an appropriate paradigm to achieve this. A reinforcement-based robot can improve its performance over time without needing extensive previous knowledge about the task. This is quite appealing but, on the other hand, makes the learning process very slow. The following section will describe several extensions to the basic reinforcement learning framework that considerably speed up the convergence to suitable sensorimotor mappings (or policies, as they are customarily called in the control and reinforcement learning fields), thus making it possible to build practical learning mobile robots.

Lin (1991) combined *Q-learning* (a widely studied reinforcement learning technique) and teaching. The controller had one feedforward network for each discrete action the robot can perform. The input to each ANN was the current sensory perception and the output was a prediction of the *Q-value* of that perception-action pair. The robot normally took the action with the highest Q-value (Q-LEARNING FOR ROBOTS). In Lin's experiment, a human teacher brought the robot to its goal several times along efficient paths. Then, the robot learned the appropriate Q-values, and hence good policies, from these examples. The taught navigation sequences helped reinforcement learning by biasing the search for suitable actions toward promising parts of the action space.

Thrun (1995) also used Q-learning, but integrated it with explanation-based learning (EBL). EBL requires a domain theory that is previously learned by a set of feedforward ANN (action models) in a supervised manner, one network for each discrete action the robot can perform. Each network receives the current sensory perception and predicts the next perception and Q-value. In addition to action models, the robot has also a Q network per action similar to that of Lin (1991). As before, the Q networks encode the control policies. Finally, for each actual sequence of actions taking the robot either to the goal or to a failure, the robot explains the observed example in terms of its domain theory by computing the derivatives of the policy with respect to the action model networks. These derivatives are used to bias the supervised learning of the policy (i.e., the Q networks). It is worth noting that since the action models are task independent, they are learned once and can be used across the different tasks faced by the robot.

The previously discussed reinforcement-based robots perform discrete actions, while for smooth operation they should take continuous actions. Millán (1996, 1997) has implemented *Actor-Critic* architectures instead of Q-learning for this purpose. Key components of his learning architecture are the use of *local networks* and the incorporation of *bias* into the network. Local networks make the robot learn incrementally new sensorimotor rules (or tune existing ones) without degrading the performance of other rules. The robots use built-in reflexes (basic domain knowledge) as bias. There are two benefits of bias. First, it accelerates the learning process since it focuses the search process on promising parts of the action space immediately. Second, it makes the robot operational from the very beginning and increments the safety of the learning process. The ANN is trained on-line by means of a combination of reinforcement learning and self-organizing rules. Every time the robot fails to generalize its previous experience to the current sensory perception, it uses the reflexes and adds a new unit to the network. The robot may also add a new unit whenever it receives an advice from humans. This unit is integrated into a dynamic self-organizing map and associates a region around the current perception to either the computed reflex or the advice. The resulting sensorimotor rule is then tuned by means of reinforcement learning and self-organizing rules. Experimental results show that a few minutes suffice for the robot to navigate efficiently in office environments of moderate complexity, in which the robot can easily get trapped inside concave areas.

Recently, reinforcement learning has been shown to be a suitable framework to model reward-based navigation in animals. For example, Arleo and Gerstner (2000) employed Q-learning in continuous space to drive action units one synapse downstream from their hippocampal place cells. Due to the coarse space code provided by the localized overlapping place fields, Q-learning converges in few trials, which is consistent with the rapid acquisition of goal-oriented behavior of animals. Several action modules share the same space representation and guide the robot to multiple targets.

## Discussion

For mobile robots to undertake real-world tasks with unreliable sensors and actuators, whose responses greatly depend on the specific working environment, they must exhibit adaptive capabilities. Neural networks naturally cope with the learning task of analyzing the perception-action interactions for navigation, localization, and map building. Even though different ANN approaches have solved some instances of these three aspects of robot navigation, there does not exist a complete navigation system that is purely made of neural components. From an engineering standpoint, such a complete mobile robot must incorporate other types of learning techniques to generate more abstract models of its perceptions, actions, and sensorimotor rules (Kaiser et al., 1995). In addition, the engineering perspective calls for combining learning capabilities with alternative techniques to build successful mobile robots such as those of Thrun and co-workers (Thrun, 1998a). On the other hand, a different perspective looks at animals for inspiration to develop the necessary neural components of a complete robot navigation system. There are numerous efforts along this *bio-inspired* direction (Biologically Inspired Robotics and Neuroethology, Computational) in which reinforcement-based learning (Reinforcement Learning and Q-Learning for Robots) and hippocampal models (Cognitive Maps and Hippocampus: Spatial Models) are keystones of this type of future intelligent (because adaptive) mobile robots.

# Rodent Head Direction System

*David S. Touretzky and William E. Skaggs*

## Introduction

The brain of the rat contains an inertial compass distributed across a collection of anatomical areas (Figure 1). Head direction (HD) cells in these areas fire maximally when the rat's head is pointed in a specific *preferred direction*, with a gradual falloff in firing as the heading departs from that direction. This directional specificity is independent of the rat's location or behavior. Within a population of HD cells, preferred directions are uniformly distributed around the circle. Although there is no topographic ordering of the cells in any known HD area, it is convenient to refer to a population of HD cells as if they were arranged around a ring according to their preferred directions. Thus, given a population of HD cells, for any direction the rat is facing, a "bump" of activity will be observed over the population, and the bump location will shift around the ring as the animal's heading changes.

Head direction is an internal, cognitive representation, not a simple reflection of sensory stimuli or motor activities. Maintenance of the HD activity bump is thought to be evidence for attractor networks operating in the rodent brain. Because of the HD system's interesting functional properties, it has been the focus of a very productive interaction between neurophysiologists and computational modelers.

## Sensory Cues and Head Direction

In order to maintain an accurate heading estimate in the dark or in an unfamiliar environment, the rat must integrate its head angular velocity, which is sensed by the vestibular system. Other possible sources of angular velocity information include motor efference copy and optic flow, but lesions of the vestibular nuclei suffice to abolish stable HD responses (Blair, Cho, and Sharp, 1998). Experiments have shown that even passive rotations, if rapid, are compensated for by the HD system (i.e., the animal's heading estimate changes accordingly), probably because they are above the threshold of the vestibular system. Slow passive rotations are not compensated.

While the bump representation is maintained even in the absence of visual input, when rats forage in the dark in a radially symmetric environment such as a cylinder, the HD system drifts out of alignment after a few minutes, owing to cumulative integration error. Normally the HD system utilizes a correction mechanism based on visual landmarks—and perhaps other perceptual cues—to keep itself aligned with the environment.

In an often repeated experimental paradigm, HD cells are recorded while a rat forages for scattered food pellets in a gray cylindrical arena with a white card on the wall serving as a prominent

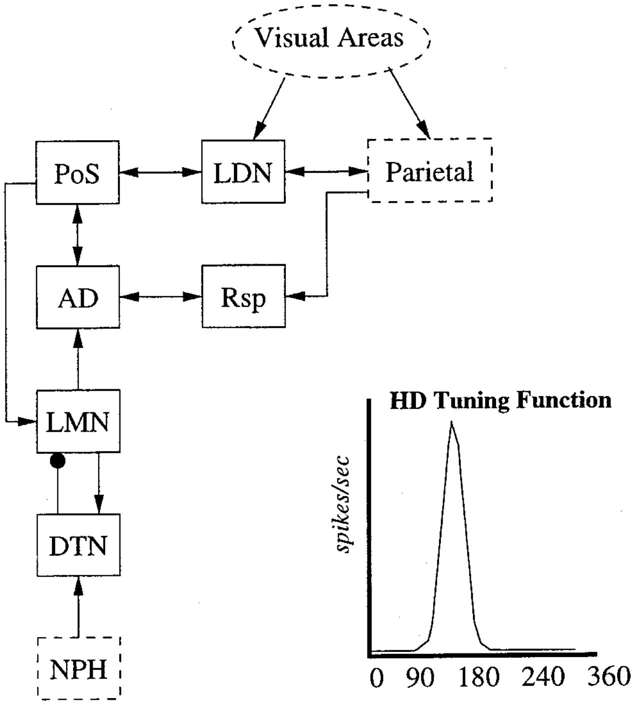

**Figure 1.** Organization of the rodent head direction system. AD, anterior dorsal nucleus of the thalamus; DTN, dorsal tegmental nucleus; LDN, lateral dorsal nucleus of the thalamus; LMN, lateral mammillary nucleus; NPH, nucleus prepositus hypoglossi; PoS, postsubiculum; Rsp, retrosplenial cortex. Graph at lower right shows the tuning curve of a typical head direction cell.

directional cue. When the cue card is rotated to a different location, the tuning curves of HD cells typically rotate by the same angle as the cue card was rotated, indicating that the cue card is exerting "control" over the HD system. The realignment is a gradual process and may require 1 to 2 minutes to complete (Knierim, Kudrimoti, and McNaughton, 1998).

The influence of visual cues on the HD system is a function of experience. After 1 minute of exposure to a novel environment, little or no control is exerted over the HD system by a cue card, but 8 minutes of exposure is enough for control to develop (Goodridge et al., 1998). The influence of visual landmarks also depends on their being perceived as stable. If rats are repeatedly disoriented before being placed in the cylinder, so that their HD system is randomly oriented, the cue card will appear at a different bearing on each trial, and its influence on the HD system will be substantially diminished (Knierim, Kudrimoti, and McNaughton, 1995).

Conflicts can be introduced between vestibular and visual cues by placing the rat in a cylinder whose floor and wall rotate independently. Under these conditions either the vestibular or the visual cues can win out, depending on circumstances.

## The Head Direction Circuit

Head direction cells were first discovered in the postsubiculum (PoS, also called dorsal presubiculum) by Ranck, and studied in depth by Taube, Muller, and Ranck (1990a, 1990b). They were subsequently found in the lateral dorsal nucleus of the thalamus (LDN: Mizumori and Williams, 1993), anterior dorsal thalamic nucleus (AD: Blair and Sharp, 1995; Taube, 1995), lateral mammillary nucleus (LMN: Blair et al., 1998; Stackman and Taube, 1998), dorsal tegmental nucleus (DTN: Sharp, Tinkelman, and Cho, 2001; Bassett and Taube, 2001), and several other areas. The firing properties of HD cells differ somewhat in the different areas. For example, PoS HD cells are best correlated with the rat's present heading, and their tuning curves are Gaussian shaped and independent of angular velocity. The tuning curves of AD HD cells distort at higher angular velocities, and the activity of these cells is best correlated with the rat's heading roughly 25 ms in the future. This quantity, the *anticipatory time interval* (ATI), was determined by plotting separate tuning curves for left versus right turns. PoS HD cells have an ATI of around zero, but when firing rate is plotted against present heading for an AD HD cell, the peaks of the two curves do not coincide. When firing rate is plotted against future heading, strong overlap of the two tuning curves is obtained for headings around 25 ms in the future. For example, an AD cell whose preferred direction is 120° when the rat is motionless will appear to have a different preferred direction when the rat is turning. During a turn at 320°/s, the cell will fire at its peak rate when the rat's head passes through 112° for a clockwise turn, or 128° for a counterclockwise turn. This can be interpreted as the cell having a fixed preferred direction of 120° but anticipating the rat's heading by 25 ms. The peak firing rates of AD HD cells, but not PoS HD cells, increase with angular velocity.

LMN HD cells have roughly Gaussian tuning curves modulated by angular velocity, but with a preferred turning direction. Cells that prefer clockwise turns increase their firing rate as angular velocity increases in the clockwise direction and decrease their firing rate as angular velocity increases in the counterclockwise direction, relative to the rate observed when the animal's head is not turning at all. Stackman and Taube (1998) observed an ATI of approximately 95 ms for LMN HD cells. But Blair et al. (1998) reported that LMN HD cells have an ATI of only 40 ms, and whereas their peak firing rate changes only slightly with velocity, the width of the tuning curve contracts as angular velocity increases in the preferred turning direction. The tuning curve width does not contract for turns in the opposite direction.

DTN HD cells have much broader tuning curves than PoS, AD, or LMN HD cells. Their firing rate is velocity modulated, and they have a preferred turning direction, as do LMN cells, but their tuning curve widths do not change with velocity (Sharp et al., 2001; Bassett and Taube, 2001). DTN also contains angular velocity cells that are not directionally tuned. These cells fire at a baseline rate when the rat is still, and increase their firing with increasing angular velocity for turns in the preferred direction, or decrease it for turns in the nonpreferred direction. DTN receives projections from the nucleus prepositus hypoglossi (one of the vestibular nuclei), and may be the place where angular velocity information first enters the HD system.

LDN HD cells have tuning curves similar to PoS cells, but they are dependent on visual input (Mizumori and Williams, 1993). If the rat is brought into the recording area in the dark, its LDN HD cells are quiescent. When the lights are turned on, LDN activity increases, resulting in normal HD responses in about 2 minutes. Since LDN projects to PoS, this may be a route by which visual information enters the HD system.

Lesions of AD disrupt the head direction signal in PoS, but lesions in PoS leave the AD HD signal largely intact, although the tuning curve broadens somewhat, and the control of visual landmarks over the HD system is impaired. The persistence of the HD signal may be because AD receives a projection from LMN, and from retrosplenial cortex, which also contains some HD cells. Bilateral but not unilateral LMN lesions abolish the AD HD signal (Blair et al., 1998).

## Attractor Models of the Head Direction System

An attractor network is a recurrent neural network whose dynamics generate stable states (attractors) to which the system returns when perturbed. Skaggs et al. (1995) proposed that attractor dynamics could explain the shape of HD cell tuning curves, the stability of HD activity in the face of fluctuating sensory input, the control of the HD system by vestibular and visual cues, and the requirement for landmark stability. Zhang (1996) offered the first mathematical formulation of an attractor network as a model of an HD area. Goodridge and Touretzky (2000) modeled the interactions among PoS, AD, and LMN, including reproducing the distortions of AD tuning curve shapes with angular velocity. Sharp, Blair, and Cho (2001) proposed that the reciprocal connectivity between DTN and LMN could constitute an attractor network at the earliest stage of the HD system. This agrees with the observation that LMN cells have the largest ATI, AD cells anticipate less, and PoS cells, which are even further downstream, are hardly anticipatory at all.

The common mechanism in all bump attractor models is local excitation combined with global inhibition. Assuming for convenience that cells are arranged by preferred direction, each cell excites its nearby neighbors, as in Figure 2, with the strength of the excitatory connection falling off as a Gaussian function of the difference in their preferred directions. To prevent runaway excitation, HD cells also excite global inhibitory units (not shown), which provide uniform negative feedback onto the excitatory population. The stable states of this network consist of a bump of activation located somewhere on the ring. Noise in the network tends to be suppressed by the attractor dynamics, so the shape of the bump persists, and in the absence of external input, its location remains fixed. In addition to accounting for the stability of HD tuning curves, this model also explains the observation of Knierim et al. (1995) that when the HD system drifts, all cells drift in unison: the difference in preferred directions of any two simultaneously recorded cells remains constant.

Applying an external input to a spot on the ring underlying one flank of an attractor bump causes the bump to shift until it is centered over the external input. This is the mechanism Skaggs et al. (1995) proposed to explain how visual landmarks exert control over the HD system. In their model, landmark feature detectors looking at specific egocentric bearings would learn excitatory connections onto the appropriate HD cells as the animal became familiar with its environment. For example, if while facing north the animal saw landmark X ahead and to its right, via Hebbian learning, a feature detector that responds to "X ahead and to the right" would develop excitatory connections onto active HD cells, whose preferred directions would be close to 360°. If the HD system later drifted as a result of accumulated integration error, when the animal attended to the scene, external input from feature detectors would pull the bump back into alignment with the environment.

The greater the magnitude of the external input applied to the flank of a bump, the faster the bump moves. This property can be used to integrate angular velocity if the magnitude of the external input scales with velocity. But if the external input is applied far from the peak, so that it does not lie on the flank of the bump, its effect will be suppressed by the attractor dynamics. If it is applied in equal amounts to both flanks of the bump, the bump will stay put.

Angular velocity integration in an attractor network therefore requires input from a population of velocity-sensitive cells that

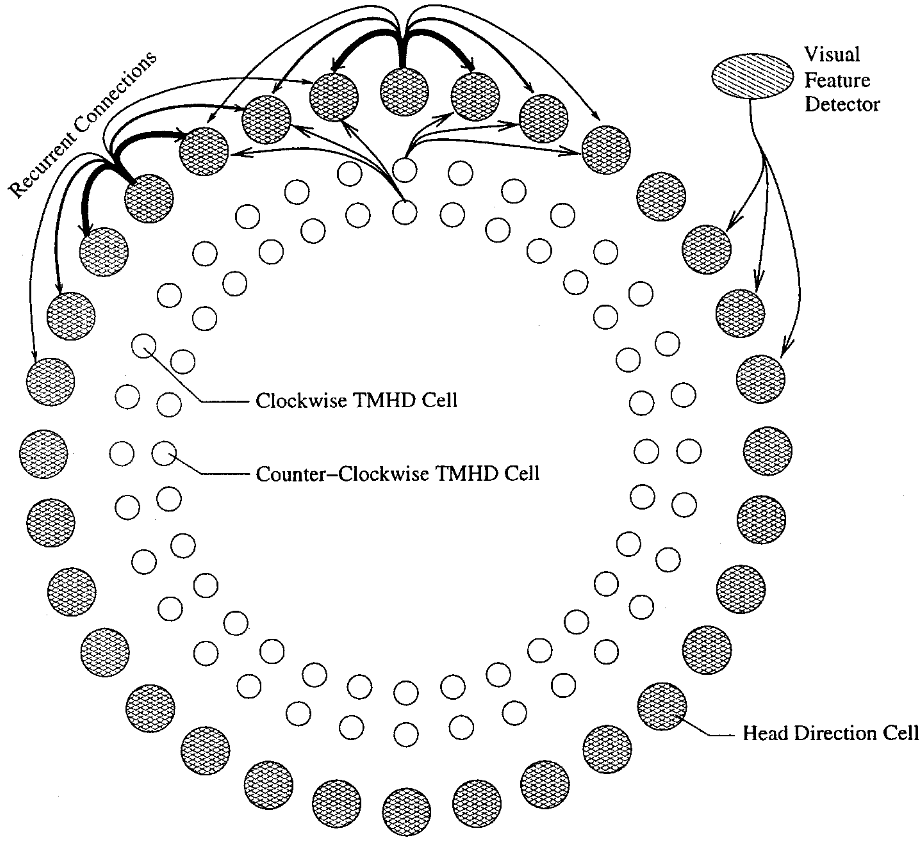

**Figure 2.** Architecture of an attractor-based head direction system model (after Skaggs et al., 1995).

exhibit HD tuning (so the input is focused on the correct flank of the attractor bump) and a turning preference. Blair and Sharp (1995) called these turn-modulated head direction (TMHD) cells. TMHD cells with a clockwise turning preference should make excitatory projections onto attractor HD cells with preferred directions slightly to the right of their own; TMHD cells with a counterclockwise turning preference should project to attractor HD cells slightly to the left. When the animal is still, both populations of TMHD cells should fire at the same rate, supplying identical input to both flanks of the attractor bump. When the animal is in a clockwise turn, the clockwise TMHD population should increase its firing rate, while the counterclockwise population should decrease its rate, in proportion to the angular velocity. Hence the bump would receive more input on its right flank, and begin shifting to the right. The opposite would occur for counterclockwise turns.

Cells in LMN seem to meet all the requirements for the hypothesized TMHD population: they show normal HD tuning, velocity modulation, and a turning preference. In the Goodridge and Touretzky (2000) model, the clockwise and counterclockwise LMN populations both project to AD. Since AD does not appear to have recurrent connections, it cannot function as an attractor network, and thus cannot exhibit all the stability properties of such a network. But AD HD cells integrate information from LMN, PoS, and perhaps retrosplenial HD cells, and AD projects to PoS. The attractor network is located in PoS, which does have recurrent connections. This model explains why the firing of PoS HD cells is independent of angular velocity, while AD HD cells are influenced by velocity.

In a complementary attractor model by Sharp et al. (2001), DTN cells make inhibitory projections onto LMN cells, which in turn make excitatory projections back onto the DTN population. DTN cells also receive angular velocity information from vestibular nuclei. HD cells in LMN and DTN have different tuning properties, but their interaction is hypothesized to produce the attractor dynamics required to integrate angular velocity.

HD cells in other areas, such as retrosplenial cortex and caudate nucleus, could also contribute to the functioning of the “core”' HD system. Further work may explain why there are so many HD areas, and why the difference in ATI values for PoS, AD, and LMN cells is so much greater than can be accounted for by synaptic delays alone.

# Schema Theory

*Michael A. Arbib*

## Introduction

Schema theory complements neuroscience's well-established terminology for levels of *structural* analysis (brain region, neuron, synapse) with a *functional* vocabulary, a framework for analysis of behavior with no necessary commitment to hypotheses on the localization of each *schema* (unit of functional analysis), but which can be linked to a structural analysis whenever appropriate. Schemas provide a high-level vocabulary that can be shared by brain theorists, cognitive scientists, connectionists, ethologists, and even kinesiologists, even though the implementation of the schemas may differ from domain to domain. This article presents a general perspective, notes but does not emphasize learning models for schemas, and focuses on two issues: structuring perceptual and motor schemas to provide an action-oriented account of behavior and cognition (as relevant to the roboticist as the ethologist); and how schemas describing animal behavior may be mapped to interacting regions of the brain. Schema-based modeling becomes part of neuroscience when constrained by data provided by, for example, human brain mapping, studies of the effects of brain lesions, or neurophysiology. The resulting model may constitute an adequate explanation in itself or may provide the framework for modeling at the level of neural networks or below. Such a *neural* schema theory provides a functional/structural decomposition, in strong contrast with models that employ learning rules to train a single, otherwise undifferentiated, neural network to respond as specified by some training set.

## Schemas: History and Comparisons

Central to our approach is the notion of the "active organism," which seeks from the world the information it needs to pursue its chosen course of action. In *action-oriented perception*, current sensory input is itself a function of the subject's active exploration of the world, which is directed by *anticipatory schemas*, which Neisser (1976) defines as plans for perceptual action as well as readiness for particular kinds of sensory structure. This view has resonances with that of Piaget (1971, pp. 6–7): "Any piece of knowledge is connected with an action . . . [T]o know an object or a happening is to make use of it by assimilation into an action schema . . . [namely] whatever there is in common between various repetitions or superpositions of the same action." Acting on the basis of an action schema usually entails the *expectation* of certain consequences. Piaget talks of *assimilation*, the ability to make sense of a situation in terms of a stock of schemas, and *accommodation*, whereby the stock of schemas may change over time as the expectations based on assimilation to current schemas are not met. Piaget traces the cognitive development of the child from reflexive schemas through eye-hand coordination and object permanence all the way to schemas for language and abstract thought.

Head and Holmes introduced the term schema to neurology in 1911, speaking of the *body schema* (Frederiks, 1969, reviews relevant literature): "Anything which participates in the conscious movement of our bodies is added to the model of ourselves and becomes part of those schemata: a woman's power of localization may extend to the feather of her hat." A woman with unilateral damage to the parietal lobe may lose awareness that the body on the opposite side actually belongs to her—not only ignoring painful stimuli but even neglecting to dress that half of the body. Damage to the thalamus and the somatosensory system may also produce disorders of the body schema.

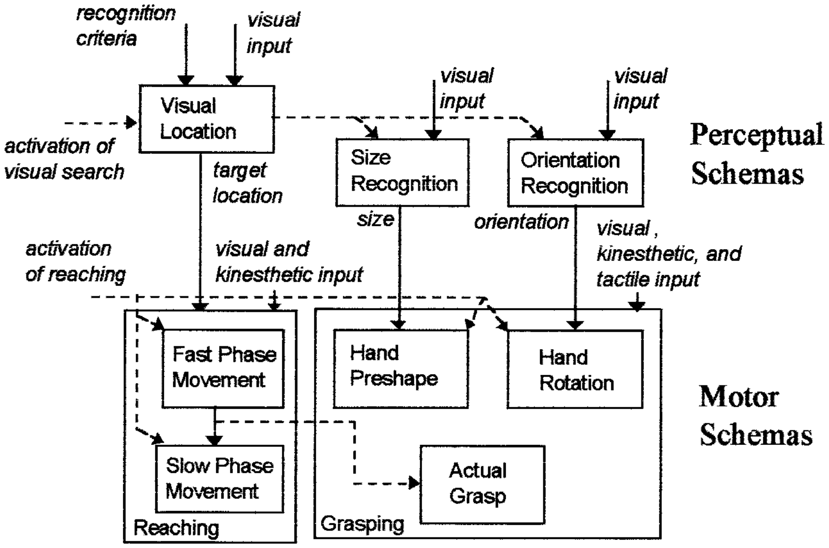
Bartlett (1932) carried the schema idea into cognitive psychology, with a schema being "an active organization of past reactions [or] experiences, which must always be supposed to be operating in any well-adapted organic response." He stressed the constructive character of remembering. When people try to recall a story, they reconstitute it in their own terms—relating what they experience to a familiar set of schemas—rather than by rote memorization of details. Instead of thinking of ideas as impressions of sense data, schema theory posits an active and selective process of schema formation (cf. Piaget's notion of assimilation), which in some sense constructs reality as much as it embodies it. More generally, cognitive psychology views schemas as cognitive structures built up in the course of interaction with the environment to organize experience. Not only is sensory input coded by instantiating certain schemas (we say a schema is instantiated when active copies are running, and refer to these copies as "schema instances"), as seeing a chair instantiates an instance of the "chair schema," but the current stock of schema instances may also instantiate related action schemas such as "sitting" and general schemas such as "furniture" while inhibiting other competing schemas. Shallice (1988, p. 308n) stresses that the schema "not only has the function of being an efficient description of a state of affairs—as in, say, Bartlett's usage—but also is held to produce an output that provides the immediate control of the mechanisms required in one cognitive or action operation. The usage is thus more analogous to Piaget's view than to Bartlett's original concept." In a connectionist vein, Rumelhart et al. (1986) suggest how schemas may be seen as emergent properties of adaptive, connectionist networks, but they neither relate schemas to action nor show how schemas may be combined to form assemblages (see discussion later in this article).

Schmidt (1976) offered a schema theory of discrete motor skill learning. Through experience, the subject builds up a *recall schema* that pairs the response specifications of a movement with the actual outcome. Later, this recall schema can be consulted to infer, from a desired outcome, the response specification that will produce it. Similarly, a *recognition schema* pairs the desired outcome with the expected sensory consequences of each movement. The recall schema is what is now known in the literature of motor control as an "inverse model" (SENSORIMOTOR LEARNING)—it goes from a desired response to a pattern of commands that achieves it, rather than the "direct" causal path from commands to action; while the recognition schema corresponds to Neisser's anticipatory schema.

Arbib (1981; Arbib, Érdi, and Szentágothai, 1998, Chapter 3 for an exposition) offered a schema theory more tightly constrained by the need to explain the neural basis of behavior, stressing that a schema expresses a function that need not be co-extensive with the activity of a single neuronal circuit. (This view was foreshadowed in the work of Kilmer, McCulloch, and Blum (1969) who posed the general question of how the nervous system could set the organism's "overall mode of behavior" through the cooperative computation [no executive control] of modules, each of which aggregates the activity of many neurons.) A *schema* is what is learned about some aspect of the world, combining knowledge with the processes for applying it; a *schema instance* is an active deployment of these processes. A *perceptual schema* not only determines whether a given "domain of interaction" (an action-oriented generalization of the notion of object) is present in the environment, but can also provide parameters concerning the current relationship of the organism with that domain. Each schema instance has an *activity level* that indicates its current salience for the ongoing computation. The activity level of a perceptual schema signals the credibility of the hypothesis that what the schema represents is indeed present, whereas other schema parameters represent other salient properties such as size, location, and motion of the perceived object. Given a perceptual schema, we may need several schema instances, each suitably tuned, to subserve our perception of several instances of its domain. *Motor schemas* provide the control systems that can be coordinated to effect a wide variety of actions. The *activity level* of a motor schema instance may signal its "degree of readiness" to control some course of action (thus enriching somewhat the related notion of motor pattern generators; see MOTOR PATTERN GENERATION).

Schema instances may be combined (possibly with those of more abstract schemas, including coordinating schemas) to form *schema assemblages*. For example, an assemblage of perceptual schema instances may combine an estimate of environmental state with a representation of goals and needs. A *coordinated control program* is a schema assemblage that processes input via perceptual schemas and delivers its output via motor schemas, interweaving the activations of these schemas in accordance with the current task and sensory environment to mediate more complex behaviors. Figure 1 shows the original coordinated control program. As the hand moves to grasp an object, it is *preshaped* so that when it has almost reached the ball, it is of the right shape and orientation to enclose some part of the object prior to gripping it firmly. Moreover (to a first approximation), the movement can be broken into a fast initial movement and a slow approach movement, with the transition from the fast to the slow phase of trans-

**Figure 1.** Hypothetical coordinated control program for reaching and grasping. Note that different perceptual schemas (at the top) are required to provide parameters for the motor schemas (at the bottom) for the control of "reaching" (arm transport ≈ hand reaching) and "grasping" (controlling the hand to conform to the object). Note too the timing relations posited here within the "Hand Reaching" motor schema and between the motor schemas for "Reaching" and "Grasping." Dashed lines—activation signals; solid lines—transfer of data. (Adapted from Arbib, 1981.)



port coming just before closing of the fingers from the preshape so that touch may take over in controlling the final grasp. The top half of Figure 1 shows three perceptual schemas: successful location of the object activates the schemas for recognizing the size and orientation of the object. The outputs of these perceptual schemas are available for the control of the hand movement by concurrent activation of two motor schemas, one controlling the arm to transport the hand toward the object and the other preshaping the hand, with finger separation and orientation guided by the output of the appropriate perceptual schemas. Once the hand is preshaped, it is only the completion of the fast phase of hand transport that "wakes up" the final stage of the grasping schema to shape the fingers under control of tactile feedback. (This model anticipates the much later discovery of perceptual schemas for grasping in a localized area [AIP] of parietal cortex and motor schemas for grasping in a localized area [F5] of premotor cortex. See Grasping Movements: Visuomotor Transformations.)

Neuroscience and cognitive psychology often view working memory as storing a single item (e.g., the location of a target, or a single phone number) for a short delay period between observation of the item and its use in some action, after which it is discarded. Here, we extend the notion to insist that working memory may hold a range of items relevant to upcoming actions, and these items may remain accessible for extended periods so long as they remain relevant. Schema-based modeling of action-oriented perception (Visual Scene Perception) then views the *short-term memory* (STM) of an organism as a working memory that combines the schema instances encoding relevant aspects of, and plans for interaction with, the current environment. This assemblage is dynamic, as certain schema instances are discarded from memory ("de-instantiated") while others are added ("instantiated"). *Long-term memory* (LTM) is provided by the stock of schemas from which STM may be assembled. New sensory input as well as internal processes can update STM. The internal state is also updated by knowledge of the state of execution of current *plans* that specify a variety of coordinated control programs for possible execution. Jeannerod (1997) surveys the role of schemas and other constructs in the cognitive neuroscience of action.

## Schemas for *Rana Computatrix*

A schema model becomes a neural model, as distinct from a purely functional model, when explicit hypotheses are offered as to how the constituent schemas are played over particular regions of the brain. To exemplify this, consider approach and avoidance in the frog (Visuomotor Coordination in Frog and Toad; and see Arkin et al., 2000, for a related discussion of behavioral models of the praying mantis as a basis for robotic behavior). A frog surrounded by dead flies will starve to death, but the frog will snap with equal "enthusiasm" at a moving fly or a pencil tip wiggled in a fly-like way. On the other hand, a larger moving object can trigger an escape reaction. Thus, a highly simplified model of the functioning of the brain of the frog has signals from the eye routed to two basic perceptual schemas, one for recognizing small moving objects (foodlike stimuli) and one for recognizing large moving objects (enemylike stimuli). If the small-moving-object schema is activated, it will in turn trigger the motor schema that gets the animal to approach what is apparently its prey. If the perceptual schema for large-moving-object is activated, it will trigger the motor schema for avoidance, causing the animal to escape an apparent enemy.

The biological model relates these schemas to anatomy. Each eye of the frog projects to regions on the opposite side of the brain, including the important visual midbrain regions called the *tectum* and the *pretectum* (in front of the tectum). If we hypothesize that the small-moving-object schema is in the tectum, while the large-moving-object schema is in the pretectum, the model (Figure 2*A*) predicts that animals with a pretectal lesion would approach small moving objects, but would not respond at all to large moving objects. However, Peter Ewert in Kassell studied toads with the pretectum removed and found that they responded with approach behavior to both large and small moving objects. This observation leads to the new schema-level model shown in Figure 2*B*. We replace the perceptual schema for *small* moving objects of Figure 2*A* by a perceptual schema for *all* moving objects and leave the right-hand column the way it was. The inhibitory pathway from the large-moving-object perceptual schema (in the pretectum) to the all-moving-object schema ensures that the model yields the normal animal's response to small moving objects with approach but not avoidance. This model explains our small database on the behavior of both normal animals and those with a lesion of the pretectum.

We have thus shown how hypotheses about neural localization of subschemas may be tested and refined by lesion experiments. The important point is that models expressed at the level of a network of interacting schemas can really be testable biological

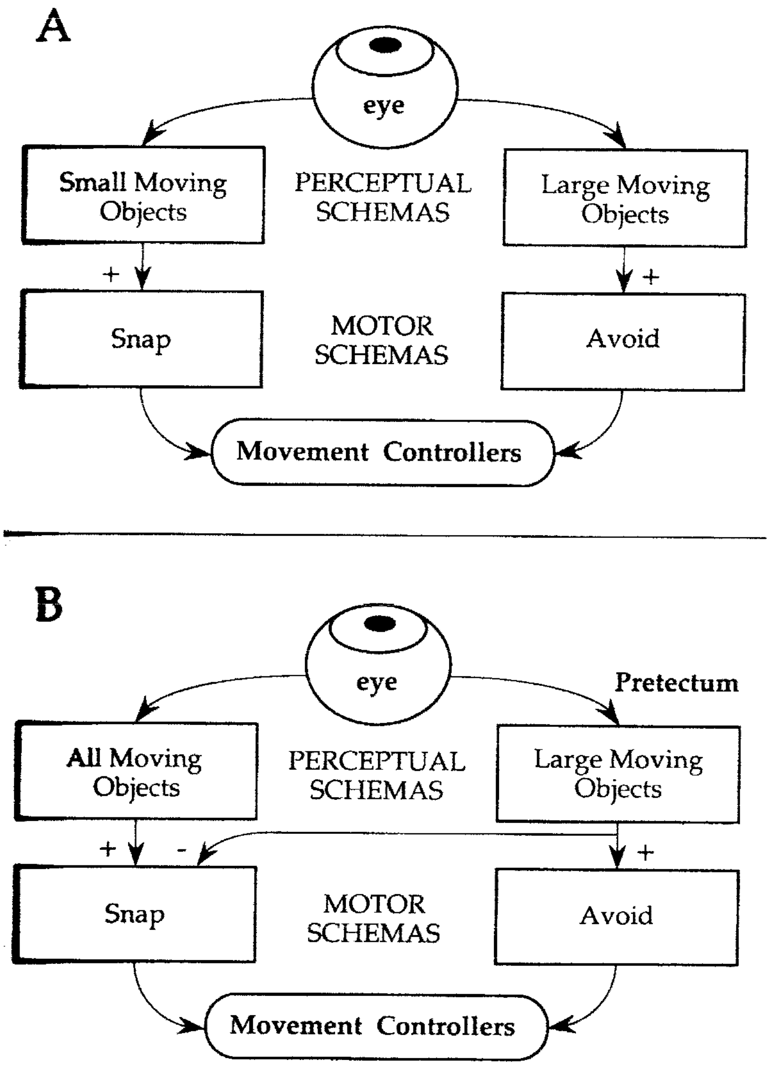


**Figure 2.** *A*, A "naive" schema program that represents the perceptual and motor schemas for frog approach behavior (snap at small moving objects) as completely separated from those for avoidance. *B*, A schema program for approach and avoidance that takes into account data on the effect of lesioning the pretectum. In particular, the "approach schema" is *not* localized in the tectum alone since it depends on pretectal inhibition for its integrity.

models. Subsequent work has extended work on *Rana computatrix* ("the frog that computes"; Arbib et al., 1998, for a partial review) at the level of both schemas and neural networks for phenomena such as detours and path planning, avoidance behavior sensitive to the trajectories of predators, and details of snapping behavior that link neural control to biomechanics. The work constitutes a grounding example of work in modeling neural mechanisms in overall animal behavior (Neuroethology, Computational).

## Coordinated Control Programs and Motor Schemas

We have seen that schemas can be combined to form *coordinated control programs* that control the phasing in and out of patterns of schema co-activation and the passing of control parameters from perceptual to motor schemas. The notion of schema is thus *recursive*—a schema defined functionally may later be analyzed as a coordinated control program of finer schemas, and so on until such time as a secure foundation of neural localization is attained. The model of Figure 1 distinguished two phases of arm movement—a fast phase controlled by a ballistic schema (i.e., one that moves rapidly to completion, unaffected by feedback), followed by a slow phase controlled by a schema that does admit error-correction by use of sensory feedback. However, Jeannerod et al. (1992) showed that reaching is subject to modification by sensory input even during the fast phase. If the target of a pointing task was perturbed at movement onset, the subject did not complete a ballistic movement toward the initial target before moving on to the new target. Rather, a smooth adjustment was made about 100 msec after target perturbation to a new trajectory terminating at the new target, without loss of accuracy. To address such data (and more), Hoff and Arbib (1993) extended the use of Optimization Principles in Motor Control (q.v.) by showing how to embed an optimality principle for arm trajectories into a controller that can use feedback to resist noise and compensate for target perturbations, and a predictor element to compensate for delays from the periphery. The result is a feedback system that can *act like* a feedforward system described by the optimality principle in "familiar" situations, where the conditions of the desired behavior are not perturbed and accuracy requirements are such that "normal" errors in execution may be ignored. However, when perturbations must be corrected for or when great precision is required, feedback plays a crucial role in keeping the behavior close to that desired, taking account of delays in putting feedback into effect.

Another claim embodied in Figure 1 is that the transition from preshaping to enclosing is controlled by, but does not influence, the transition in the transport phase. However, data show that when the hand has unexpectedly to open wider (if object size is increased during reach) transport slows by about 200 msec, but if target location is perturbed, the hand temporarily closes so that maximum aperture is delayed as transport takes longer to reach the new target. Hoff & Arbib (1993) designed a controller for the preshape schema to tradeoff an optimality criterion needed to prevent discontinuous "jumps" in the preshape and a "cost" for having the hand open more than a certain amount. The latter yields the partial reclosing of the hand during prolonged movement caused by location perturbation. Their strategy for coordinating the motor schemas is set forth in Figure 3. Here, the Enclose schema is a replica of the Preshape schema with the only exception that its starting point is the maximum aperture achieved by the preshape schema (there seems to be a linear relation between the actual object size and the maximum aperture achieved). The coordinating schema receives from each of the constituent schemas—Transport, Preshape, Enclose—an estimate of the time that it needs to move for execution. Then, whichever schema is going to take longer, Transport or Grasp (Preshape + Enclose), is given the full time it needs, while the other schema will be slowed down to apply its optimality criterion over the longer time base. This yields a satisfactory match between data and simulation.

The implication (a truth better known in motor control than in other areas of neurophysiology) is that much is to be learned at the level of schema analysis prior to, or in concert with, the "lower level" analysis of neural circuitry. Although the hypotheses developed in this section allow us to gain insight into the interaction of a number of different processes, they also pose major challenges for further neurophysiological investigation.

## Discussion

### *Perceptual and Motor Schemas*

We have suggested that schemas provide some sort of action-oriented memory, yet have made a distinction between perceptual schemas and motor schemas. Why not combine these two constructs into a single notion of schema that integrates sensory analysis with motor control, as suggested in the earlier quote from Shallice? Indeed, there are cases in which such a combination makes sense. However, recognizing an object (an apple, say) may be linked to many different courses of action (to place the apple in one's shopping basket; to place the apple in the bowl at home; to pick up the apple; to peel the apple; to cook with the apple; to eat the apple; to discard a rotten apple, etc.). Of course, once one has decided on a particular course of action, then specific perceptual and motor subschemas may be invoked. But note that, in the list just given, some items are apple-specific whereas other invoke generic schemas for reaching and grasping. It was considerations like this that led me to separate perceptual and motor schemas—a given action may be invoked in a wide variety of circumstances; a given perception may, as part of a larger assemblage, precede many courses of action. Putting it another way, there is no one "grand apple schema" that links all "apple perception strategies" to "every act that involves an apple." At the same time, however, note that, in the schema-theoretic approach, "apple perception" is not mere categorization—"this is an apple"—but may provide access to a range of parameters relevant to interaction with the apple at hand. The *Rana* example shows this in simplest form. In Figure 2*A*, the two schemas at left may be combined into a single unitary prey schema and the two at right into a single unitary predator schema. However, the lesion study suggested splitting perception from action since it is recognition of the large moving object that inhibits the prey-catching schema—based on the view that tectum and pretectum are "more perceptual" and the brainstem to which they project is "more motor."

A detailed example of how schema theory extends to more "cognitive" realms than basic patterns of sensorimotor coordination is offered by the schema-based interpretation in the VISIONS computer vision system (see VISUAL SCENE PERCEPTION for references). This system shows the importance of schema theory within artificial intelligence (i.e., even when there is no claim to model the brain). Similarly, schemas have played an important role in the development of behavior-based robots (REACTIVE ROBOTIC SYSTEMS).

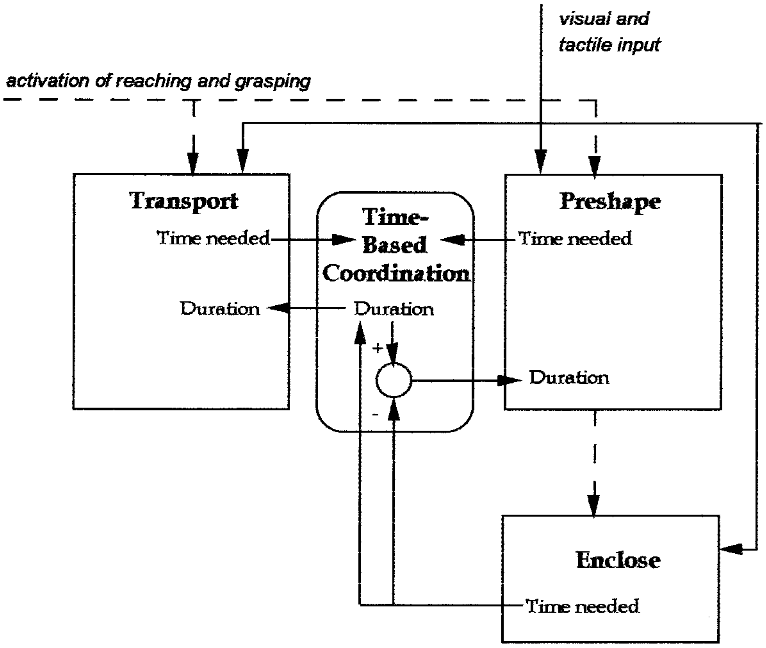

**Figure 3.** Feedback controllers for transport and preshape. "Co-operative computation" between subprograms is mediated by a coordinating schema ensuring that both reaching and grasping have adequate movement time (Hoff and Arbib, 1993).

### *Schemas and Their Assemblages Are Adaptable*

Head himself considered schemas as plastic entities, which are subject to constant change, and adaptation is at the heart of Piaget's account of assimilation and accommodation. Although the examples of schemas given in the three figures above are fairly stable—as we explored the way in which schemas could be combined into coordinated control programs, and ways in which the psychological or neural correlates of such schema assemblages could be tested—it must be emphasized that schemas, and their connections with each other, change through the processes of accommodation. These processes adjust the network of schemas so that over time they may well be able to better handle a wide range of situations.

Work on Hybrid Connectionist/Symbolic Systems (q.v.; see also Sun, 1995) has somewhat similar motivations to schema theory: In decomposing a cognitive model into a network of interacting processes, one may find at a given state of knowledge that quite different models will be appropriate for different components: some cognitive processes are best captured by symbolic models, some by connectionist models, and some by biologically realistic neural models. This leads to the development of hybrid systems. Schema theory is consistent with this in that it allows the schemas in an "assemblage" to be implemented in different ways so long as the input and output codes are compatible on any connection. However, it adds that what may appear to be disjoint schemas when implemented at one level may turn out to involve overlapping networks of subschemas when involved at a more detailed level (a simple example is given in Figure 2*B*). On the other hand, if we agree to the schema decomposition offered by high-level analysis, we may apply connectionist training procedures to adapt the initial schema structures if these are encoded by (artificial) neural networks.

### *Beyond Action and Perception*

Through learning, a complex schema network arises that can mediate first the child's, and then the adult's, reality. Through being rooted in such a network, schemas are interdependent, so that each finds meaning only in relation to others. For example, a house is defined in terms of parts such as a roof, yet a roof may be recognized because it is part of a house that is recognized on the basis of other criteria such as "people live there." Each schema enriches and is defined by the others (and may change when a formal linguistic system allows explicit, though partial, definition). Though processes of schema change may affect only a few schemas at any time, such changes may "cohere" to yield dramatic changes in the overall pattern of mental organization. There is change yet continuity, with many schemas held in common, yet changed because they must now be used in the context of the new network. Arbib and Hesse (1986) offer an epistemology rooted in this view of schema theory, and show how it may be expanded to link "schemas in the head" with the "social schemas" that form the collective representations (to use Durkheim's phrase) shared by a community. Schemas have also been used in a "computational, neo-Piagetian" approach to language acquisition and may also be used in modeling language processing with special attention to the links between action, action and object recognition, and language (see Language Evolution: The Mirror System Hypothesis) and in relating these processes to neural schemas.

# Scratch Reflex

*Paul S. G. Stein*

## Introduction

An organism can scratch itself in response to a stimulus at a site on the body surface (Stein, 1983). Mechanical force is the stimulus that has been used in many studies of scratching. In frogs, chemical irritation has also been used to activate scratching. During successful scratching, a nearby limb moves toward and rubs against the site. If a different site is stimulated, different limb movements are required for a successful scratch. The stimulated site may be on a part of the body such as the shell of a turtle (Stein, 1989) or the back of a frog (Berkinblit, Feldman, and Fukson, 1989), or it may be on a part that can move with respect to the body such as the ear of a cat (Kuhta and Smith, 1990) or the elbow of a frog (see Stein, 1983). In each case, the organism can generate a successful scratch. (Since space in the reference list is limited, the reader is referred to the articles by Stein, 1989, Stein and Smith 1997, and other papers by the author for fuller references to the literature.)

Some organisms do not require the entire central nervous system to produce a successful scratch reflex. Some vertebrates with a complete spinal cord transection at the level of the neck or upper back, termed *spinal vertebrates*, can perform a successful hindlimb scratch in response to a stimulus delivered to a site on the body surface posterior to the complete transection. This stimulus excites neural networks in the spinal cord posterior to the complete transection (Stein, 1983, 1989). Scratching has been demonstrated in several spinal vertebrates: dog (Sherrington, 1906), cat (Arshavsky, Gelfand, and Orlovsky, 1986; Orlovsky, Deliagina, and Grillner, 1999), turtle (Stein, Mortin, and Robertson, 1986; Stein, 1989; Earhart and Stein, 2000), and frog. In frog, scratch reflex is also termed *wiping reflex* (Berkinblit et al., 1989; see also MOTOR PRIMITIVES).

Site specificity of scratch reflex in spinal vertebrates is impressive. The spinal frog's hindlimb can wipe off an acid-soaked piece of paper from its elbow. Successful wipes of the elbow by the hindlimb occur when the elbow is close to the neck as well as when the elbow is close to the midbody (see Stein, 1983). Spinal cord neuronal networks can generate complex sensorimotor transformations even when disconnected from supraspinal structures.

## Strategies of Scratching: The Forms of a Scratch

The set of all successful scratches is constrained by the physical construction of the organism's limbs and body, i.e., its biomechanics. For some organisms, there may be a set of sites on the body surface, e.g., sites on the middle of the back of a turtle or a human, that cannot be rubbed directly by a limb of that organism. There may be some sites that can be scratched by using only one strategy of movement; for example, a human can scratch some sites on the upper back using only a strategy in which the elbow is placed over the shoulder. These sites belong to a set termed a *pure-form domain*. While the same motor strategy is used to rub against each site within a pure-form domain, parametric adjustment of limb movement is required to reach each specific site. There may be other sites that can be scratched by using either of several strategies; for example, a human can scratch a site on the side of the thorax using either the hand or the elbow. These sites belong to a set termed a *transition zone*. Each scratch movement strategy is termed a *form* of the scratch (Stein, Mortin, and Robertson, 1986). The concept of movement form can be applied to other motor acts. There are several forms of locomotion in mammals, e.g., walk, trot, and gallop (Stein and Smith, 1997; see also GAIT TRANSITIONS). Forward stepping and backward stepping are among the forms of stepping that humans produce.

The spinal turtle produces several scratch strategies. In each strategy, a distinct portion of the hindlimb is used to exert force against the stimulated site (Stein, Mortin, and Robertson, 1986). The turtle uses the dorsum of the foot for *rostral scratching*, the side of the knee for *pocket scratching*, and the side of the foot or heel for *caudal scratching*. Biomechanical constraints play a key role for each of these movement strategies. The rostral scratch is the only strategy that can be used to place a portion of the hindlimb against a site on the region that connects the upper shell and the lower shell in the middle of the body. The foot cannot reach sites in the pocket region just anterior to the turtle's hip; only the side of the knee can be used to generate force against a site in the pocket region. Thus, the spinal turtle can select the biomechanically appropriate form that produces successful scratches; selection of the proper scratch strategy does not require supraspinal structures, i.e., the brainstem and the brain. Experiments described in a later section establish form selection as an intrinsic property of spinal cord neural networks.

## Coordinate System Transformations in the Scratch Reflex

Several transformations occur during scratching. First, a stimulus-to-sensory transformation takes place on the body surface when the stimulus activates primary afferent neurons. Second, a sensory-to-motor transformation takes place within the central nervous system (CNS). Third, a motor-to-mechanical transformation takes place in the limb. It is possible to examine all three transformations at the same time during actual scratching. For neuronal network studies, it is useful to examine the first and second transformations in the absence of the third transformation, i.e., in the absence of movement. Experiments that examine the response to a tactile stimulus that elicits scratch motor output while neuromuscular synapses are blocked are described in later sections.

Several coordinate systems help to describe the different transformations. First, the rectilinear orthogonal Cartesian coordinate system is useful in a scientist's description of the site on the body surface that receives the sensory stimulus as well as the position in space of the limb that rubs against the site. Second, the muscle/motor-pool coordinate system is useful for describing the output of the CNS. The set of motor neurons that synaptically activate a given muscle is termed a motor pool. Each muscle of the body and/or its motor pool can be viewed as a dimension of a coordinate system. Each dimension's amplitude is determined by the intensity of activation of each muscle/motor-pool (see MOTONEURON RECRUITMENT). During each movement, there is a distinct *motor pattern* of muscle/motor-pool activation that occupies a region of an abstract space whose dimensions are time and muscles/motor-pools. Third, the body degree-of-freedom, also termed joint-angle, coordinate system is useful for describing multijointed limb movements. Some body joints, e.g., the knee, have a single degree of freedom and involve only a single dimension. Other body joints, e.g., the hip, have several degrees of freedom and therefore require several dimensions. Each movement form has a distinct trajectory in time and degree-of-freedom space.

## Coordinate System Analyses of the Turtle Scratch Reflex

Data obtained from studies of the scratch reflex in the spinal turtle (Stein, 1989) allow application of the concepts outlined in the previous section. These data are described in this section. Other data obtained from frog (Berkinblit et al., 1989; see also Motor Primitives) and from cat (Arshavsky et al., 1986) are also consistent with these concepts.

### *Cartesian Coordinate Description of Receptive Fields*

If a stimulus applied to a site on the body surface elicits a specific form of scratch reflex in which a nearby limb reaches toward and rubs against the stimulated site, then that site is within the receptive field for that form of scratch. In the spinal turtle, there is a receptive field for rostral scratch, a receptive field for pocket scratch, and a receptive field for caudal scratch. There is also a rostral-pocket transition zone and a pocket-caudal transition zone (Stein et al., 1986).

Stimulation of most sites in one form's receptive field elicits only scratches of that form; these sites constitute the pure-form domain of that form's receptive field. The *pure-form domain* for each scratch form is the set of sites in which only one scratch form is biomechanically possible. There is also a set of transition-zone sites located between the pure-form domain for one form and the pure-form domain for another form. The *transition zone* is the set of sites in which more than one scratch form is biomechanically possible. Stimulation of a site in this transition zone can elicit either one scratch form, the other scratch form, or a blended response of both scratch forms. There are two types of blends: the switch response and the hybrid response. In a *switch response*, several cycles of one form are followed smoothly by several cycles of the other form. In a *hybrid response*, each of several successive cycles has two rubs per cycle; one rub utilizes one scratch form, and the other rub utilizes the other scratch form.

The occurrence of blends supports the notion that there is shared neural circuitry between the neural network that generates one form of scratch and the neural network that generates another form of scratch. In particular, analyses of blends support the concept that interneurons controlling the rhythm of hip movements are shared among the networks responsible for each of several forms of scratching (Berkowitz and Stein, 1994; Stein et al., 1995; Stein, McCullough, and Currie, 1998; Berkowitz, 2001).

### *Muscle/Motor-Pool Coordinate Description of Motor Patterns*

The electromyographic (EMG) activity of individual muscles that play critical roles for each scratch form may be recorded during scratching in the spinal turtle (Earhart and Stein, 2000). The monoarticular knee extensor muscle is active during the rub against the stimulated site for all three forms of scratch. Scratching in the turtle is rhythmic; all three forms of scratching display rhythmic alternation between hip flexor muscle activity and hip extensor muscle activity. Timing of the monoarticular knee extensor muscle is distinct for each scratch form. The monoarticular knee extensor muscle is active (1) during the latter part of hip flexor muscle activity in a rostral scratch, (2) during hip extensor muscle activity in a pocket scratch, and (3) after the burst of hip extensor muscle activity in a caudal scratch. The motor pattern of muscle/motor-pool activation is distinct for each scratch form.

### *Body Degree-of-Freedom Coordinate Description of Movement*

The time course of hip angle (angle of hip flexion/extension) and knee angle (angle of knee flexion/extension) has been studied during each of the three forms of turtle scratch reflex (see discussion in Earhart and Stein, 2000). Rhythmic alternation between hip flexion and hip extension occurs for all three scratch forms. Timing of knee extension in the cycle of hip flexion and extension is distinct for each scratch form. The knee extends during the latter part of hip flexion in a rostral scratch; the knee extends during hip extension in a pocket scratch; the knee extends after hip extension is completed in a caudal scratch. A specific *movement pattern* in the joint-angle coordinate system is distinct for each form; that is, there is regulated timing of knee extension in the cycle of hip movement.

The movement pattern for each form in time and joint-angle space is similar to the motor pattern for each form measured in time and muscle/motor-pool space. In both spaces for each form of the scratch, there is a regulated timing of the knee with respect to the cycle of the hip. Similar changes of timing of a distal joint in the cycle of a proximal joint have been observed for other behaviors, e.g., forward versus backward stepping in humans.

## Spinal Cord Networks for Scratch Reflex

Spinal cord networks responsible for producing the scratch reflex in the cat (Arshavsky et al., 1986) and in the turtle (Stein, 1989; Currie and Stein, 1992; Berkowitz and Stein, 1994; Berkowitz, 2001; Stein and Daniels-McQueen, 2002) are partially understood. This understanding relies upon the demonstration that the spinal cord can produce a motor pattern in the absence of actual movements. Movements are prevented by muscle acetylcholine receptor blockade with a specific antagonist, e.g., curare. The motor pattern is measured as the electroneurographic (ENG) activities of specific motor pools in response to a stimulation of a site in a scratch receptive field. The ENG motor patterns recorded in the absence of movements are termed *fictive* motor patterns.

The ENG motor pattern for each scratch form in the spinal immobilized turtle is generated in response to stimulation of a site in the receptive field for that scratch form. Each motor pool monitored in the immobilized turtle using ENG recording techniques innervates a muscle that was previously monitored using EMG recording techniques during actual movements. The ENG motor pattern is an excellent replica of the EMG motor pattern recorded during actual movements. These results establish that spinal cord neuronal networks select the appropriate scratch motor pattern in response to stimulation of a specific site on the body surface; thus, motor strategy selection is a property of spinal cord neuronal networks. These rhythmic motor patterns are produced in an open-loop condition without benefit of timing cues from movement-related sensory feedback; thus, rhythmic motor pattern generation is an intrinsic property of spinal cord neuronal networks.

Motor patterns produced in the absence of movement-related feedback are termed *central motor patterns*. The neuronal network responsible for generating a central motor pattern for a behavior is termed a *central pattern generator* (CPG) for that behavior (Stein et al., 1997). A goal of current research is to reveal the properties of the CPG for each scratch form. It is possible that the CPG for one scratch form shares no neural circuitry with the CPG for another scratch form; such a lack of overlap in circuitry is not likely to occur, however. Single-neuron recordings in the turtle support the hypothesis that the CPG for the rostral scratch may share neural elements with the CPG for the pocket scratch (Berkowitz and Stein, 1994; Berkowitz, 2001).

The scratch motor pattern is not independent of movement-related sensory input, however. Motor patterns are subject to important modulations due to sensory input (see Motor Pattern Generation). For example, EMG recordings during actual scratching in the cat demonstrate amplitude and phase modulations of the motor pattern due to sensory feedback during paw contact with the stimulated site (Kuhta and Smith, 1990); similar modulations of the EMG motor pattern are also seen in the spinal turtle when the foot catches against the rod that is used to deliver the mechanical stimulus (Stein, 1983).

### *Localization and Distribution of Spinal Cord Neuronal Networks*

The spinal cord is a segmental structure. Each segment receives sensory input from a specific region of the body surface termed the *dermatome* of that spinal segment. Each segment contains the cell bodies of motor neurons that innervate a specific set of muscles. The hindlimb enlargement is the set of spinal segments that contain the cell bodies of motor neurons that innervate hindlimb muscles.

Anterior segments of the hindlimb enlargement play an important role in scratch rhythm generation in the cat (Arshavsky et al., 1986) and in the turtle (Stein, 1989). In all limbed vertebrates, the anterior portion of the hindlimb enlargement contains hip flexor motor neurons and knee extensor motor neurons. A scratch motor rhythm is produced by the most anterior segment of the turtle hindlimb enlargement in response to stimulation of a site in that segment's dermatome. A rhythmic pocket scratch motor pattern is produced by the three most anterior segments of the turtle hindlimb enlargement in response to stimulation of a site in the dermatome of the most anterior segment. The spinal segment just anterior to the hindlimb enlargement also contributes to rhythmogenesis. Thus neuronal networks for scratching are contained in and distributed among a set of spinal segments.

### *Multisecond Excitability Changes in Scratch Neuronal Networks*

The turtle scratch motor response can continue for several seconds after the termination of sensory stimulation (Currie and Stein, 1992). For an additional several seconds after the cessation of motor neuron activity, there is an increased excitability of spinal cord neuronal networks. This afterexcitability is form specific and is a physiological measure of spinal cord selection processes. NMDA receptors contribute to this afterexcitability (Currie and Stein, 1992; see also NMDA Receptors: Synaptic, Cellular, and Network Models). The long time constant of NMDA receptor activation is well suited for multisecond excitability changes.

Spinal cord neurons, termed long-afterdischarge interneurons, are activated by stimulation in a region of a scratch receptive field and are active for many seconds after the cessation of stimulation. Long-afterdischarge interneurons may play a role in motor pattern selection in scratch neuronal networks. NMDA receptors contribute to the excitability of long-afterdischarge interneurons (Currie and Stein, 1992).

### *Broad Tuning of Interneurons in Neuronal Networks for Scratching*

There is broad tuning in the responses of individual turtle interneurons activated by stimulation of sites in the receptive fields for the rostral scratch and for the pocket scratch (Berkowitz and Stein, 1994; Berkowitz, 2001). Some of these interneurons are activated throughout the entire region of the scratch receptive fields for each of several forms. Many of these interneurons may be members of both the rostral scratch CPG and the pocket scratch CPG. For each interneuron, there is usually a site whose stimulation results in the highest frequency of action potentials; stimulation of other sites usually results in interneuron firing frequencies that decrease as the distance from the site that evokes the greatest response increases. These data are consistent with the hypothesis that motor pattern selection results from the summed activities of a population of broadly tuned interneurons that are shared by several CPGs.

### *Scratch CPG Rhythmogenesis*

Reciprocal inhibition between hip flexor and hip extensor interneurons plays a major role in spinal cord scratch rhythmogenesis; additional mechanisms for rhythmogenesis must exist, however, since hip flexor motor rhythms are generated in the absence of hip extensor motor activity (Stein et al., 1995; Stein, McCullough, and Currie, 1998). During quiescence of hip extensor motor neuron activity, there is also quiescence of hip extensor interneuron activity (Stein and Daniels-McQueen, 2002). This supports the concept that interneurons that are active during hip flexor motor output are rhythmogenic. Left-right interactions also play a key role in rhythmogenesis (Stein et al., 1995; Stein, McCullough, and Currie, 1998).

## Discussion

Scratching can be used to uncover important characteristics of neuronal networks that perform sensory-to-motor transformations. Future experiments are required for a more complete understanding of the properties of these neuronal networks.

# Self-Organization and the Brain

*Christoph von der Malsburg*

## Introduction

There is a fundamental difference between brain and computer. The computer is based on the algorithmic division of labor. It relies on the separate existence of minds that program and interpret. The brain is a physical, dynamical system to which the algorithmic scheme cannot be applied except in a metaphorical sense. The brain is not digital, not deterministic in any operational sense, and in its inner workings it never gets help from a separate interpreting and planning mind. Instead, the brain is organized on the basis of physical interactions between its elements and of the nested processes of evolution, ontogenesis, and state organization. Unfortunately, our thinking about brain and mind is still very much in the grips of the algorithmic scheme, and we are always in danger of seeing in evolution a programmer and in the genome a program, of taking perception as a mere preparation of material for a "higher level" always just outside our field of view, or of subscribing to a model of learning that relies on the presence of an experimenter to select and prepare the learning patterns and their encoding.

Self-organization is the process by which ordered structures arise in dynamical systems (see PATTERN FORMATION, BIOLOGICAL; COOPERATIVE PHENOMENA; Haken, 1978; Ball, 1999). The theory of evolution has always been a theory of self-organization (EVOLUTION OF THE ANCESTRAL VERTEBRATE BRAIN; EVOLUTION OF GENETIC NETWORKS; EVOLUTION OF ARTIFICIAL NEURAL NETWORKS), and the perspective of self-organization is gaining growing acceptance as well at the level of morphogenesis (not treated here) and the organization of neural connectivity (see DEVELOPMENT OF RETINOTECTAL MAPS; OCULAR DOMINANCE AND ORIENTATION COLUMNS) and brain state (see DYNAMIC LINK ARCHITECTURE). But our ideas about self-organization will have to be developed much further before they can get algorithmic thinking totally out of the way.

## Self-Organization in General

Self-organization is the phenomenon by which simple mechanisms of growth and interaction lead to the establishment of complex structures of global order. The phenomenon dominates our world, from the crystalline structure of minute snowflakes to the flow patterns in our coffee cup, atmosphere, and oceans to the formation of stars, planetary systems, and galaxies. Its most awesome expression, however, is found in the structures of the living world. Elementary arrangements cooperate and compete to form more complex patterns, these in turn conspiring to create structures of higher and higher order. What distinguishes winning patterns is the degree of harmony of their elementary arrangements within their smaller and larger contexts. The most interesting aspect of the phenomenon is the tremendous contrast between the simplicity of elementary interactions and the complexity and beauty of the structural order they create. Although a silent revolution in favor of self-organization as a fundamental principle has swept the intellectual world within the past two or three decades, we are still far from realizing the full impact of the phenomenon on our comprehension of things.

Self-organized structures are characterized by inherent order—symmetries, self-similarity, repetition, and many other kinds of regularity: the mechanisms of self-organization are not free to create arbitrary arrangements and can only select from a relatively narrow universe of ordered patterns. For example, although no two snowflakes are ever alike, they realize a vanishing subset of all arbitrary arrangements of water molecules. The amount of information needed to specify a self-organized pattern is therefore very modest, tremendously smaller than the (logarithm of) number of all random arrangements of elements. In consequence, describing phenomena in terms of self-organized structures is a very powerful tool, and focusing attention on those structures is of great scientific importance.

Although science still has to struggle to find and formulate much of the universe of structured patterns that can be realized by self-organization, this universe is preexisting in the mathematical sense. (To give a specific example, the set of all possible periodic crystal lattices can be completely specified mathematically.) It is impressive to see to what extent the structure of this universe is determined by laws and relationships operating at higher levels and independent of the detail of elementary mechanisms and interactions. Structure is determined to a large extent from the top down, supporting the hope that even systems as complex as the brain can ultimately be understood in relatively simple terms.

In an elementary process of self-organization, a system makes the transition from a simple, relatively unstructured initial state that is in the process of becoming unstable to a more structured final state in which the dynamic forces reach equilibrium again. The transition starts with random *fluctuations*, which are small deviations from the initial state. The process is governed by three types of interactions: fluctuations self-amplify, fluctuations cooperate, and fluctuations compete. In the interplay between these interactions, certain constellations of fluctuations collude to form patterns on a larger scale.

A simple and well-understood example of self-organization, originally proposed by Bénard, is a flat pan filled with liquid and heated from below. (Other examples of self-organizing systems are discussed in COOPERATIVE PHENOMENA.) In an initial state, the liquid is at rest. When the temperature gradient is strong enough, the initial state becomes unstable, and fluctuations in the form of small regions of upwelling or downwelling liquid start to grow in amplitude. These fluctuations are self-amplifying, as upward motion draws more hot liquid from the bottom, creating a column of fluid that is hotter and lighter than the surrounding fluid, and similarly for downward motion. Fluctuations cooperate, with vertical movement in one small column dragging along movement in neighboring columns. And they compete, as upward movement in one place must be made up by downward movement in other places. These interactions establish convection cells, regions of coherent motion, which typically take the shape of hexagons or rolls (the latter being akin to the parallel bands of clouds sometimes seen in the sky), often of impressively regular arrangement. In a given system, fluctuations can be defined on several levels. In the Bénard system, for instance, "fluctuations" may be identified with droplets of moving liquid, as I just did, but also with whole coordinated patterns of mutually consistent up-and-down movement, which may have the form of sinusoidal waves fluctuating in amplitude.

The dynamic properties of interacting fluctuations, and consequently the selection of particular final structures, usually is subject to so-called control parameters (among the control parameters of the Bénard system are the temperature gradient, the viscosity, and the depth of the liquid). Moreover, a pattern resulting from self-organization may set the stage for more self-organization, sometimes making a final result dependent on the detailed history of a long chain of processes. This aspect is especially important in biology, whose structures are the result of phylogenetic and ontogenetic history.

## Mathematical Methods

There are three types of theoretical tools to describe and understand self-organizing systems: computer simulation, statistical mechanics, and dynamical differential equations and the attendant fields of catastrophe theory and stability analysis. Statistical mechanics is a method to derive relations between global properties of physical systems from the statistics of the constituent atoms or molecules. Typical global parameters are temperature, energy, volume, and pressure. From a very simple basic idea ("all detailed configurations of the system compatible with global parameters are attained with equal probability") all interesting quantities can be derived mathematically (see STATISTICAL MECHANICS OF NEURAL NETWORKS and Hertz, Krogh, and Palmer, 1991). Important applications of statistical physics are phase transition systems. They fall into "universality classes." It is remarkable to what extent the qualitative behavior of systems in a given universality class is independent of detailed material properties. What above was called "harmony" materializes in statistical physics as a quantity called free energy (great harmony is low free energy).

Many self-organizing systems can be completely characterized by continuous variables and their deterministic interactions (in Bénard's system these are the local velocity of the flowing liquid and the forces acting on it). Such systems are conveniently described as systems of coupled differential equations (see Haken, 1978; see also COOPERATIVE PHENOMENA). These are always of nonlinear type and can be solved analytically (that is, with pencil and paper) only in the rarest cases. Computer simulation is a convenient way to explore the behavior of such systems. However, since the behavior of a system can depend in unexpected ways on the precise settings of parameters, it is profitable to analyze this behavior using stability analysis (see DYNAMICS AND BIFURCATION IN NEURAL NETS; COOPERATIVE PHENOMENA; Haken, 1978). As a result, a simpler description of the system is derived in the form of a small number of superimposable patterns ("linear modes") and differential equations describing the behavior of their amplitudes. Stability analysis is thus a powerful conceptual tool to make the transition from a description at the level of microscopic building elements to macroscopic modes of behavior.

## Self-Organization in the Brain

The brain is often cited as the most complex entity in the universe. And indeed it is an awesome array of structure that spans many orders of magnitude. Although this can also be said of a simple rock, what distinguishes the brain is the purposeful arrangement of its detail. Pathological alteration at any level—molecular, synaptic, cellular, or macroscopic—easily leads to serious functional deficit. On the other hand, much of the variation from individual to individual, or even from second to second in a given individual, seems to be fully compatible with physiological function. This raises the great puzzle of how the myriad important functional relationships are created and maintained in the brain. According to an old mode of thinking, a Creator, or Mother Nature, or a genetic program is in control of every molecular reaction with exquisite algorithmic foresight. Although this thought pattern of "hetero-organization" under control of a preexisting detailed plan still governs many a thought subconsciously, it is quickly losing dominance, giving way to models of self-organization at all levels—evolution, ontogenesis, learning, and functional organization. As a result, instead of blindly accepting any arbitrary brain structure as of equal a priori likelihood, the explicit examination of mechanisms of organization in evolution and ontogenesis yields powerful constraints on what to expect, reducing the search space of experimental science by many orders of magnitude.

A potent argument against the brain as irreducible heap of structure is the gross mismatch between the amount of information contained in its detail as measured naively and the amount of available genetic information. The direct specification of an arbitrary wiring pattern of the $10^{14}$ connections between the $10^{10}$ neurons in the human cerebral cortex would, for instance, take more than $10^{15}$ bits of information. By comparison, there are little more than $10^{9}$ bits in the human genome. This mismatch of more than six orders of magnitude vanishes if the genes are required only to specify the rules of the game and some control parameters for ontogenetic self-organization. As a consequence, the resulting connectivity patterns, far from random, have to be highly regular. Some of this regularity is known to us and has, for instance, the form of topographic organization. The bulk of the connective architecture of the brain, however, is unknown and very difficult to determine experimentally. The most parsimonious way to describe the brain (including individual variations) would be in terms of generative rules and appropriate theoretical tools to retrace ontogeny. Intimate knowledge of the laws of organization is also a prerequisite for analysis and cure of many ailments of the brain, much more than mere knowledge of static structure (even if it could be had).

The evolution of the brain cannot possibly be imagined as a progression of mutation and selection at the level of individual cells or synapses ("evolution by rote"). This search space would just be too large, even on the time scale of hundreds of millions of years, and the resulting information could not be transmitted from generation to generation through the limited genome. In reality, however, as the genes determine the laws of self-organization and its control parameters, the search space is much smaller. Evolution restricts itself to finding fruitful architectures and tuning them to the particular biological needs of the species by alterations at the control parameter level.

The neurosciences are making extensive use of inductive generalization from a few strategic observations. This is possible only on the basis of the regularities that are the hallmark of self-organization. Progress could be accelerated and many a false start and expensive investigation avoided if we had a clearer picture of the control structures and regularities of the brain as a self-organizing entity. So far the surface has hardly been scratched.

An immense amount of experimental and theoretical work will have to be done. The perspective of self-organization is not a magic bullet that reduces the brain problem to armchair theorizing and a few simple equations. Our nervous system is made up of a bewildering variety of cell types of different anatomy, molecular makeup, and behavioral repertoire, and our brain has an immensely convoluted gross anatomy of interconnected nuclei and areas. Even if the details of neural connectivity could be derived from general laws, these general laws are conditioned from below and above by the underlying behavioral repertoire of the constituent elements and the gross boundary conditions. The amount of information in our genome may be much smaller than any naively calculated information content of the brain, but it is still a very large quantity.

In order for the brain to guide the animal safely through life, it must be in tune with the environment. How can it be so? One important answer evidently is that the brain learns through examples. Unfortunately, this process is far from being fully understood. Each situation with which a brain has to cope is unique. Only appropriate analysis and coding makes information from one scene applicable to others. These mechanisms of analysis and proper representation are unlikely to be learned themselves from example. They exist prior to experience (as postulated by Immanuel Kant) and rely to a large extent on self-organization. Although this sounds like a daring proposition, requiring the universe of self-organized brain structures to be generally in tune with the structure of the environment by "preestablished harmony," no other solution to the epistemology riddle is in sight. The self-organized ontogenesis of brain structures constitutes a natural language, and all evolution had to do was use this language to write the particular text that defines us.

### *Activity Self-Organization*

In the formulation of McCulloch and Pitts (1943), neural networks have binary signals and synchronized switching and are thus equivalent to digital machines. Just as in digital machines, these networks and their activity have no inherent tendency to fall into organized patterns. McCulloch and Pitts do not discuss any mechanism for the generation of networks or the underlying logical functions to be realized. These are based entirely on the algorithmic schema and must be structured on the basis of a separate programmer's insight. With appropriate changes, however, neural networks can be made to self-organize. For this, some combination of giving up synchrony of switching, introducing graded instead of binary signals, and specializing connectivity patterns to near symmetry (between the forward and backward connection between two neurons) seems to be important. Essential for self-organization is a tendency to iteratively approach stationary states (or nearly stationary states).

The self-organization of activity patterns is most simply discussed and modeled in homogeneous two-dimensional sheets of neurons with short-range excitation and longer-range inhibition, assumptions that are consistent with what is known about cortical anatomy. A homogeneous activity distribution in a sheet of neurons becomes unstable when the slope of the input-output function of the tissue grows beyond a critical value (see DYNAMICS AND BIFURCATION IN NEURAL NETS). Small fluctuations in signal strength then start to grow and self-amplify. Due to short-range excitation, they cooperate locally; through longer-range inhibition they compete. As a consequence, organized patterns grow.

Under idealized conditions these patterns may have the form of regular arrays of blobs or of parallel stripes. Under more realistic conditions one observes more or less regular waves or arrays of blobs, closely corresponding in character to ripples in sand under irregularly moving water, and many other systems.

Such activity patterns are found in the visual cortex of cat and monkey with optical or other recording techniques. These patterns may play a role in the generation and expression of the regular columnar arrangement of cellular properties such as OCULAR DOMINANCE AND ORIENTATION COLUMNS (q.v.). They have also been proposed as an explanation for visual hallucinations during migraines or states of intoxication (see PATTERN FORMATION, BIOLOGICAL).

If, as is the reigning opinion, neural connections are the repository of knowledge in the brain, activity self-organization is the mechanism by which elementary knowledge (in the form of connections) is combined into useful thought patterns. An admittedly very simple first model of this process is associative memory (Hertz et al., 1991; see also COMPUTING WITH ATTRACTORS). Activity states are stored by HEBBIAN SYNAPTIC PLASTICITY (q.v.), that is, by strengthening connections between neurons that are simultaneously active in a state. Later, the state can be dynamically recreated by self-organization, starting from an incomplete version of it. The model thus treats self-organization at two levels, the formation of connections and the formation of activity states. The model has been fully analyzed by the methods of statistical physics, which helped to identify important parameters and gave useful information on memory capacity. It may be hoped that the obvious weaknesses of the associative memory model—it only recreates states established previously and cannot generalize to new scenes—can be overcome to create a more realistic model of brain state organization.

The main reason for associative memory's weakness is the monolithic character of its activity states. Lately, much experimental and theoretical study has been devoted to spatiotemporal patterns as a means to segregate the mass of neurons simultaneously active in a given brain state into separate chunks (corresponding to separate objects in a scene) by synchronizing the signals of neurons within chunks and desynchronizing them between chunks (see SYNCHRONIZATION, BINDING AND EXPECTANCY).

### *Network Self-Organization in Ontogenesis*

Network self-organization conforms to a simple scheme (von der Malsburg, 1995). A network and its inputs create activity patterns. These are characterized by statistical correlations between pairs of neural signals. In response to these correlations, individual synapses are changed by HEBBIAN SYNAPTIC PLASTICITY (q.v.). In terms of the general scheme of self-organization discussed above, elementary fluctuations are deviations of synaptic strengths from their initial state. Fluctuations self-amplify as result of the positive feedback between excitatory synapses and the correlations they create. Cooperation rules between synapses that converge on the same neuron if their activity is correlated, as a consequence of which they help each other establish favorable postsynaptic activity. Competition rules between synapses if the activity states they favor are not compatible with each other. The altered network creates modified patterns of signal correlations, which in turn modify synaptic strengths. This feedback loop may create a runaway situation that drives the network state away from the initial, unstructured state. Because of their elementary interactions, natural alliances exist between synapses, and the network that finally wins is a constellation of connections that is optimal in terms of cooperation and competition.

The ontogenesis of fiber projection systems has been studied in great detail in the example of the retinotectal system (see DEVELOPMENT OF RETINOTECTAL MAPS; von der Malsburg, 1995). There seems to be a consensus that three major mechanisms are guiding fibers: gross routing, fiber positioning, and fiber sorting. Apparently, the first two mechanisms are based on gradients of morphogens that guide fibers first to the target structure and then to their target position within that structure. These mechanisms are simple extensions of general themes of morphogenesis (see the chapter on bodies in Ball, 1999). The retinotectal system shows considerable flexibility in dealing with unexpected variations imposed experimentally or by anomalous development. The projection can, for instance, adjust to changed relative size of retina and tectum. The adaptability of the retinotectal system is explained by the third mechanism, fiber sorting. This mechanism has been shown to be dependent on neural activity. It has been modeled with great success and is now a prime paradigm for neural network self-organization. Other instances of network self-organization deal with the ontogenesis of OCULAR DOMINANCE AND ORIENTATION COLUMNS (q.v.; see also von der Malsburg, 1995) and of structures in the barrel field of the rodent cortex.

According to recent evidence, synapses can change their weight on a very rapid time scale (for a review see Hempel et al., 2000). It might be surmised that these changes are controlled by network-created short-term signal fluctuations in a rapid version of HEBBIAN SYNAPTIC PLASTICITY (q.v.). If that is the case, a process of network self-organization may be active, adapting the connectivity pattern of the brain to the current context in which it is operating on time scales of fractions of seconds to minutes (see DYNAMIC LINK ARCHITECTURE).

## Conclusion

The theme of self-organization currently receives surprisingly little attention in the brain theory community. And yet there is a tremendous, largely uncharted territory to be explored. The easily accessible geometrical patterns of activity and connectivity have been modeled in hundreds of publications. However, the material with which neural self-organization plays has the form of a *net-*

*work*, in which neighborhood is defined in terms of neural connectivity and not (or at least not directly) in terms of two- or three-dimensional geometry. We therefore must prepare ourselves for a totally new universe of network and activity patterns in which order is defined in terms of abstract relationships and quantities, and not in terms of pretty pictures. Second, the theory of self-organization has hitherto focused on the establishment of static structures. The nervous system, however, is about the generation of purposeful, nested processes evolving in time. Third, getting the simulation of a self-organizing system to work, that is, to create the intended type of patterns, is still an art. There are usually quite a few control parameters in a system, and they must all be put in the right ballpark. Blind search is usually out of the question for quantitative reasons. In view of the variability of the physiological state of the nervous system, evolution cannot simply have developed fixed values for these parameters. Nature must have developed general mechanisms to actively and autonomously regulate its systems, such as to produce interesting self-organized processes and states.

Finally, it will be important to understand the process of brain organization as a cascade of steps, each one taking place within the boundary conditions established by the previous one, and the theory of such cascades is as yet nonexistent. The tremendous creativity inherent in our brain's state organization cannot be well understood without knowing the arena set up by ontogenesis and learning, and ontogenesis cannot well be understood without understanding the genetic control structure set up by evolution. The perspective of self-organization is more of a program for future work than an accomplished success. There is a new continent to be discovered. It is the continent where our mind lives. It is time to set sail.

# Self-Organizing Feature Maps

*Helge Ritter*

## Introduction

A first and very important step in many pattern recognition and information processing tasks is the identification or construction of a reasonably small set of important features in which the essential information for the task is concentrated.

The *self-organizing feature map* (SOFM) is a nonlinear method by which such features can be obtained with an unsupervised learning process. It is based on a layer of adaptive units ("neurons," Figure 1) that gradually develops into an array of feature detectors that is spatially organized in such a way that the location of the excited units becomes indicative of statistically important features of the input signals.

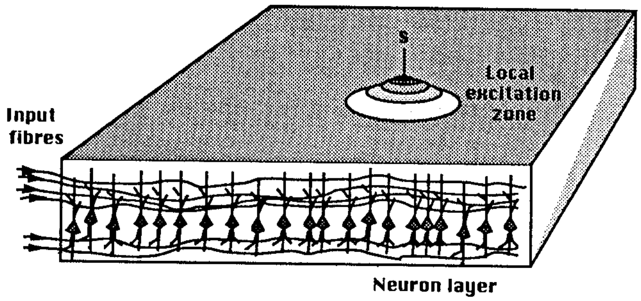

**Figure 1.** Schematic representation of a feature map. Nerve fibers providing the input signal excite the neurons via synaptic connections. Lateral interactions restrict the neural responses and the synaptic adaptation to a local excitation zone. Each possible position *s* of the excitation zone can be viewed as a compressed image in a two-dimensional space of the original stimulus features.

The linking of input signals to response locations in the map can be viewed as a nonlinear projection from a signal or input space to the (usually) two-dimensional (2D) map layer. The resulting "compressed image" of the (usually higher-dimensional) input space has the property of a topographic map that reflects important metric and statistical properties of the input signal distribution: distance relationships in the input space (expressing, e.g., pattern similarities) are approximately preserved as distance relationships between corresponding excitation sites in the map, and clusters of similar input patterns tend to become mapped to coherent areas whose size varies in proportion to the frequency of the occurrence of their patterns.

This resembles in many ways the structure of topographic feature maps found in many brain areas, for which the SOFM offers a neural model that bridges the gap between microscopic adaptation rules postulated at the single neuron or synapse level and the formation of experimentally better accessible, macroscopic patterns of feature selectivity in neural layers. From a statistical point of view, the SOFM provides a nonlinear generalization of principal component analysis and has proved valuable in many application contexts, ranging from pattern recognition and optimization to robotics (Ritter, Martinetz, and Schulten, 1992; Kohonen, 1995).

## The Basic Feature Map Algorithm

The SOFM algorithm provides an unsupervised learning rule by which the adaptive units (neurons) can tune their response properties in such a way that the described, topographic map structure arises. The process is iterative and is driven by a sequence of activity patterns on some shared set of (afferent) input lines (Figure 1), at each step activating and adapting some local group of neurons.

Successful self-organization of the map requires the following: (1) the neurons must be exposed to a sufficient number of different inputs; (2) for each input, only the synaptic input connections to the excited group are affected; (3) similar updating is imposed on many adjacent neurons; and (4) the resulting adjustment is such that it enhances the same responses to a subsequent, sufficiently similar input (Kohonen, 1982).

A standard formulation of this process models the input patterns as vectors $\mathbf{x}$ from some pattern space $V$ (whose dimensionality $n$ is given by the number of input lines) and the neural layer as a set of formal neurons occupying discretes sites $r$ in a (e.g., planar) grid $A$. The response of a neuron at site $r$ is determined by the dot product $\mathbf{x} \cdot \mathbf{w}_r$, where $\mathbf{w}_r$ is the vector of the neuron's synaptic connection strengths with the $n$ afferents carrying the input pattern $\mathbf{x}$.

For each input $\mathbf{x}$, the adaptive changes in the layer are confined to a local group of neurons centered at the site $s$ for which $\mathbf{x} \cdot \mathbf{w}_s$ is maximal. This is achieved by modulating the adaptive changes for other sites $r$ with an activity profile $h_{rs}$ that has its peak at $r = s$ and that decays to smaller values with increasing distance $\|r - s\|$ from $s$ ("neighborhood cooperation"; it is essential that $\|r - s\|$ be taken in the space of the lattice $A$, not in the original signal space $V$):

$$\mathbf{w}_r^{(new)} = (1 - \epsilon \cdot h_{rs})\mathbf{w}_r^{(old)} + \epsilon \cdot h_{rs} \cdot \mathbf{x} \qquad (1)$$

Equation 1 can be justified by assuming the traditional Hebbian law for synaptic modification together with an additional nonlinear, "active" forgetting process for the synaptic strengths (Kohonen, 1995).

A rather realistic modeling choice for $h_{rs}$ is, e.g., a Gaussian

$$h_{rs} = \exp\left(-\frac{\|r - s\|^2}{\sigma^2}\right) \qquad (2)$$

whose variance $\sigma^2/2$ will control the radius of the group.

Consequently, neurons that are close neighbors in $A$ will tend to specialize on similar patterns. After learning, this specialization is used to define the mapping from the space $V$ of patterns onto the (discretized) space $A$: each pattern vector $\mathbf{x} \in V$ is mapped to one of the discretized neuron sites of $A$. The image of $\mathbf{x}$ under this mapping is defined to be the location $s = s(\mathbf{x})$ associated with the neuron for which $\mathbf{x} \cdot \mathbf{w}_s$ is largest ("winner neuron").

A frequently useful modification of this basic algorithm is to replace the winner criterion for the site $s(\mathbf{x})$ by a different one. A frequent choice is minimizing the Euclidean difference $\|\mathbf{x} - \mathbf{w}_s\|$ (which is equivalent to maximizing $\mathbf{w}_s \cdot \mathbf{x}$ when the vectors are normalized), but many other similarity measures can also be used to obtain SOFMs.

## Visualization of Feature Maps

There are two main ways to visualize a feature map. The first approach labels each neuron in $A$ by the test pattern that excites this neuron maximally (best stimulus). It yields a partitioning of a map into coherent regions of similarly specialized neurons and resembles the experimental procedure by which sites in a brain area are labeled by those stimulus features that are most effective in exciting neurons at this site. In the example in Figure 2, each training and test pattern consisted of 13 simple binary-valued features describing one of 16 animals (Ritter and Kohonen, 1989) whose similarity relationships are reflected in the resulting partitioning of the SOFM.

**Figure 2.** Visualization of a 10 × 10 feature map for a set of pattern vectors describing binary features of 16 animal species. The spatial arrangement of the labeled map regions reflects the similarity relationships between the animals.

In the second approach, the feature map is visualized as a "virtual net" in the original pattern space $V$. The virtual net is the set of weight vectors $\mathbf{w}_r$ displayed as points in the pattern space $V$ and connected by lines between those pairs $(\mathbf{w}_r, \mathbf{w}_s)$, whose neuron sites $(r, s)$ are nearest neighbors in the lattice $A$. While the virtual net is very well suited to display the topological ordering of the map, its use is limited to continuous and at most three-dimensional (3D) spaces. Figures 3*A* and 3*B* show the development of the virtual net of a 2D 20 × 20 lattice $A$ from a disordered initial state (Figure 3*A*) into an ordered final state (Figure 3*B*) when the stimulus density is concentrated along the surface $z = x \cdot y$ in the cube $V$ given by $-1 < x, y, z < 1$.

## Discussion

*The main characteristics of the feature map algorithm.* Geometrically, the adaptive process (Equation 1) can be viewed as a sequence of local deformations of the virtual net in the space of input patterns so that it *approximates the shape of the stimulus density* $P(\mathbf{x})$ in the space $V$. A good approximation is possible if the topology of the virtual net (which is the same as the topology of the lattice $A$) and the topology of the stimulus density are the same (as, e.g., in Figures 3*A* and 3*B*). Otherwise, e.g., if the dimensionalities of the stimulus manifold and the virtual net differ, the resulting approximation can only partially fulfill the goal of matching spatially close points of the stimulus manifold to points that are neighbors in the virtual net. An example is depicted in Figure 3*C*, where the map manifold is 1D (a chain of 400 units), the stimulus manifold is 2D (the surface $z = x \cdot y$), and the embedding space $V$ is 3D (the cube $-1 < x, y, z < 1$). In this case, the dimensionality of the virtual net is lower than the dimensionality of the stimulus manifold (this is the typical situation), and the resulting approximation resembles a "space-filling" fractal curve.

*Properties of the features that are represented in a feature map.* The geometric interpretation of the previous section suggests that a good approximation of the stimulus density by the virtual net requires that the virtual net be oriented tangentially at each point of the stimulus manifold. Therefore, a $d$-dimensional

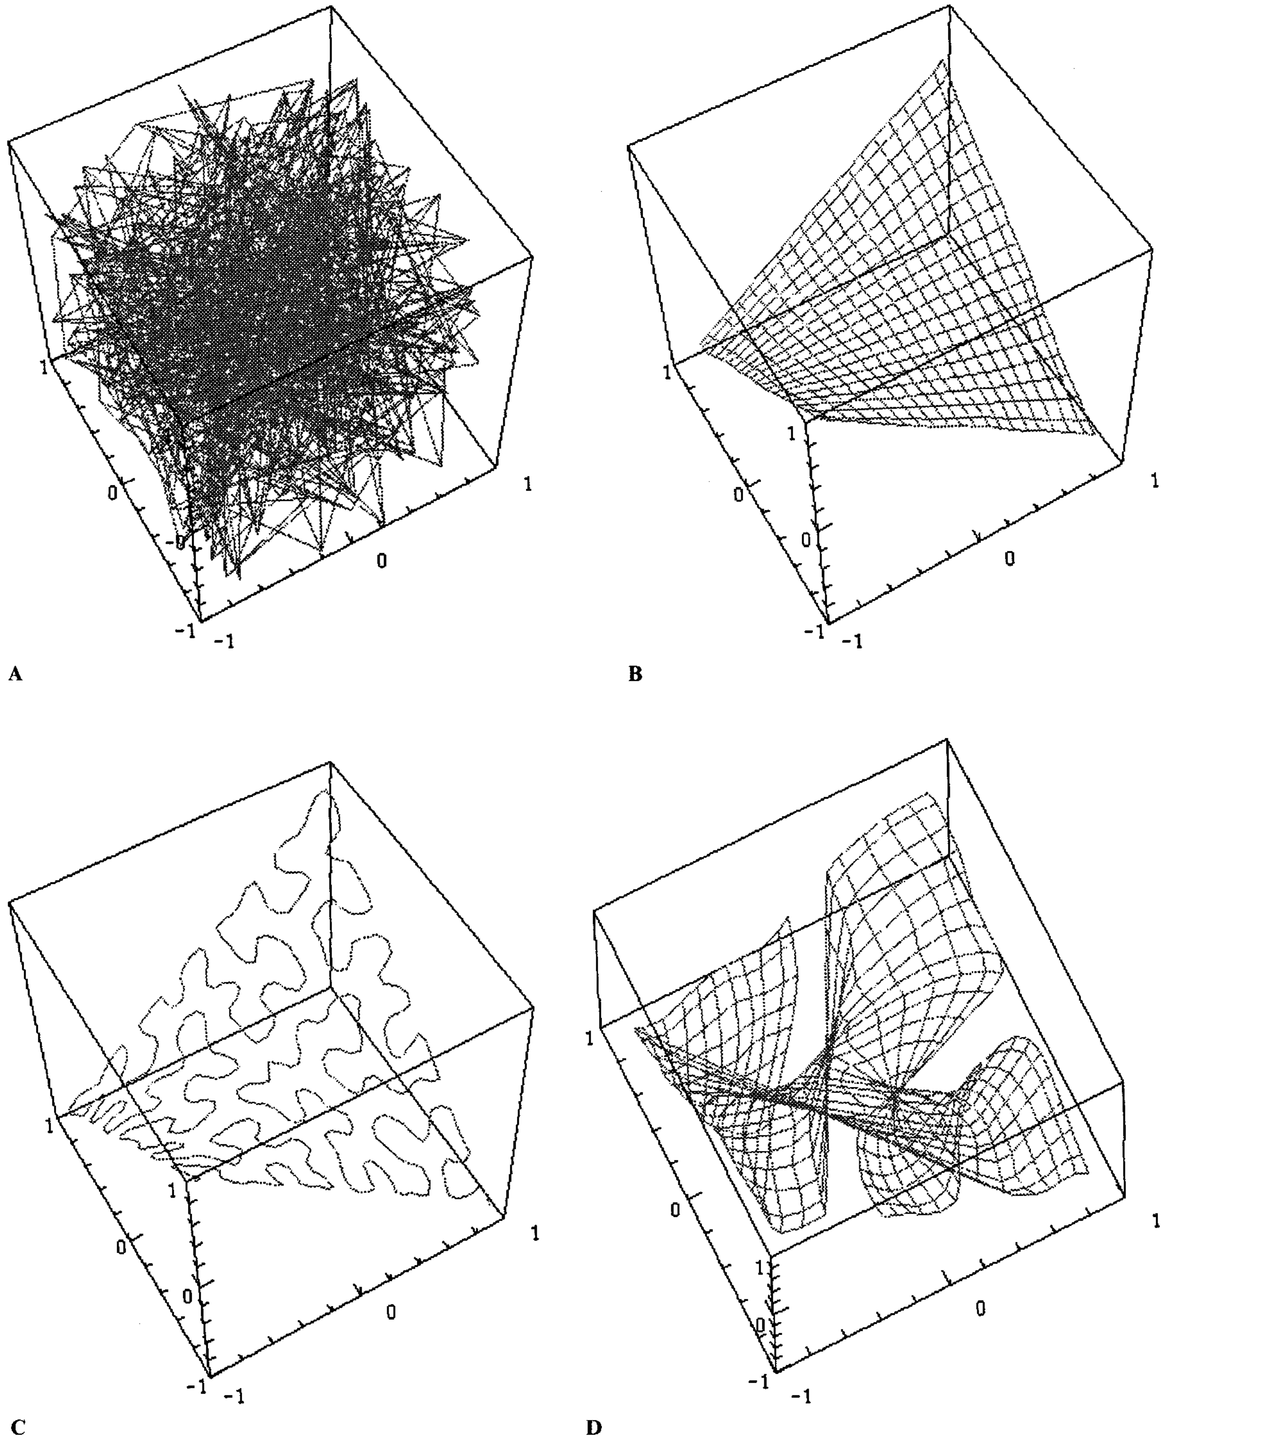

**Figure 3.** Top: Initial, disordered (*A*) and final, ordered (*B*) configuration of the "virtual net" for a two-dimensional feature map, developing under the influence of a two-dimensional stimulus density that is embedded in a three-dimensional signal space. *C*, *Dimension conflict:* when replacing the two-dimensional feature map of parts *A* and *B* with a one-dimensional chain, a space-filling fractal curve results. *D*, A *topological defect* is characterized by several patches of globally conflicting local orderings.

feature map will select a (possibly locally varying) subset of *d* independent features that capture as much of the variation of the stimulus distribution as possible. This is an important property that is also shared by the method of Principal Component Analysis (PCA) (q.v.). An important difference, however, is that the selection of the "best" features can vary smoothly across the feature map and can be optimized locally. Therefore, the SOFM can be viewed as a nonlinear extension of PCA.

*Relationship of the feature map to more traditional approaches.* The SOFM shares with a number of other approaches the goal of forming lower-dimensional, distance-preserving mappings of data, which is a general task in data analysis known as *multidimensional scaling* (see Data Clustering and Learning). Usually, these methods are based on a direct minimization of some *projection index* that quantifies, e.g., the degree of distance distortion, or some measure of "interestingness" (e.g., non-Gaussianity of the resulting image distribution). An example of the first type is the nonlinear *Sammon mapping*, while examples of the latter type are the *projection pursuit methods* that lead to various linear projections (of which PCA can be viewed as a special case when the interestingness measure is just the data variance).

There is also the following relationship with *vector quantization*, which considers the task of finding discrete encodings for continuous signals satisfying certain optimality requirements, such as minimal reconstruction error. The determination of the site $s(\mathbf{x})$ of the winner neuron in a SOFM can be considered as assignment of a code $s$ to a data vector $\mathbf{x}$. From this code, $\mathbf{x}$ can be reconstructed (decoded) approximately by taking $\mathbf{w}_s(\mathbf{x})$ as its reconstruction, with an average (mean square) reconstruction error

$$E = \int P(\mathbf{x})(\mathbf{x} - \mathbf{w}_{s(\mathbf{x})})^2 d^d\mathbf{x} \tag{3}$$

It can be seen that in the special case $h_{rs} = \delta_{rs}$ (absence of neighborhood cooperation), the adaptation rule (Equation 1) is a stochastic minimization procedure for $E$, and becomes equivalent to a standard algorithm for finding an optimized set of codebook vectors $\mathbf{w}_s$, in vector quantization terminology. However, a further source of reconstruction errors may be the *confusion* of two codes $s'$, $s''$ with some probability $p(s', s'')$. This situation requires the minimization of a more general error measure, now given by

$$E = \sum_{s',s''} p(s', s'') \int_{s(\mathbf{x})=s'} P(\mathbf{x})(\mathbf{x} - \mathbf{w}_{s''})^2 d^d\mathbf{x} \tag{4}$$

It can be shown that the (approximate) minimization of this error measure, and therefore the construction of an optimal code for this more general situation, is closely related to the feature map formation, provided one takes $h_{ss'} = p(s, s')$; i.e., the neighborhood cooperation in the map is derived from the "confusion matrix" $p(s, s')$ (Luttrell, 1994).

*The stationary states of the feature map algorithm.* A *stationary state* is a configuration for which the average change of weights per adaptation step vanishes. A stationary state is stable if all sufficiently small perturbations from it decay on the average. However, for a given stable stationary state, this still leaves the possibility that there may exist "very unlikely" sequences of adaptation steps that lead to a different stationary state. If such sequences exist, a stable stationary state is called *metastable*; otherwise it is called *absorbing*. Only the absorbing states are the "true" final states of the time evolution of a feature map. However, if the system is driven into a metastable state, it may become "trapped" for such a long time that the state cannot be distinguished from a true absorbing state within realistic observation times. Usually, the metastable states are those that occur as only partially ordered, while those states that intuitively appear as fully ordered seem to have the property of being absorbing (Erwin, Obermeyer, and Schulten, 1992a, 1992b).

*Speed and reliability of the ordering process in relation to the various parameters of the model.* The convergence process of a feature map can be roughly subdivided into a first ordering phase, in which the correct topological order is produced, and a subsequent fine-tuning phase. So far, rigorous convergence proofs for the full process have only been obtained for the 1D case, and for the 2D case when the correct topological order is specified along the border of $A$. Since for many geometrically intuitive definitions of order in dimensions greater than 1 one can show that they do not lead to absorbing states for the SOFM process, a very general ordering proof for higher dimensions is unlikely to exist. For a good overview on these and other theoretical aspects of the SOFM, see Cottrell, Fort, and Pagès (1998).

A very important role for the ordering phase is played by the neighborhood kernel $h_{rs}$. Usually, $h_{rs}$ is chosen as a function of the distance $\|r - s\|$; i.e., $h_{rs}$ is translation invariant. The algorithm will work for a wide range of different choices (locally constant, Gaussian, exponential decay) for $h_{rs}$, but for fast ordering the function $h_{rs}$ should be convex over most of its support. Otherwise, the system may get trapped in partially ordered, metastable states and the resulting map will exhibit "topological defects," or conflicts between several locally ordered patches (Figure 3*D* shows a typical example) (Erwin et al., 1992a, 1992b).

Another important parameter is the distance up to which $h_{rs}$ is significantly different from zero. This range sets the radius of the adaptation zone and the length scale over which the response properties of the neurons are kept correlated. The smaller this range, the larger the effective number of degrees of freedom of the network and, correspondingly, the harder the ordering task from a completely disordered state. Conversely, if this range is large, ordering is easy, but finer details are averaged out in the map. In addition, for Gaussian neighborhood kernels, a sufficiently large range also makes the function $h_{rs}$ convex over the entire network. Therefore, formation of an ordered map from a very disordered initial state is favored by a large initial range (a sizable fraction of the linear dimensions of the map) of $h_{rs}$, which then should decay slowly to a small final value (on the order of a single lattice spacing or less). Although statistical considerations seem to dictate a $1/t$ decay law, the faster exponential decay is suitable in many cases.

It should be noted that the absence of a general ordering proof is mainly of theoretical concern. In practical applications, one usually will start with an already ordered configuration (oriented, e.g., along the major principal axes of the data distribution) and apply the SOFM process for the fine-tuning phase.

*Quantitative characterizion of the ordering achieved with a feature map.* The difficulty of characterizing the achieved ordering is partly due to the difficulty of defining order for embeddings of higher-dimensional lattices in higher-dimensional spaces. A more modest goal is the construction of some cost or energy function that is minimized by the algorithm and that then can serve as a measure of "progress" toward a converged state (without, however, necessarily telling much about the geometric ordering properties of such a state). A good candidate is the function $E$ in Equation 4; however, it has been rigorously shown that the SOFM algorithm does not admit an exact energy function, rendering Equation 4 only an approximation. Remarkably, the approximation can be made exact by changing the SOFM winner criterion for the determination of $s(\mathbf{x})$ (Heskes and Kappen, 1993; Luttrell, 1994):

$$s(\mathbf{x}) = \arg\min_r \sum_{r'} h_{rr'}\|\mathbf{x} - \mathbf{w}_{r'}\| \tag{5}$$

This winner criterion is more costly to compute, and the modified process seems to resemble the SOFM sufficiently closely to warrant the substitution of Equation 5 with the simpler but theoretically less satisfying original winner criterion in practical applications.

In applications, the data topology often is unknown, and the use of a SOFM can only be considered in an attempt to find out how well the (usually) 2D map can approximate the unknown data topology. Various measures of the faithfulness of the resulting maps have been suggested, but their practical usefulness has been limited by their complexity, which usually far exceeds that of the SOFM algorithm itself.

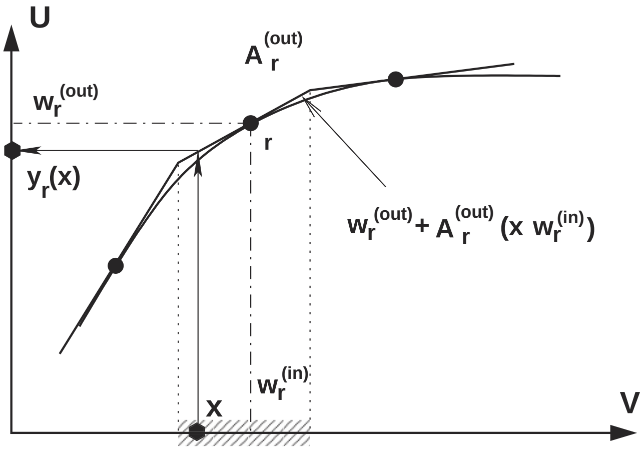

**Figure 4.** Extended feature map for learning nonlinear input-output mappings. The input-output mapping $V \rightarrow U$ is defined by a collection of locally valid linear mappings, one for the vicinity (shaded subregion in $V$) of the (input) weight vector $\mathbf{w}_s^{(in)}$ of each neuron. Defining these mappings requires an additional weight vector $\mathbf{w}_s^{(out)}$ and a matrix $\mathbf{A}_s$ (not shown) per neuron. These additional parameters are adapted with a perceptron error correction rule.

*Relationship between stimulus density and weight vector density.* During the second, fine-tuning phase of the map formation process the density of the weight vectors becomes matched to the signal distribution. Regions with high stimulus density in $V$ lead to the specialization of more neurons than regions with lower stimulus density. As a consequence, such regions appear magnified on the map; that is, the map exhibits a locally varying *magnification factor*. In the limit of no neighborhood, the asymptotic density of the weight vectors is proportional to a power $P(\mathbf{x})^{\alpha}$ of the signal density $P(\mathbf{x})$ with exponent $\alpha = d/(d + 2)$. For a nonvanishing neighborhood, the power law remains valid in the 1D case, but the original SOFM algorithm leads to a different exponent $\alpha$ that now depends on the neighborhood function (Ritter, 1991). For higher dimensions, the relation between signal and weight vector distribution is more complicated, but the monotonic relationship between local magnification factor and stimulus density seems to hold in all cases investigated so far. Here, too, the modified winner criterion (Equation 5) leads to a simplification and yields a density exponent $\alpha = d/(d + 2)$, independent of the neighborhood function.

*The effect of a "dimension conflict."* In many cases of interest, the stimulus manifold in the space $V$ is of higher dimensionality than the map manifold $A$, and as a consequence, the feature map will display those features that have the largest variance in the stimulus manifold. These features have also been termed *primary*. However, under suitable conditions, further, *secondary* features may become expressed in the map. The representation of these features is in the form of repeated patches, each representing a full "miniature map" of the secondary feature set. The spatial organization of these patches is correlated with the variation of the primary features over the map: the gradient of the primary features has larger values at the boundaries separating adjacent patches, while it tends to be small within each patch. The conditions for the occurrence of secondary features have been analyzed for simplified situations (Ritter et al., 1992; Obermayer, Blasdel and Schulten, 1992). These results show that the stability of a 2D map with only two primary features requires that the ratio of the variance of the primary features across the range of the neighborhood function and of the variance of the signal manifold perpendicular to the directions of the primary features be below a certain threshold. If the signal distribution is such that no such map configuration exists, additional features will become expressed in the map, with the role of the secondary features assigned to the features with the lower variance.

*Modeling the properties of observed brain maps.* Many regions in the brain are known to be topographic representations of sensory surfaces. It has been shown that the qualitative structure, including, e.g., the spatially varying magnification factor, and certain experimentally induced reorganization phenomena can be reproduced with the Kohonen feature map algorithm (Ritter et al., 1992). A more stringent test is provided by the more complex maps that are found in the visual cortex. In V1, there is a hierarchical representation of the features: retinal position, orientation, and ocular dominance, with retinal position acting as the primary feature. The secondary features, orientation and ocular dominance, form two correlated spatial structures: (1) a system of alternating bands of binocular preference and (2) a system of regions of orientation-selective neurons arranged in parallel iso-orientation stripes such that orientation angle changes monotonically in the perpendicular direction. The iso-orientation stripes are correlated with the binocular bands such that both band systems tend to intersect perpendicularly. In addition, the orientation map exhibits several types of singularities that tend to cluster along the monocular regions between adjacent stripes of opposite binocularity. It turns out that all these features, including even many quantitative aspects, can be remarkably well reproduced by the Kohonen feature map algorithm (Erwin, Obermayer, and Schulten, 1995). One may conclude that despite its computational simplicity, the Kohonen feature map algorithm can successfully model a striking range of features of observed brain maps.

*Variants of the basic SOFM algorithm.* The basic SOFM algorithm is an on-line learning method that admits the formulation of an analogous batch variant (batch SOFM; Kohonen, 1995) in which adaptation steps occur only after entire epochs, during which all (or a larger number of) patterns have been presented. When $T_s$ denotes the subset of patterns for which neuron $s$ was selected as winner in the current epoch, the batch SOFM adaptation step at the end of the epoch is given by

$$\mathbf{w}_r^{(new)} = \frac{\sum_{\mathbf{x} \in T_s} h_{rs} \cdot \mathbf{x}}{\sum_{\mathbf{x} \in T_s} h_{rs}} \tag{6}$$

The advantages of the batch algorithm are the absence of any learning rate and its enlarged possibilities for various optimizations to allow the training also of very large maps and for very large data sets (for details, see Kohonen, 1995).

One major possibility for reducing the number of nodes, as required, e.g., for higher dimensional maps, is the use of *linear interpolation*. In particular, the extension of the basic feature map to produce a vectorial output value from a *locally valid linear map*

$$\mathbf{y}_r(\mathbf{x}) = \mathbf{w}_r^{(out)} + \mathbf{A}_r(\mathbf{x} - \mathbf{w}_r^{(in)}) \tag{7}$$

(Ritter et al., 1992) has proved useful in many contexts. Here, the additional quantitities are *output weights* $\mathbf{w}_r^{(out)}$ and matrices $\mathbf{A}_r$. Selection of a winner neuron $s$ and adaptation of the input weights $\mathbf{w}_r^{(in)}$ proceed as in the original SOFM algorithm, while the output weights $\mathbf{w}_r^{(out)}$ and $\mathbf{A}$ can be trained with a perceptron rule.

A Bayesian generalization of the SOFM has been proposed and analyzed by Luttrell (1994). Here, both the winner selection $\mathbf{x} \rightarrow$

$s(\mathbf{x})$ and the decoding $s \to \mathbf{w}_s$ are replaced by probabilistic mappings, leading to generalized SOFM versions that can be connected with channel coding theory. The resulting formalism has been used to formulate a SOFM variant for the mapping of *distance data* (Graepel and Obermayer, 1999), for which no explicit pattern vectors but only pairwise distances are given as training information. Another idea from statistics, the use of a generative model as a departure point for the generation of topographic maps, has led to the GTM method (Bishop, Svensén, and Williams, 1997). Here the map is derived from a probability density that is concentrated along a low-dimensional, parametrized manifold whose parameters are estimated by the maximum likelihood approach.

A good collection of articles on major recent developments on the SOFM is contained in Oja and Kaski (1999).

*Applications of the feature map algorithm.* Artificial feature maps have proved useful in many pattern recognition applications. The classic example is the *Neural Typewriter* of Kohonen, where a feature map is used to create a map of phoneme space for subsequent speech recognition. Subsequent work has demonstrated the possibility of creating feature maps of language data that are ordered according to higher-level, semantic categories (Ritter and Kohonen, 1989) and of deriving very large-scale maps to support navigation in very large databases, such as the Internet. Other applications of the feature map include process control, image compression, time series prediction, optimization, generation of noise-resistant codes, synthesis of digital systems, and robot learning. Kohonen's *Self-Organizing Maps* (1995) contains a good survey of SOFM applications, with additional comments on SOFM uses in an Internet database.

# Semantic Networks

*John A. Barnden, Mark G. Lee, and Manuela Viezzer*

## Introduction

Semantic networks (SNs) are a way of representing information abstractly by means of a graphical notation that makes use of interconnected nodes and arcs. They are commonly used in symbolic cognitive science. There are interesting similarities and differences between SNs and neural networks (NNs). Some attempts have been made to implement or emulate SNs in NNs and to form hybrid SN-NN systems.

SNs were originally developed for couching "semantic" information, either in the psychologist's sense of static information about concepts or in the semanticist's sense of the meanings of natural language sentences. However, they are also used as a general knowledge representation tool. The more elaborate types of SNs are similar in their representational abilities to sophisticated forms of symbolic logic. (For more information on SNs, see Sowa, 1984; Rich and Knight, 1991, chaps 4, 9–11; Lehmann, 1992.)

## The Nature of Semantic Networks

As with NNs, there are many different styles of SNs. However, all SNs share the following general features:

- The nodes are to be interpreted (by us) as standing for physical or nonphysical entities in the world, classes or kinds of entities, relationships, or concepts.
- The links, which are almost always directed, encode specific relationships between entities, concepts, etc., where the type of the relationship is specified by a symbolic label on the link.

We roughly characterize SNs as being either *restricted* or *general*, although there are cases in between. The restricted class is typified by the small fragment shown in Figure 1. Nodes represent kinds, activities, or individuals (all named in the diagram by lowercase labels). IS-A links and INST links are the characteristic links of restricted SNs. Other links, like MAIN-LOCOMOTION in the fragment, are usually called roles and used to represent properties of the kinds. IS-A is the subkind relationship, whereas INST is the instance (i.e., individual-to-kind) relationship. IS-A links are often labeled as A-KIND-OF or AKO links. The individuals in the fragment are Canny and Osten, whereas the kinds are canary, ostrich, bird, and animal.

The central purpose of a restricted network is to organize concepts, kinds, or classes into a taxonomy, which may or may not be

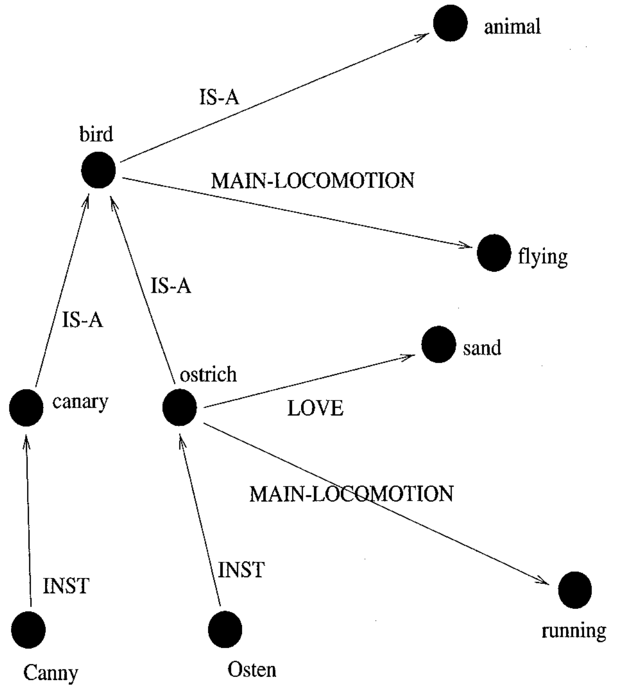

**Figure 1.** Fragment of a semantic network, restricted class (see text).

strictly hierarchical, and to state properties of the included entities. A general principle is the following:

- Information general to a class, kind, or concept should be held at the node representing it, and not repeated at nodes for subclasses, subkinds, or subconcepts (or particular instances of them); instead, these subentities implicitly *inherit* the information at the former node (inheritance principle).

An allied fundamental principle is the following:

- Information attached to a node can contradict information attached to an ancestor node; in that case the former information overrides the latter (default-overriding principle).

Here, an ancestor node of a node N is a node that can be reached from N by a succession of IS-A links, or by an INST link and then possibly some IS-A links. Thus, the fragment in Figure 1 says that birds (in general) have flying as their main method of locomotion, but that for ostriches (in general), the main method of locomotion is running. On the other hand, canaries in general, and Canny in particular, implicitly inherit the flying because no node between those nodes and the bird node has a MAIN-LOCOMOTION link contradicting the flying. Osten inherits the running of ostriches in general, and their love of sand.

The general type of SN is typified by the fragment shown in Figure 2. The *q* node represents the proposition that every pig loves rain. Alternatively, it represents the situation of every pig loving rain. The fragment shown is a direct analogue of the logic formula

$(\forall x)$ is-pig $(x) \Rightarrow$ loves $(x,$ rain$)$

Although general SNs often contain taxonomic information, this information is less important to the overall purpose of the network. Rather, the focus is on representing entire sentences, propositions, or situations using a network format instead of an algebraic one. The idea goes back to Frege's *Begriffsschrift* and Peirce's relational graphs, and has been exploited to express the semantics of natural language, as, for example, in discourse representation theory (Kamp and Reyle, 1993).

In contrast to restricted networks, general networks usually have only a small selection of link labels, typified by those in Figure 2. Often, labels have a close connection to deep case relationships in natural language semantic theories (see the AGENT and OBJECT links in Figure 2). Relationships such as loving are now represented by nodes (see the *loves* node in Figure 2) rather than by link labels (see the LOVE link in Figure 1). Also, the more elaborate general SNs have facilities analogous to the connectives and quantifiers of formal logic (see the *implication* and *forall* nodes in Figure 2). The QUANT link to the *forall* node says that the *q* node represents a universally quantified proposition. The VAR link points to the *x* node, playing the role of the variable *x* in the formula above. The BODY link points to the body of the proposition, which has the form of an implication proposition (*i* node). ANTE stands for antecedent, and CONSE represents consequent. PRED links point from nodes representing simple propositions to the nodes for the predicates in the propositions. ARG stands for argument.

One of the problems to be handled when SNs are used to represent propositions is to express correctly the scope of logical operators. This can be achieved by including explicit nodes to represent propositions, like node *q* in Figure 2, thus turning the SN into what is often called a *propositional semantic network*. The first propositional semantic network to be implemented was the MIND system, by Stuart Shapiro, which then evolved into the SNePS system (see Shapiro and Rapaport, 1992).

Thus, formal logic expressions can be recast as SNs. However, the two forms of representation are not equivalent, partly because SNs implicitly involve implementational assumptions that facilitate some particularly important operations (see below), whereas formal

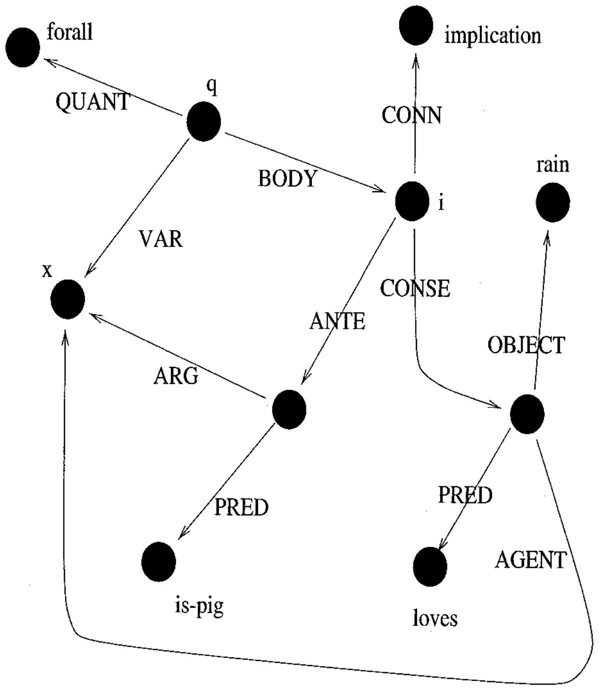

**Figure 2.** Fragment of a semantic network, general class (see text).

logic is devoid of implementational assumptions. Also, to parallel the inheritance-blocking features of SNs in logic, one has to turn to special, advanced forms of logic (for an introduction, see Rich and Knight, 1991, chap. 7; see also Brachman et al., 1991). Moreover, several SN approaches have made radical claims as to what should and what should not be represented. For example, the SNePS family of SNs argues for a totally intensional representation of knowledge (Shapiro and Rapaport, 1992).

Among current logical systems, description logics capture the features of restricted SNs and are used to reason about taxonomic information. Some versions of description logic support nonmonotonic reasoning and belief revision to cope with the conflicting information that may result from applications of the overriding defaults principle (see Brachman et al., 1991).

## Processing in Semantic Networks

Sometimes SNs are used as static data structures that change only when external programs manipulate them. However, it is possible to embed some processing mechanisms in the networks themselves, thus giving SNs a self-modifying ability similar to that of NNs.

One common and basic type of processing in SNs is *spreading activation*. During the course of spreading activation, if one node is active at some moment, then the nodes directly connected to it can become activated. A given episode of activation spreading might only pass activation across links of specific types. Activation here is often a yes-no matter, as opposed to the graded activation typically used in NNs. However, graded activation can be used in SNs.

A common variant of activation spreading is *marker passing*. Markers are symbolic objects, usually of several different types. The markers that a node send out depend in some possibly complex way on the markers it receives from other nodes. Markers are often simple symbolic objects, bearing no information except their type. However, more complex markers are used in some SNs; for instance, a marker can contain information on its node of origin or the nodes or links it has passed through. Complex markers are used in the system of Charniak (1986), for example. A marker can have a graded energy level that affects its ability to cause a receiving node to produce a marker in response (see the system of Hendler in Barnden and Pollack, 1991).

The main motivation for activation spread or marker passing is to allow *intersection search*. For instance, consider an SN system used in understanding natural language text. Marker passing might start with nodes representing the word senses of various words in the text. The collisions of markers at nodes means that paths have been found between word senses. This information can be used to help disambiguate the words (see Yu and Simmons, 1990). Marker passing can also be used to manage simple inheritance reasoning. For instance, in Figure 1, Osten's main locomotion method could be found by sending out a marker from the Osten node and constraining it to travel only along a chain of IS-A links, possibly preceded by a single INST link, and followed by one MAIN-LOCOMOTION link. If the system prefers answers found first to answers found later, the *running* answer is preferred over the *flying* answer, thereby effecting the desired handling of exceptions (blocking of inheritance).

Marker passing is important, but is generally used only for restricted purposes. In general networks that handle more elaborate reasoning, the brunt of the inferencing is typically done by subnetwork matching and construction processes (see Cravo and Martins, 1993, for an advanced implemented system).

In any SN with INST and IS-A links, inheritance reasoning is simpler and quicker than it would otherwise be. In SNs without the special links, or in ordinary logical frameworks, traversal of taxonomic relationships is a more elaborate process. These observations rely on certain strong implementational assumptions that are generally made about SNs, though usually only tacitly. The assumptions apply both to computer implementations of SNs and to hypothesized realizations of SNs in the brain. One of the assumptions is that, if a processing mechanism is attending to a given node N, then it can efficiently transfer attention to nodes connected by single links to N.

Inheritance reasoning can also be given a probabilistic interpretation where every arc between nodes in the SN is given a probability from 1.0 to 0.0 of being traversed. Such networks are termed Bayesian. Bayesian networks are used in reasoning with uncertainty. The probabilities associated with individual arcs can be automatically learned from data. Pearl (2000) gives an extensive overview of such networks.

Finally, SNs can have *attached procedures or rules*. These are algorithms, expressed in some symbolic format, that are attached to nodes or links, and they typically have localized effects supporting particular inference functions. (For a brief introduction to this topic, see Rich and Knight, 1991, chap. 4 and section 10.3.2.)

Marker passing and attached procedures can also be combined, as in Petri nets, where there are passive nodes, called places, active nodes, called transitions, and sets of rules for marking places with tokens and for executing, or firing, transitions.

## Contrasts to Neural Networks

In NNs, in contrast to the case of general SNs, activation spread is almost always the only mechanism for short-term computation (as opposed to long-term computation, such as slow adaptation). Moreover, the types of activation spread and marker passing in SNs are typically more complex than activation spread in NNs, especially when complex markers are used. In strong contrast to almost all NNs, the topology of an SN, especially a general SN, can be changed by processing mechanisms in arbitrarily extensive and complex ways in the short term.

NN links do not have type labels. As a result, NNs do not treat different input links differently for the most part. Instead, a weighted sum of the input values is formed, submerging the identities of different links. The most salient exception to this is the differentiation of input links into excitatory and inhibitory links, but this distinction is crude compared with the link differentiation by labels in SNs. Nevertheless, NN links that impinge on other links and modulate them (see NEUROMODULATION IN INVERTEBRATE NERVOUS SYSTEMS) can be used to obtain many of the effects of link typing in SNs.

When an NN link is directed, activation can spread in only one direction across the link. It is less common to impose this constraint in SNs. It is therefore easier in SNs to express asymmetric relationships between nodes without consequently constraining the accessibility of the nodes from each other. As an example of the problem raised for NNs, consider the use of symmetric links in some artificial NNs, notably Hopfield nets (see STATISTICAL MECHANICS OF NEURAL NETWORKS). These allow activation spread in both directions, but do not directly support conceptually asymmetric relationships. More indirect methods are needed to handle such relationships (see Barnden and Srinivas, 1991).

As a result of all these differences, SNs cope much more readily with many of the representational and processing needs that arise in high-level cognitive activities such as commonsense reasoning and natural language understanding. The needs in question are listed in ARTIFICIAL INTELLIGENCE AND NEURAL NETWORKS (q.v.). NNs have difficulty in rapidly creating new, complex bodies of information, and in structurally matching complex, and possibly highly temporary, bodies of information. Certainly, any direct parallel of subnetwork matching and subnetwork creation in SNs is difficult to achieve in typical NNs (but see DYNAMIC LINK ARCHITECTURE). However, some NN systems have been developed that can directly implement SNs (see the next section). They depart from mainstream NNs in that they have more elaborate and specialized structure.

On the other hand, NNs appear to have advantages with respect to other needs posed by high-level cognition (see ARTIFICIAL INTELLIGENCE AND NEURAL NETWORKS). These other needs include context sensitivity, graceful degradation, and automatic adaptation. A contrastive factor here is that link weights are fundamental in NNs but relatively uncommon in SNs. This difference confers a graded associativity quality on NNs that has no direct parallel in most SNs, although the length of a path between two SN nodes has often been assumed to encode the strength of association between them: the shorter the path, the stronger the association.

## Bringing Semantic and Neural Networks Together

Several researchers have overtly used NNs to implement or approximately emulate SNs. Other work has aimed at mixed systems that combine NNs with SNs or are compromises between the two. Major examples of the implementation/emulation type of work can be found in Hinton (1989) and in the chapters by Barnden, by Bookman and Alterman, and by Diederich, Dyer, and Shastri in Barnden and Pollack (1991). Touretzky (1990) describes a framework that is not aimed specifically at semantic networks but that could readily implement them. Because of the complexity of the systems that implement or emulate SNs, we omit description of them here.

For examples of combined SN-NN systems, see the chapters by Hendler and Lehnert in Barnden and Pollack (1991). In the Hendler case, nodes in the SN can also serve as input-output nodes in an NN. Markers passed to such SN nodes cause them to inject neural activation into the NN, and vice versa. The symbolic markers have a numeric strength, and this affects the level of neural activation instigated by a marker. The NN acts as an intermediary between SN nodes, allowing an SN node representing one concept to stimulate an SN node encoding a similar concept. The NN is trained by backpropagation to associate concepts with sets of low-level features. Concepts are thereby viewed as similar according to the extent to which they share features. Hendler's system makes symbolic reasoning less rigid by enriching it with similarity-based reasoning.

For compromises between SNs and NNs, see the chapters by Eskridge and Kokinov in Holyoak and Barnden (1994). Unlike Hendler's system, these systems are not divided into separate neural and semantic parts. In Eskridge's system, nodes communicate by means of numerical activation signals, much as in NNs, but symbolic markers travel along with the numerical activation, the links have labels, activation can be constrained to spread only over links with specified labels, links can be dynamically created, and specialized SN processing rules can be invoked. The system performs complex analogical processing, with the symbolic aspects coping with complex structure manipulation and the neural aspects helping with retrieval of source analogues and with weighing of alternatives.

## Discussion

NNs and SNs have much in common and should be regarded as two points in a rich, quasi-continuous space of computational architectures rather than as radically different types of network. There are important differences in the nature and usage of links and in the degree to which computation can be thought of as local to individual nodes (although in restricted SNs the computation can be as local as it is in NNs). There are various ways of implementing or emulating SNs in NNs, and of forming hybrid SN-NN systems.

# Sensor Fusion

*Allen M. Waxman*

## Introduction

Sensor fusion is not the sole purview of the modern brain but rather an old and common strategy in nature, and of great relevance to a variety of applications. It is a means by which multiple sensing modalities and interacting modality-specific processing streams can cue one another, enhance or depress cross-modality responses to stimuli, generate cross-modality expectations, and provide complementary evidence supporting or negating a decision (e.g., the detection of prey, or the recognition of an object). Studies of sensory interactions in flatworms, crustaceans, insects, and fishes (see references in Stein and Meredith, 1993), snakes (Newman and Hartline, 1982), cats and monkeys (Stein and Meredith, 1993; Stein, Wallace, and Stanford, 1999), and humans (Stein and Meredith, 1993; Giard and Peronnet, 1999; Shimojo and Shams, 2001) point to multiple levels of sensory integration in brain. From multimodal sensory receptors to midbrain organs (i.e., tectum or superior colliculus) to corticotectal feedback pathways and temporal-prefrontal lobe activation, it is clear that sensor fusion impacts an animal's ability to detect and track objects (i.e., its attentive and orienting behaviors) as well as its decision-making abilities (i.e., to recognize an object from its multimodal signature). Thus, the many sensory pathways that have developed in living systems to process chemical, mechanical, thermal, visual, and auditory stimuli have generally formed two classes of pathways that also project to one another, one that is modality specific and one that is integrated across sensory modalities.

Sensor fusion is of direct relevance to the military defense (Hall and Llinas, 1997), intelligence, remote sensing (Pohl and van Genderen, 1998), medical, robotics, and manufacturing communities. Multiple specialized sensors have been developed to provide the data necessary for decision making in each of these application areas. Yet it is often acknowledged that today's information shortcomings can be overcome, not necessarily with still more and better sensors, but rather with tomorrow's sensor fusion systems. Witness the multitude of methods, systems, and applications for sensor fusion that are reported annually at conferences such as the MSS (formerly IRIS) National Symposium on Sensor and Data Fusion 1988–2002, the International Conference on Information Fusion 1998–2002, and the SPIE conference on Sensor Fusion: Architectures, Algorithms, and Applications 1997–2002. However, approaches motivated by or derived from biological sensor fusion strategies have been embraced by relatively few (Toet, van Ruyven, and Valeton, 1989; Anastasio, Patton, and Belkacem-Boussaid, 2000; Fay et al., 2000; Fisher et al., 2001; Waxman et al., 1995, 1997, 2001).

## Biological Insights

There is an extensive and growing literature on sensor fusion in biological systems. Methods of observation in the living animal include electrophysiological recording from single cells, event-related potential (ERP) monitoring from arrays of scalp electrodes, functional magnetic resonance imaging (fMRI) and position emission tomography (PET) of the living brain, and direct psychophysical experiments on humans. Some of the most significant studies lead to the following insights.

### *Snakes*

Newman and Hartline (1982) have studied the integration of visual and thermal infrared signals in the optic tectum of the rattlesnake and python. Both visual signals from the retina and infrared signals from the pit organs project onto the tectum in orderly maps of sensory space (i.e., retinotopically) that are in register with one another. Newman and Hartline identified six classes of bimodal neurons that display highly nonlinear multimodal interactions, including AND cells, OR cells, response-enhanced cells (e.g., cells in which the response to a visual stimulus is enhanced in the presence of an infrared stimulus), and response-depressed cells (e.g., cells in which the response to an infrared stimulus is depressed in the presence of a visual stimulus). These single-cell responses indicate that both cooperative and competitive nonlinear processes are at play, all in the service of orienting the snake toward its potential prey. They are, in fact, reminiscent of opponent-color multispectral interactions observed in primate retinal ganglion cells (Waxman et al., 1997).

### *Cats and Monkeys*

In mammals, the tectum has evolved into the superior colliculus (SC). A midbrain organ involved in attentive and orienting behavior, it aims to *keep your eye on the ball.* The definitive works of Stein and Meredith (1993) and Stein et al. (1999) make clear that the seven-layered SC receives direct sensory input to its deep layers from visual, auditory, and somatosensory neurons, as well as significant feedback from single-modality cortical areas, and that it projects up to higher centers via thalamus and down to brainstem and spinal cord motor pathways in order to control the pointing of sensory organs (see Stein and Meredith, 1993, for anatomical drawings of the SC). These sensory and cortical inputs all form topographically registered maps in the deep layers, in a coordinate system tied to the moving retina (requiring the existence of learned transformations between retinal, head, and body coordinates). Moreover, one also finds motor maps (of vector displacement) in registration as well, providing all sensory modalities common access to the machinery that turns the eyes, ears, and head in order to find and track that target object. More than 50% of deep-layer neurons are multisensory (bimodal and trimodal), exhibiting both cross-modal response enhancement and response depression. These neurons have receptive fields, often with center-surround spatial profiles and noncoincident but overlapping temporal profiles. These cells are well designed (in fact, they develop postnatally, from experience) to detect complementary evidence supporting or negating the detection and localization of targets from their multimodal signatures.

An interesting and significant phenomenon observed among multisensory neurons in SC is that of *inverse effectiveness* in cross-modal response enhancement. Multisensory neurons that respond weakly to unimodal stimuli can be greatly enhanced in their response to multimodal stimuli, in contrast to the modest enhancement observed among multisensory neurons that respond strongly to unimodal stimuli. This effect has been shown to be consistent with the interpretation that multisensory neurons in SC compute the conditional probability (in the sense of Bayesian estimation theory) that a target is present, given the unimodal or multimodal stimulus (Anastasio et al., 2000). However, it is clear from electrophysiological studies that response enhancement in multisensory neurons is due to cortical feedback to the SC that develops after birth (Stein et al., 1999).

### *Humans*

It thus seems likely that the human SC is responsible for our being fooled by both the ventriloquist and the television set. Interactions between visual and auditory activations on registered maps in SC convince us that the sound is actually coming from the mouths of those dummies! Even our perception of human articulated sounds is strongly influenced by the visual shape of moving lips (i.e., the McGurk effect). And what we think we see is easily altered by the sounds we hear, even for very simple stimuli such as flashes and beeps. Shimojo and Shams (2001) review this and many other cross-modality target detection and tracking experiments in which cortical activation is monitored via fMRI and ERP measurements. They note the significance of transient/discontinuous stimuli, regardless of modality, and the apparent ability of these stimuli to influence multimodal perceptions.

Beyond orienting behaviors devised to detect, localize, and track objects, when it comes to the task of object recognition from multimodal signatures, we humans also employ a good deal of cortex while preserving old successful strategies. Observations of ERPs (Giard and Peronnet, 1999) reveal signs of cross-modality response enhancement and response depression as well as new neural activity (not seen with single-modality stimuli derived from the object) in the right frontotemporal area, generally considered an associative area of brain.

## Technological Implementations

A great deal of work has been done on the military problem of tracking multiple targets from multiple sensors using Bayesian statistical inference methods, and cast in the context of higher levels of information fusion (Hall and Llinas, 1997). The information-theoretic concept of mutual information, in conjunction with perceptron neural networks, has recently been applied to audiovisual fusion and speaker localization (Fisher et al., 2001).

With application to remote sensing and environmental monitoring, it is commonplace to utilize imagery derived from multiple airborne and space-based sensors (Pohl and van Genderen, 1998). However, most image fusion methods employed are based on global statistical methods (e.g., Principal Component Analysis, q.v.) and false color overlay of separate modalities. These approaches do not derive or benefit from biological approaches to sensor fusion. Early methods for fusion of two complementary imaging modalities, in particular visible (reflected) and thermal (emitted) infrared imagery, also did not utilize biological fusion strategies, but did build on known multiresolution representations in visual processing (Toet et al., 1989). A successful approach to visible-infrared image fusion based on single-opponent color processing in the retina was developed by Waxman et al. (1997) and enabled a color night vision technology. This approach was extended to accommodate three and four imaging modalities by means of double-opponent color processing (as in primary visual cortex), and a target learning and recognition capability based on the fused sensor signature was incorporated (Fay et al., 2000). Biological architectures for visual 3D object learning and recognition, which fuse evidence over multiple views in an *aspect network* and apply to multiple imaging modalities, are summarized in Waxman et al. (1995).

### Real-Time Night Vision Enhancement

Figure 1 illustrates an opponent-color architecture for fusing multiple images in real time. It requires that the imagery be collected in an optically registered manner, or separately registered to a common reference frame. Shown here are three modalities of wide dynamic range imagery, low-light visible (VIS), short-wave infrared (SWIR), and thermally emitted long-wave infrared (LWIR), that provide different views into the night. These distinct modalities are fused into a single natural color image (shown here in gray scale, but see Fay et al., 2000, for several color renderings). Multiple center-surround shunting neural networks are used to create enhanced *on-* and *off-center* (e.g., hot and cold LWIR) responses, as well as *single-* and *double-opponent* cross-modality contrasts that serve to decorrelate the input imagery. The outputs of the network are mapped to the human opponent-color YIQ representation and converted to RGB color for display. Similar networks comprised of a variety of such opponent-color fields have been used to fuse two, three, and four imaging modalities, and have been further combined with 3D imagery obtained from a ladar in real-time. Using fuzzy ARTMAP neural networks (Carpenter et al., 1992) in conjunction with a target designation interface, we incorporated field-adaptive target learning and recognition based on fused image data.

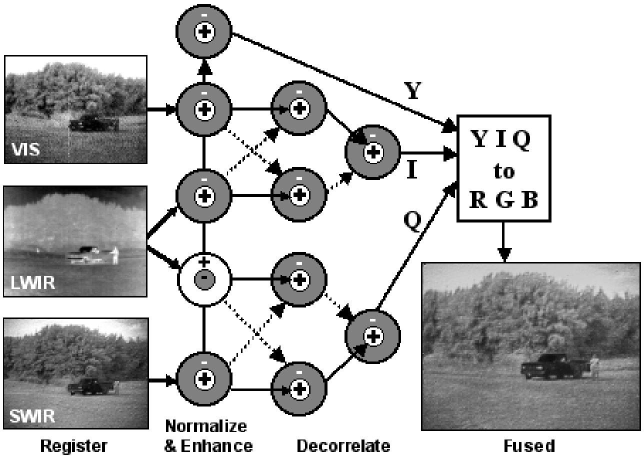

**Figure 1.** Color night vision through the real-time fusion of multiple imaging sensors (visible, short-wave, and long-wave infrared). Contrast enhancing *on-* and *off-channel* and *opponent-color* receptive fields are built from center-surround shunting neural networks. (See Fay et al., 2000, for color rendering of the fused output image.)

### Multisensor Fusion and Exploitation

Imagery and signals collected by multiple platforms over a common geospatial area can be brought into registration by means of a 3D site model (i.e., terrain data and building models), as indicated in Figure 2 (Waxman et al., 2001). Forming a layered database of multiple registered modalities, opponent-sensor image fusion (see Figure 1) and spatial feature extraction (oriented edges, extended boundary contours, texture measures, and 3D slopes and curvatures) support interactive 3D visualization and also augment the database. The layered data are well organized for interactive pattern learning and search, for each pixel now corresponds to a complete feature vector. With the aid of a graphical user interface, an analyst selects example and counterexample (context) pixels of the object of interest, and, treating these as training data, a *search agent* is created using fuzzy ARTMAP neural networks. Additionally, the agent sorts the many elements of the feature vector and identifies those features that are salient to the target in context. The agent then conducts a first-pass search for the object of interest (e.g., roads, buildings, vehicles) in the fused imagery. Subsequent searches will use these detections as context in guided search. A separate search agent is trained for each object of interest in the fused data set. These same methods for image fusion and mining have been successfully applied to spectral MRI and MRI/SPECT in medical imaging.

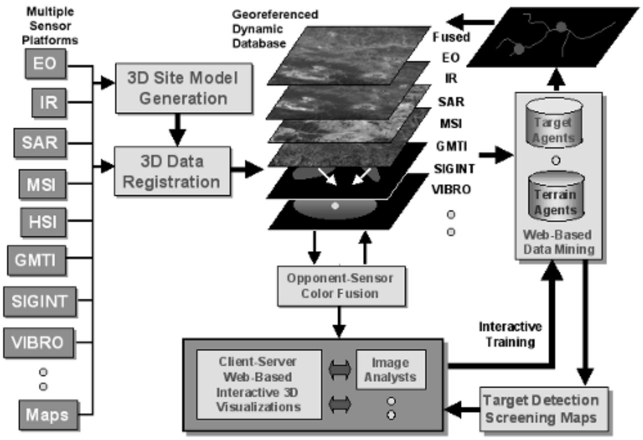

**Figure 2.** Architecture for fusion and exploitation (i.e., data mining) of multisensor data in a geospatial context. (A prototype fusion system is described in Waxman et al., 2001.)

## Discussion

Biological systems, from simple to complex, all demonstrate the capacity for fusing multiple sensing modalities. In humans, auditory-visual fused localization underlies the daily experience of watching television, in which speech seems to emanate from the visual image of the actor on the screen and not from the speakers beside the TV. Lessons learned from the rattlesnake visible-infrared fusion pathway and its similarity to opponent-color processing in the mammalian retina have led to real-time architectures for color-fused night vision. The existence of registered multimodal maps and bimodal neurons in mammalian SC, as well as the cortical feedback pathways to the SC, has led to an architecture and prototype system for fusion and exploitation of multisensor surveillance data in a geospatial context. Observed interactions in human frontotemporal cortices reflect associative processes underlying multisensor object recognition.

Statistical, information-theoretic, and neural network methods of sensor fusion provide complementary tools for turning data into decisions in the context of knowledge. It remains to be seen if neural methods can rise to the challenge of higher levels of sensor and information fusion, for which knowledge-based systems are required. However, in our experience the unique insights obtained from biological system design yield distinct advantages in the development of adaptive sensor fusion systems for real-world problems.

# Sensorimotor Interactions and Central Pattern Generators

*Avis H. Cohen and David L. Boothe*

## Introduction

Movement through the world requires that the environment be integrated and understood. An organism must navigate obstacles, seek sustenance, and avoid predators. Movement requires further that the organism integrate the visual, auditory, and other environmental information within its machinery for locomotion. Each of us in our daily interactions with the world is familiar with the seamless way in which our nervous system combines sensory and motor information. Thus, we know in a simplistic sense that sensory and motor systems are integrated. How this integration is performed by a nervous system is currently poorly understood. Much work has been done on motor and sensory systems in isolation. Less work has been done on how these systems interact. In this article we offer an interpretation of currently existing empirical evidence and argue from this evidence for some very basic properties of the biological systems performing sensorimotor integration.

A considerable amount of the experimentation on sensorimotor integration has focused on how sensory information modulates motor system activity. The flow of information commonly explored is from sensory to motor. Two main types of experiment have been performed to elucidate this relationship: reflex-type experiments, and studies of how sensory inputs modulate central pattern generators (CPGs). Peripheral feedback, including that from tactile receptors, muscle afferents, and other proprioceptive feedback, passes up to the somatosensory cortex, but first synapses within the spinal cord, where there are reflex circuits that respond to such inputs. Additionally and perhaps more functionally relevant, sensory input is filtered and processed locally, where the spinal pattern generator circuitry fits its response into the ongoing locomotion as appropriate. Thus, although the brain receives much of the sensory input, the responses to spinal inputs are first the responsibility of the local spinal circuitry. The first section of this article discusses the impact of sensory information on CPGs.

The influence of motor systems on sensory activity is less well characterized. Recent evidence shows that vertebrate motor systems can strongly influence sensory input. In the second section we show that the interplay between sensory feedback and motor output is more complex than is often suggested, and that behavior is strongly affected by movement and movement-related activity.

Studying motor and sensory systems in isolation, one can easily miss the massive interaction between these systems. An understanding of this interaction is crucial for explaining the simplest behaviors of an organism in its environment. What is most surprising about this interaction is not that it exists, but its pervasiveness. Interaction between motor and sensory systems exists from the first steps of sensory detection to the highest levels of processing. In the third section of this article we show that this type of two-way interaction also exists between the cortex and spinal cord.

The older and more usual view is that the spinal cord performs rhythmic and rapid reflexive-type behaviors that require the spinal circuitry and its speed locally, whereas more complex activities are the province of cortex or at least supraspinal centers. In this view, the descending systems send commands to lower-level systems, which respond appropriately. However, this distinction may not be so marked (Jankowska and Lundberg, 1981). Cortical commands now are viewed as integrated with CPG circuitry to produce volitional movements. We present evidence that the integration is considerably richer than the old view or even than the new view would suggest.

There is no doubt that cortical systems contribute to sensorimotor integration. What is in doubt is that motor cortex sends commands to a passively responsive spinal cord. Motor commands are acted on only as spinal circuits independently and thoroughly process all incoming information. In the view that we present, spinal cord and cortex are highly integrated. Movements result from an ongoing interactive process. The actual form that movements take is largely a product of spinal circuitry and its synergies, while the cortex is expected to perform other, more complex tasks that integrate somatosensory and motor systems with other inputs to which the cortex has unique access, such as vision, audition, and olfaction.

In such a limited review, it is inevitable that the material be selective. This review is not intended to be complete but rather to suggest the different types of evidence available.

## Sensory to Motor Flow of Information

The most common view of sensory feedback is that it provides information regarding the position of the organism as it moves through space. Appropriate to this role, the feedback can correct a CPG on a cycle-by-cycle basis to maintain the organism in proper relationship to its environment (Rossignol, Lund, and Drew, 1988). For example, the hip joint angle of the cat can trigger a new step cycle as the body is propelled over its respective limb on the ground. Whelan and Pearson (1997) have also found that stretch of muscle spindles can trigger a new step cycle through contractions of appropriate muscles. In these ways, the cycle periods are able to accommodate changes in the velocity of the animal. Similarly, the bending of the tailfin in dogfish or lamprey entrains the swimming so that swim cycles are appropriate lengths for the environmental conditions. Thus, if the body is not able to adequately bend against a strong current, this will be compensated for by a longer cycle. This type of sensory regulation is accomplished at the level of the spinal cord and requires no descending input, although descending input will influence and weaken the responses if present (Whelan and Pearson, 1997). All CPGs must have some stimulus that can trigger or prolong a new cycle as necessary in order to guarantee that the CPG's movements are adaptive.

Another well-documented role for sensory feedback is to elicit reflexive responses to environmental perturbations. This is also accomplished at the spinal level, where sensory inputs are gated through the CPG during ongoing activity (Rossignol et al., 1988). A sensory stimulus can elicit phase-dependent responses that are quite unlike the reflex responses that such stimuli would induce in the absence of CPG activity. For example, an obstacle encountered by the paw dorsum will produce an enhanced flexion during the flexion phase of the step cycle, but it will produce an enhanced extension during the extension phase. This guarantees that the limb is properly supported at the moment it is raised to avoid the obstacle. The contralateral limb is also integrated with such responses. That is, the limb opposite the stimulus must be positioned to support the responsive limb before it will flex over such an obstacle (Hiebert et al., 1994). Such phase-dependent responses to perturbations are very common across CPGs. For each rhythmic movement there are classes of stimuli that elicit such responses (Rossignol et al., 1988). In the case of locomotion, the response requires no input from descending systems and is seen in spinal animals as well as intact animals.

## Motor to Sensory Flow of Information

More recently, new evidence has accumulated to indicate that the relationship between the CPG and its sensory feedback is not unidirectional. Dubuc and his colleagues (Nussbaum et al., 1996) first found that there is a feedforward signal coming from the CPG that can be recorded as a dorsal root potential. This is a phasic presynaptic modulation of the sensory terminals in the spinal cord. The modulation is sufficient in some cases to trigger action potentials in the sensory fibers even during fictive locomotion, that is, locomotor pattern generator activity in the absence of movement (reviewed in Nussbaum et al., 1996). Thus, the signals cannot be coming from any source other than the CPG. A similar phenomenon has been found in cockroach flight, in locust walking, and in lamprey swimming. This phenomenon thus seems to be quite general, occurring across a wide range of animals from invertebrates and vertebrates and from cats to lampreys (reviewed in Cohen, 1992).

In the cockroach, the role of phasic modulation seems quite straightforward to interpret. It apparently provides the circal fibers with activity that is phase locked to the flight as a kind of preemptive sensory input during the movement. The situation in cat is more problematic, and the role of presynaptic modulation remains somewhat uncertain. Nussbaum et al. (1996) postulate three possible mechanisms by which the presynaptic modulation, acting as presynaptic inhibition, could influence the activity of primary sensory afferents. First, presynaptic inhibition could reduce the amount of transmitter being released presynaptically. This presynaptic inhibition would reduce the strength of the postsynaptic signal. Second, presynaptic activity could elicit antidromic action potentials in the primary sensory afferent axon. These antidromic action potentials could interfere with orthodromic discharges directly in the axon, or they could desensitize the axon at the first node of Ranvier. This anitidromic stimulation would therefore also reduce the influence of primary sensory afferents on postsynaptic cells. Third, presynaptic inhibition could conceivably cause orthodormic action potentials in other axonal collaterals. These orthodromic action potentials could then cause postsynaptic response elsewhere in the spinal cord. The existence of this third possibility is not well confirmed, nor is the overall functional impact of these effects clear.

Evidence has been accumulating for additional roles that sensory feedback may play. We and others have found that movement and the sensory feedback generated by that movement can change the state of the CPG and significantly alter the pattern of the behavior. In some cases the changes are on a time scale that outlasts a single cycle and have effects that are not predicted by any of the above examples. Two examples will be presented, one invertebrate and one vertebrate.

In the case of locust flight, removal of the hindwing tegulae results in an immediate change in the motor pattern. The wingbeat frequency decreases, and the interval between the activity of depressor and elevator muscles increases. Over a period of 2 weeks, the motor pattern can return to normal even without regeneration of the tegulae (Buschges, Ramirez, and Pearson, 1991). These changes indicate that the intact frequency and phase structure of the movement is normally a function of the CPG as well as the input from the wing sensors.

In the lamprey, slow changes evoked by sensory stimuli can continue over a time period that outlasts the sensory stimulation by varying numbers of cycles (Kiemel and Cohen, 2001). A small-amplitude bending movement of the isolated spinal cord is known to entrain the rhythm of fictive swimming, but more recently it has been found that the bending also leads to a speeding of the bursting that outlasts the bending for one or more cycles. The bending required for this effect can be very low amplitude and can last for as little as one cycle. Consequently, the longer-lasting, slowly decaying excitatory effect of the movement is apt to be seen during intact locomotion. In the latter, the sensory feedback would be a direct consequence of the muscle activation pattern generated by the CPG during its normal activity.

This type of slowly decaying excitation seen in lamprey could be interpreted as an example of positive feedback. That is, the CPG generates movement that in turn causes the CPG to go faster. However, the relationship between the frequency of the bending and the increase in the frequency is weak. If this is indeed positive feedback, then the gain is apparently less than 1, as the effects are limited (Prochazka, Gillard, and Bennett, 1997). The role for this type of excitation is unclear. A modeling study of the slowly decaying excitation (Verschure and Cohen, unpublished) offers some insights into possible roles the excitation might play. The model consists of the six-element neural network model for the lamprey segmental oscillator coupled to a reticulospinal element and receiving tonic drive to initiate bursting. This model was first proposed by Buchanan and Grillner (Grillner, Wallén, and Brodin, 1991). To it was added slowly decaying positive feedback from stretch receptors connected to the motor neuron output. The bursting remained controlled and stable over a wide range of parameter values. Rather than being destabilizing, this type of slowly decaying excitation seemed to offer a new potential control mechanism. Interestingly, the system became autonomous, with no need for tonic drive and with the frequency of bursting highly sensitive to the gain and the duration of the stretch receptor feedback. This type of response may well depend on the balance of excitation and inhibition in a particular network. There was no attempt to test the effect of input with fewer or weaker inhibitory connections. However, it seems apparent that the well-studied lamprey CPG has no shortage of inhibitory neurons (Grillner et al., 1991). While such control mechanisms remain conjectural, the model does suggest that such types of excitation might perhaps be examined in new ways. One fairly definite role that this excitation could play is to change the gain on the system. That is, it seems likely that the excitation could increase the responsiveness of the CPG to other inputs.

In the lamprey (Guan, Kiemel, and Cohen, 2001) the changes induced by the movement have now additionally been implicated in altering the intersegmental coupling of the CPG. In the lamprey, the phase delays among the segments as well as the frequency of the movement are also altered by the movement. This was found in lamprey spinal cords induced to swim with the muscle present. There was no brain or tail, with the spinal cord kept as it is normally during the generation of fictive swimming; the spinal cord was exposed to the bath by removal of the dorsal musculature. The other muscle was left intact, and the preparation was pinned with a single pin at either the rostral or caudal end of the body to provide lateral stability (Figure 1). The burst pattern of the muscle was monitored with electromyography.

The cycle frequencies in such a preparation were consistently faster than the bursting of the respective isolated spinal cord. The phase delays were also consistently shorter. Thus, there is an alteration in the basic parameters of the movement in the presence of the muscle and movement. Using methods developed by Kiemel and Cohen (1998), the characteristics of the intersegmental coupling were measured in spinal cords with the long-range coupling reduced by lesions. Reducing the coupling was necessary since without the reduction, the values for the total coupling are all too near the asymptotic limit to be differentiated. In the presence of movement, the total coupling strength was found to be greatly enhanced in all spinal cords tested in this way. There were also changes in the ratio of ascending to descending short-range coupling. It has been shown in the isolated spinal cord of the lamprey

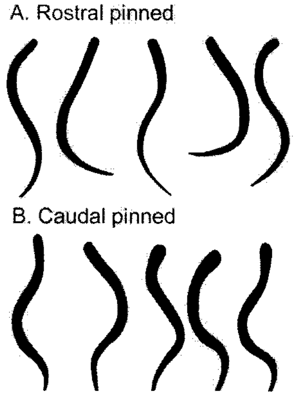

**Figure 1.** Reduced lamprey preparation, with body and muscle largely intact, swimming in response to bath applied D-glutamate (see Guan et al., 2001, for details of the preparation). Shown are the movements during one cycle of swimming when the body was pinned at the rostral end (*A*) and at the caudal end (*B*). Aside from the pinning, there was no difference in treatment between the two episodes of movement.

that after long-range coupling has been almost eliminated through lesions, the ascending short-range coupling is stronger than the descending short-range coupling (Guan et al., 2001). However, in the presence of movement and movement-related feedback, short-range coupling is found to be predominantly descending. Thus, movement and movement-related feedback can alter not only the movement parameters but also the underlying functional properties of the spinal circuitry. The movement could also be strikingly different, depending on which end of the body was allowed to be free (Cohen et al., unpublished) (Figure 1). It is important to note that this complexity is seen in the absence of the brain, and thus depends solely on the spinal cord–body interface.

## Spinal Cord-Cortical Interactions

As discussed elsewhere in this *Handbook* (see Chains of Oscillators in Motor and Sensory Systems), many studies of spinal cord treat it as a series of bidirectionally coupled oscillators. The coupling between the segmental oscillators in lamprey has been found to be very strong and is likely to be strong in other vertebrates as well. As such, the removal of one such oscillator or input to any oscillator, will alter the behavior of the other oscillators, regardless of their location within the informational stream. One can conclude from this that as sensory input travels up the spinal cord, it is shared with local circuits before it reaches the cortex. However, additional evidence is needed to truly make the case that motor and sensory systems are integrated across all levels, and not just across the spinal cord.

Interactions between cortex and spinal cord appear to be highly integrated. Indeed, there is evidence that there are neurons in the primary motor cortex of cats that are phasically active during locomotion of the animal. Thus, the strongest descending cortical outputs are most likely to be influenced by preexisting motor activity. This could mean that as the cortical neurons send motor commands to the limbs, the signals are apt to be properly timed to fit within the context of the ongoing locomotion. This is reasonable, as descending neurons must act in the proper context of the animal's movement or the commands will be inappropriate and maladaptive.

Neurons in the posterior parietal cortex of awake, unrestrained rats have also recently been found to exhibit activity linked to motor activity (McNaughton et al., 1994). Many of these cells responded strongly to specific types of locomotion. However, often these same cells would not respond to locomotor movements such as left turns or right turns. If the cells were responding to somatosensory or environmental information alone, one would expect them to respond in either the left turn or right turn case or to some specific position in space. In some animals a specific motion such as turning was compared with an attendant somatosensory state, such as passive bending of the animal. Less than 20% of the movement-related activity seemed to be explained by possible somatosensory or environmental inputs. Thus, the majority seemed to be predominantly motor in their responses.

Recently, it has been shown that the presence of cortical systems can speed up and enhance the responses over that of spinal animals (Hiebert et al., 1994). In some ways, this observation is counterintuitive, as the spinal cord should be faster alone. There are a number of possible explanations for this phenomenon. One is that cortical neurons can alter the response properties of the spinal neurons, making them more excitable, or perhaps the cortex is more adept at responding to unexpected events. Whatever the explanation, while the spinal cord has the capacity to respond by itself, in intact animals the descending systems participate to make the responses more adaptive. This more rapid response in intact animals to certain types of stimuli is still consistent with integration taking place locally, as spinalized animals do respond to the stimuli, but much more slowly. What the cortex could be providing is some expectation or change in gain such that it picks up that something is novel more quickly than the spinal cord alone.

In conjunction with the discussion in the previous section, the three cases discussed in this section show that sensorimotor interactions across all levels are bidirectional, and that CPG-generated activity has influences on cortical areas thought only to be influenced by or involved in the processing of sensory activity.

## Conclusion

Sensory and motor systems are integrated across all levels of the nervous system, from the spinal cord to the cortex. When one considers CPGs and their interactions with sensory input, one sees a remarkable range of phenomena. The simple stimulus-response reflex is a minimal component. At the spinal cord level, responses to sensory stimuli are modulated by the CPG to produce adaptively altered responses, and sensory stimuli adjust the length and amplitude of the CPG cycle. However, sensory input is also filtered by the CPG itself, while sensory input can also alter the state of the spinal activity on a slower time scale and in more ways than is often described. Although sensory input performs the traditionally considered corrective and monitoring functions, in interaction with the CPG it can also change the overall frequency and relative timing of the muscles, as well as altering intersegmental coordination. At the cortical level, CPG input modulates the activity of pyramidal cells, most likely so that their descending signals will occur at appropriate times in the cycle.

The goal is for the organism to produce adaptive behavior. This can only occur if all levels of the nervous system are aware of and responsive to activity at other levels. The cortex is privy to information from all sensory modalities, several of which do not reach the spinal pattern generator. The cortex is responsible for integrating all of this rich sensory input and generating desired responses. However, cortical neurons, while integrating all of this sensory information, must be aware of the state and activity of the limbs and trunk musculature if cortical activity is to move the organism properly through the environment. The spinal pattern generator is the first line of proprioceptive sensory integration, but the spinal cord and the other levels of the nervous system mutually interact to meet the needs of the organism.

# Sensorimotor Learning

*Daniel M. Wolpert and J. Randall Flanagan*

## Introduction

Skilled motor behavior is neither the result of rapid sensorimotor processes nor of fast or powerful effector mechanisms. Rather, the secret lies in the way tasks are organized and controlled by the nervous system. What sets humans apart from many robots that are far stronger and faster is our ability to select motor commands—both predictive and reactive—that are tailored to the task at hand and the physical properties of the environment. At the heart of our ability to deal with different tasks and contexts is sensorimotor learning.

Whereas some simple species show no motor learning, the need for motor learning arises in species in which the organism's environment, body, or task change. Specifically, when such changes are unpredictable, they cannot be prespecified in a control system, and therefore flexibility in the control process is required. Skills such as running on complex terrain or manipulating novel tools place a premium on motor learning. Similarly, as body size and proportions change with development, significant changes in the controller are required. Finally, learning is the only mechanism fast enough to allow us to master new tasks that are specified by social conventions, such as writing or dancing.

This article focuses on one perspective of motor learning, that is using internal models to learn transformations between sensory and motor variables. Both experimental and computational approaches to the study of internal model learning are reviewed.

## Internal Models

The study of motor control is fundamentally concerned with the relationship between sensory signals and motor commands. Mapping between motor commands and sensory signals is bi-directional, and to specify the direction under consideration, a definition is adopted in which *forward* indicates the causal direction from motor commands into their sensory consequences, and *inverse* indicates the opposite direction; for example, transforming a desired sensory consequence into the motor commands that would achieve it.

The transformations from motor commands to their sensory consequences and vice versa are determined by the physics of the environment, musculoskeletal system, neural conduction and processing, and the sensory receptors. However, these physical transformations may also be represented internally within the central nervous system, and the phrase *internal model* is used to distinguish the actual transformation and it representation in the nervous system. Thus, the internal forward dynamic model is a model within the brain that can predict how our arm will move—and the sensations that will arise—given a specific motor command.

Forward internal models capture the causal relationship between actions and their outcomes. Based on the efference copy produced in parallel with motor commands, the forward model predicts the sensory consequences of the ensuing movement. The central nervous system can use this prediction in several ways (Miall and Wolpert, 1996; ACTION MONITORING AND FORWARD CONTROL OF MOVEMENTS). One use of a forward model is to provide a fast internal loop that helps stabilize feedback control systems. Feedback control in biological systems is subject to potential difficulties with stability, because the sensory feedback through the periphery is delayed by a significant amount. Such delays can result in instability when trying to make rapid movements under feedback control. In predictive control, a forward model is used to provide internal feedback of the predicted outcome of an action. This internal feedback can be used before sensory feedback is available, thereby preventing instability.

Inverse models also play an important role in motor control. A particularly clear example of an inverse dynamic model arises in the vestibulo-ocular reflex (VOR). The VOR couples the movement of the eyes to the motion of the head, thereby allowing an organism to keep its gaze fixed in space (VESTIBULO-OCULAR REFLEX). This is achieved by causing the motion of the eyes to be equal and opposite to the motion of the head. In effect, the VOR control system must compute the motor command that is predicted to yield a particular eye velocity. This computation is an internal inverse model of the physical relationship between muscle contraction and eye motion.

We need to learn an inverse model in order to accurately estimate the motor commands required to achieve a desired sensory response. The feedforward control this allows is essential for most natural movements in which feedback is available too late to guide movement. There have been many control systems proposed in the literature that use direct control; that is, control architectures that do not explicitly use internal models. However, any good controller can be thought of as implicitly implementing an inverse model of the system being controlled. In order words, knowledge about the physical behavior of the system being controlled is employed by the controller.

## Internal Model Learning

Skilled motor behavior requires both inverse and forward internal models. These models capture information about the properties of the sensorimotor system. These properties are not static but change throughout life, both on a short time scale, as a result of interactions with the environment, and on a longer time scale, as a result of growth. Internal models must therefore be adaptable to changes in the properties of the sensorimotor system. A major aspect of motor learning can be viewed as the acquisition of forward and inverse internal models appropriate for different tasks and environments (Wolpert and Ghahramani, 2000; Wolpert, Ghahramani, and Flanagan, 2001).

### *Forward Model Learning*

In supervised learning the target output can be provided by an external teacher, for example during imitation learning. However, the target output can also be specified internally based on sensory signals and higher-level goals. Such *self-supervised* learning is involved in the acquisition of a forward model that tries to predict the sensory consequence of an outgoing motor command (Figure 1, top). Here, the desired output of the model is readily available; it is the actual sensory consequence. The environment, therefore, readily provides an appropriate training signal to learn predictors of sensory feedback. The difference between the predicted and actual sensory feedback can be used as an error signal to update a predictive model. The neural mechanisms that lead to such predictive learning in the cerebellum-like structure of electric fishes have recently been partially elucidated (Bell, 2001; ELECTROLOCATION).

### *Inverse Model Learning: Supervised*

An inverse model must learn to convert desired consequences into motor commands. One possible way to do this is with direct inverse modeling in which the inverse model observes the motor system during a “motor babbling” stage in which random motor commands are applied. The inverse model then observes the consequences of the motor commands and learns to associate these consequences (as its input) with the motor command that caused them (as its output). After learning, the inverse model’s input is the desired sensory consequence and its output should be the appropriate motor commands. This direct inverse modeling approach is well behaved for linear systems. For nonlinear systems, however, a difficulty arises that is related to the general “degrees-of-freedom problem” in motor control. In many motor systems different motor commands can lead to the same consequence. Therefore, during learning the inverse model will try to associate one outcome with many different motor commands, each of which will lead to this outcome. The inverse model will therefore learn to associate this outcome with the average of all motor commands that can cause it. However, in general, the average of all the motor commands, each of which individually lead to a common outcome, will not lead to the same outcome and therefore, in practice, direct inverse modeling fails.

Two learning mechanisms have been developed to deal with the problem associated with direct inverse model learning, These rely on transforming the outcome error back into a motor error that can be used to train the inverse model. For example, when we throw a dart, the error we receive is coded in visual coordinates. This sensory error must be converted into motor command errors suitable to update the inverse model. The two principal methods proposed in the motor control literature for solving this problem are “feedback error learning” and “distal supervised learning.”

Kawato, Furukawa, and Suzuki (1987) developed the feedback error learning approach to inverse model learning, which avoids the problem of direct inverse modeling (Figure 1, bottom). Feedback error learning makes use of a feedback controller to guide the learning of the inverse (feedforward) model. The total motor command acting on the motor system is the sum of the feedback control signal and the output from the inverse model. The feedback controller transforms the trajectory error, in sensory coordinates, into

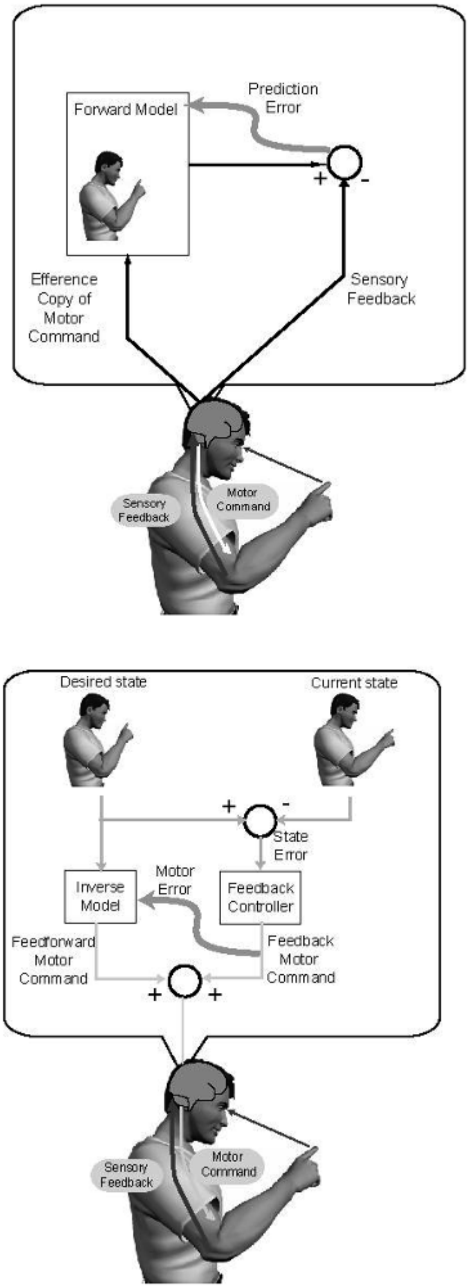

**Figure 1.** Schematics of forward model and inverse model learning. Top panel shows the forward model using a copy of the descending motor command, known as efference copy, to predict the sensory consequences of action. This prediction can be compared to the actual sensory feedback to generate a prediction error, which can be used (thick arrow) to update the forward model. The bottom panel shows a schematic of feedback-error learning. The aim is to learn an inverse model that can generate motor commands given a series of desired states. A hard-wired and low gain feedback controller is used to correct for errors between desired and estimated states. This generates a feedback motor command that is added to the feedforward motor command generated by the inverse model. If the feedback motor command goes to zero, then the state error will, in general, also be zero. Therefore the feedback motor command is a measure of the error of the inverse model and is used as the error signal to train it.

a feedback motor command, and this forms the error signal used to train the inverse model. This training signal therefore represents the sensory error converted into motor command coordinates. If the feedback motor command can be driven, through learning, to zero, then the inverse model is providing the appropriate motor command (because the outcome error must be zero) and the inverse model has been learned. Even for nonlinear systems, the feedback-error-learning method is generally successful.

In distal supervised learning, a forward model is used to convert outcome errors into errors in the motor command (Jordan and Rumelhart, 1996). The forward model must itself be learned from observations of the motor commands and their consequences on the motor system. The distal supervised learning approach is therefore composed of two interacting processes, one process in which the forward model is learned and another process in which the forward model is used in the learning of the inverse model. For the learning of the inverse model, the inverse model and the forward model are joined together and are treated as a single composite learning system. During this training process, the parameters in the forward model are held fixed and the errors in outcome propagated through the network to update the parameters of the inverse model only. In this way, the forward model is used to convert the outcome errors into motor errors.

### *Inverse Model Learning: Reinforcement*

In *reinforcement learning* (Reinforcement Learning in Motor Control), for each input to and output from the learning system, the environment provides feedback in the form of either reward or punishment. The overall performance measure that the system tries to maximize is the sum of total future rewards that may be weighted to favor immediate gain over longer-term gain. The concept of an overall punishment signal, or cost, from reinforcement learning has been very influential in motor control (Optimization Principles in Motor Control). Because of kinematic redundancy, almost any task can, in principle, be achieved in infinitely many ways. Consider, for example, the number of ways in which you could press an elevator button. Given all these possibilities, it is surprising that almost every study of the way the motor system solves a given task shows highly stereotyped movement patterns, both between repetitions of a task and between individuals on the same task. Such stereotypy is predicted when we consider tasks within the optimal control framework, in which a dynamic system (e.g., the arm) must be controlled so as to minimize a cost function (e.g., error reaching to a target). Mathematically, optimal control theory and reinforcement learning theory are equivalent. The difference is in emphasis: the former usually focuses on continuous state systems with known dynamics and known cost function, while the latter focuses on discrete state systems with unknown dynamics and cost functions that must be learned through experience. An important idea in motor learning has been to try to reverse-engineer the cost function the CNS uses, i.e., what is being optimized, from observed movement patterns and perturbation studies. For example, it has been proposed that there is noise in the motor command and that the amount of noise scales with the magnitude of the motor command. In the presence of such noise the same sequence of intended motor commands, if repeated many times, will lead to a probability distribution over movements. Aspects of this distribution, such as the spread of positions or velocities of the hand at the end of the movement, can be controlled by modifying the sequence of motor commands. In a simple aiming movement, the cost is the final error, as measured by the variance about the target. Assuming the presence of signal-dependent noise, a model that minimizes this cost accurately predicts the trajectories of both saccadic eye movements and arm movements

Different neural structures may be particularly adapted for different computational forms of learning (Doya, 2000). For example, the dopaminergic systems in the basal ganglia have been tied to signals that one would expect in reinforcement learning, such as expected reward, and dysfunctions of these systems are related to movement disorders, addiction, and other problems that could be related to reinforcement signals. Similarly, signals in the cerebellum have been linked to supervised errors. It has been shown that climbing fibres, which may act as a training signal to the cerebellum, can be used to train an inverse dynamic model of the eye (Kawato, 1999).

## Novel Dynamic Learning

Recent work on motor learning has focused on the representation of the inverse dynamic model. When subjects make point-to-point movements in which the dynamics of their arm are altered, for example by using a robot or rotating room to generate a force field acting on the arm, they initially exhibit trajectories that deviate from their normal paths and velocity profiles (for reviews see Mussa-Ivaldi, 1999; Lackner and DiZio, 2000). However, over time, subjects adapt and move naturally in the presence of the force field. This can be interpreted as adaptation of the inverse model or the incorporation of an auxiliary control system with a new internal model to counteract the novel forces experienced during movement. Several theoretical questions have been addressed using this motor learning paradigm. The first explored the representation of the controller and in particular whether it was best represented in joint or Cartesian space. This was investigated by examining the generalization of motor learning at locations in the workspace remote from where subjects had adapted to the force field (Shadmehr and Mussa-Ivaldi, 1994). By assessing in which coordinate system the transfer occurred, evidence was provided for joint-based control. Another important advance was made in a study designed to answer whether the order in which states (positions and velocities) were visited was important for learning or whether having learned a force field for a set of states subjects would be able to make natural movements when visiting the states in a novel order. The findings showed that the order was unimportant and argued strongly against a rote learning of individual trajectories. In addition it has been shown that state-dependent fields are learned more efficiently than temporally changing fields, and that during learning both forward and inverse models are simultaneously adapted with the forward model leading.

## Modular Learning

Recently, research has begun to shift away from examining learning of a single internal model to considering how we are able to learn a variety of tasks. Many situations that we encounter are derived from a combination of previously experienced situations, such as novel conjoints of manipulated objects and environments. Internal models can be regarded conceptually as motor primitives, which are the building blocks used to construct intricate motor behaviors with an enormous vocabulary. By modulating the contribution to the final motor command of the outputs of a set of internal models, an enormous repertoire of behavior can be generated. One architecture that is capable of learning to act in multiple situations is the MOSAIC model (for review see Wolpert, Miall, and Kawato, 1998). In this architecture a set of forward models (predictors) are used as a set of hypothesis testers to assess which predictor best models the current task. This information is then used to weigh the outputs of a set of corresponding inverse models (controllers). This system can simultaneously learn multiple predictors and controllers as well as how to select the controller appropriate for a given task.

Recent studies have shown that after learning two different contexts, the CNS can appropriately mix the outputs both within the visuomotor domain and across the visuomotor and dynamic domains. Our understanding of the mechanisms of motor learning has gained from examining how learning one task can interfere with learning others. When trying to learn two opposing dynamic or visuomotor rearrangements interference occurs when they are presented in quick succession, but not when they are separated by several hours (Brashers-Krug, Shadmehr, and Bizzi, 1996). This suggests that motor learning undergoes a period of consolidation during which time the motor memory is susceptible to being disrupted. However, if the sensorimotor context is different, then opposite internal models can be simultaneously maintained in motor working memory and subsequently consolidated. For example, subjects can learn and consolidate two opposing force fields if the configuration of the wrist is different for the two fields. In contrast, arbitrary changes in context, such as color cues, are not sufficient for learning of two opposing fields. This suggests that the internal model captures a mapping between motor commands and sensory consequences that is determined by the force field but does not represent the force field per se. Recent studies have suggested that subjects are able to independently learn visuomotor and dynamic transformations presented in close temporal proximity. However, it appears that such independence is only observed when the two transformations depends on different kinematic variables (e.g., a position-dependent visuomotor rotation and a velocity-dependent force field).

Recent evidence indicates that the cerebellum plays a central role in the long-term storage of internal models (for a review see Wolpert, Miall, and Kawato, 1998). In addition it has been suggested that the spinal cord may store a small set of MOTOR PRIMITIVES (q.v.) or basis functions (Bizzi et al., 2000). The idea is to simplify control by combining a small number of primitives, for example patterns of muscle activations (synergies), in different proportions rather than individually controlling each muscle (Mussa-Ivaldi, 1999).

## Introduction

*The brain is an information-processing machine.* Although this statement is commonplace, for a long time most neurobiologists understood the word "information" in it only in the informal, qualitative sense. However, in recent years, quantitative studies based on Shannon's information theory (Shannon, 1948; Cover and Thomas, 1991) have markedly sharpened our understanding of neuronal coding.

Only a few years after Shannon's invention of information theory, MacKay and McCulloch (1952) attempted to estimate the information transmission capacity of single spiking neurons. Assuming that it is limited only by the refractory time (1 ms) and the discriminability of successive spikes, one easily obtains an upper bound on the transmission rate of the order of 1,000 bits/s. A more restrictive bound is obtained by computing the actual entropy of spike trains. This is less than the above limit, because neurons spike less than half the time and different 1 ms intervals are not independent. Still, numbers on the order of 500 bits/s are found.

Now, if neurons are intrinsically very noisy devices, reliable transmission will require a high degree of redundancy, and the actual rate at which they convey information will be correspondingly lower. It has been commonplace to suppose that this is the case, but neural firing may appear noisy to us only because we do not understand it. To achieve even the beginning of an understanding of how the brain works, it is necessary to measure the rate at which neurons actually carry information.

Of course, we do not know how much of the measured information is actually used by downstream neurons. However, measurements of information transmission can usefully identify features of the neural code and thereby help us understand how the brain computes.

An alternative approach to the problem of neural coding is to try to do decoding: optimally estimating the stimulus, given the neuronal response (see, e.g., POPULATION CODES and the review by Borst and Theunissen, 1999).

In the 1970s, Eckhorn and Pöpel (1974, 1975) laid the foundation for much subsequent work on measuring transmitted information by calculating the rate at which neurons in the cat lateral geniculate nucleus carried information about a random train of visual flashes, independent of a priori assumptions about how it was coded. They found rates from about 10 bits/s to as high as 60 bits/s, depending on how fast the stimulus was flashed.

In the 1980s and 1990s, several groups extended this approach. Among them were William Bialek, Rob de Ruyter, and their collaborators (de Ruyter van Steveninck and Bialek, 1988; Bialek and Rieke, 1992), who studied information transmission by single neurons involved in vision in flies, hearing in frogs, and mechanoreception in crickets; and Barry Richmond and co-workers (Optican and Richmond, 1987; Heller et al., 1995), who made similar analyses for spatial pattern vision in monkeys. By now, the quantitative characterization of neurons in terms of information transmission rates has become a standard tool.

Here we review two recent approaches to measuring transmitted information. The first, employed by Bialek and his collaborators, is based on direct estimation of the spike train entropies in terms of which transmitted information is defined. The second, developed by Panzeri and Schultz, is based on an expansion to second order in the length of the spike trains.

## Entropy and Information

Whatever system we are interested in, the formal characterization of the problem is the same. The animal is presented a stimulus $s$ from some set $S$, and the response of a neuron (or several neurons) is measured. For spiking neurons, the response can be represented completely generally in the following way. Time is divided into intervals (typically 1 ms) small enough that there is never more than one spike per interval. The response can then be described by a binary vector with one component per interval, equal to a 1 or 0 according to whether or not the neuron fired a spike in that interval. We denote this vector simply by $r$ and the whole set of responses by $R$.

To get a grasp of what "transmitted information" means, consider an experiment in which many spike trains are recorded for many stimuli. There is generally intrinsic variability in the system or the measurement process, so we formulate our description of the problem in terms of distributions of stimuli and responses. The fact that the responses depend to some extent on the stimuli means that the stimulus-conditional response probabilities $P(r|s)$ are not in general equal to the unconditional or stimulus-averaged probabilities $P(r) = \Sigma_s P(r|s)P(s)$. We expect that the variability of the responses evoked by a given stimulus will generally be less than that of the entire response set. The transmitted information is a simple measure of this variability difference.

A general way of characterizing variability is as an entropy. Thus, the total or unconditional response entropy $H(R) = -\Sigma_r P(r) \log_2 P(r)$ describes the variability of the entire response ensemble. Analogously, the response entropy conditional on a given stimulus $s$ is $H(R|s) = -\Sigma_r P(r|s) \log_2 P(r|s)$. Its average over $s$, denoted $H(R|S)$—the average response variability for a fixed stimulus—is termed the *noise entropy*. The transmitted information $I(R; S)$, also called the mutual information between stimuli and responses, is simply the difference between the total and noise entropies: $I(R; S) = H(R) - H(R|S)$. Although the corresponding difference for a single $s$, $H(R) - H(R|s)$, is not necessarily positive (a single stimulus might evoke highly variable responses), $I(R; S)$ can be proved to be non-negative. It is zero only when the stimulus-response relationship is completely random, and it takes its maximum possible value $H(R)$ only when the response is deterministic (for a given stimulus, every response is identical).

Therefore, the calculation of the transmitted information requires simply the accurate estimation of the conditional probabilities $P(r|s)$ and, from them, the total and averaged conditional entropies, as described above. If one has sufficient data, one can just estimate response probabilities as the fraction of all responses with a particular value of $r$. This can be difficult because the full response space has such a high dimensionality: $2^T$ bins for spike trains $T$ time units long.

The difficulty can be circumvented by employing specific models for the encoding, i.e., for the relevant conditional probabilities. Almost all the work mentioned above was done this way. This reduces the dimensionality of the response space, but at a cost: particular features of the results might be artifacts of the model used. Recent investigations have concentrated instead on model-independent methods, and here we review two sets of studies along these lines.

## Direct Calculations

In the approach taken by Bialek's group (Strong et al., 1998), one tries to estimate the probabilities $P(\{t_i\})$ and $P(\{t_i\}|s)$ directly from histograms of the data. (We use the notation $\{t_i\}$ for the response $r$ to emphasize that we mean the entire set of spike times, not just a spike count or some other low-dimensional measure.) These estimated probabilities are then used to calculate the total and noise entropies $H(R)$ and $H(R|S)$ and thereby the transmitted information, as described above.

In the experimental paradigm used, the fly views the moving pattern for very long periods, and we are interested in the information transmission rate. To estimate this, one considers time windows of length $T$ and tries to extrapolate to the limit of very long windows. For small $T$, it is easy to make reliable entropy estimates directly (consider a 1 ms window in which only two responses are possible, spike or no spike), but these estimates ignore possible correlations between spikes at different times. For very large $T$, on the other hand, the exponentially growing dimensionality of the space of responses prevents one from estimating their probabilities reliably from histograms based on the data.

The solution is to start with small $T$, then go to larger and larger windows, trying to identify the large-$T$ trend while the estimates are still reliable. The estimated entropy rates (entropies divided by $T$) at lower values of $T$ fit a nice straight line as a function of $1/T$, so it is simple to extrapolate to $1/T = 0$ to estimate the asymptotic rates.

The difference between the resulting total and noise entropy rates (Figure 1) gave an estimate of 78 ± 5 bits/s (1.8 bits/spike) for a time-discretization window $\Delta t = 3$ ms. Reassuringly, this number is consistent with those found by other methods (de Ruyter van Steveninck and Bialek, 1988; Bialek and Rieke, 1992).

The noise entropy was just about half of the total entropy; that is, half of the total observed variability in the neuronal firing is signal and half is noise.

Varying $\Delta t$, one can explore how much information is encoded in spike timing at different degrees of precision. The transmission rate was found to vary roughly logarithmically with $\Delta t$, with a maximum value of 90 bits/s found for a resolution of 0.7 ms.

## T-Expansion

Panzeri and Schultz (2001) and Schultz and Panzeri (2001) observed that it was possible to make a formal expansion of both the total and noise entropies in powers of $T$, the length of the time interval over which the response is measured. The computational advantage of using this expansion is that, working, say, to second order in $T$, one only need estimate the quantities $P(t^a|s)$ (the probability, given stimulus $s$, of a spike from unit $a$ at time $t^a$, conditional on stimulus $s$) and $P(t_1^a, t_2^b; S)$ (the joint probability of a spike from unit $a$ at time $t_1^a$ and one from unit $b$ at time $t_2^b$, also conditional on $s$), not the full conditional response probabilities $P(\{t_i^a\}|s)$. Thus, fewer data are required to make a robust estimation.

Beyond second order in $T$, the expansion becomes very cumbersome, but the second-order expansion proves quite accurate for

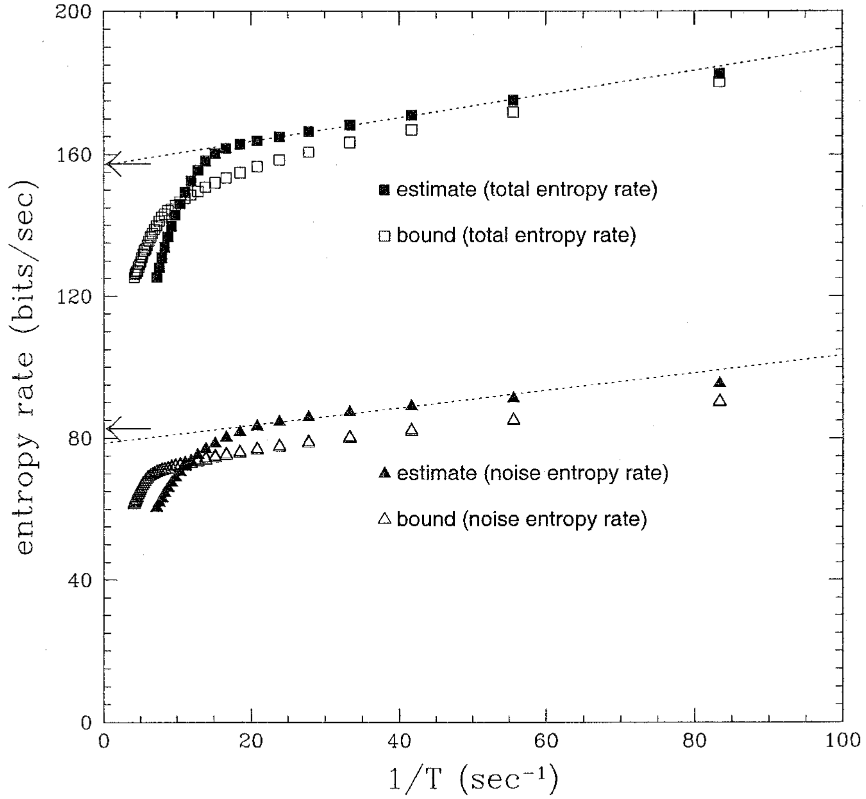

**Figure 1.** Procedure for estimating total and noise entropy rates. Entropies are estimated for finite-time window width $T$, plotted functions of $1/T$, and extrapolated to $T = \infty$. Here the bin width $\Delta t = 3$ ms. The upper sets of points are for the total entropy and the lower sets are for the noise entropy. Also shown (open symbols) are the Ma bounds. The dashed lines show the extrapolations T → ∞. (From Strong et al., 1998. Reprinted with permission.)

experimentally relevant response times (20–100 ms). Furthermore, the first- and second-order terms can be written in a way that isolates the potential effects of spike timing and of correlation in both signal and noise, permitting direct insight into the nature of the neuronal code.

We now examine these terms. For generality, we consider the case of multiple neurons, labeled by an index $a$ running from 1 to $C$. The response $r$ is the full set of spike times $t_i^a$ of all the neurons. The expansion takes the form

$$I(\{t_i^a\};\, S) = TI_t(\{t_i^a\};\, S) + \frac{T^2}{2} I_{tt}(\{t_i^a\};\, S) + \mathrm{O}(T^3) \qquad (1)$$

The first-order term has a very simple form:

$$TI_t(\{t_i^a\};\, S) = \sum_{a=1}^{C} \int \mathrm{d}t^a \left\langle \bar{r}_a(t^a|s) \log_2 \frac{\bar{r}_a(t^a|s)}{\bar{r}_a(t^a)} \right\rangle_s \qquad (2)$$

Here $\bar{r}_a(t^a|s)$ is the average firing rate at time $t^a$, conditional on stimulus $s$, and $\bar{r}_a(t^a) = \langle \bar{r}_a(t^a|s)\rangle_s$ is the rate averaged over all stimuli. Since Equation 2 is a linear sum over each time $t$ and cell $a$, it gives the information gained about the stimulus (i.e., the entropy reduction) from knowing the spike train, if each response time bin and cell were to convey independent information. Deviations from independent information transmission (i.e., synergy or redundancy effects) are expressed by the second-order term, considered next. Correlations between cells or between spikes for a given cell do not enter at first order in $T$.

At order $T^2$, correlations between pairs of spikes affect the result. We can describe these correlations by some auxiliary quantities $\gamma_{ab}(t_1^a,\, t_2^b|s)$ and $\nu_{ab}(t_1^a,\, t_2^b)$, defined as follows. Consider, for stimulus $s$, the joint probability rate of a spike at time $t_1^a$ by neuron $a$ and one by neuron $b$ at $t_2^b$, which we write in the form

$$P(t_1^a,\, t_2^a;\, s) = \bar{r}_a(t_1^a|s)\bar{r}_b(t_2^b|s)[1 + \gamma(t_1^a,\, t_2^b|s)] \qquad (3)$$

If different spikes were independent, the joint probability rate would just be the product of the separate single-spike rates, i.e., $\gamma(t_1^a,\, t_2^b|s) = 0$. The quantity $\nu_{ab}(t_1^a,\, t_2^b)$ measures correlations in the rates across stimuli in an analogous way:

$$\nu_{ab}(t_1^a,\, t_2^b) = \frac{\langle \bar{r}_a(t_1^a)\bar{r}_b(t_2^b)\rangle_s}{\bar{r}_a(t_1^a)\bar{r}_b(t_2^b)} - 1 \qquad (4)$$

In terms of these quantites, the second-order transmitted information can be written

$$\begin{aligned}\frac{T^2}{2} I_{tt}(\{t_i^a\};S) = {} & \frac{1}{2 \ln 2} \sum_{ab} \int \mathrm{d}t_1^a \mathrm{d}t_2^b \bar{r}_a(t_1^a)\bar{r}_b(t_2^b) \Big\{ \nu_{ab}(t_1^a,\, t_2^b) \\ & + [1 + \nu_{ab}(t_1^a,\, t_2^b)] \ln \frac{1}{1 + \nu_{ab}(t_1^a,\, t_2^b)} \Big\} \\ & + \tfrac{1}{2} \sum_{ab} \int \mathrm{d}t_1^a \mathrm{d}t_2^b \langle \bar{r}_a(t_1^a|s)\bar{r}_b(t_2^b|s)\gamma(t_1^a,\, t_2^b|s)\rangle_s \\ & \times \log_2 \frac{1}{1 + \nu_{ab}(t_1^a,\, t_2^b)} + \tfrac{1}{2} \sum_{ab} \\ & \times \int \mathrm{d}t_1^a \mathrm{d}t_2^b \langle \bar{r}_a(t_1^a|s)\bar{r}_b(t_2^b|s)[1 + \gamma(t_1^a,\, t_2^b|s)] \\ & \times \log_2 \left\{ \frac{\langle \bar{r}_a(t_1^a|s')\bar{r}_b(t_2^b|s')\rangle_{s'}[1 + \gamma(t_1^a,\, t_2^b|s)]}{\langle \bar{r}_a(t_1^a|s')\bar{r}_b(t_2^b|s')[1 + \gamma(t_1^a,\, t_2^b|s')]\rangle_{s'}} \right\} \Big\rangle_s\end{aligned} \qquad (5)$$

We consider the three terms on the right-hand side of Equation 5 separately. The first one is the only one that would be there if there were no correlations between spikes. It is always negative. Since the first-order term (Equation 2) grows linearly with time but the total information is bounded, the rate of information accumulation has to slow down with time, and this term is the first place where we see that effect. The second term reflects the effect of spike correlations, through $\gamma(t_1^a, t_2^b|s)$, but these correlations are averaged over stimuli (weighted in proportion to the rates $\bar{r}_a(t_1^a|s)$ and $\bar{r}_b(t_2^b|s)$ they evoke). Thus, this term describes the effects of *stimulus-independent* firing correlations. The final term, which cannot be negative, is the part of the information due to stimulus-dependent correlations.

This treatment was for the complete neuronal response, i.e., $r$ is the set of firing times $t_i^a$ for all the neurons. Often, one is interested in how much information is carried by the spike count alone, independent of the firing times. This information can be expanded in the same way, and the result is analogous to Equations 2 and 5. The differences are, first, there are no time integrals; second, the conditional and unconditional spike counts replace the full response rates $\bar{r}_a(t^a|s)$ and $\bar{r}_a(t^a)$; and third, there is no longer any time dependence in the correlation coefficients $\gamma_{ab}(s)$ and $\nu_{ab}$.

To see what one can learn from this kind of analysis, we review its application to data from rat barrel cortex (Panzeri et al., 2001). In the experiment, single whiskers were stimulated and the responses of 106 neurons were collected and analyzed.

The first significant finding was that a substantial fraction of the total information carried by these neurons about which whisker was being stimulated was encoded temporally. That is, there was considerable information carried by the full response (the complete sets of spike times) that was not carried by the spike counts alone. The size of this effect varied a lot from neuron to neuron, but, on average, including spike timing added about 50% to the information contained in the spike count.

The nature of the temporal code employed by these neurons can be explored further by examining the contributions from the separate terms in Equations 2 and 5. Figure 2 shows the principal findings. Most of the information (83%) could be accounted for without taking any spike correlations into account. More specifically, different stimuli evoke responses with different PSTHs $\bar{r}_a(t^a|s)$, and these differences account for most of the dscriminability of the stimuli. For example, $\bar{r}_a(t^a|s_1)$ might rise a lot faster than $\bar{r}_a(t^a|s_2)$. In this case an early spike would be a good indication that it was evoked by $s_1$ rather than $s_2$. Indeed, in the present case, the first-spike time alone conveyed (on average) as much information as could be gained from all spikes, ignoring correlations. Almost all of the remaining 17% of the information (13.5%) was coded in stimulus-independent correlations (i.e., the second term on the right-hand side of Equation 5), with only 3.5% in stimulus-dependent correlations (the final term).

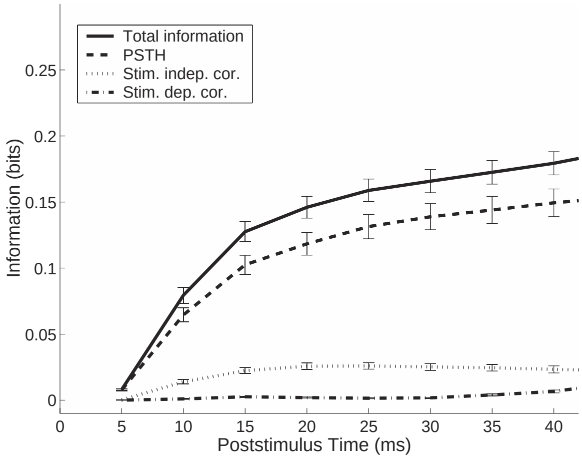

**Figure 2.** Autocorrelations carry little information about stimulus position in rat somatosensory cortex: Contributions to the transmitted information from PSTHs (dashed line; Equation 2 and the first term on the right-hand side of Equation 5), stimulus-independent correlations (dotted line; second term on the right-hand side of Equation 5), and stimulus-dependent correlations (dashed-dotted line; third term on the right-hand side of Equation 5). Bars denote SEM. (Redrawn from Panzeri et al., 1998.)

## Discussion

These examples illustrate how, given sufficient data, neural information transmission can be measured systematically and accurately, and how one can begin to sort out details of the neural code employed by the brain in specific cases. The computational technology is by now rather well developed, and we can expect that in the future it will be applied to more and more data, in different animals, in different brain regions, and in the context of different brain functions. One can then hope that, integrating this knowledge with the insight gained from exploring the implications of particular coding strategies (see SPARSE CODING IN THE PRIMATE CORTEX and FEATURE ANALYSIS), a coherent general picture of the encoding and computational strategies employed in neural processing will begin to emerge. An extensive and readable treatment of these and related issues can be found in the book by Rieke et al. (1997).

# Sequence Learning

*Peter Ford Dominey*

## Introduction

The forward linear progression of time imposes a fundamental sequential structure on all behavior, and thus the capacity to store and manipulate sequential information is of central importance for adaptive systems. Sequential structure is not unidimensional, however, and the potentially dissociable aspects of sequence processing are likely to be associated with distinct neural systems. From this perspective, the current article will characterize behavioral sequences in terms of their serial, temporal, and abstract structure, and aspects of the associated neural processing systems.

Serial structure or order is defined by the relation between an element or set of elements, and its successor. This dimension can be characterized in terms of length and complexity. *Length* is the number of elements in the sequence. *Complexity* refers to the maximum number of elements that must be remembered in order to know the correct successor. Temporal structure is defined in terms of the durations of elements (and the possible pauses that separate them), and intuitively corresponds to the familiar notion of rhythm. Thus, two sequences may have identical serial structure and different temporal structure, or the opposite. Abstract structure is defined in terms of generative rules that describe relations between repeating elements within a sequence. Thus, the two sequences A-B-C-B-A-C and D-E-F-E-D-F have different serial structure, but are both generated from the same abstract structure 123-213, and are thus said to be isomorphic. While perhaps not exhaustive, these three dimensions at least partially span the space of possible behavioral sequence structure. This article focuses on how these different dimensions of sequence structure can be encoded in neural systems based on behavioral studies in different patient and control groups, and related simulation studies. Related issues in temporal sequence learning are found in the articles Temporal Sequences: Learning and Global Analysis; Temporal Pattern Processing; and Recurrent Networks: Learning Algorithms (q.v.).

## Learning Serial and Temporal Structure

### *Aspects of Recurrent Networks*

A fundamental property of a sequence processing system is that the state of the system should contain information about the current sequence element, but should also be influenced by the succession of previous elements. This is the case for recurrent networks in which context units receive inputs from units encoding internal state and feed back into these state units. These recurrent connections between the state and context units allow information from previous time steps to influence the current network activity, thus providing a representation of sequence context. Learning that requires modification of recurrent connections, however, introduces significant technical challenges. Specifically, after an input is presented, multiple network cycles can occur before an output is generated and the error is evaluated and corrected. A given connection weight in the recurrent network has contributed to the error, but in a different way on each successive cycle of information passing through this weight. The technical problem thus arises in unraveling this weight's contribution to the error over these successive time steps in order to implement the error-reducing learning. A number of methods have been developed to deal with the complexity of applying learning algorithms to recurrent connections (Pearlmutter, 1995, and Recurrent Networks: Learning Algorithms). In general, many of these methods of resolving the problem of learning in recurrent networks over multiple time steps are biologically implausible, because they are not consistent with forward running time, and/or because they have excessive computational and memory storage requirements.

The method used by Elman (1990) in the simple recurrent network (SRN) is to cut off the temporal history at one or two time steps, yielding a simplified learning method but still quite efficient sequence learning capability. The SRN has been demonstrated to be sensitive to serial structure in a number of different domains including representing regularities in the serial structure of language (Elman, 1990), modeling finite-state automata (Cleeremans, Servan-Schreiber, and McClelland, 1989), speech segmentation (Christiansen, Allen, and Seidenberg, 1998), and simulating human performance in sensorimotor sequence learning (Cleeremans, 1993) in serial reaction time (SRT) tasks.

### *Sequence Learning in the Serial Reaction Time Task (SRT)*

The serial reaction time task (SRT) developed by Nissen and Bullemer (1987) has been quite extensively used in the study of human sequence learning, and is thus an interesting object for simulation studies. In the SRT task, reaction times (RTs) for visual stimuli that are presented in a repeating sequence are reduced with respect to RTs for stimuli in randomly presented series (see Figure 1*B*). This RT difference is the measure of sequence learning. One of the principal manipulations in the SRT paradigm has been the performance of a concurrent or "dual" task that typically impairs the sensorimotor learning (Nissen and Bullemer, 1987). Curran and Keele (1993) proposed the existence of dissociable attentional and nonattentional forms of sequence learning, and that the dual task disrupts attentional sequence learning, while leaving the less efficient nonattentional learning intact. Cleeremans (1993) suggested alternatively that the dual task impairs the processing of successive sequence elements, and he thus introduced random noise to the activity of a subset of units in a simple recurrent network (SRN) during SRT learning, resulting in perturbed performance quite similar to that observed in human subjects in dual task conditions (Cleeremans, 1993). This, however, leaves open the question of how the dual task conditions introduced processing noise to produce such a perturbation in sequence learning.

Stadler (1995) suggested that the dual task condition disrupts sequence learning by preventing consistent temporal organization of the sequence due to the delays introduced during the response-stimulus interval (RSI) by the dual task processing. He thus demonstrated experimentally that the introduction of random delays during the RSI perturbs sequence learning in a manner quite similar to that of the dual task condition, while introducing a purely attentional load with no temporal disorganization does not. This suggested that dual task results could be explained without resorting to dissociable learning mechanisms. Testing this temporal disorganization hypothesis directly in a simulation study would require the presentation of successive elements with realistic RSI delays.

### *A Temporal Recurrent Network*

Temporal structure in sequences can be encoded by systems that employ mechanisms including distributions of delay lines (Temporal Sequences: Learning and Global Analysis) between units, time-dependant short-term memory elements (Temporal Pattern Processing), and the temporal dynamics of recurrent networks, though this is not the case for the standard implemen-

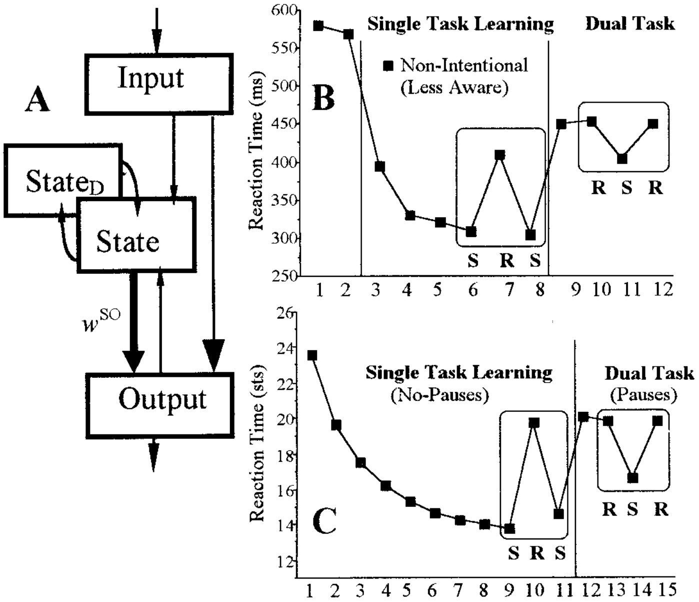

**Figure 1.** *A*, TRN architecture. Each structure is a 5 × 5 matrix of leaky integrator neurons with sigmoid firing thresholds. Reinforcement learning in $w^{SO}$ synapses binds activation patterns in State to output activations in Output. *B*, SRT learning. Mean RTs for successive blocks of 120 sequence elements. RTs for sequentially presented stimuli in blocks 3–6 are reduced, and then increase in random block 7, revealing learning. Learning expression reduced in dual task as revealed by reduced difference in random (block 11) vs. sequence (blocks 10 and 12) RTs. (Data from Experiment 1 of Curran and Keele, 1993.) *C*, Simulation of SRT learning by the TRN. RTs are reduced as $w^{SO}$ synapses associate sequence-specific State activity with corresponding predictable sequence elements, yielding stronger activation and faster rise to threshold for sequence (S) vs. random (R). Dual task conditions achieved by introduction of random pauses as suggested by Stadler (1995), simulating human data in *B*. (Data from Dominey, 1998.)

tations of the SRN where the next element is expected on the next network cycle as discussed previously. Dominey, Arbib, and Joseph (reviewed in Dominey et al., 1998) introduced an alternative sequence learning model that takes full advantage of the temporal dynamics of a recurrent network, while eliminating the complexity of learning in recurrent connections (see Figure 1*A*). Recurrent connections in the State network of leaky integrator neurons—considered to represent cortico-cortical connections in prefrontal cortex (PFC)—are preset with random values that vary between −0.55 and +0.45, and do not change during learning. Associative learning takes place in modifiable connections between the recurrent state layer and the output layer, corresponding to dopamine-related plasticity in corticostriatal synapses. Neurons in the simulated PFC (State in Figure 1) demonstrated receptive fields sensitive both to the spatial location of sequence elements, and their serial order, as observed in electrophysiological recordings in PFC of the non-human primate (Dominey, Arbib, Joseph in Dominey et al., 1998).

With respect to the SRT task (Figure 1*B*), as a sequence is successively repeated and learned, reaction times for predictable elements in the sequence become progressively reduced due to increased State-Output connection strengths that yield more rapid activation of the leaky integrator neurons in Output for elements in the repeating sequence. Thus the model naturally displays reduced RTs for predictable sequence elements (Figure 1*C*).

### *Processing of Serial and Temporal Structure*

Given its fixed recurrent connections, the TRN exploits the temporal coding capabilities of a recurrent system while avoiding the complexity of recurrent learning, and is thus well adapted to examining the effects of serial and temporal structure in SRT learning. During SRT learning, we introduced random delays during the RSI interval between the model response and the next sequence elements, to simulate the effects of dual task learning as in Stadler's (1995) experiment. This temporally distorted input produced a degraded representation of the sequence in the recurrent network, resulting in weaker activation of the learned State-Output associations, and a corresponding increase in reaction times. This argues for the temporal structure disruption hypothesis of Stadler (1995) and explains human sensitivity to perturbations in temporal structure of such sequences (Dominey, 1998). In contrast, if temporal structure is introduced in a systematic (rather than random) way that is coherent with the serial structure then these regularities can be represented in a systematic way in the recurrent network and can be learned (Dominey in Dominey and Ramus, 2000).

Indeed, serial and temporal structure are often correlated in behavioral sequences, a condition that likely plays an important role in behavioral sequence learning. In particular, in the earliest phases of language acquisition it is likely that sensitivity to correlations in serial and temporal structure provides the foundation for the construction of more complex linguistic representations. Christiansen et al. (1998) thus demonstrated how the SRN can exploit multiple cues, each of which alone is insufficient, in learning to segment words in a continuous stream. Because of the temporal processing constraints of the SRN, temporal structure is coded symbolically in these simulations, rather than in real time.

In this context the TRN was confronted with human performance in which newborns discriminate between languages in different rhythm classes based on their temporal structure (Dominey and Ramus, 2000). Simulating these results with the TRN, sentences from five different languages were recoded as consonant-verb (C-V) sequences, where the only defining information was the rhythmic structure. Like children, the TRN was able to discriminate between languages from different rhythm classes (e.g., English and Spanish) but not between languages from the same rhythm class (e.g., Dutch and English).

## Learning Abstract Structure

Although it has been demonstrated that the serial and temporal structure of sequences can be processed by a common architecture, it is not clear that this generalization extends to abstract structure. In an elegant presentation of abstract structure processing in the infant, Marcus et al. (1999) demonstrated that after only 2 minutes' total exposure to 16 sound sequences such as "le-di-di, ji-we-we . . ." 7-month old infants can extract the common abstract structure (in this case ABB), and can transfer this knowledge in order to recognize new sequences as isomorphic (matching) or not with the learned pattern.

Marcus et al. concluded that infants can learn rules such as ABB, in which A and B represent variables that can be instantiated with new values during generalization and transfer to new sequences, and that such rule representations cannot be realized by statistical methods or standard sequencing models including the SRN. In a series of comments in *Science* and *Trends in Cognitive Science*, opponents argued that if training and transfer domains shared overlapping representations, then statistical learning methods and the SRN would work. Marcus et al. countered that transfer can still be observed even when there is no overlap in the representation, and that systems that require this overlap will fail in these cases.

Addressing this transfer issue, Dienes, Altmann, and Gao (1999) modified the SRN by adding additional units and connections for representing the transfer domain, and for learning the mapping from training to transfer domains. This model has been able to explain a significant set of results from the artificial grammar learning domain, in which this issue of transfer is a central question. Thus the “overlap” problem is solved by learning, but in a manner that avoids representation of the common rule. One behavioral result of this mapping strategy is that transfer is not immediate, but requires significant exposure to the new material for the mapping to be learned.

It remains likely, however, that the “rule” vs. “instance” distinction is behaviorally and neurophysiologically valid (reviewed in Dominey et al., 1998). In this context, we observed in human adults that the serial and abstract structure of sequences, such as ABCBAC and DEFEDF, can be learned independently (Dominey et al., 1998). In implicit (naive) conditions, subjects learned serial structure, but were unable to exploit knowledge of the underlying abstract structure 123-213 when exposed to a new “isomorphic” sequence based on this abstract structure. Indeed, only when subjects were explicitly aware of a possible underlying abstract structure were they able to learn both the serial and abstract structure and rapidly transfer the abstract knowledge to new isomorphic sequences. When exposed to this task, the TRN learned only the serial structure, independant of the abstract structure. This is because the network lacks a representation of the internal relations that characterize abstract structure. To address this representational deficit, we modified the TRN to contain a set of short-term memory (STM) components, that store the 7 ± 2 previous sequence elements, and a recognition function applied to this STM to detect repetition relations, with the recurrent network operating on these relations. In this context, ABCBAC is represented as “u,u,u, n-2, n-4, n-3” where “u” corresponds to unique or nonrepeating, and “n-2” corresponds to repetition of the element 2 positions behind (Dominey et al., 1998). The thus modified abstract recurrent network (ARN) operates on these abstract sequence representations rather than their serial structure. This is consistent with the idea that, to the extent that the training and transfer domain do not overlap, a recurrent network is not enough, and additional hardware is required. For Dienes et al. (1999) the additional hardware was used to construct the mapping between training and transfer domains. In Dominey et al. (1998) it allowed representation of the internal or “abstract” structure of the rule that describes the general mapping itself.

## Neuropsychological Evidence for the Serial/Abstract Dissociation

If the hypothesis that serial and abstract structure are treated by dissociable neurophysiological processes is correct, then we should be able to isolate patient groups that display this dissociation. In this context, Parkinson’s disease is characterized by motor disorders of akinesia, tremor, and rigidity that result from a massive destruction of midbrain dopamine-producing neurons. This deterioration has significant impact on the functional organization of the frontostriatal system that is the neuroanatomical correlate of the TRN sequence learning model. Thus, numerous studies indicate that the implicit learning of the serial structure of sensorimotor sequences is impaired in these patients. Interestingly, we demonstrated that these patients retained a significant capability to acquire and transfer knowledge of abstract sequential structure to new isomorphic sequences in a serial reaction time task, suggesting that while implicit sequence learning relies on an intact frontostriatal system, explicit learning of abstract structure does not (or less so). In contrast, it is known that schizophrenic patients tend to perform well on automated, implicit processing, with more difficulty on explicit attentional processing, functionally associated with a hypofrontality. Accordingly, we observed that schizophrenic patients displayed an intact capability to learn serial structure, but failed to learn abstract structure. These results from simulation and neuropsychological studies support the hypothesis that processing of serial and abstract structure rely on dissociable neural mechanisms. These and related studies are reviewed in Dominey et al. (1998).

## Relation to Language Processing

Although language clearly requires task specific capacities, it is likely that more generalized capabilities to process serial, temporal, and abstract sequential structure could also come into play. This applies both for learning to segment speech into words (Christiansen et al., 1998), and in the use of abstract generative rules for structural transformations.

Syntactic comprehension is the process of determining “who did what to whom” from a purely syntactic analysis. Considering the sentences “Sally$^1$ was introduced to Bill$^2$ by John$^3$” vs. “John$^3$ introduced Sally$^1$ to Bill$^2$,” we see that ordering of the agent (John), object (Sally), and recipient (Bill) vary in these active and passive sentences. In a simplified manner, if we consider syntactic comprehension as a recovery of the canonical (active) structure, then the passive to active transformation can be characterized by the abstract rule 123-312. In this context we can predict that if syntactic comprehension shares a common neurophysiological basis with abstract structure manipulation, then performance deficits in the two tasks should be correlated.

In order to test this prediction, we compared performance in syntactic comprehension and in abstract sequential structure processing in a population of aphasic patients with syntactic comprehension deficits. Linear regression revealed that performance in the two tasks was highly correlated, suggesting a common underlying neurophysiological basis. This observation was likewise replicated in a population of schizophrenic patients that displayed correlated deficits in their processing of syntactic and abstract structure (Lelekov et al., 2000).

While such correlation results argue for shared neurophysiological processing, they do not rule out explanations based on a more global cognitive deficit. In order to examine this issue more directly one can exploit brain imagery techniques during the performance of these abstract and syntactic tasks. In this context, we note that the on-line identification of syntactic structures (e.g., active, passive, relative, etc.) is largely guided by closed class function words (e.g., to, by, the) that thus play a crucial role in allowing a parser to apply syntactic knowledge. ERP studies have demonstrated that grammatical function words evoke a left anterior negativity (LAN) between 400–600 ms (reviewed in Hoen and Dominey, 2000). In a related study, Hoen and Dominey (2000) examined brain potentials associated with the processing of special “function” symbols that trigger one of two possible abstract rules that will apply in a cognitive sequencing task. The objective was to determine if these nonlinguistic function symbols would be processed in the same neural networks as grammatical function words in natural language. In order to examine this process in a nonlinguistic sequencing context, two abstract structure conditions were studied (1) ABC*X*BCA and (2) ABC*Y*DEF. In condition (1) the function symbol "X" indicates that the second triplet will be a systematically transformed version of the first triplet. In condition (2) the function symbol "Y" indicates that the second triplet will have no relation to the first. When brain responses to the function symbols X and Y were compared, a relative left anterior negativity was observed for X vs. Y, with a temporal and topographic scalp localization quite similar to the LAN observed for function word processing (Hoen and Dominey, 2000).

These patient and ERP studies suggest a framework in which grammatical markers, either in the form of distinct function words, or as morphological markers, would indicate the appropriate syntactic frames (abstract structure), while these syntactic frames would be applied to open class words for syntactic comprehension. Interestingly, this framework maps quite naturally onto the dual-process TRN/ARN model for the treatment of serial/temporal and abstract structure. Function words (or their morphological equivalents) are processed in the recurrent network of the TRN, thus defining the syntactic context. Open class nouns are stored in the STM components of the abstract network ARN, and based on the syntactic context, these STM components (and thus the contained nouns) are then linked with their corresponding thematic role and retrieved appropriately. In this configuration, the model is able to learn the mapping between syntactic structure and the corresponding conceptual or thematic structure in order to successfully complete a standard syntactic comprehension task. Although this represents an interesting extension of sequential cognition toward language processing, it is clearly a preliminary first step that leaves much work ahead.

## Discussion

At the outset of this article, it was suggested that behavioral sequences can be considered in terms of their serial, temporal, and abstract structure. A behavioral sequence learning framework was thus established in which serial and temporal structure are represented in a temporal recurrent network (TRN) with recurrent connections implemented in corticocortical connections of the frontal cortex. State activity in the recurrent network is then functionally associated with behavioral responses via modifiable corticostriatal projections. A dissociated abstract recurrent network (ARN) that is required for manipulating abstract structural relations is potentially implemented in a distributed network that includes the perisylvian cortex in and around Broca's area. The proposal that transfer of sequence knowledge to a new domain requires additional, dissociable, processes remains an open debate. Though the approaches are somewhat different, both Dienes et al. (1999) and Dominey et al. (1998) argued that recurrent networks alone could not address this transfer, which requires additional representational capabilities. Indeed, it is likely that both approaches of between-domain mapping and abstract rule representation are neurophysiological realities.

# Short-Term Memory

*Emmanuel Guigon, Etienne Koechlin, and Yves Burnod*

## Introduction

It is generally agreed that two temporally distinct neural processes contribute to the acquisition and expression of brain functions. Transient variations in membrane potential (neuronal activity), on a time scale of milliseconds, reflect the flow of information from neuron to neuron and define the function of neuronal networks. These variations can result in long-lasting (and possibly permanent) alterations in neuronal operations, for instance through activity-dependent changes in synaptic transmission.

There is now strong evidence for a complementary process acting over an intermediate time scale. A wide variety of temporal patterns of activity are actively generated by neurons and local circuits of neurons; an example is the transformation of transient inputs into long-lasting sustained or oscillatory activity. Experimental studies in invertebrates have demonstrated that such temporal patterns produce motor programs and are generated both by the molecular properties of each neuron and by the connectivity of the local network (Harris-Warrick and Marder, 1991; Marder et al., 1996). In vertebrates, long-lasting activities are neural correlates of transient memory processes. These patterns of activity allow past events to be represented and behavioral reactions to future, predictable events to be prepared (see Prefrontal Cortex in Temporal Organization of Action). That these patterns also result from both the intrinsic properties of single neurons and the synaptic interactions between neurons is now well recognized (Llinás, 1988; Marder et al., 1996; Durstewitz, Seamans, and Sejnowski, 2000).

In this article, we discuss cellular and neural network mechanisms that could be involved in the formation of short-term memory (STM) traces in the vertebrate brain. We address three issues: (1) What are the different types of STM traces? (2) How do intrinsic and synaptic mechanisms contribute to the formation of STM traces? (3) How do STM traces translate into long-term memory representations of temporal sequences? We note that we are concerned here neither with exact definitions and properties of psychological concepts nor with detailed biophysical or biochemical mechanisms involved in the characterization of short-term memory processes, but only with computational mechanisms underlying these processes. We also note that these mechanisms may well underlie a wide variety of seemingly different biological processes (e.g., emergence of orientation selectivity in visual cortex, dynamics of head-direction cells in the limbic system, directional tuning in motor cortex) and so may be relevant to understanding brain functions.

## Types of Neural Short-Term Memory Traces

As shown in Figure 1, two broad types of STM traces exist. In the first type (Figure 1*A*), transient inputs are transformed into long-lasting activity patterns. The output traces could represent a membrane potential, a discharge frequency, or any biophysical or biochemical variable (e.g., intracellular calcium concentration). Ideally, the level of maintained activity would be proportional to the intensity of the input stimulus (intensity memory; Figure 1$A_1$), or tuned about a preferred (spatial) stimulus (spatial memory or memory field; Figure 1$A_2$). Spatial and intensity memory mechanisms are relevant to working memory, or the ability to hold relevant information in memory for future utilization in the guidance of behavior. Neural correlates of working memory are found mainly in the anterior regions of the cerebral cortex (e.g., prefrontal cortex) as stimulus-selective sustained neuronal discharges (see Prefrontal Cortex in Temporal Organization of Action). Complete references on the issue of working memory models can be found in Durstewitz et al. (2000).

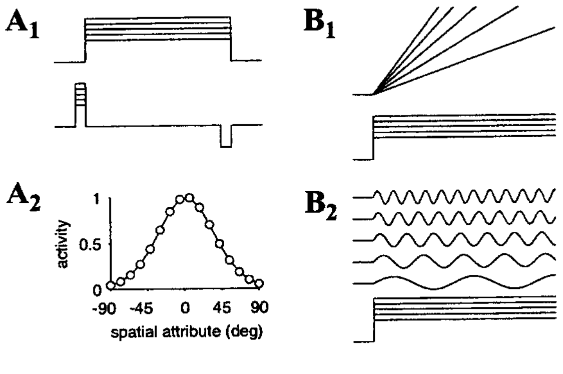

**Figure 1.** Types of STM traces. $A_1$, Intensity memory. Intensity of a transient input (lower trace) is translated into a long-lasting activity (upper trace) of equal (or proportional) amplitude. Five activity traces are shown, corresponding to five input intensities (in the same order). Horizontal time scale and vertical intensity scale are not specified (same as for $B_1$ and $B_2$). $A_2$, Spatial memory. The memorized value of a spatial attribute (here 0°) is represented by a tuned activity distribution in a population of neurons selective to this attribute. $B_1$, Activity ramp. A constant input (lower trace) is translated into a time-varying linearly increasing activity (upper trace). The slope of output activity is proportional to input intensity. $B_2$, A constant input is translated into oscillations (the output traces are shown separately for clarity). Oscillatory frequency is proportional to input intensity.

In the second type of STM trace (Figure 1*B*), constant inputs are transformed into time-varying outputs, such as ramps with different slopes (Figure 1$B_1$) or oscillations at different frequencies (Figure 1$B_2$) or of different amplitudes (not shown). Again, characteristics of the output patterns (slope, frequency, amplitude) should be related to the intensity of the input. Activity ramps are found as correlates of preparatory and anticipatory processes in sensorimotor and cognitive behaviors. They are ubiquitous in cortical parietal and frontal region, and could participate in muscular recruitment, preparation for response, and decision-making processes (Hanes and Schall, 1996). Little attention has been paid to the formation of ramps. Oscillatory activities are mentioned here because they are typical STM traces to which a central role in many behavioral processes has been attributed (see Sleep Oscillations). Cellular and network mechanisms of oscillations are dealt with in the literature (see Oscillatory and Bursting Properties of Neurons) and are not addressed here.

Many other STM traces could be built by combining these two types. Furthermore, in physiological recordings, additional time-varying components would be found in inputs and outputs corresponding to different types of variability in neural processing.

## Cellular and Network Mechanisms of STM Traces

### *Sustained Activity*

The basic mechanism for the formation of maintained activities is a neuron with a recurrent excitatory connection

$$\tau \frac{dI}{dt} = -I + wf(I) + I_{\text{in}} \tag{1}$$

where $I$ is a variable that could represent the total synaptic current, $f(I) = 1/[1 + \exp(s(0.5 - I))]$, the firing rate of the neuron, $w$ is the weight of the recurrent connection, and $I_{\text{in}}$ is the input current. The bifurcation diagram of this equation was plotted with $I_{\text{in}}$ as a parameter (Figure 2*A*). For $I_{\text{in}} < I_1$ and $I_{\text{in}} > I_2$, the equation has a single, stable, fixed point. Elsewhere there are three fixed points: two are close to the minimum and maximum firing rate, respectively, and are stable (lower and upper branches in Figure 2*A*). The third one is unstable (dashed middle branch). Transient inputs elicit transition between the stable states (Figure 2*B*).

This model is illustrative of a general class of neural networks in which persistent states arise from reverberating activity through recurrent excitatory loops (see Computing with Attractors). The main drawback of these models is that the level of maintained activities is close to the neural saturation level, and the resting level is silent (Figure 2*A*), in contradistinction to physiological observations. More realistic persistent activities are found when excitation and inhibition are represented by different neuronal populations (Durstewitz et al., 2000). Furthermore, low- and high-frequency persistent states can coexist when inhibition slightly dominates excitation.

The models just discussed describe neural processing in terms of firing rate or synaptic current, whereas a physiologically realistic representation is defined by equations governing membrane potential (i.e., Hodgkin-Huxley equations and equations for synaptic inputs; see Synaptic Interactions). Thus, an open question is

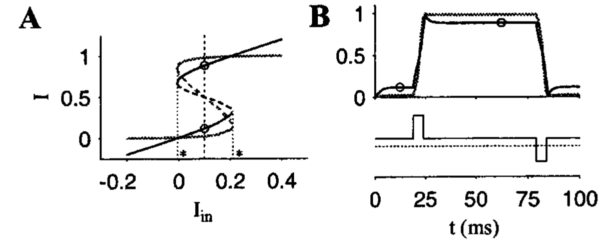

**Figure 2.** *A*, Bifurcation diagram of Equation 1. The plot depicts the value of equilibrium state synaptic currents (black curve) and corresponding firing rates (gray curve). States belonging to plain (dashed) lines are stable (unstable). Vertical dotted lines delimit a region with three equilibrium states and define input currents $I_1$ and $I_2$ (asterisks). *B*, Activity profile (same conventions as in *A*) for $I_{\text{in}} = 0.1$ (vertical dashed line in *A*) and transient excitatory and inhibitory inputs (lower trace). Steady states are indicated by ○. Parameters were $\tau = 2$, $s = 10$, $w = 0.8$.

whether similar properties would be found in a biophysically realistic model of a spiking neuron. Simulations show that the ability of a neural network to maintain robust delay activity at physiological rates (e.g., 15–20 Hz) depends on the nature of synaptic transmission. In fact, the largest component of the synaptic transmission, mediated by AMPA receptors, has a fast decay, which leads to persistent discharges at frequencies above 50 Hz (Wang, 1999). The contribution of slow synaptic transmission through NMDA receptors could help bypass this effect and reduce the frequency of persistent activity to the required level (Wang, 1999). However, it is unknown whether the density of NMDA receptors is large enough to play such a role.

We discussed how maintained activity can result from recurrent interactions within neuronal populations. Alternatively, maintained activity could correspond to the depolarized state of an intrinsically *bistable* neuron (Marder et al., 1996). Intrinsic bistability is characterized by the existence of two or more stable states (e.g., a hyperpolarized state and a more depolarized state in which the neuron discharges), with the transition from one state to the other effected by transient synaptic events (Marder et al., 1996). Numerous examples of bistability have been described in the literature, both in invertebrates (e.g., *Aplysia*, crab stomatogastric ganglion) and in vertebrates (spinal cord, cerebellum, thalamus). The cellular bases of bistability generally involve a low-threshold persistent inward conductance, i.e., a depolarizing conductance that activates in the subthreshold range and does not inactivate (see Ion Channels: Keys to Neuronal Specialization). If the neuron is endowed with a spiking mechanism, the depolarized state corresponds to the discharge of action potentials; otherwise it is a plateau potential.

The models described so far maintained persistent activities in an all-or-none fashion, at a level prescribed by their structure. These observations support the concept of a subset of strongly and uniformly connected neurons representing a discrete attractor (see Cortical Hebbian Modules). In the following paragraphs we show that adequate choice of recurrent synaptic interactions allows memory encoding of continuously valued variables (intensity or spatial memory; see Figure 1*A*).

*Intensity memory* (Figure 1$A_1$) can be addressed in the framework of linear recurrent neural networks, i.e.,

$$\tau \frac{d\boldsymbol{I}}{dt} = -\boldsymbol{I} + \boldsymbol{W}\boldsymbol{I} + \boldsymbol{I}_{\text{in}} \tag{2}$$

where $\boldsymbol{I}$ is the $N$-dimensional vector of output activities and $\boldsymbol{W}$ is a symmetric synaptic matrix. This equation, which is a multidimensional linear generalization of Equation 1, can be solved explicitly for $\boldsymbol{I}$,

$$\boldsymbol{I}(t) = \sum_{i=1}^{N} a_i(t)\mathbf{e}_{\mathbf{i}}$$

where $\{e_i\}$ are the eigenvectors of $\boldsymbol{W}$. Persistent activity appears in the case where one eigenvalue (index $k$) of $\boldsymbol{W}$ is equal to 1 and all the other eigenvalues are smaller than 1. The solution becomes

$$\boldsymbol{I}(t) \approx \frac{\mathbf{e}_{\mathbf{k}}}{\tau} \int_0^t \boldsymbol{I}_{\text{in}}(t') \cdot \mathbf{e}_{\mathbf{k}}\, dt' \tag{3}$$

This equation shows that the network can hold a faithful memory of the amplitude of a transient input. However, this property is lost when the synaptic matrix is even slightly perturbed. This would also be the case in a nonlinear version of this model.

This principle was used in the framework of conductance-based spiking models by Seung et al. (2000) to explore brainstem networks involved in the control of eye position. In this model, brainstem neurons are integrators that convert transient signals driving changes in eye position into a persistent memory of eye position (Figure 3*A*).

The linear recurrent network described by Equation 2 can also generate *spatial memory* profiles. This occurs when (1) each neuron $i$ is identified by a periodic parameter $\theta_i$ (e.g., a preferred direction in $[0; 2\pi]$), (2) the $\{\theta_i\}$ are uniformly distributed in $[0; 2\pi]$, and (3) the synaptic weight between neurons $i$ and $j$ is $W_{ij} = \cos(\theta_i - \theta_j)$. In this case, $\boldsymbol{W}$ has only two non-zero eigenvalues equal to 1, and acts as a filter that suppresses all harmonics $\geq 2$ in the input signal. Thus, the network generates and maintains a cosine distribution of activity from any nonuniform transient input. The constraint on the eigenvalues of $\boldsymbol{W}$ can be relieved in a nonlinear version of Equation 2:

$$\tau \frac{d\boldsymbol{I}}{dt} = -\boldsymbol{I} + \boldsymbol{W}[\boldsymbol{I}]_+ + \boldsymbol{I}_{\text{in}} \tag{4}$$

where $[\ ]_+ ([u]_+ = u$ if $u \geq 0$, otherwise $[u]_+ = 0)$ translates current into firing rate. In this case, a spatially selective activity profile can persist in the presence of a constant background (Figure 3*B*). This behavior appears in the case of strong, spatially modulated excitatory connections and corresponds to the existence of a continuous line of stable states (Hansel and Sompolinsky, 1998).

A realistic implementation of spatial memory was described by Compte et al. (2000). Their network involved (1) excitatory and inhibitory neurons modeled as leaky integrate and fire units (see

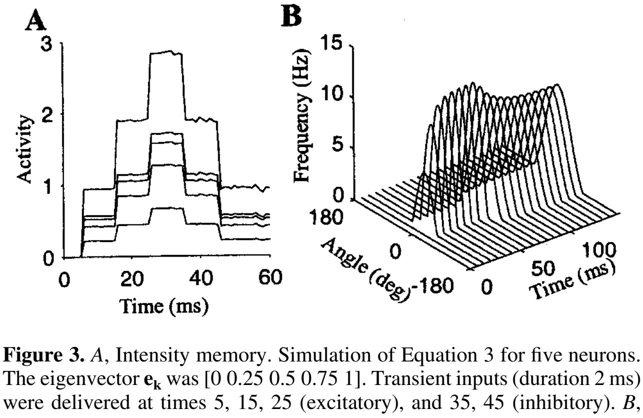

**Figure 3.** *A*, Intensity memory. Simulation of Equation 3 for five neurons. The eigenvector $\mathbf{e}_{\mathbf{k}}$ was [0 0.25 0.5 0.75 1]. Transient inputs (duration 2 ms) were delivered at times 5, 15, 25 (excitatory), and 35, 45 (inhibitory). *B*, Spatial memory. Simulation of Equation 4. Matrix $\boldsymbol{W}$ was made of local Gaussian excitation and global inhibition. A tuned activity profile (width 40°) was presented at time 10 and replaced at time 50 by an untuned profile of the same amplitude.

Single-Cell Models), (2) spatially structured connections between the excitatory neurons, and (3) slow (NMDA) synaptic transmission (Wang, 1999). The model displayed both low spontaneous activity and robust stimulus-evoked selective persistent discharges at physiological frequencies (~20–30 Hz). In the preceding model (Equation 4), spatial pattern formation resulted from a continuous bifurcation. On the other hand, there is genuine network bistability in the present model, which authorizes transition between resting and activated states by transient excitatory inputs. Compte et al. (2000) observed a drift in time of persistent activity patterns in the presence of noise, which resulted in a degraded memory of encoded stimuli. In fact, in all models, the spatial patterns are only marginally stable (Hansel and Sompolinsky, 1998).

An attractive hypothesis would be that both synaptic and intrinsic properties contribute to the formation of persistent activity. Lisman, Fellous, and Wang (1998) proposed that NMDA receptor–mediated bistability could participate in the maintenance of selective working memory activity. Camperi and Wang (1998) used conditional bistability in a continuous attractor network (Equation 4) and showed that it can contribute to the stability of maintained activities against perturbations, although it was not involved in their maintenance per se.

On the whole, these mechanisms provide reasonable clues to how sustained activities can be maintained in neuronal populations. However, several questions remain open: (1) All of the models have built-in instability and require finely tuned synaptic weights to work appropriately. Is this instability a characteristic feature of sustained discharges in the nervous system? How could this instability be removed? Which mechanisms allow the development and maintenance of exact synaptic structures? (2) The models have many features in common and apply to the emergence of orientation selectivity in visual cortex, dynamics of head-direction cells in the limbic system, directional tuning in motor cortex, and persistent activities in prefrontal cortex. Are there definite differences in the neural substrate of these functions? For instance, is the putative role of slow synaptic transmission identified by some models a characteristic feature of prefrontal cortical circuits?

## *Activity Ramp*

When a constant current is injected in a neuron, a time-varying pattern of activity is observed that depends on passive properties of the neuron (membrane time constant) and active membrane characteristics (voltage-gated ionic conductances). The former effect is illustrated by the voltage response of a passive membrane

$$\frac{dV}{dt} = -\frac{V}{\tau} + I$$

for different values of $\tau$ and different $I$. The time to reach a threshold $V_\theta$ is given by

$$T_\theta = -\tau \ln\left(1 - \frac{V_\theta}{\tau I}\right)$$

This relation is strongly nonlinear and shows that neither $I$ nor $\tau$ can efficiently be used to specify a duration. At best it could be used for durations below 50 ms.

The same is approximately true in a Hodgkin-Huxley model (see Axonal Modeling) because the sodium and potassium conductances of the action potential are weakly activated in the subthreshold range. The time to reach a given frequency is not yet an appropriate timing mechanism, because steady-state discharge settles within a few time constants.

At the single neuron level, robust STM properties arise from the presence of a slowly inactivating potassium (Ks) conductance (Marder et al., 1996; Delord et al., 2000). The functioning principle of the Ks conductance is the following. It creates a slowly decaying hyperpolarizing current whose initial level can be specified by prior conditioning of the neuron. For instance, prior hyperpolarization sets a large persistent outward current that slows down the rate of membrane potential changes in the subthreshold range during a subsequent depolarization. Figure 4*A* shows that the latency-to-the-first-spike can be up to 10 s in the presence of a Ks conductance with an inactivation time constant of 2 s, and the relationship between the injected current and the latency is close to linear for a latency of up to approximately 7 s.

The Ks conductance also influences the suprathreshold behavior of the neuron. The discharge frequency gradually increases toward its steady-state level as the Ks current decays (Figure 4*B*). Both the initial and final frequency increase with the level of injected current, which results in a modest change in the slope of the time–frequency curve with the injected current (Figure 4*C*). Recruitment at variable rates, as described in Figure 1$B_1$, can be approached by combining the effect of Ks conductance and synaptic interactions in a population of uniformly connected neurons (Figure 4*B*) (Delord et al., 2000). In this case, because of recurrent excitation, a smaller amount of injected current is required to obtain a given steady-state frequency. Thus the initial frequencies are lower and vary in a smaller range. Accordingly, the slope is more strongly modulated by the injected current than in the absence of synaptic interactions (Figure 4*C*). The strength of this modulation is directly controlled by the strength of synaptic weights (Figure 4*D*). Thus, adaptive recruitment at variable rates is made possible by the simultaneous action of synaptic and intrinsic properties in a neural network. Interestingly, slowly inactivating potassium conductances are found in neurons of most regions of the central nervous system with a time constant ranging from hundreds of milliseconds to several tens of seconds (Llinás, 1988).

Could a similar property be obtained by purely synaptic effects? In fact, the linear recurrent network described by Equation 2 has the required property (Figure 3*A*). The formation of persistent activities begins by a linear ramp with a slope proportional to the amplitude of the input current (Equation 3). However, as mentioned

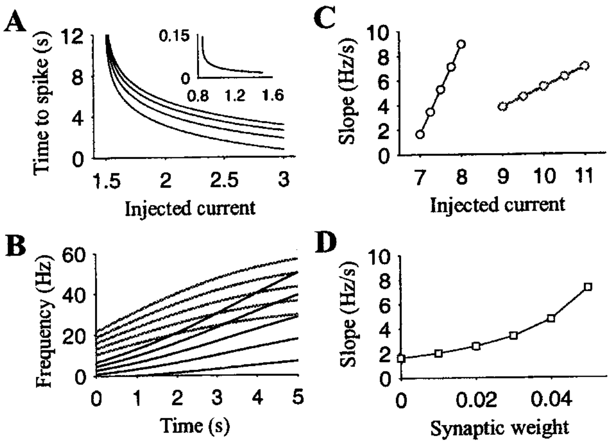

**Figure 4.** *A*, Time to the first spike as a function of the injected current in the presence of a Ks conductance in a Hodgkin-Huxley model. The curves correspond to different initial level of availability of the Ks conductance (maximal for the upper curve). The result in the absence of Ks conductance is shown at upper right. *B*, Time course of frequency increase for different levels of injected current in a recurrent (dark lines) and nonrecurrent (gray lines) network. *C*, Slope of the frequency increase as a function of the injected current (linear regression on the results of *B*). *D*, Slope of the frequency increase as a function of the synaptic weight in the recurrent network. Details on the methods can be found in Delord et al. (2000).

earlier, exactly tuned synaptic weights are necessary to the proper functioning of the network. It is unclear whether the nervous system can reach the required degree of accuracy in the adjustment of synaptic weights (Seung et al., 2000).

## From Short-Term to Long-Term Memory Traces

Synaptic plasticity is a central mechanism in models of learning and memory (see HEBBIAN SYNAPTIC PLASTICITY). The most popular approach involves shaping functions of neural networks by activity-dependent modification of synapses based on Hebbian learning rules. Accordingly, information stored in long-term memory reflects correlation (i.e., temporal contiguity) between transient neuronal activities on a time scale of 0–100 ms. Sutton and Barto (1981) recognized that learning rules based on temporal contiguity are inappropriate to represent temporal dependencies in, for example, the framework of classical conditioning. They proposed that STM traces (synapse-specific and output traces) are involved in the acquisition of new conditioned behaviors. This principle has led to the development of the temporal difference algorithm, which provides a powerful way to learn predictions of future events (see REINFORCEMENT LEARNING). In this framework, STM traces are translated into a long-term representation of the temporal structure of behavior. A related approach applied to the prefrontal cortex is described in Guigon et al. (1995).

## Discussion

STM traces become essential as soon as the time scale of behavior extends beyond the duration of phasic signaling (e.g., ~0–500 ms)—in other words, in almost any behavioral situation. We discussed cellular and network mechanisms involved in the formation of STM traces. We described simplified network models that provide mathematical conditions for the formation and stability of STM traces, and more detailed realistic models with which to assess the biophysical basis of these phenomena.

Despite impressive results, our understanding of these mechanisms is far from complete. First, each neuron is endowed with a wealth of intrinsic properties (Llinás, 1988), very few of which have been considered in models. The respective contribution of synaptic and intrinsic factors is unknown. Second, persistent discharges and ramps constitute a small subset of the rich dynamic repertoire of neural populations observed in vivo, and it is unclear how they can be combined to form more complex memory traces. Third, the great majority of models fail to be robust facing noise and inexact tuning of parameters (e.g., synaptic weights). A future challenge is to relate these pieces of memory to cognitive functions that are very demanding of temporary storage and manipulation of information, such as planning, reasoning, and language use.

# Silicon Neurons

*Rodney Douglas and Christof Rasche*

## Introduction

Silicon neurons are analog electronic circuits fabricated in complementary metal-oxide-silicon (CMOS) using very large-scale integration (VLSI) methods. CMOS is a medium for manufacturing transistors whose conductivity can be altered by an applied electric field. This technology is commonly used to construct the digital circuits found in general-purpose computers, but the silicon neurons discussed in this article are not a kind of digital computer. Instead, the same CMOS VLSI technology is used to construct analog circuits whose physics is analogous to the physics of membrane conductivity. This analogy permits the circuits to emulate the electrophysiological behavior of biological neurons in real time, while the high component density offered by VLSI technology provides a means of fabricating large networks of silicon neurons.

Neuronal systems are difficult to model because they are composed of large numbers of nonlinear elements and have a wide range of time constants. Consequently, their mathematical behavior can rarely be solved analytically. The usual approach is to simulate these problems on a general-purpose digital computer (Koch and Segev, 1998). But for any given computer, the speed of these simulations is limited by the shortest time constant in the problem. Furthermore, the simulation time slows dramatically as the number and coupling of elements increase. By contrast, silicon neurons operate in real time, and the speed of the network is independent of the number of neurons or their coupling. Thus, networks of silicon neurons are especially suited to the investigation of questions that arise from the real-time interaction of the system with its environment. Nevertheless, the design of special-purpose hardware is a significant investment, particularly if it is analog hardware, since analog VLSI (aVLSI) design is still very much an art form.

Analog VLSI has a controversial role in the study of neural computation. This controversy arises out of a debate over the role of precision in computation. Digital computation is guaranteed precise to the number of bits used in the computation. However, the most compact analog circuits have low precision as a result of uncertain calibration between transistors. Some proponents of neuromorphic aVLSI design claim that these circuits provide a natural route for exploring the principles of biological computing, which must also make do with low precision (Mead, 1989). Unlike the ideal components used in conventional computers, real neurons are not homogeneous. Even within a morphological class such as the pyramidal cells of the cerebral cortex, they show a wide range of behavior. They are poorly insulated conductors; they have a variety of nonlinear conductance elements and large amounts of stray capacitance; they are sensitive to environmental changes; and a significant fraction of them malfunction or stop during the operational life of the system. Nevertheless, the smallest vertebrate brain is vastly more competent at interaction with the real world than are our most elaborate supercomputers. From the level of conductances, through synapses to neurons and networks, the nervous system elements obtain precision, speed, and computational power using imperfect elements. Understanding the architectures and adaptive processes that allow the nervous system to extract precise information from a noisy and ambiguous environment with uncalibrated components is a central problem of computational neuroscience (see SYNAPSE TRANSMISSION). Analog VLSI circuits have similar intrinsic variability, and so synthesis of silicon neurons is a method of exploring the principles of computations that must use unreliable components. The philosophy of neuromorphic engineering is that the medium of computation is an intrinsic part of the computation itself.

## Mapping Neurons into CMOS

The strategy for mapping neurons into CMOS varies between research groups, and this article will not review the full range of options that are being explored. Instead, we will focus on a few examples that are representative of the various types. The feature that distinguishes a silicon neuron from an ANN neuron is that it includes a large number of time constants. The silicon neuron's dynamical complexity implies that the input-output relationship of silicon neurons cannot be encapsulated by a single sigmoidal function; instead, a given synaptic input will have a different effect on the output, depending on where and when it is applied.

Conceptually, the neuron can be divided into four parts: the dendrite, which receives inputs; the soma, which translates the inputs to an output; the axon, which distributes the output; and the synapses, which transmit the output to the target neurons. At a more physical level, traditional modelers of biological neurons have divided the continuous neuronal membrane of the dendrites and soma into a series of compartments to facilitate numerical computation (Koch and Segev, 1998) (see DENDRITIC PROCESSING). Each compartment is considered to be isopotential and spatially uniform in its properties. The connectivity of the compartments mirrors the spatial morphology of the modeled cell.

Elias has constructed neuromorphic VLSI neurons with 112 passive compartments that model the leakiness of the cellular membrane and the axial resistance of the intracellular medium using space-efficient switched capacitors to implement resistances (Elias and Northmore, 1999). Each compartment provides passive temporal filtering of the inputs. More recently, we have incorporated circuits that model voltage-dependent conductances into the dendritic compartments (Figure 1*D*). The resolution of the segmentation is a compromise between the questions that must be addressed by the model, the resources required by each compartment, and error tolerance. For example, neurons with between 5 and 30 compartments are a common compromise for digital simulations of cortical and hippocampal circuits (Koch and Segev, 1998).

The simplest electronic somatic model is a single passive compartment that produces a digital spike event when it is charged to a threshold voltage. This integrate-and-fire neuron (see SINGLE-CELL MODELS) has been used for various purposes ranging from sensors to general network simulations. For example, Elias uses an integrate-and-fire model for his dendrites (Elias and Northmore, 1999). Boahen extended a silicon integrate-and-fire neuron to include a spike-frequency adaptation mechanism. This version is used in a neuromorphic retina.

The oscillatory character of neurons is compactly expressed in mathematical models such as the FitzHugh-Nagumo or Morris-Lecar model (see OSCILLATORY AND BURSTING PROPERTIES OF NEURONS). Both models have been implemented (Linares-Barranco et al., 1991; Patel and DeWeerth, 1997) (Figure 1*F*). The latter is used to model the intersegmental coordination of the lamprey.

In addition to the passive properties of the lipid membrane, the biological neuronal membrane contains active ionic channels. In the silicon neurons of Douglas and Mahowald (Mahowald and Douglas, 1991), the compartments are populated by modular subcircuits, each of which emulates a particular ionic conductance (see ION CHANNELS: KEYS TO NEURONAL SPECIALIZATION). The dynamics of these circuits is qualitatively similar to the Hodgkin-Huxley mechanism without implementing their specific equations. The various modules that have been designed and tested so far emulate, for example, the sodium and potassium spike currents, persistent sodium current, various calcium currents, calcium-dependent potassium current, potassium A current, nonspecific leak current, and an exogenous (electrode) current source. The prototypical circuits are modified in various ways to emulate the particular properties of a desired ion conductance. For example, some conductances are sensitive to calcium concentration rather than membrane voltage and require a separate voltage variable representing free calcium concentration. Synaptic conductances (see below) are sensitive to ligand concentrations, and these circuits require a voltage variable representing neurotransmitter concentration. This array of ionic conductances, with their different time constants, gives rise to state-dependent dynamics within the compartments. These circuits can be composed to approximate the electrophysiological behavior of various neurons, for example pyramidal cells (Figure 1*E*). The somatic conductances have been extended to permit the neuron to adapt its discharge sensitivity curve to the statistics of its input current (Shin and Koch, 1999) (Figure 1*G*; see also ACTIVITY-DEPENDENT REGULATION OF NEURONAL CONDUCTANCES).

Even more detailed models have been fabricated by Dupeyron and colleagues. They used Bi-CMOS technology to implement the detailed differential equations of the Hodgkin-Huxley formalism. Their goal is to build a silicon nerve cell that can interact directly and exactly with real neurons investigated during experiments (Dupeyron et al., 1996)

See text for more details.

Biological neurons communicate with one another through axons that ramify widely to make connections with many target neurons. It is impractical to hardwire every network configuration that one might wish to emulate. Instead, the connectivity of an emulator can be made reconfigurable. One approach is to provide direct connections between neurons that can be configured by sets of switches that are under digital control (Van der Spiegel et al., 1994). This approach requires a large silicon area for the switches, but it has the advantage of continuous communication between neurons. It is appropriate when the neuron output is encoded as a continuous analog variable. An alternative approach is to use the high speed of electrical signals in metal wires to multiplex slow neuronal signals.

Action potential representations of neuronal output are compatible with multiplexing because the output of the neuron is active only during the action potential. Furthermore, the action potential is a digital amplitude signal that can be robustly transmitted between chips. Digital amplitude signals are robust to noise and interchip variability and have been used to advantage in VLSI neural networks (Murray and Tarassenko, 1994). Event-based digital data-encoding methods, such as the address-event representation (AER) (Mahowald, 1994), virtual wires (Elias and Northmore, 1999), and that used by Vittoz et al. (Mortara, Vittoz, and Venier, 1995), broadcast action potential events occurring in neurons onto a common data bus. Many silicon neurons can share the same bus because switching times in CMOS and on the bus are much faster than the switching times of neurons. Events generated by silicon neurons can be broadcast and removed from a data bus at frequencies of more than a megahertz. Therefore, more than 1,000 address-events could be transmitted in the time it takes one neuron to complete a single action potential. Multiplexing strategies are most effective if, as in their biological counterparts, only a small fraction of the silicon neurons embedded in a network are active at any time.

Event-based digital encoding methods facilitate network reconfigurability. These digital multiplexing schemes work by placing on the common communications bus the identity (a digital address) of the neuron generating an action potential. In some implementations, the bus broadcasts this source address to all synapses, which decode the addresses (Figure 2*A*). In this way those synapses that should be "connected" to the source neuron detect that it has generated an action potential, and they initiate a synaptic input on the dendrite to which they are attached. In other implementations (Deiss, Douglas, and Whatley, 1999), the so-called address-event is translated from a postsynaptic bus to a presynaptic bus through a programmable lookup table that maps the addresses of source neurons to (lists of) destination synapse addresses. The topology of the network is defined by the mapping of source neurons to

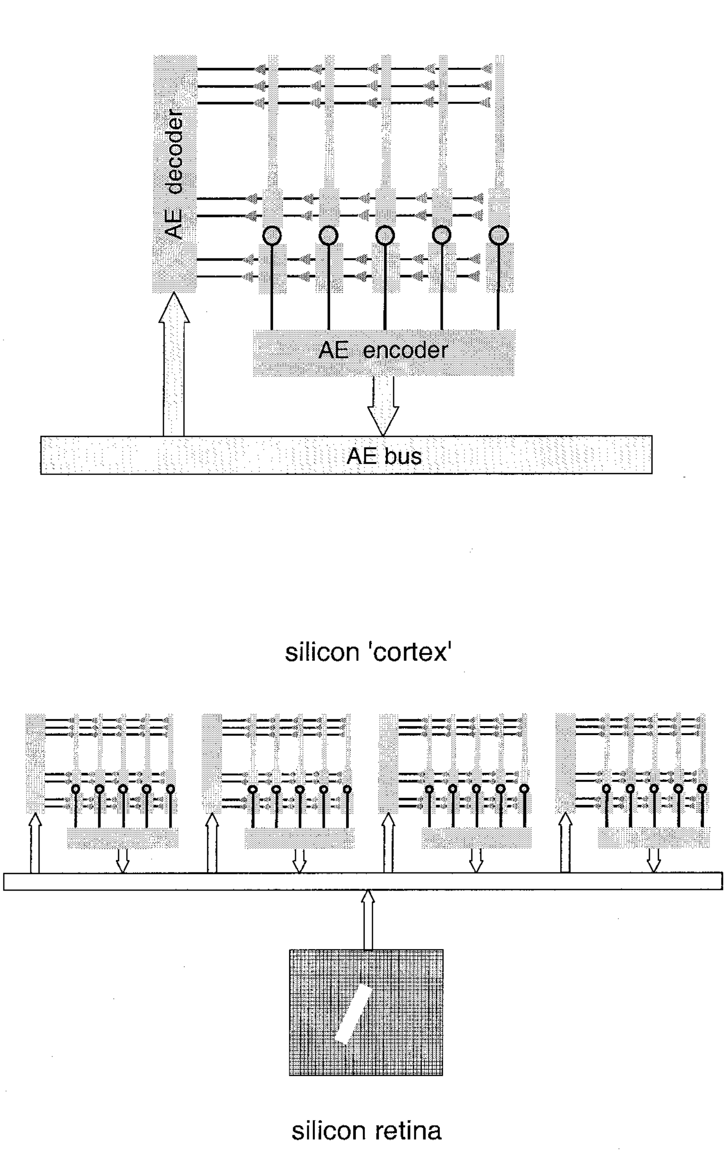

**Figure 2.** Connections between silicon neurons based on address-event representation. This figure shows an implementation in which source addresses are broadcast to all synapses, and the synapses decode the addresses. *A*, Multineuron chip attached to an address-event (AE) bus. Action potentials generated by neurons (gray broomsticks) are detected by an on-chip AE encoder that broadcasts the binary addresses of the source neurons on the AE bus. AE decoders activate the destination synapses "connected" to the source neurons. *B*, A silicon retina sends address-events to a number of multineuron chips communicating over a common AE bus in a manner similar to that implemented in the system described in Deiss, Douglas, and Whatley (1999).

destination synapses as defined by the content of the lookup table.

Synaptic circuits have been developed that approximate AMPA and NMDA (see NMDA Receptors: Synaptic, Cellular, and Network Models) excitatory synapses; and also the potassium-mediated and chloride-mediated (shunting) inhibitory synapses (Douglas and Mahowald, 1995). Synaptic response often depends on the history of its own presynaptic input, on a wide range of time scales. We have developed circuits that emulate the short-time-scale synaptic depression (Figure 1*A*). On longer scales, a spike-based learning synapse has been implemented that modifies its synaptic weight according to the correlation of pre- and postsynaptic spikes (Häfliger and Mahowald, 1999) (Figure 1*B*).

## Working with Analog Silicon

Custom CMOS circuits are created by an iterative process of design, fabrication, and experiment. In the design phase, the correspondence between elements of the analog circuit and those of the neural system are established, and the variable parameters identified. Computer simulations and mathematical analyses of the proposed circuit subunits are useful at this stage. The electronic circuit design is then transposed into a layout design that expresses the circuit as a sandwich of layers in the silicon chip. The layout is drawn with specialized computer-aided design (CAD) software on a workstation or personal computer. The final layout instructions are used by the silicon foundry to fabricate the chip. The MOSIS service at the University of Southern California's Information Sciences Institute (http://www.mosis.org/) accepts layout by electronic mail and returns a fabricated chip in about 10 weeks. Through the MOSIS service, fabrication costs range from approximately $600 for four pieces of a small 2.2 × 2.2 mm 2.0-$\mu$m feature size chip suitable for prototyping a few neurons to $15,000 for 20 pieces of a large 9.4 × 9.7 mm 1.2-$\mu$m feature size chip suitable for fabricating a retina or a network of silicon neurons. The European Union's Europractice initiative offers a similar IC prototyping service (http://www.imec.be/europractice).

It is important to consider the range of desired behaviors when designing the circuits. Within certain limits, the dynamics of the model neurons can be varied parametrically when the neuron is in use. Often, the behavior of analog circuits can be controlled by the voltages applied to the gates of their various transistors. In the Douglas and Mahowald compartmental model neurons, these parameters determine, for example, the temporal dynamics of activation and inactivation, the voltages at which they occur, and the maximum conductance that can be obtained when fully activated. The effect of changing these parameters is immediate. Thus, the electrophysiological "personality" of the silicon neuron can be switched rapidly, for example, from a regular adapting to a bursting pyramidal cell, as in Figure 1*E*. Of course, only the parameters that were incorporated into the design at the time of fabrication are available for reconfiguring the performance of the neuron. If additional properties are required, another silicon neuron with different morphology or different types of channels can be fabricated using variations of the basic circuit modules.

To produce compact circuits, it may be necessary to make approximations in the design of the circuit modules. For example, the analog conductances may saturate, and hence these neurons would not perform as real neurons if they were clamped at voltages very far away from the resting potential. These errors are insignificant when the cell is operating in the physiological range because the linear regions of the circuits are arranged in such a way that the deviation from true neuronal behavior is minimized within that range.

The circuits constituting the neuron must be arranged spatially on the surface of the chips. One possibility is to distribute the dendritic compartments of individual neurons across multiple chips (Van der Spiegel et al., 1994). This approach is useful because the number of compartments, and hence the number of synaptic inputs to a particular neuron, is not limited by the chip boundaries. However, this division requires a method of transmitting accurately between multiple chips the analog voltages and currents at the compartment boundaries. Even if such analog values are accurately conveyed between chips, the values may be misinterpreted because of the interchip variability, the so-called mismatches, inherent in the technology. The alternative approach of Elias is to fabricate entire silicon neurons, and networks of neurons on the same chip. The single-chip solution is appropriate for networks of simple neurons that have only local connectivity mediated by graded synapses, such as the outer layers of the retina (Mahowald, 1994). It is also appropriate for networks of spiking neurons distributed across multiple chips, where only robust, action potential events need be transmitted between chips. However, the number of neurons that can be fabricated on a single chip is limited and depends on the complexity of the neuron. A large development chip has an area of roughly 100 mm$^2$. Using 1.2-$\mu$m fabrication technology, a retinal chip can accommodate a roughly 100 × 100 array of simplified photoreceptors together with horizontal cells, bipolar cells, amacrine cells, and retinal ganglion cells (Boahen, 1999). For more comprehensive neurons and more general connectivity, a reasonable target would be a linear array on the order of 100 neurons, each having up to about 10 dendritic compartments. The number of synapses (on the order of 10 to 100) that can be incorporated depends on the size of the synaptic circuits, which in turn depends on their degree of biological realism. There are ways to improve the number of synaptic inputs. One possibility is to map multiple presynaptic inputs into a single postsynaptic circuit. This strategy can raise the effective number of inputs by an order of magnitude. An additional consideration is that as the technology used to implement aVLSI designs continues to evolve toward smaller feature sizes, further improvements in scale can be expected. Nevertheless, an important focus of work must be the development of more compact synapses. Learning synapses that autonomously modify their stored connection strengths in a Hebbian way are another important element of current work (see, e.g., Häfliger and Mahowald, 1999).

Once the chip has been fabricated, its performance is explored using experimental methods similar to those used in a real neurophysiological preparation, except that many more variables can be observed. For example, the response of the analog chip to stimulation is measured in real time with an oscilloscope. Except for the variable parameters included in the design, the circuits cannot be altered after fabrication, and so errors in the specification of the neuron cannot be corrected as easily as in software simulations. Also, care must be taken to plan experiments before the chip is fabricated so that instrumentation circuitry can be included to observe the state of interesting analog variables. The designs of circuits evolve with understanding gained by experiment.

## Discussion

A number of groups are currently investigating the properties of analog silicon neurons in networks. At the time of this writing, the scale of these networks ranges from tens of neurons to several thousands of neurons. The next 5 years should see increases in the number of neurons implemented in a single system, owing both to an improvement in the basic fabrication technology and to improved implementations. The optimal degree of biological realism is an open question and is likely to be task dependent. Furthermore, the cost of a computational element ultimately depends on the device physics of the computational primitives, so that more effective methods for performing a computation may eventually become available. The most promising path for the development of these networks is interfacing them to sensors and effectors that can interact dynamically with the real world. Analog VLSI is not the only way to build such systems, but it does have some striking advantages. Analog emulation is inherently parallel, the circuits are extremely compact by comparison with a digital circuit performing an equivalent computation, and the power consumption is often a few orders of magnitude less than their digital equivalents. These properties lend themselves to the construction of small, autonomous neuromorphic systems that can interact directly with the world and so provide a platform for studying animal behaviors by emulation.

# Simulated Annealing and Boltzmann Machines

*Emile H. L. Aarts and Jan H. M. Korst*

## Introduction

Simulated annealing was introduced in the 1980s by Kirkpatrick, Gelatt, and Vecchi (1983) and Černý (1985) as a local search approach to handle hard combinatorial optimization problems. The approach is based on randomized techniques that are quite similar to the Monte Carlo methods used in statistical physics. The origin of the method lies in the physical annealing process, which is used to find low-energy states of solids. Since its introduction, simulated annealing has been extensively used in a remarkably broad range of applications, including computer engineering, molecular physics, biology, chemistry, and cognitive engineering. Meanwhile, the approach has established a strong position as a successful optimization tool. In this article, we concentrate on what is known as *basic simulated annealing*, thus discarding the wealth of generalized approaches that have been developed. (The interested reader is referred to Aarts and Korst, 1989, 2001.)

Boltzmann machines were introduced by Hinton and Sejnowski (1983) as a class of artificial neural networks that can be viewed as an extension of discrete Hopfield networks (Hopfield, 1982) in two ways. First, they replace the greedy local search dynamics of Hopfield networks with a randomized local search dynamics. Second, they replace the relatively simple Hebbian learning rule with a more powerful stochastic learning algorithm. Boltzmann machines are randomized neural networks that implement computational features similar to those used in simulated annealing. The resulting neural networks can perform optimization, classification, and learning tasks. Boltzmann machines apply massive parallelism and adaptive adjustment of neural states and interneural connection weights through the self-organization of stochastic computing elements. This class of neural networks is interesting for three reasons. First, it offers a generalized approach to the three basic connectionist issues, i.e., search, representation, and learning (Hinton, 1989). Second, it is supported by a mathematical formalism that facilitates analysis of the network's dynamics and learning properties. Third, it is relatively easy to implement in hardware. Again, we restrict ourselves in this article to a presentation of the basic properties. For a more elaborate treatment we refer to Zwietering and Aarts (1991).

There is a close relation between simulated annealing and Boltzmann machines. Boltzmann machines can be viewed as a massively parallel implementation of simulated annealing, thus offering a means to speed up considerably the slow convergence of sequential simulated annealing implementations. Moreover, simulated annealing is the built-in self-organization technique of a Boltzmann machine, thus providing this class of neural networks with a powerful stochastic learning and retrieval mechanism.

## Simulated Annealing

The use of simulated annealing presupposes the definition of a combinatorial optimization problem and a neighborhood. A *combinatorial optimization problem* is a set of problem instances where each *instance* is a pair $(\mathcal{S}, f)$ with $\mathcal{S}$ the set of feasible solutions and $f : \mathcal{S} \to \mathbb{Z}$ a cost function that assigns a cost value to each solution. The problem is to find a *globally optimal solution*, i.e., an $i^* \in \mathcal{S}$ such that $f(i^*) \leq f(i)$, for all $i \in \mathcal{S}$. Furthermore, $f^* = f(i^*)$ denotes the optimal cost value, and $\mathcal{S}^* = \{i \in \mathcal{S} | f(i) = f^*\}$ denotes the set of optimal solutions. A *neighborhood function* is a mapping $\mathcal{N} : \mathcal{S} \to 2^{\mathcal{S}}$, which defines for each solution $i \in \mathcal{S}$ a set $\mathcal{N}(i) \subseteq \mathcal{S}$ of solutions that are in some sense close to $i$. The set $\mathcal{N}(i)$ is called the *neighborhood* of solution $i$, and each $j \in \mathcal{N}(i)$ is called a *neighbor* of $i$. We shall assume that $i \in \mathcal{N}(i)$ for all $i \in \mathcal{S}$. A solution $\hat{\imath} \in \mathcal{S}$ is *locally optimal (minimal)* with respect to $\mathcal{N}$ if

$$f(\hat{\imath}) \leq f(j) \quad \text{for all } j \in \mathcal{N}(\hat{\imath})$$

The set of locally optimal solutions is denoted by $\hat{\mathcal{S}}$.

Roughly speaking, simulated annealing starts with an initial solution in $\mathcal{S}$ and then continually tries to find better solutions by searching neighborhoods and applying a stochastic acceptance criterion. This is laid out schematically in Figure 1. The procedure INITIALIZE selects a start solution from $\mathcal{S}$, GENERATE selects a solution from the neighborhood of the current solution, and STOP evaluates a stop criterion that determines termination of the algorithm.

Simulated annealing continually selects a neighbor of a current solution and compares the difference in cost between these solutions to a threshold. If the cost difference is within the threshold, the neighbor replaces the current solution. Otherwise, the search continues with the current solution. The sequence $(t_k \mid k = 0, 1, 2, \ldots)$ denotes the thresholds where $t_k$ is used at iteration $k$ of the algorithm and is given by a random variable with expected value $\mathbb{E}(t_k) = c_k \in \mathbb{R}^+$, $k = 0, 1, 2, \ldots$. The thresholds $t_k$ follow a probability distribution function $F_{c_k}$ over $\mathbb{R}^+$. Simulated annealing uses randomized thresholds with values between zero and infinity, and the probability of a threshold $t_k$ being at most $y \in \mathbb{R}^+$ is given by $\mathbb{P}_{c_k}\{t_k \leq y\} = F_{c_k}(y)$. This implies that each neighboring solution can be chosen with a finite probability to replace the current solution.

The basic simulated annealing version of Kirkpatrick et al. (1983) and Černý (1985) takes for $F_{c_k}$ the negative exponential distribution with parameter $1/c_k$. This choice is identical to the following *acceptance criterion*. For any two solutions $i, j \in \mathcal{S}$, the probability of accepting $j$ from $i$ at the $k$th iteration is given by

$$\mathbb{P}_{c_k}\{\text{accept } j\} = \begin{cases} 1 & \text{if } f(j) \leq f(i) \\ \exp\left(\dfrac{f(i) - f(j)}{c_k}\right) & \text{if } f(j) > f(i) \end{cases} \tag{1}$$

The parameter $c_k$ is used in the simulated annealing algorithm as a *control parameter*, and it plays an important role in the convergence of the algorithm. A characteristic feature of simulated annealing is that, besides accepting improvements in cost, it also accepts, to a limited extent, deteriorations in cost. Initially, at large values of $c$, large deteriorations are accepted; as $c$ decreases, only smaller deteriorations are accepted, and finally, as the value of $c$ approaches 0, no deteriorations at all are accepted. Arbitrarily large deteriorations are accepted with positive probability; for these deteriorations, however, the acceptance probability is small.

```
procedure SIMULATED_ANNEALING;
begin
   INITIALIZE ($i_{\text{start}}$);
   $i := i_{start}$;
   $k := 0$;
   repeat
      GENERATE ($j$ from $\mathcal{N}(i)$);
      if $f(j) - f(i) < t_k$ then $i := j$;
      $k := k + 1$;
   until STOP;
end
```

### *The Relation with Physics*

The origin of simulated annealing and the choice of the acceptance criterion can be found in the physical annealing process. In *condensed matter physics, annealing* is a thermal process for obtaining low-energy states of a solid in a *heat bath*. It consists of the following two steps: first, the temperature of the heat bath is increased to a high value, at which the solid melts; second, the temperature is carefully decreased until the particles of the melted solid arrange themselves in the ground state of the solid. In the liquid phase, all particles of the solid arrange themselves randomly. In the ground state, the particles are arranged in a highly structured lattice, and the energy of the system is minimal.

The physical annealing process can be modeled successfully by computer simulation methods based on *Monte Carlo techniques* such as first proposed by Metropolis et al. (1953), who gave a simple algorithm for simulating the evolution of a solid in a heat bath to *thermal equilibrium*. The analogy between the annealing of a physical many-particle system and the application of simulated annealing to a combinatorial optimization problem is obvious: solutions in a combinatorial optimization problem are equivalent to states of the physical system; the cost of a solution is equivalent to the energy of a state, and transitions to neighbors are equivalent to state changes. The control parameter plays the role of the temperature.

### *Asymptotic Convergence*

Simulated annealing can be viewed as a sampling process whose outcomes are neighboring solutions. This class of processes can be mathematically modeled using finite Markov chains. Let $\mathbb{O}$ denote a set of possible outcomes of a sampling process. A *Markov chain* is a sequence of *trials* satisfying the *Markov property*, which states that the probability of the outcome of a given trial depends only on the outcome of the previous trial. In the case of simulated annealing, a trial corresponds to a transition, and the set of outcomes is given by the finite set of solutions.

The convergence of simulated annealing follows from the *stationarity* property of Markov chains and can be formulated as follows. Let $(\mathcal{S}, f)$ be an instance of a combinatorial optimization problem and $\mathcal{N}$ a neighborhood function that is defined in such a way that any two solutions in $\mathcal{S}$ can be reached from each other in a finite number of steps. Then the Markov chain associated with basic simulated annealing has a stationary distribution $q(c)$, whose components denote the probability of finding a solution $i \in \mathcal{S}$ after a large number of trials at control parameter value $c$. The components are given by

$$q_i(c) = \frac{|\mathcal{N}(i)| \exp\,(-f(i)/c)}{\sum_{j \in \mathcal{S}} |\mathcal{N}(j)| \exp\,(-f(j)/c)} \quad \text{for all } i \in \mathcal{S} \tag{2}$$

Furthermore,

$$q_i^* \overset{def}{=} \lim_{c \downarrow 0} q_i(c) = \begin{cases} \dfrac{1}{|\mathcal{S}^*|} & \text{if } i \in \mathcal{S}^* \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

where $\mathcal{S}^*$ denotes the set of optimal solutions.

### Cooling Schedules

The theoretical results just presented imply convergence to optimality after an infinite number of trials. A finite-time implementation of the algorithm, which, as a consequence of the above, can no longer guarantee finding an optimal solution, may result in a much faster execution of the algorithm without giving in too much on the solution quality. A *finite-time* implementation of simulated annealing is obtained by generating a sequence of homogeneous Markov chains of finite length at descending values of the control parameter (Aarts and Korst, 1989). For this, a set of parameters must be specified that governs the convergence of the algorithm. This set of parameters is referred to as a *cooling schedule*. It specifies

- an *initial value* of the control parameter,
- a *decrement function* for lowering the value of the control parameter,
- a *final value* of the control parameter (implicitly), specified by a *stop criterion*, and
- a finite *length* of each homogeneous Markov chain.

Typical cooling schedules in simulated annealing start at sufficiently large initial values of the control parameter, thus allowing acceptance of virtually all proposed transitions. Next, the decrement function and the Markov chain lengths are chosen such that at the end of each individual Markov chain, the probability distribution of the solutions is close to the stationary distribution, which is referred to as *quasi-equilibrium*. Since at large values of $c$, the probability distribution of the solutions equals the stationary distribution by definition (cf. Equation 2), one may expect that the cooling schedule enables the probability distribution to "closely follow" the stationary distributions, so that, as $c \downarrow 0$, the probability distribution is close to $q^*$, the uniform distribution on the set of optimal solutions given by Equation 3. It is intuitively clear that large decrements in $c$ require longer Markov chains in order to restore quasi-equilibrium at the next value of the control parameter. Thus, there is a trade-off between large decrements of the control parameter and small Markov chain lengths. Usually, one chooses small decrements in $c$ to avoid extremely long chains, but alternatively, one could use large values for the Markov chain length in order to be able to make large decrements in $c$.

The search for adequate cooling schedules has been the subject of many studies over the past years. The interested reader is referred to Aarts and Korst (2001).

### Issues from Practice

During its 20 years of existence, simulated annealing has been applied to a large variety of problems, ranging from practical, real-life problems to theoretical test problems. VLSI design, atomic and molecular physics, and picture processing are the three problem areas in which simulated annealing is probably most frequently applied. The set of theoretical test problems includes almost all of the well-known problems in discrete mathematics and operations research, such as coding, graph coloring, graph partitioning, and sequencing and scheduling problems (see Aarts and Lenstra, 1997). General overviews of applications of simulated annealing are given by Aarts and Korst (1989) and Collins, Eglese, and Golden (1988).

Broadly speaking, after 20 years of practical experience, it is widely accepted that simulated annealing can find good solutions for a wide variety of problems, but often at the cost of substantial running times. As a result, the true merits of the algorithm become obvious in industrial problem settings, where running times are of little or no concern. As an example, we mention design problems, since in those cases one is primarily interested in finding high-quality solutions, whereas design time often plays only a minor role. A well-known successful simulated annealing area in this respect is VLSI design.

## Boltzmann Machines

A Boltzmann machine is a neural network consisting of a set $\mathcal{U}$ of two-state neurons that are interconnected by a set $\mathcal{C}$ of weighted symmetric connections. A neuron $u \in \mathcal{U}$ can be in one of two states: either it is firing, corresponding to state 1, or it is not firing, corresponding to state $-0$. A *configuration* $k$ is a $|\mathcal{U}|$-dimensional vector that describes the global state of the neural network. The state of an individual neuron $u$ in configuration $k$ is given by $k(u)$. The set of all configurations is denoted by $\mathcal{R}$. A connection $\{u, v\} \in \mathcal{C}$ is *activated* in a given configuration $k$ if both $u$ and $v$ have state 1, i.e., if $k(u) \cdot k(v) = 1$. The set of connections may contain self-connections whose role is similar to that of thresholds in classical neural networks, i.e., $\{\{u, u\} \mid u \in \mathcal{U}\} \subset \mathcal{C}$. A weight $w_{u,v} \in \mathbb{R}$ is associated with the connection between neurons $u$ and $v$. By definition, $w_{u,v} = w_{v,u}$ for each pair $u, v \in \mathcal{U}$. The weight is a quantitative measure of the *desirability* that $\{u, v\}$ be activated. If $w_{u,v} > 0$, it is desirable that $\{u, v\}$ be activated; if $w_{u,v} < 0$, it is undesirable. Connections with a positive (negative) weight are called *excitatory* (*inhibitory*). The *energy function* $E : \mathcal{R} \to \mathbb{R}$ assigns to each configuration $k$ a real number, called the *energy*, which equals the negated sum of the weights of the activated connections, i.e.,

$$E(k) = -\sum_{\{u,v\}\in\mathcal{C}} w_{u,v}k(u)k(v) \qquad (4)$$

Generally speaking, the energy is low if many excitatory connections are activated and is high if many inhibitory connections are activated. The energy is a global measure indicating to what extent the neurons in the network have reached a consensus about their individual states, subject to the individual weights. Since the weights impose local constraints, these networks are also often called *constraint satisfaction networks* (Hinton and Sejnowski, 1983). The basic idea of implementing local constraints as connection weights in networks dates back to the work of Moussouris (1974).

### Network Dynamics

Self-organization in a Boltzmann machine is achieved by allowing neurons to change their states from 0 to 1 or the reverse. Let the network be in configuration $k$. Then a *state change* of neuron $u$ results in a configuration $l$, with $l(u) = 1 - k(u)$ and $l(v) = k(v)$ for each $v \neq u$. Furthermore, let $\mathcal{C}_u$ denote the set of connections incident with neuron $u$, excluding $\{u, u\}$. Then the *difference in energy* $\Delta E_k(u) = E(l) - E(k)$ induced by a state change of neuron $u$ in configuration $k$ is given by

$$\Delta E_k(u) = (2k(u) - 1)\left(w_{u,u} + \sum_{\{u,v\}\in\mathcal{C}_u} w_{u,v}k(v)\right) \qquad (5)$$

The effect on the energy, resulting from a state change of neuron $u$, is completely determined by the states of its adjacent neurons and the corresponding connection weights. Consequently, each neuron can locally evaluate its state change, since no global calculations are required.

In a Boltzmann machine, the response of an individual state change of neuron $u$ to its adjacent neurons in a configuration $k$ is a stochastic function that is given by

$$\mathbb{P}_c\{\text{accept a state change of neuron } u \mid k\} = \frac{1}{1 + \exp(-\Delta E_k(u)/c)} \quad (6)$$

where $\Delta E_k(u)$ is given by Equation 5 and $c \in \mathbb{R}^+$ again denotes the control parameter.

State changes in a Boltzmann machine are governed by simulated annealing. For the sake of presentation, we distinguish between two models, *sequential Boltzmann machines* and *parallel Boltzmann machines*.

*Sequential Boltzmann machines.* In a sequential Boltzmann machine, neurons may change their states only one at a time. The resulting iterative procedure can be described as a sequence of Markov chains where each chain consists of a sequence of trials and the outcome of a given trial depends probabilistically only on the outcome of the previous trial. A *trial* consists of two steps: given a configuration $k$, first a neighboring configuration $k_u$ is generated, determined by a neuron $u \in \mathcal{U}$ that proposes a state change. Second, whether or not $k_u$ is accepted is evaluated. If it is accepted, the outcome of the trial is $k_u$; otherwise it is $k$. If the probability of accepting a state change is given by the response function of Equation 6, we obtain the following result, which is analogous to the results of Equations 2 and 3. Given a sequential Boltzmann machine with a response function given by Equation 6, then the following two statements hold:

1. The probability $q(c)$ of obtaining a configuration $k$ after a sufficiently large number of trails carried out at a fixed value of $c$ is given by

$$q_k(c) = \frac{\exp(C_k/c)}{\sum_{l \in \mathcal{R}} \exp(C_l/c)} \quad (7)$$

2. For $c \downarrow 0$, Equation 7 reduces to a uniform distribution over the set of configurations with minimum energy.

*Parallel Boltzmann machines.* To model parallelism in a Boltzmann machine, we distinguish between synchronous and asynchronous parallelism. In *synchronous parallelism*, sets of state changes are scheduled in successive trials, where each trial consists of a number of individual state changes. During each trial, a neuron is allowed to propose a state change exactly once. Synchronous parallelism requires a global clocking scheme to control the synchronization. For an extensive treatment of synchronously parallel Boltzmann machines and related work, see Little and Shaw (1978), Peretto (1984), and Zwietering and Aarts (1991). Here, we briefly summarize the most important results. The main result is a conjecture, which states that under certain mild conditions a stationary distribution different from Equation 7 is attained, which converges as $c$ approaches 0 to a distribution over the set of configurations for which the so-called *extended consensus* is maximal, where the extended consensus is a modified energy function. A proof of this conjecture is an open problem. However, for two special cases, correctness can be proved. These are the cases of *limited parallelism*, where neurons may change their states simultaneously only if they are not adjacent, and *full parallelism*, where in each trial all neurons may change their states simultaneously.

In *asynchronous parallelism*, state changes are evaluated concurrently and independently. Units generate state changes and accept or reject them on the basis of information that is not necessarily up to date, since the states of adjacent neurons may have changed in the meantime. Asynchronous parallelism does not require a global clocking scheme, which is of advantage in hardware implementations. However, this type of parallelism cannot be modeled by Markov chains but requires a completely different approach, and so far little progress has been made in this direction. A brief discussion on the subject can be found in Aarts and Korst (1989).

## Combinatorial Optimization and Classification

The ability of a Boltzmann machine to obtain low-energy configurations can be used to handle combinatorial optimization (CO) and classification problems.

*Combinatorial optimization.* A Boltzmann machine can be used to solve CO problems by defining a correspondence between the configurations of the Boltzmann machine and the solutions of the CO problem in such a way that the cost function of the CO problem is transformed into the energy function associated with the Boltzmann machine. In general, this can be done by formulating the CO problem as a 0–1 integer programming problem. The values of the 0–1 variables correspond to the states of the neurons. The cost function and the constraints that go with the CO problem are implemented by choosing the appropriate connections and their weights. In this way, minimizing the energy in the Boltzmann machine is equivalent to solving the corresponding CO problem. More specifically, it is often possible to construct a Boltzmann machine such that the following properties hold:

1. Each locally minimal configuration of the Boltzmann machine corresponds to a feasible solution.
2. The lower the energy of the corresponding configuration, the better the cost of the corresponding feasible solution.

These properties imply that a feasible solution can be obtained and that configurations with near-minimal values of the energy function correspond to near-optimal solutions of the CO problem. This feature enables Boltzmann machines to be used for approximation purposes, as we have demonstrated for several well-known problems, including the traveling salesman problem, graph coloring, and independent set (Aarts and Korst, 1989).

*Classification.* A classification problem can be formalized as a pair $(\mathbb{O}, \mathcal{S})$, where $\mathbb{O}$ denotes a set of *objects* and $\mathcal{S}$ a collection of disjoint subsets $\mathcal{S}_1, \ldots, \mathcal{S}_l$ that partition $\mathbb{O}$. The problem is to determine for a given object $o \in \mathbb{O}$ the subset $\mathcal{S}_j \subset \mathcal{S}$ to which it belongs. In practice, the set of objects is usually very large, and providing an explicit description of each subset is impracticable. The subsets are therefore often implicitly described by specifying a number of "typical" examples for each subset. To use a Boltzmann machine for solving classification problems, the set of neurons is subdivided into three disjoint subsets, $\mathcal{U}_i$, $\mathcal{U}_h$, and $\mathcal{U}_o$, denoting the sets of *input, hidden*, and *output neurons*, respectively. The states of the input neurons are fixed by some *input pattern*. This pattern is a coded representation of an object $o \in \mathbb{O}$ that is to be classified. The remaining neurons then adjust their states to minimize the energy, subject to the fixed states of the input neurons. After minimization of the energy, the states of the output neurons represent the subset $\mathcal{S}_j$ to which $o$ is thought to belong. In this way, a Boltzmann machine can implement a given input-output function.

To implement a given input-output function on the input and output neurons, hidden neurons are usually required in addition. The minimum number of hidden neurons required to solve a given classification problem strongly depends on the intrinsic complexity of the input-output function that is to be implemented (Aarts and Korst, 1989). For classification problems, choosing appropriate connection weights is often difficult, since different items may give rise to conflicting connection weights. However, a Boltzmann machine can often acquire a given input-output function by learning from examples, as shown in the next section.

## *Learning*

Learning in a Boltzmann machine takes place by examples that fix the states of the *environmental neurons*, i.e., the input and output neurons. The hidden neurons are used to construct an internal representation that captures the regularities of the examples fixing the states of the environmental neurons. The learning algorithm we discuss starts by setting all connection weights equal to zero. Next, a sequence of learning cycles is completed, each consisting of two phases. In the first phase, or the *fixed phase*, examples of a given input-output function successively fix the states of the environmental neurons, and for each example the Boltzmann machine is equilibrated using the current set of connection weights. In the second phase, the *free-running phase*, all neurons are free to adjust their state, and again the Boltzmann machine is equilibrated. In both phases, we assume the Boltzmann machine to use limited parallelism. At the end of each learning cycle the connection weights are modified using statistical information obtained from the two phases. This process is continued until the average change, over a number of learning cycles, of the connection weights approaches zero. If the learning is successfully completed, then the Boltzmann machine is able to complete a partial example, i.e., a situation where only a subset of the environmental neurons is fixed, by minimizing the energy. In this way a Boltzmann machine not only can reproduce given examples but also is often capable of classifying correctly objects that in some sense resemble the objects that are used during learning.

*Extension of the network structure.* The set of environmental neurons is denoted by $\mathcal{U}_{io} = \mathcal{U}_i \cup \mathcal{U}_o$. An *environmental configuration l* is determined by the states of the neurons $u \in \mathcal{U}_{io}$. The state of an environmental neuron $u$ in an environmental configuration $l$ is denoted by $q_l(u)$. $\mathcal{Q}$ denotes the set of all environmental configurations. With each environmental configuration $l$, a subspace $\mathcal{Q}_l$ can be associated given by

$$\mathcal{Q}_l = \{k \in \mathcal{R} \mid \forall u \in \mathcal{U}_{io} : r_k(u) = q_l(u)\}$$

which consists of all configurations for which the states of the environmental neurons are given by $l$.

The *learning set* $\mathcal{T}$ consists of the environmental configurations that can be used to fix the environmental neurons during learning. Clearly, $\mathcal{T} \subseteq \mathcal{Q}$.

*Toward a learning algorithm.* Here we discuss the basic elements of the Boltzmann machine learning algorithm proposed by Ackley, Hinton, and Sejnowski (1985). The objective of the learning algorithm is to modify the connection weights such that a Boltzmann machine in a free-running phase tends, with a large probability, to be in those environmental configurations that belong to the learning set. To this end we introduce two probability distributions, $d$ and $d'$, defined over the set of environmental configurations. $d_l$ is the probability of obtaining an environmental configuration $l$ in a fixed phase. $d'_l$ is the probability of obtaining an environmental configuration $l$ in a free-running phase. The probability distribution $d$ is determined by the environmental configurations in the learning set and by the frequency at which they are used to fix the environmental neurons. $d_l$ is large if $l$ belongs to the learning set, and $l$ is frequently used to fix the environmental neurons. The probability distribution $d'$ depends on the connection weights and, as is pointed out below, $d'$ can be defined by using the stationary distribution of Equation 7. The objective of the learning algorithm can be formulated as follows: *modify the connection weights of the Boltzmann machine such that $d'$ is close to $d$.* If $d \approx d'$, then the Boltzmann machine can determine for a given input the corresponding output. More generally, if a subset of the environmental neurons is fixed, then the Boltzmann machine can determine the most probable corresponding environmental configuration.

An information-theoretic measure of the distance between the two probability distributions $d$ and $d'$ is the divergence $G$ (Kullback, 1959), given by

$$G = \sum_{l \in \mathcal{Q}} d_l \ln \frac{d_l}{d'_l} \tag{8}$$

It can be shown that $G = 0$ if and only if $d_l = d'_l$ for all $l \in \mathcal{Q}$, and $G > 0$ otherwise. For further properties of $G$, we refer to Aarts and Korst (1989). The objective of the learning algorithm can be rephrased as: *minimize G by modifying the connection weights*.

Before we describe how $G$ is minimized, we re-address the network dynamics. Using Equation 7, we know that after equilibration in a free-running phase, the Boltzmann machine tends to be in low-energy configurations. If equilibrium is achieved, $d'_l$ is given by

$$d'_l(c) = \sum_{k \in \mathcal{Q}_l} q_k(c)$$

where $q_k(c)$ are the components of the stationary distribution given by Equation 7. The partial derivative of $G$ with respect to $w_{u,v}$ can be written as

$$\frac{\partial G}{\partial w_{u,v}} = \frac{p'_{u,v} - p_{u,v}}{c} \tag{9}$$

where $p_{u,v}$ and $p'_{u,v}$ denote the probabilities of connection $\{u, v\}$ being activated at equilibrium in the fixed and the free-running phases, respectively (see, e.g., Aarts and Korst, 1989). To minimize $G$, it suffices to collect statistics on $p_{u,v}$ and $p'_{u,v}$, and to iteratively change the connection weight proportionally to the difference between the probabilities, i.e.,

$$w_{u,v} := w_{u,v} + \eta(p'_{u,v} - p_{u,v}) \tag{10}$$

where $\eta \in \mathbb{R}^+$ is called the *learning parameter*.

Informally speaking, the learning algorithm consists of the following steps:

1. Set all connection weights to zero.
2. Complete a number of learning cycles, until $d \approx d'$, where each learning cycle consists of the following steps:
   a. Fixed phase: use a number of examples to fix the environmental neurons, equilibrate for each example, and collect statistics on $p_{u,v}$.
   b. Free-running phase: equilibrate and collect statistics on $p'_{u,v}$.
   c. Modify connection weights.

By definition, environmental configurations $l$ not included in the learning set $\mathcal{T}$ have a corresponding probability $d_l = 0$. Consequently, $G$ is not properly defined for these environmental configurations unless $d'_l = 0$, which can only be realized by infinitely large connection weights, owing to the stochastic nature of the Boltzmann machine optimization. To avoid this problem, a *noise ratio* is introduced that allows the environmental neurons in the fixed phase to change their states with a certain probability. Furthermore, the use of noise suppresses the unlimited growth of connection weights. This was found to be essential for obtaining good results.

The average case performance and time complexity of the learning algorithm depend on the following issues:

1. The parameters of the learning algorithm, viz., the cooling schedule, the learning parameter, noise ratio, and the number of examples per cycle.

2. The ratio between the environmental and the hidden neurons.
3. The way the neurons are connected.
4. The intrinsic difficulty of a given classification problem.

Many studies in the literature have considered the influence of these issues on the performance of the learning algorithm. Most of these studies were based on experimental evaluations. The overall conclusion is that learning in a Boltzmann machine is rather slow. This is essentially due to the time needed to equilibrate and collect statistics. Several approaches that might speed up the learning algorithm have been proposed, including hardware acceleration, multivalued neurons, and higher-order choices for the energy function. For further reading refer to Aarts and Korst (1989).

# Single-Cell Models

*Christof Koch, Chun-Hui Mo, and William Softky*

Most of the roughly ten billion neurons in the human cerebral cortex are tiny, membrane-bound bags of saltwater, shaped like trees (including roots). Each is surrounded by more salt water and by other neurons, many of which it is connected to. The vast majority of them communicate by means of brief, all-or-none pulses (called spikes, or action potentials), each lasting a bit less than a millisecond.

Researchers often want to distill the complex shape and behavior of a real neuron into a simpler model, either to guide a neurobiological experiment or to construct a functional network. But choosing which neuronal properties to keep and which to ignore is heavily influenced by how one interprets the pulses. In particular, it is common to reduce the train of action potentials issued by a neuron with an equivalent point process, but beyond that much is in dispute.

Most theories assume that information is carried in the average rate of pulses over a time much longer than a typical pulse-width, so that the occurrence times of particular pulses simply represent jitter in an averaged analog signal. A neural model in such a theory might be a mathematical function that produces a real-valued output from its many real-valued inputs; that function could be linear or nonlinear, static or adaptive, and might be instantiated in analog silicon circuits or in digital software.

However, a few theories assume that each single neural pulse carries reliable, precisely timed information. A neural model in such a theory fires only on the exact coincidence of several input pulses, and quickly "forgets" when it last fired, so that it is always ready to fire on another coincidence. Whether real neurons operate in this regime or in the slower average-rate regime awaits further neurobiological experiment. Both types of codes and single-neuron models have special features and advantages; understanding the models touches issues of bandwidth, nonlinearity, and the fundamental precision and function of single nerve cells. Of course, it is well possible that the nervous system uses both, depending on place, time, and circumstance.

## Formal Models

It is easiest to understand and analyze the models that are the least like real neurons. Virtually all such models share two features in common. First, each model neuron combines many inputs, both "excitatory" and "inhibitory," into a single output. And each neuron has at least one internal state variable (conceptually corresponding to the cell's average membrane potential), which increases monotonically with the total amount of excitatory input and decreases with inhibitory input. Thus, the neuron is constrained to "adding up" (in a rough sense) its positive and negative inputs, and *cannot* independently assign an arbitrary value to each of its possible input combinations.

### *McCulloch-Pitts Model*

The McCulloch-Pitts model neuron (see Koch, 1999, for details), more than fifty years old, has many progeny present in digital circuits, in the form of logic gates. The explicit assumptions of this model are that each binary "pulse" represents a logical statement (i.e., *true* or *false*), and that each neuron performs an exact, noise-free, synchronous computation on its input pulses.

If any one of the model neuron's inhibitory inputs is active, the output is shut off, or inactive. Otherwise, all the active excitatory inputs $x_i$ are multiplied by their *synaptic weights* $w_i$ and then added up. However, only if this activity level exceeds a preset *threshold* $\theta$ is the output active:

$$Y = \begin{cases} 1 & \text{if } \sum_i w_i x_i > \theta \text{ and no inhibition} \\ 0 & \text{otherwise} \end{cases} \tag{1}$$

McCulloch and Pitts showed that a large enough number of such units, with weights and connections set properly and operating synchronously, could in principle perform any possible computation (Arbib, 1987).

An even simpler model is the *linear* neuron, which simply adds up its inputs and delivers the sum as output, with no thresholds or other nonlinearities. The neuron's real-valued output is the sum of its inputs $x_i$, weighted by real-valued coefficients $w_i$:

$$Y = \sum_i w_i x_i \tag{2}$$

Networks of linear neurons can be treated analytically, using well-established matrix methods. Unlike the spikes and rates from real neurons, outputs from the linear model can become negative or arbitrarily large.

### Perceptron Model

Rosenblatt's Perceptron model (see Koch, 1999, for details) is formally similar to the McCulloch-Pitts model, having synchronous inputs and producing outputs between zero and one. But the perceptron creates a real-valued (not binary) output, representing the *average firing rate* of the cell. As with the linear model, the internal variable $V$ of a perceptron is the weighted sum of its inputs:

$$V = \sum_i w_i x_i \tag{3}$$

A *threshold* or *bias* $\theta$ is subtracted from $V$ and is then passed through a continuous and monotonically increasing function $g$:

$$Y = g(V - \theta) \tag{4}$$

The nonlinear function $g$ is *sigmoidal*: it asymptotes zero as $V \ll \theta$ and saturates at 1 for $V \gg \theta$ (Figure 1*C*). This function mimics the empirical relationship between the cell's input current and its firing rate in several ways: the output is non-negative, it is very small below $\theta$, it monotonically increases with input, and the firing rate has an upper bound.

### Hopfield Neurons

In Hopfield's binary model (see Koch, 1999, for details), the output of neuron $i$ is the step function of $V_i$ and the threshold $\theta$,

$$Y_i = \begin{cases} 0 & \text{if } V_i < \theta \\ 1 & \text{if } V_i > \theta \end{cases} \tag{5}$$

Unlike the McCulloch-Pitts or the Perceptron model, each Hopfield neuron updates its state at a *random* time, independently of any other neurons.

Both Hopfield's binary and continuous-valued models (Figure 1*C*) are similar to perceptrons in isolation, but can act as associative memories in highly interconnected networks.

### Polynomial Neurons

The appeal of models like those discussed previously is that only a very simple function of the inputs—a weighted sum—is neces-

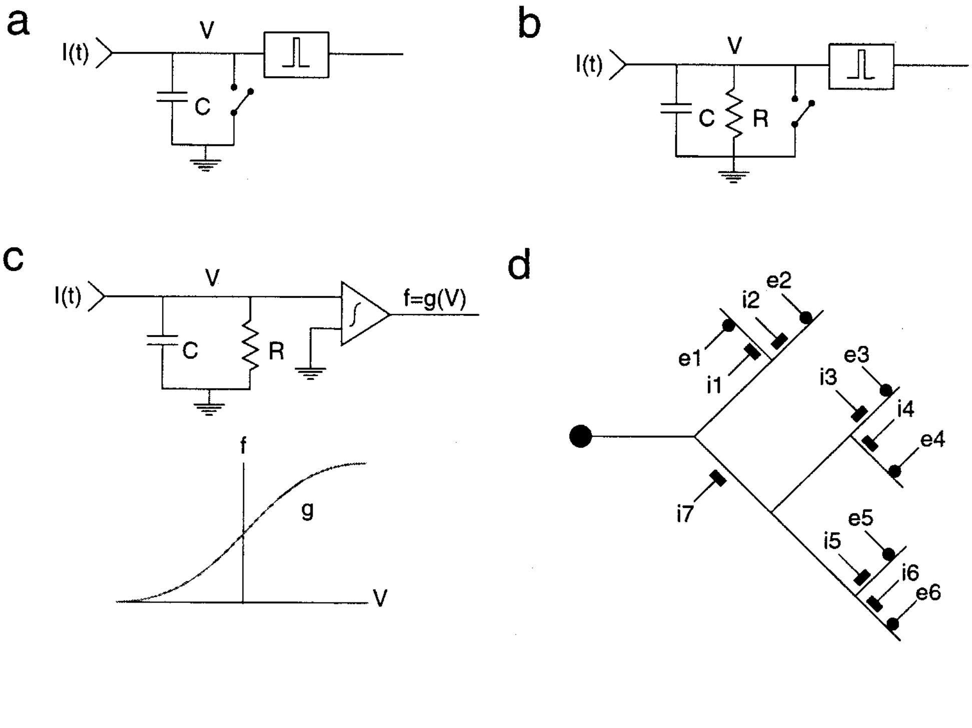

**Figure 1.** Simple neuronal models expressed in the commonly used electrical circuit idiom. In (*A–C*), the entire neuron is reduced to a single spatial compartment (point-model). The summed synaptic input is described by a net current $I(t)$. *A*, An integrate-and-fire unit. If the voltage $V$ exceeds a fixed threshold, a unit pulse is generated, and all charge on the capacitance is removed by resetting $V$ to zero. The output of this and the leaky integrate-and-fire model (*B*, in which charge leaks away with a time constant given by the product of the capacitance $C$ and resistance $R$) is a series of asynchronous spikes (*C*). In a rate neuron, these discrete pulses are replaced by a continuous output rate whose amplitude is proportional to the inverse of the average interspike interval. The monotonically increasing relationship between $V$ and the output rate $f = g(v)$ can be thought of as the discharge function of a population of spiking cells. *D*, Nonlinear, saturating interactions can be mediated in a passive dendritic tree by synapses that increase the postsynaptic conductance. The interaction between excitation (circles) and inhibition of the shunting type (elongated boxes) is of the AND-NOT type and is specific in space and in time. For instance, the inhibitory synapse $i_7$ vetos excitation $e_3$ or $e_6$ but has only a negligible effect on $e_1$. (Modified from Koch and Segev, 2000).

sary for them to work. However, such a sum cannot distinguish among the individual contributions to it. For the neuron to respond strongly to correlations among particular input pairs or groups, one must include multiplicative terms, and then sum over the products. Such a *sigma-pi* ($\Sigma$ = sum, $\Pi$ = product) neuron computes its internal state as the sum of contributions from a set of monomials

$$V = a_1 + b_1 x_1 + b_2 x_2 + c_1 x_1^2 + c_2 x_1 x_2 + \cdots \quad (6)$$

This state variable can then be passed through the usual nonlinear function $g$. It is clear that such "neurons" are computationally richer than linear or threshold units—just one can implement parity, exclusive-or, or *lookup table* functions. Furthermore, such models also better represent the operations of real neurons containing highly branched dendrites with voltage-dependent membrane conductances (Mel, 1994).

## Biophysical Models

Although many crucial properties of real neurons remain unknown, biophysical models incorporate some known properties of neural tissue. Like real, spiking neurons, these models produce spikes rather than continuous-valued outputs.

### *Integrate-and-Fire Models*

This family of single-cell models, about a century old, divides the membrane behavior conceptually into two distinct and discontinuous regimes: a prolonged period of linear "integration" (adding up of inputs), and a sudden "firing" (Figure 1*A* and *B*). The "integrate-and-fire" model relaxes the requirement that a single set of continuous differential equations describe the cell's two very different regimes. The cell voltage starts from zero, rising or lowering according to the synaptic input. When the voltage reaches a certain threshold $\theta$, the cell instantly fires an output pulse and resets the voltage. After a refractory period—a brief "dead time" during which the cell cannot fire at all—the unit is ready to fire again.

The simplest type of integrator model is a leak-free capacitance (Figure 1*A*). With steady, DC input current, it acts like a relaxation oscillator or a current-to-frequency converter, producing regular output pulses at a rate depending on the input current.

If the input instead arrives in brief excitatory pulses (e.g., spikes from other cells), so that $N$ pulses are necessary to reach threshold, then this model acts like a divide-by-$N$ counter, firing on every $N$th input pulse. Its output rate depends on the *average* of the overall firing rate of the inputs. For small, random input pulses, the output firing will be fairly regular as the input randomness is averaged out. The fact that such a neuron can smooth out input noise is one of its great advantages.

The addition of a leak resistance in parallel to the capacitance makes a *leaky integrate-and-fire neuron,* which will only fire if the excitatory input is strong enough to overcome the leak (Figure 1*B*). The time constant $\tau = RC$ divides the model's operation into two qualitatively distinct regimes: temporal integration and fluctuation-detection. When $\tau$ is larger than the mean time between output spikes, the leak is insignificant and the model temporally integrates its input (Figure 2). When $\tau$ is much smaller than the average output interval, then production of a spike depends not on the *average* input but on input *fluctuations*: only a rare fluctuation will bring the voltage above threshold. Here, the output represents a precisely timed threshold-crossing computation with a binary output—in this regime the neuron is neither linear nor analog.

Integrate-and-fire models can account for remarkable many aspects of the behavior of real neurons (Koch, 1999).

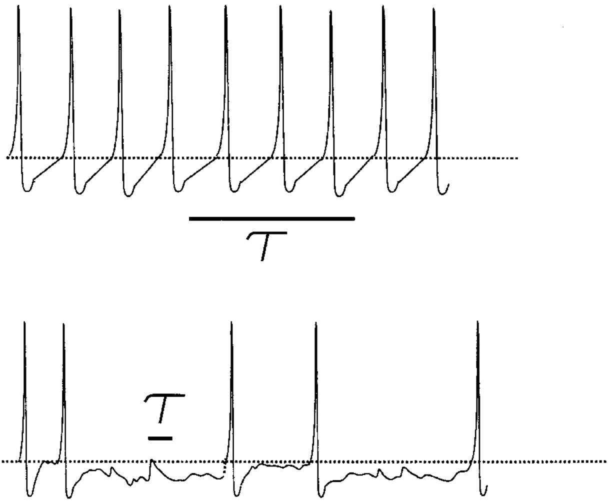

**Figure 2.** A schematic of the two distinct operating regimes of an integrate-and-fire model. The top trace shows how current input ramps up the neuron's internal "voltage" to produce regular spikes. The input current determines the *average slope* of the voltage between spikes. This can only occur if the interval between spikes is less than the neuron's time constant, so that the spiking frequency reliably reflects the average input current. A strikingly different situation is shown in the lower trace, where a relatively shorter time constant causes the neuron to *forget* when its last spike occurred. Now the input current determines the *average voltage* between spikes, which is nearly constant and below spiking threshold. Here a spike is only generated by a brief fluctuation so that each spike can be interpreted as the distinct binary output of a fast, multiplicative computation, reporting the precise coincidence of several contributing inputs.

### *The Hodgkin-Huxley Model of Squid Axon*

Biophysically much more accurate single-cell models that can account for the very complex, nonstationary behavior of real neurons are lumped under the catch-all name of Hodgkin-Huxley models, since they use a mathematical formalism little different from that set out fifty years ago in the ground-breaking work of Hodgkin and Huxley (1952) on the electrodynamics of the squid axon. The dynamics are modeled by numerous coupled, nonlinear differential equations that describe the behavior of continuous currents that depend in a nonlinear manner on the membrane potential.

In its quiescent state, the inside of a typical neuron has a negative voltage (relative to the extracellular fluid). The cell membrane acts like a capacitor. The electrical charge carriers (various species of ions such as $Na^+$, $K^+$, $Cl^-$, and $Ca^{2+}$) pass through special pores or *ionic channels* embedded in the membrane (Hille, 1992). Although each individual channel is either open or closed (in a partially stochastic manner), the current through many channels in parallel is well approximated by continuous, deterministic equations, much as the laws of electrical current describe averages over many electrons. That is, the continuous, macroscopic, and deterministic membrane currents derive from binary, microscopic, and stochastic ionic channels.

In the simplest case, the channels' collective behavior resembles an ohmic (or passive) resistor across the membrane. The combination of the resistance and the capacitance creates a membrane time-constant $\tau$, which is typically between 5 and 50 ms.

Other ion channels are nonlinear: their conductance *depends on* voltage. For instance, an action potential occurs when the membrane potential becomes depolarized enough that voltage-controlled sodium channels open, initiating the fast positive-feedback event of a spike. One spike lasts between one-half and one milliseconds, and is followed by a few milliseconds of *refractory period* during which it is difficult or impossible to fire another spike.

This process was described by Hodgkin and Huxley in 1952 in one of the most successful of all models in neurobiology: a four-dimensional set of coupled, nonlinear, partial differential equations. Those equations describe the initiation and propagation of action potentials in axons well enough that they are often treated as "gospel truth," although they are technically imperfect phenomenological fits rather than expressions derived from first principles.

Simplified versions—the so-called *FitzHugh-Nagumo* and van der Pol oscillator equations (see Koch, 1999, for details)—yield qualitatively the same kind of subthreshold behavior and limit-cycle oscillations as the original Hodgkin-Huxley equations, but their reduced parameters are more difficult to be interpreted biophysically.

Although the Hodgkin-Huxley methodology is powerful, it suffers from the drawback that it requires detailed knowledge of a myriad of parameters. It is frequently difficult to properly constrain all of these degrees of freedom.

## *Modified Single-Point Models*

More realistic neural models must account for Nature's rich array of nonlinear currents and additional internal variables, only some of which are understood.

*Internal Variables.* Most of the simple models outlined previously have only a single internal variable: the membrane potential. An additional variable, such as the concentration of free, intracellular calcium, can give a wider array of functions. Calcium concentration roughly represents a running average of the cell's recent activity. This temporal averaging—along with the ability of calcium ions to remain trapped near synapses—makes it a candidate for modulating synaptic strength. Calcium also participates in "adaptation," a hysteresis effect in which the calcium accumulated from past spikes makes it more difficult to fire new ones.

*Additional Ionic Currents.* Most neurons typically contain a dozen or more *nonlinear* ion channels, whose conductance depend on the cell voltage. There are slow positive feedback currents, such as calcium and persistent sodium currents, which tend to amplify large voltage excursions. There are also negative-feedback currents like those found for potassium, which tend to hyperpolarize the cell, acting like a kind of active inhibition or adaptation. These "active" currents can strongly influence a cell's response to input, its input, but their strengths in real cells are often unknown. For a discussion of the computational significance of all of these, see Koch (1999).

## *Compartmental Models*

The *single-point* models discussed previously assume that neurons do not have any significant spatial extent. However, most real neurons have intricate dendritic trees (where the synaptic input arrives), as well as an axon and its branches (where the output spike is carried away). The unique shapes of those dendrites and axons can distinguish between various cell classes.

Axons are usually thought of as delay lines without any significant information processing ability (see AXONAL MODELING). Dendrites, however, display a much richer repertoire of information processing operations. The simplest "passive" dendrite model, pioneered by Rall (1989), is a single capacitive, resistive cable. Its voltage is characterized by the *cable equation,* which has two main parameters: $\tau$ is the membrane time constant, and $\lambda$ the electronic space constant, is a characteristic distance over which a steady-state voltage attenuates. Signals always attenuate and temporally smooth as they spread from their sources in such a dendritic cable (Rall, 1989). For a review of compartmental methods, see the handbook by Koch and Segev (1998).

Because dendrites with branches are not as easily analyzed, modelers resort to discretizing the cable equation (like decomposing the dendritic tree into hundreds of simple electrical compartments connected by Ohmic resistors, as in Figure 3. Note the right branches of the dendritic tree contain arbitrary active membrane component.).

## *Computation with Passive Dendrites*

*Low-pass filtering.* As predicted by linear cable theory, one important computational function that passive dendrites can perform is low-pass filtering. This operation removes high temporal frequencies from voltage response to input signal and generates voltage attenuation and temporal delay.

*Synaptic Saturation.* Real synapses—whether slow or fast, inhibitory or excitatory, passive or voltage gated—are best modeled as *conductance* in the cell membrane in series with driving potentials. Synaptic input is not a constant current or voltage source, but rather changes the electronic properties of postsynaptic membrane. Postsynaptic potential (PSP) saturates when synaptic input becomes stronger. As a result, the PSP for two synaptic inputs arriving together is usually smaller than the sum of PSPs of two independent input. When many synapses are simultaneously active, their increased conductance further attenuates distant input (by reducing $\lambda$) and makes the cell sensitive to fluctuations at a faster timescale (by reducing $\tau$).

*Shunting Inhibition.* If the driving potential of the inhibitory synapse is close to the resting potential of the cell, it is called *shunting inhibition*. Such an inhibition can veto excitation locally *only* if the inhibition lies on the path between the location of the excitatory synapse and the cell body. Shunting inhibition enables local nonlinear computation at the dendrite level and endows single neurons with more powerful computational abilities (Figure 1*D*).

## *Computation with Active Dendrites*

Experiments have revealed that dendrites contain not only passive membranes but also nonlinear "active" ones (Stuart, Spruston, and Häusser, 1999). These active membranes have voltage-dependent sodium, calcium, or potassium channels that readily perform local nonlinear computation (Figure 3). Given these active channels, action potential can backpropagate to remote dendrites from soma, providing a communication mechanism between soma and dendrites. Such a mechanism can be critical to the Hebbian learning rule-based synaptic plasticity.

*Synaptic Input Amplification.* Input impedances at distal arbors are usually higher than those of proximal large dendrites. Therefore, distal inputs generate higher local excitatory postsynaptic potential (EPSP), which will be amplified more by local active channels. This amplification can offset the attenuation along the cable so that synapses near and far from the cell body are equally effective. Recent evidence (Magee and Cook, 2000) shows synaptic conductance changes increasing as one moves along the apical dendrite away from the soma in CA1 pyramidal neurons. Such a progressive increase in conductance seems to be the mechanism rendering EPSP size insensitive to input location.

*Coincidence Detection.* Biophysically plausible proposals for coincidence detection exploit fast sodium action potential generation in spines and distal basal dendrites to achieve sub-millisecond res-

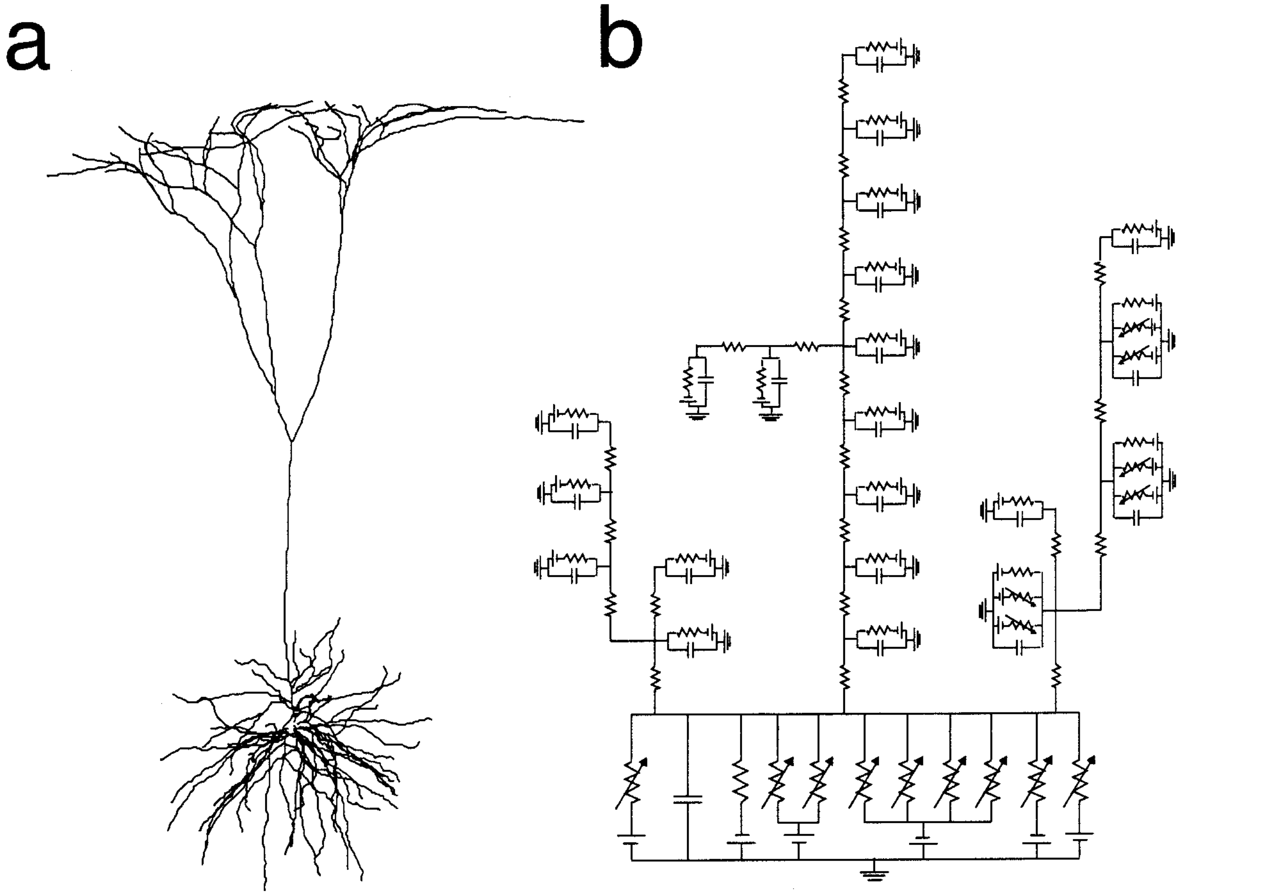

**Figure 3.** The most realistic form of single-neuron model numerically simulates the electrical properties of a branched cell membrane. First, the observed shape of the cell (*A*) is approximated by a collection of connected cylinders of the appropriate length and diameter. Then, each cylinder is simulated as a single electrical unit composed of an axial resistance and membrane capacitances and resistances (*B*). Although it is computationally intensive, this numerical approach can treat the whole variety of cell shapes and nonlinear electrical properties, which are ignored by the traditional single-compartment models. Here the right branches of the dendritic tree contains voltage-dependent membrane conductance.

olution (Softky, 1994). Sakmann's group (Larkum, Zhu, and Sakmann, 1999) demonstrated dendritic coincidence detection at the 10 ms level in layer V pyramidal neurons. If an excitatory input at dendrites coincides with somatic-triggered backpropagation action potential, a powerful calcium spike may be triggered at the dendrite level. This long-lasting (10 ms or longer) calcium spike in turn triggers a burst of sodium potential at the soma.

*Multiplication Operation.* Multiplication is one of the simplest but most important nonlinear operations that serve as the basis for many computation models, such as those for optomotor response of insects and motion perception in primates. Nonlinear interaction by voltage-dependent channels at dendrites might provide a mechanism to implement multiplication.

*Synaptic Clustering.* The distribution of synapse on active dendrites can be very important because spatially close, simultaneous synaptic inputs will be amplified more by active channels. The difference in amplification is large enough to generate orientation selectivity in V1 cell models (Mel, Ruderman, and Archie, 1998).

## Discussion

After several decades of research, we understand only some of the most fundamental functions of nerve cells.

### *Learning*

The most remarkable feature of the nervous system is its ability to change its internal structure in response to previous input—that is, to learn. Theoretical aspects of learning are covered elsewhere (see the three road maps on learning in Part II of the *Handbook*). However, at the single-cell level, there are many issues left to resolve.

Strengthening or weakening a single synapse weight, $w_{ij}$, seems to involve complex events, including calcium accumulation on both sides of the connection. However, there are several different types of increase and decrease, occurring under different circumstances and lasting from seconds to days. These mechanisms are not yet well understood, especially in the cerebral cortex. Markram and colleagues (1997) controlled the relative timing of presynaptic and postsynaptic action potentials in a pair of excitatory-coupled neurons, measuring its effect on the strength of synaptic coupling between the two cells. If the presynaptic spike preceded the postsynaptic one by as little as 10 ms, synaptic strength increased (long-term potentiation, LTP). Conversely, if the postsynaptic spike preceded the presynaptic one, synaptic coupling decreased (long-term depression, LTD). This gives rise to powerful, temporally asymmetric Hebbian learning rules.

A potent (but poorly understood) type of learning could occur as axonal branches and connections "die off," while other branches form elsewhere and connect to other cells. If such structural plasticity participates in learning, then at least as much information could be stored in the existence/nonexistence of the synaptic connections as in their current-pulse amplitudes or "strengths."

### *The Dendrites*

Although most input to cortical cells arrives on an intricately branched dendritic tree, we do not understand how the tree processes the input. Whether those tiny dendrites smooth out brief, localized input fluctuations—or instead amplify them—depends on the type of nonlinear membrane properties to be found there. Nonlinear dendrites can make a single "neuron" function as a large collection of distinct, multiplicative subunits.

### *Slow Analog versus Fast Digital*

There are two distinct, self-consistent interpretations of single-neuron function, which are diametrically opposed, but there is evidence for both (Figure 2).

In the most popular interpretation, the fundamental computation is like that of a Perceptron or a Hopfield neuron: a slow real-valued output resulting from slowly varying real-valued inputs, in which the timing of single spikes is inconsequential. Indeed, decades of experiments on most parts of the brain have found that only average rates—and not individual spike times—correlate with simple stimuli.

This corresponds to an integrate-and-fire neuron gathering many small inputs, smoothing out their irregularities in the dendritic tree, summing the results in the cell body, and producing a firing rate as output. Here the internal variable is the *average current* into the cell body, and the output firing rate can be interpreted as current into the *next* cell (the cell voltage is just a repeating ramp whose phase has no significance). This form of computation is most effective when the fluctuations in current are small, so that the cell fires in response to the mean current.

An alternative is McCulloch and Pitts' original interpretation of their binary neuron: the "active" state corresponds to a *single spike* rather than to an prolonged firing rate, so that every spike carries some kind of independent message. Although such a model can in principle transmit information much faster than an analog neuron, there are four fundamental criticisms of it: Are binary computations more appropriate than analog ones? Is there any need for such a high bandwidth? Can that high bandwidth be implemented in a realistic cell? And how sensitive is such a cell to the noise that exists in the cortex?

Other neural systems—such as the fly's visual system—can indeed carry significant information by single spikes. And there is a need for *some* improved neural bandwidth to solve problems of segmentation and binding. But there is so far no solid evidence that most cortical areas need such fast temporal resolution.

This single-spike regime corresponds to an integrate-and-fire type of cell that fires according to its instantaneous (rather than average) voltage, so it is sensitive to input fluctuations. However, in order for the cell to respond reliably to fluctuations, the average current must not dominate them—otherwise the mean current will ramp up the voltage and fire the cell, fluctuations or not.

# Sleep Oscillations

*Alain Destexhe and Terrence J. Sejnowski*

## Introduction

The brain spontaneously generates complex patterns of neural activity. As the brain falls asleep, the rapid patterns characteristic of aroused states are replaced by low-frequency, synchronized rhythms of neuronal activity. At the same time, electroencephalographic (EEG) recordings shift from low-amplitude, high-frequency rhythms to large-amplitude, slow oscillations. In what follows, we focus primarily on this slow-wave sleep, rather than rapid eye movement (REM) sleep, whose oscillatory properties resemble those of wakefulness.

The thalamus and cerebral cortex are intimately linked by means of reciprocal projections. The thalamus is the major gateway for the flow of information toward the cerebral cortex and is the first station at which incoming signals can be blocked by synaptic inhibition during sleep. This shift contributes to the transition that the brain undergoes from an aroused state, open to influence from the outside world, to the closed state of sleep. The early stage of quiescent sleep is associated with EEG spindle waves, which occur at a frequency of 7–14 Hz. As sleep deepens, waves with slower frequencies (0.1–4 Hz) appear on the EEG. This article summarizes what is known about the biophysical mechanisms underlying spindle oscillations.

The dramatic reduction in forebrain responsiveness during sleep, the pervasiveness of these changes, and the discovery of the underlying specific cellular mechanisms, suggest that sleep oscillations are highly orchestrated and highly regulated. Experimental and modeling studies have shown how sleep rhythms emerge from an interaction between the intrinsic firing properties of thalamic and cortical neurons and the networks through which they interact (Steriade, McCormick, and Sejnowski, 1993; Destexhe and Sejnowski, 2001). These advances have raised interesting possibilities regarding the function of sleep.

## Biophysical Basis of Sleep Spindle Oscillations

Sleep spindles are characteristic of brain electrical synchronization at sleep onset, an electrographic landmark for the transition from waking to sleep that is associated with loss of perceptual awareness. Spindle oscillations consist of 7–14 Hz waxing-and-waning field potentials, grouped in sequences that last for 1–3 s and recur once every 3–10 s. Spindle oscillations constitute an interesting and well-constrained problem to investigate by computational models for several reasons. First, these oscillations are generated in the thalamus, which is a well-known structure anatomically, with well-defined connectivity between the different cell types. Second, spindles are remarkably well documented experimentally and have been extensively characterized both in vivo and in vitro (reviewed in Steriade et al., 1993; Destexhe and Sejnowski, 2001). Third, this oscillation is generated by an interplay of complex cellular properties, such as burst firing, and synaptic interactions via multiple types of postsynaptic receptors (reviewed in Destexhe and Sejnowski, 2001). Computational models are needed to understand this complex interplay, as we summarize here.

The typical electrophysiological features of spindle oscillations are shown in Figure 1*A*. The two cell types involved, thalamocortical (TC) and thalamic reticular (RE) neurons, oscillate synchronously and display burst discharges according to a mirror

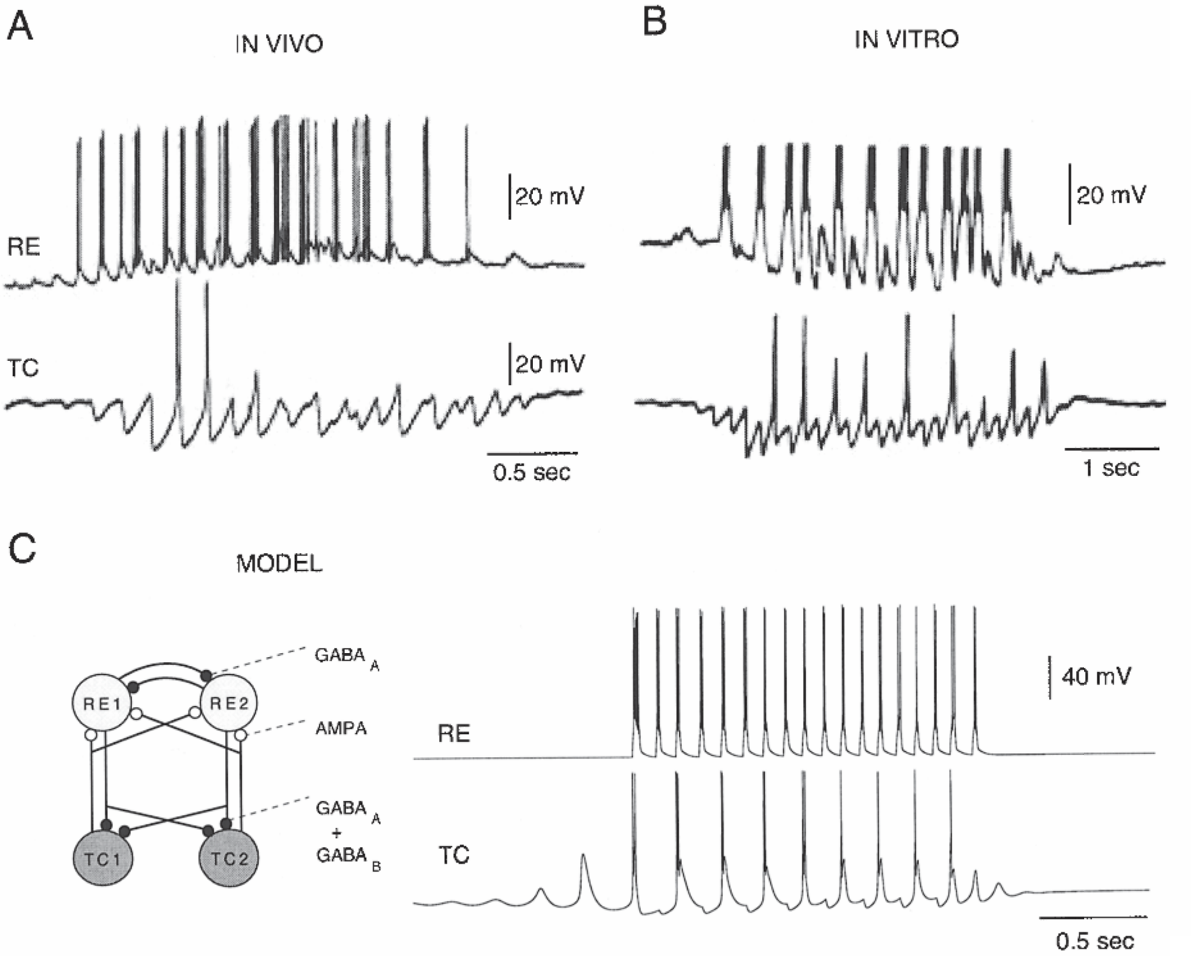

**Figure 1.** Spindle oscillations in thalamic circuits. *A*, Intracellular recordings of thalamic neurons during spindle oscillations in vivo (cats, barbiturate anesthesia; modified from Steriade et al., 1993). *B*, Intracellular features of spindle oscillations in ferret thalamic slices (spikes truncated; modified from Steriade et al., 1993). *C*, Model of spindle oscillations by interacting TC and RE cells. The intrinsic firing properties of each cell type was simulated by Hodgkin-Huxley type models for $Na^+$, $K^+$ and $Ca^{2+}$ currents, and kinetic models of postsynaptic receptors (AMPA, $GABA_A$, and $GABA_B$; see scheme) were used to represent synaptic interactions (modified from Destexhe et al., 1996; see also Destexhe, Mainen, and Sejnowski, this volume). In all three examples, RE cells generated bursts following EPSPs while TC cells generated bursts following IPSPs once every few cycles.

image: RE cells display bursts following excitatory synaptic potentials (EPSPs) while TC cells burst following inhibitory postsynaptic potentials (IPSPs). Although RE cells tend to burst at every cycle of the oscillation, TC cells only produce bursts once every few cycles. These features are typical of spindles recorded in thalamic neurons in different mammals.

Several hypotheses for the genesis of oscillations by thalamic circuits have been proposed (reviewed in Destexhe and Sejnowski, 2001). These involve reciprocal synaptic interactions between TC neurons and local inhibitory interneurons, loops between TC and RE neurons, or loops within the RE nucleus. The involvement of the RE nucleus was firmly demonstrated in a series of experiments by Steriade's group (reviewed in Steriade et al., 1993; Destexhe and Sejnowski, 2001). In particular, the deafferented RE nucleus in vivo can exhibit spindle rhythmicity in extracellular recordings. In contrast, the RE nucleus does not display autonomous oscillations in vitro, but spindles have been observed in thalamic slices based on TC-RE interactions (see Steriade et al., 1993, for a review of these issues). These in vitro spindles display the same intracellular features as in vivo (Figure 1*B*).

The genesis of spindle oscillations was investigated with computational models. First, in models of the isolated RE nucleus, RE neurons with sufficiently high connectivity interacting through GABAergic synapses generated spindle rhythmicity (Wang and Rinzel, 1993; Destexhe et al., 1994; Bazhenov et al., 1999; reviewed in Destexhe and Sejnowski, 2001). These models supported the RE pacemaker hypothesis based on in vivo recordings. Second, models including TC and RE cells showed that spindle oscillations can be obtained from TC-RE loops (Destexhe et al., 1996; Golomb, Wang, and Rinzel, 1996). The latter models supported the TC-RE mechanism suggested by thalamic slice experiments. Finally, it remained to explain why the RE nucleus oscillates autonomously in vivo but not in vitro. This apparent inconsistency was addressed by a computational model of the RE nucleus, in which oscillations depended on the level of neuromodulators (Destexhe et al., 1994). The difference between in vivo and in vitro preparations may therefore be explained by the limited connectivity between the RE neurons in the slice, and/or by the fact that slices lack the necessary level of neuromodulation to maintain isolated RE oscillations (Destexhe et al., 1994). The main prediction from this model is that applying neuromodulators to slices of the RE nucleus should induce oscillations similar to those observed in vivo.

The model for the TC-RE loop is shown in Figure 1*C*. Neurons were modeled using Hodgkin-Huxley type representations of $Na^+$, $K^+$, and $Ca^{2+}$ voltage-dependent currents (see AXONAL MODELING), which were based on voltage-clamp data on thalamic neurons (see details in Destexhe et al., 1996). These models reproduced the most salient intrinsic properties of thalamic neurons, such as the production of bursts of action potentials. Synaptic interactions were modeled using conductance-based kinetic models (see Destexhe, Mainen, and Sejnowski, this volume). Several of the main receptor types (AMPA, NMDA, $GABA_A$, and $GABA_B$) identified in thalamic circuits were incorporated into the model. Under these conditions, the circuit generated 7–14-Hz spindle oscillations with the typical features identified intracellularly in the different thalamic neuron types. The model reproduced the typical mirror image between TC and RE cells during spindles, as well as the phase relations between cells. In particular, TC cells produced bursts once every two cycles, a feature consistently observed experimentally (compare with Figure 1*A–B*). More irregular behavior, similar to the experiments, was obtained in larger networks or in the presence of the cortex (see the following discussion). The oscillations also showed the typical waxing-and-waning envelope of spindles; this property was due in the model to $Ca^{2+}$-mediated slow regulation of the $I_h$ current, a prediction that was verified experimentally (Lüthi and McCormick, 1998).

## Network Properties of Spindle Oscillations

Network properties were investigated using multiple recordings in vivo (Contreras et al., 1996) and in vitro (Kim, Bal, and McCormick, 1995). Spindle oscillations in vitro showed traveling wave patterns (Figure 2*A*). The oscillation started on one side of the slice and propagated to the other side, at a constant propagation velocity. Traveling spindle waves were simulated by computational models of networks of interconnected TC and RE cells (one-dimensional extensions of the circuit shown in Figure 1*C*), in two independent modeling studies (Destexhe et al., 1996; Golomb et al., 1996). These models were similar in spirit to the circuit shown in Figure 1*C*, but assumed that there was a topographic connectivity between TC and RE layers, consistent with anatomical data. Under these conditions, the models generated traveling waves consistent with in vitro data (Figure 2*B*).

In contrast to the thalamic slice, in recordings from the intact thalamocortical system in cats in vivo, the oscillations were remarkably synchronized over extended thalamic regions and showed little signs for traveling wave activity (Figure 2*C*). To simulate the in vivo conditions, a thalamocortical network model was developed by combining the previous model of thalamic slices with a model of deep cortical layers (see details in Destexhe, Contreras, and Steriade, 1998). The principal prediction of this model was that, in order to generate large-scale coherent oscillations, the cortex had to recruit the thalamus primarily through the RE nucleus. Because of the powerful inhibitory action of RE cells, the action of corticothalamic feedback is "inhibitory dominant" on TC cells, which property is essential to maintain large-scale synchrony (Destexhe et al., 1998). In these conditions, the same model was capable of generating large-scale synchrony in the presence of the cortex, and traveling waves in the isolated thalamus (Figure 2*D*). Consistent with these models, propagating activity has indeed been observed in the thalamus of decorticated cats in vivo (Contreras et al., 1996).

The cortical control of thalamic relay cells in the model through dominant inhibitory mechanisms has important consequences for the function of thalamocortical assemblies (see details in Destexhe and Sejnowski, 2001) and pathological situations such as absence seizures (Destexhe, 1998). As a result of inhibitory dominance, a too strong feedback can activate $GABA_B$ receptors and can entrain the *physiologically intact* thalamus into hypersynchronous rhythms at ~3 Hz. This scheme may explain the genesis of absence seizures, which are hypersynchronous ~3 Hz rhythms that appear suddenly in the thalamocortical system. These seizures can be provoked experimentally by altering the cortex, but a physiologically intact thalamus is required (Gloor and Fariello, 1988). The thalamocortical model accounts for these experiments and could simulate seizures based on inhibitory-dominant corticothalamic feedback (Destexhe, 1998). This model directly predicted that manipulating corticothalamic feedback should entrain the physiologically intact thalamus to generate hypersynchronous rhythms at ~3 Hz, a prediction that has been recently verified by two independent studies (Blumenfeld and McCormick, 2000; Bal, Debay, and Destexhe, 2000).

Finally, computational models have suggested a physiological role for spindle oscillations. The synchronized high-frequency bursts of action potentials in the thalamus provide a powerful input to the cortex, which is ideal for evoking massive calcium entry into pyramidal cells. Massive calcium entry may activate a series of biochemical cascades, leading to permanent changes of previously tagged synapses (Destexhe and Sejnowski, 2001). This scenario provides a biophysical mechanism consistent with the growing evidence that sleep serves to consolidate memories (see Destexhe and Sejnowski, 2001, for further details).

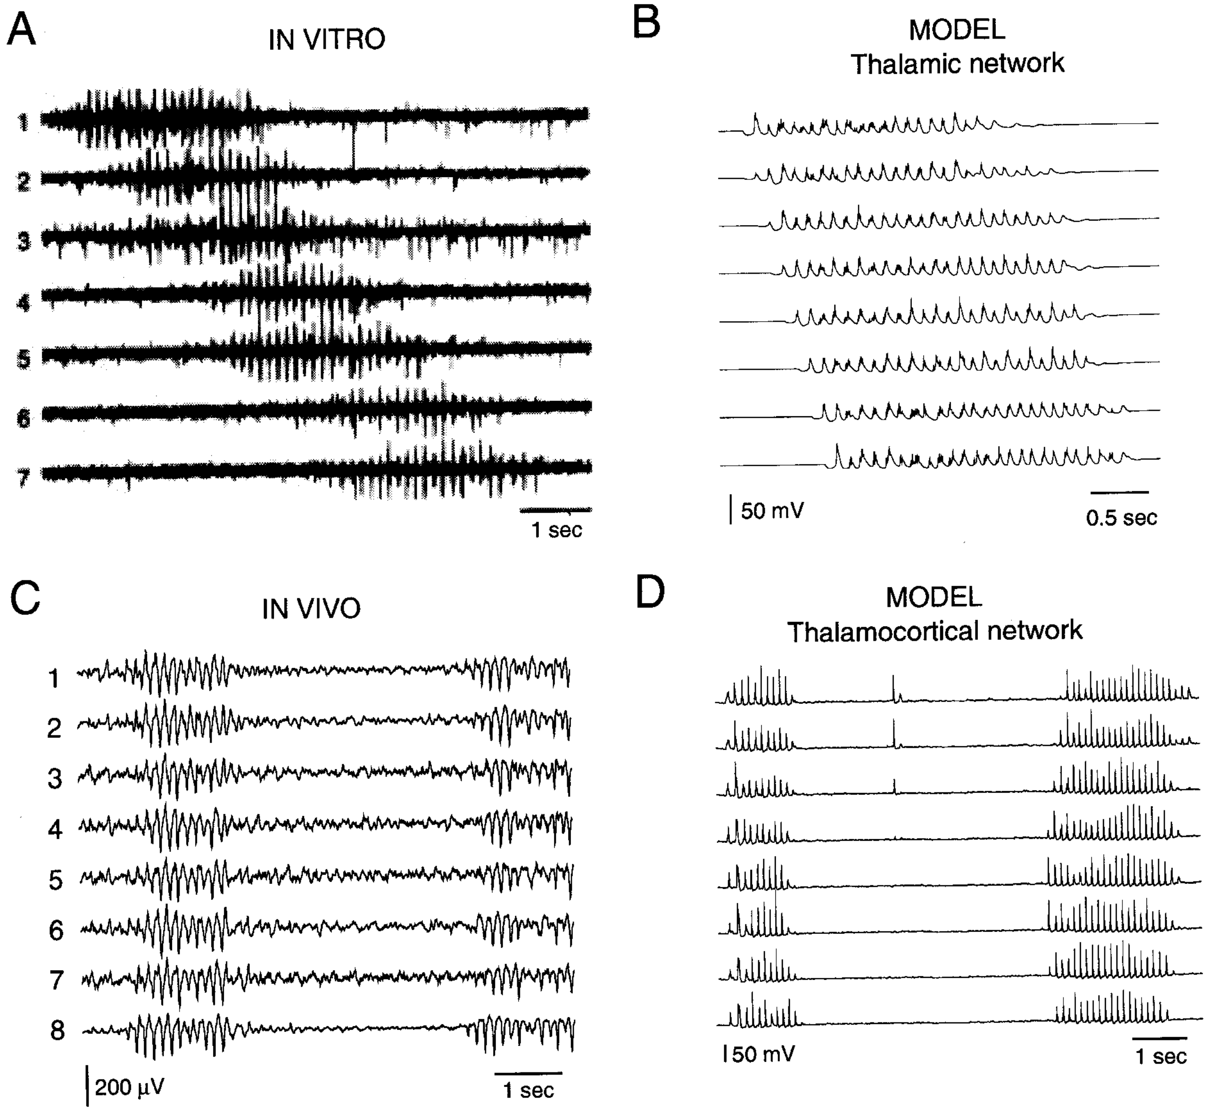

**Figure 2.** Sleep spindles in thalamic and thalamocortical networks. *A*, Propagating spindles in vitro. Spindle oscillations in an array of seven extracellular electrodes aligned along the dorsoventral axis of the slice (electrodes were separated by 250–400 $\mu$m, extending over 2–3 mm in the slice; modified from Kim et al., 1995). *B*, Propagating oscillations in a model thalamic network with reciprocal and topographic connections between TC and RE layers (100 cells total; modified from Destexhe et al., 1996). Each trace shows the averaged membrane potential (computed from ten neighboring TC cells) taken at eight equally spaced sites in the network. *C*, Large-scale synchrony of spindles in vivo. Eight extracellular electrodes were inserted along the dorsoventral axis of the thalamus in cats under barbiturate anesthesia (interelectrode distance of 1 mm; modified from Contreras et al., 1996). *D*, Large-scale synchrony in a thalamocortical network model consisting of four layers of thalamic and cortical neurons interconnected in a topographic fashion (400 cells total; averaged membrane potentials shown at ten equidistant locations; modified from Destexhe et al., 1998). While the oscillation was generated in the thalamus (see Figure 1), the large-scale synchrony depended on the cortex and was generated by corticothalamic interactions (see text for details).

We have shown here that computational models can simulate a large body of experimental data, ranging from isolated thalamic circuits to large-scale thalamocortical assemblies, also including the genesis of pathological behavior such as seizures. The challenge for future studies will be to investigate the physiological role of these slow-wave oscillations. Our present working hypothesis is that the high level of synchrony of these oscillations is ideal to recruit specific calcium-dependent biochemical cascades leading to memory consolidation, which may be one of the principal roles of sleep.

## Summary and Conclusions

Computational models of neurons using conductance-based mechanisms integrate electrophysiological data from both in vitro and in vivo preparations. This approach reconciles apparently conflicting experimental data and has generated experimental predictions (some of which have been tested and verified). In particular, a coherent framework has been proposed to explain the genesis of sleep spindles and pathological behavior, such as absence seizures, based on data from the level of ion channels to large-scale network interactions. These data have led to plausible hypotheses for a role of sleep oscillations in memory consolidation (see details in Destexhe and Sejnowski, 2001).

All models shown here were simulated using NEURON (Hines and Carnevale, 1997). Computer generated movies and NEURON programs to simulate these models are available at http://cns.iaf.cnrs-gif.fr and http://www.cnl.salk.edu/~alain/ or upon request.

# Somatosensory System

*Oleg V. Favorov and Douglas G. Kelly*

## Introduction

The somatosensory system provides the central nervous system (CNS) with information about the state of the body and about objects contacted by the body. This information contributes both to perception of the proximal surroundings and to execution of skilled movements. The somatosensory system is unique in the large number of receptor types it employs, which are responsible for qualitatively distinct types of somatic sensations. Several different types of receptors in the skin mediate sensations of contact pressure, texture, movement across the skin, flutter, vibration, pain, and temperature. Receptors located in the muscles, tendons, joints, and the skin overlying the joints mediate proprioceptive sensations of position and movement of the joints and forces acting on them.

Each class of receptors has a separate pathway through the CNS. A typical pathway starts with primary afferent neurons in the dorsal root ganglia outside the spinal cord. These neurons synapse on neurons in the spinal cord (in the case of poorly localized sensations of pain and temperature) or in the dorsal column nuclei in the medulla (in the case of finely discriminative touch and limb proprioception). These second-order neurons in turn project to the ventrobasal complex of the thalamus. The VPL nucleus of this complex receives information from the trunk and limbs, whereas the VPM nucleus receives information from the head. The ventrobasal complex relays the sensory information it receives to the cerebral cortex.

Two areas of the cerebral cortex receive direct inputs from the ventrobasal complex: the primary somatosensory area (SI) in the postcentral gyrus and the secondary somatosensory area (SII) in the lateral fissure. In addition to thalamic inputs, SI and SII also receive dense reciprocal inputs from each other. Although the idea is still controversial, it appears that SI and SII occupy hierarchically parallel, rather than serial, positions in tactile information processing (Zhang et al., 2001).

SI is subdivided into four distinct cytoarchitectonic regions, Brodmann's areas 3a, 3b, 1, and 2. Area 3a is dominated by afferent inputs from muscles, area 3b by afferent inputs from the skin. Skin information is further processed in area 1 and is combined with information from muscles and joints in area 2. SI and SII send their outputs to areas adjacent to them in the insula (for object recognition) and in the parietal lobe (for forming body image and for planning movements in the extrapersonal space), as well as to motor cortical areas (for fine motor control).

A more detailed description of the somatosensory system can be found in Hendry, Hsiao, and Bushnell (1999). The somatosensory system has been studied extensively, and a wealth of information is available about its anatomy and physiology. As a result of pioneering work by Vernon Mountcastle, special emphasis has been placed on quantifying the relationships of various attributes of tactile stimuli (e.g., the frequency and amplitude of stimulus vibration, the direction of stimulus motion along the skin, texture roughness) with the sensations these stimuli evoke in humans or monkeys. To identify the neural mechanisms underlying tactile perception, such psychophysical studies are combined with neurophysiological experiments that compare reports from the subjects with responses from peripheral receptors and from subcortical and cortical neurons. An example of this approach, focusing on the neural mechanisms of stimulus vibration frequency discrimination, is offered by Mountcastle, Steinmetz, and Romo (1990).

While experimental studies have provided many important insights, our theoretical understanding of cortical operations involved in processing somatosensory information is still very limited. Nevertheless, diverse theoretical and modeling studies of the somatosensory system, primarily at the level of the cerebral cortex, have contributed to a progressively more comprehensive understanding of somatosensory information processing. The overall view of this processing is that tactile stimulus representation in the nervous system is changed from an original form (more or less isomorphic to the stimulus itself) to a completely distributed form (underlying perception) in a series of partial transformations in successive subcortical and cortical networks. As demonstrated, for example, by Johnson et al. (1991), at the level of peripheral afferents the representation of a scanned tactile form, such as a letter of the alphabet embossed on a rotating drum, is an isomorphic neural image of that form, because of the topography of the receptor sheet and the small receptive fields (RFs) of those afferents. In contrast, at the level of SI the neural image of the stimulus already has become much more complex, as evidenced by the complexity and heterogeneity of the responses of cortical neurons, which are already sensitive to shape and temporal features of peripheral stimuli, rather than simply reflecting the overall intensity of stimulation of their RFs.

## Development of Cortical Topographic Maps

In each somatosensory cortical area the inputs from different body regions are organized topographically into detailed somatotopic maps. This topographic organization of thalamocortical connections is one of the principal determinants of how representations of peripheral stimuli are transformed in the cortex. How the topography is developed and maintained in SI has been the subject of a number of theoretical and modeling studies (see Somatotopy: Plasticity of Sensory Maps), which have identified Hebbian plasticity of thalamocortical synapses and Mexican-hat distribution of lateral connections (in which each cortical site excites its closest neighbors but inhibits more distant ones) as two necessary conditions for the development of somatotopy.

In particular, Grajski and Merzenich (1990) demonstrated that these conditions are sufficient to account for the inverse relationship that exists in the cortex between RF size and cortical magnification (i.e., the size of the cortical area representing a unit area of skin). Using a three-layer network (skin, subcortical, and cortical layers) with a Mexican-hat pattern of intrinsic connections and Hebbian plasticity of afferent and intrinsic connectivity, they successfully simulated two experimental studies. In one study, preferential stimulation of a particular restricted skin region resulted in an increase in its cortical representation, coupled with a decrease in RF size. In the second study, cortical magnification was reduced by lesioning a restricted cortical region, which led to an increase in RF size in cortical territories around the lesion.

Modeling studies of Pearson, Finkel, and Edelman (1987), Montague, Gally, and Edelman (1991), and Xing and Gerstein (1996b) offer a mechanistic explanation for the presence of discrete place-defined columns in SI. Cortical columnar organization was first discovered in SI by Mountcastle in 1950s (Hendry et al., 1999). More recently, Favorov and colleagues (Favorov and Kelly, 1996) identified a class of discrete cortical columns (*segregates*) in the SI of cats and monkeys distinguished by the relative RF locations of their constituent neurons. These columns, 0.3–0.6 mm in diameter, are separated from each other by sharp boundaries and compartmentalize SI into a honeycomb-like mosaic. The defining characteristic of segregates is that the *strongest* afferent input to local clusters of neurons *throughout* a given column comes from the *same* focal skin site (the *segregate RF center*). At the borders between segregates, the site of the strongest input shifts abruptly to a new, prominently displaced skin locus.

Although they differ in the details of their models, Pearson et al. (1987), Montague et al. (1991), and Xing and Gerstein (1996b) all identify two characteristic properties of the cortical network as responsible for the emergence of segregates during the perinatal development of SI. These properties are (1) a Mexican-hat distribution of lateral connections and (2) Hebbian-like plasticity of both afferent and lateral excitatory connections. Even though a network with two such properties may initially have somatotopically distributed afferent connections and homogeneously organized intrinsic connections, under repeated sensory stimulation it will nevertheless reorganize and spontaneously resolve into a mosaic of small, discrete regions. The excitatory intrinsic connections among neurons within each such region will strengthen greatly, whereas connections among different regions will weaken profoundly. Afferent connections will reorganize also, and neurons within each region will acquire identical or similar focal RFs, whereas neurons in adjacent regions will acquire nonoverlapping RFs. As a result, across the network, RFs will shift not continuously but in abrupt steps at the borders between these regions.

## Minicolumnar Organization of SI

Segregates in SI are composed of smaller, 0.05-mm-diameter columns called *minicolumns*. Neurons located in the same minicolumn have similar RFs, but neurons located in different, even adjacent, minicolumns typically have RFs that differ significantly in size and shape and frequently overlap only minimally on the skin, having in common only the segregate RF center (reviewed in Favorov and Kelly, 1996). Favorov and Kelly (1996) developed a model of a typical SI segregate, made up of 61 minicolumns, to evaluate a hypothesis that the prominent diversity in the RFs among minicolumns in a segregate is an outcome of cortical network self-organization during perinatal development. In the model, each minicolumn consists of three cells representative of different cell types in the cortex: an input *spiny-stellate* cell (which receives thalamic input and distributes it to all other cells of the same minicolumn and, to a lesser degree, to other nearby minicolumns), an intrinsic *double-bouquet* cell (which inhibits adjacent minicolumns), and an output *pyramidal* cell. Connections from thalamus to minicolumns were plastic; they were allowed to self-organize in accordance with a Hebbian rule during a developmental period in which the network was driven by punctate skin stimuli.

During the network's self-organization, each minicolumn is driven by its inhibitory interactions with adjacent minicolumns (mediated by double-bouquet cells) to acquire a set of afferent connections that is different from those of its immediate neighbors. On the other hand, each minicolumn is also driven by the excitatory interactions with a larger circle of its neighbors (mediated by spiny-stellate cells) to make its set of afferent connections similar to theirs. To satisfy these opposing pressures, minicolumns in the segregate arrange their afferent connections in permuted patterns, with shuffled RFs, since such shuffling satisfies the opposing pressures by moving RFs of adjacent minicolumns farther apart, while preventing RFs of the entire segregate from diverging too widely. Thus the model generates complex patterns of RFs across the segregate that are similar to those observed experimentally in microelectrode penetrations through SI segregates (Favorov and Kelly, 1996).

## Cortical Cell Tuning

Pinto et al. (1996, based on an earlier model of Kyriazi and Simons) developed a model of the first cortical stage of cell tuning in SI. They modeled the organization of a single cortical *barrel*, a discrete neuronal aggregate in layer 4 of rodent SI that receives its principal input from one of the facial whiskers. Spike trains recorded from real thalamic neurons were used as input to the model network and responses of the model neurons were compared with those recorded from real neurons in cortical layer 4. The crucial features of the model are the following: (1) cortical cells have nonlinear activation properties, (2) inhibitory cells are more responsive than excitatory cells, (3) each excitatory and inhibitory cell receives connections from multiple thalamic cells, and (4) all cortical cells are strongly interconnected. Under these conditions, the model accurately simulates the cortical response to three types of whisker stimulations (brief or prolonged deflection of a single whisker, or a sequential deflection of two whiskers in a condition-test paradigm), and it reproduces the known differences between the response properties of thalamic and cortical neurons. Specifically, excitatory cortical cells share a greater signal-to-noise ratio than thalamic cells, and they have RFs with more tightly focused excitatory centers and stronger inhibitory surrounds than do thalamic cells. Traditionally, focusing of RF properties has been assumed to be achieved by lateral inhibitory interactions among neighboring cortical columns. Pinto et al. (1996) demonstrated a different mechanism of RF focusing, based on the greater responsiveness of inhibitory neurons in a cortical column to weak stimuli applied at the RF margins, and the resulting suppression of the responses of excitatory neurons within the *same* column.

DiCarlo and Johnson (2000) studied the tuning properties of cells in the earliest somatosensory cortical area, area 3b, using scanned, random-dot stimuli and regression analysis to estimate the cells' RF structure. This analysis revealed that area 3b neurons (especially those in the upper layers) are sensitive to the orientation of elongated stimuli and the direction of their motion. The responses of the cells were well described by a spatiotemporal RF model containing three components: (1) a single elongated excitatory region; (2) one or more inhibitory regions, adjacent to and nearly synchronous with the excitatory region and responsible for orientation sensitivity; and (3) a temporally delayed inhibitory region that overlaps partially or totally the excitatory region and is responsible for directional sensitivity. The insightfulness of this model was demonstrated by its ability to accurately predict cells' responses to stimuli (moving bars) that were not used to generate the RFs of the model.

Concerning the nature of cortical cell tuning, Ryder and Favorov (2001) proposed that cortical pyramidal cells tune to causal factors operating in the environment—in the case of the somatosensory cortex, causal factors involved in the physical interactions of the body with objects around it. Causal factors manifest themselves in statistical dependencies—*suspicious coincidences*—among environmental events. Environmental events are reflected only indirectly in the spatiotemporal activity patterns of sensory receptors; in mathematical terms, they can be considered functions over the states of sensory receptors. One way to discover causal factors is to look among various functions over various subsets of sensory receptors, searching for such pairs of functions over nonoverlapping subsets of receptors that will show correlated behaviors. Such *different but correlated* functions will identify a causal factor operating in the environment that is responsible for their correlation.

Ryder and Favorov (2001) proposed that such a search for different but correlated functions is performed by the dendrites of neocortical pyramidal cells. A pyramidal cell has several basal dendrites that extend horizontally in different directions away from the soma, passing through different groups of minicolumns. These different groups of minicolumns provide different basal dendrites of the same cell with different combinations of sensory inputs, over which dendrites can implement a wide variety of nonlinear functions. Which functions? Pyramidal cells seem well set to find *correlated* functions through the plasticity of their synaptic connections. Synaptic learning in dendrites is controlled both by presynaptic activity and by the output activity of the postsynaptic cell; the latter is signaled to each synapse by spikes that are backpropagated from the soma up through each dendrite. Thus, through its contribution to the cell's output, the output of each basal dendrite can influence the strengths of synaptic connections on the cell's other dendrites, teaching them to behave the way it does, while also learning from them. Through such mutual teaching and learning, different dendrites in a cell can learn to produce correlated outputs in response to their different inputs. That is, the dendrites can discover correlated functions over their different subsets of sensory variables, thereby tuning the cell to the causal factor responsible for this correlation. Ryder and Favorov named this concept of the pyramidal cell SINBAD (a Set of INteracting BAckpropagating Dendrites).

## Cortical Dynamics

The cortical network is a complex dynamical system. Xing and Gerstein (1996a) used a model of the cortical network with spiking neurons, topographic projections between skin, thalamic, and cortical layers, and a Mexican-hat pattern of lateral connections in the cortical layer to investigate the contributions of lateral connections to the network's dynamics. They found the balance between lateral excitation and inhibition to be a key network parameter that controls the dynamical stability of the network, the sizes of RFs of cortical neurons, their temporal response patterns, and their spontaneous activity. Xing and Gerstein simulated a number of experimental manipulations of the SI network (such as cortical blockade of the inhibitory GABAergic transmission, cortical microinjections of the excitatory transmitter glutamate, local skin denervation, and local cortical lesions) and were able to account for all current observations of experimentally induced dynamic RF changes in SI, when the cortical layer operated in an inhibition-dominant mode.

Whitsel et al. (1991) proposed a model of cortical dynamics that explains why an initial cortical response to a stimulus undergoes substantial modifications with a continuous or repetitive exposure to that stimulus. According to their model, such modifications could result from activity-dependent increases in extracellular concentrations of potassium and their modulating effects on the state of NMDA receptors and neuromodulators, such as acetylcholine, and on the development of long-lasting afterhyperpolarization in active neurons. These changes in the network state translate into changes in pericolumnar inhibition, leading to progressive changes in the spatial pattern of cortical response. These changes make this pattern progressively more stimulus specific.

Favorov et al. (2002) investigated the nature of cortical dynamics in their model of the SI network, which was an extension of the earlier model of Favorov and Kelly (1996). The model was expanded to a local group of segregates (each made up of 61 minicolumns); it was also expanded to represent both the middle and the upper cortical layers, including their extensive lateral connectivity. The modeled network possesses the full range of dynamics (it exhibits a quasiperiodic route to chaos, capable of generating stable states, periodic and quasiperiodic oscillations, and chaotic fluctuations), depending on particular choices of network parameters. The complexity of the network's dynamics is limited, however, by several factors: (1) Even in the chaotic regime, it can produce only low-dimensional (less than eight) attractors, regardless of increases in the network's structural complexity. (2) Stronger stimuli, as well as moderate levels of random noise, reduce the complexity of dynamics. (3) Stimulus-evoked transients, while complex, are nevertheless to a large degree stereotypical, adhering to particular waveforms that are very stimulus specific.

Based on their model performance, Favorov et al. (2002) argue that, in addition to intended dynamical behaviors, the sheer complexity of a cortical network's structure should promote *spurious* dynamical behaviors. Dynamics observed in the model and in the somatosensory cortex suggest that such unintended dynamical behaviors are likely to be pervasive but relatively simple, contributing to rather than dominating the cortical network's response to stimuli. Many intriguing features of cortical stimulus-evoked behaviors might be attributable to spurious dynamics. We tend to expect specific mechanisms for specific dynamical behaviors, but the presence of spurious dynamics should warn us that a clearly identifiable dynamical feature does not necessarily imply a clearly identifiable cause: the cause might be distributed, everywhere and nowhere. Favorov et al. describe some of the spurious dynamical phenomena associated with the somatosensory cortical response to a brushing stimulation, illustrating how spurious dynamics can affect neurons' functional properties, cortical stimulus representation, and, ultimately, perception.

## Discussion

What picture of sensory information transformation in somatosensory cortex emerges from these studies? The first transformation takes place in the input cortical layer, layer 4. The studies of Pearson et al. (1987), Montague et al. (1991), and Xing and Gerstein (1996b) suggest that discrete *macrocolumns* (such as rodent barrels or monkey segregates) are small, sharply delineated cortical regions that, during perinatal development, come to be innervated by a selected group of thalamic neurons, sharing similar RFs, whose axons all terminate extensively *throughout* the territory of that macrocolumn. According to Favorov and Kelly (1996), within a macrocolumn, thalamocortical axons connect to the minicolumns selectively, not uniformly, so that each minicolumn receives afferent connections from a unique subset of the thalamic neurons that project to that macrocolumn. The differences in afferent inputs to neighboring minicolumns are further amplified by their lateral inhibitory interactions, decorrelating almost completely the stimulus-evoked behaviors of neighboring minicolumns. Thus, it appears that local groups of minicolumns together represent a variety of different, but related sensory information concerning a local region of the stimulus space, with adjacent minicolumns tuned to extract only minimally redundant information about what takes place in that stimulus space. Such local cortical environments are exactly the right informational environments for pyramidal cells, to be mined by them in their search for causal factors.

The next transformation of sensory information takes place in the upper and deep cortical layers. Spiny-stellate cells of layer 4 provide their outputs to pyramidal cells lying above and below them in the same and nearby minicolumns. According to Ryder and Favorov (2001), pyramidal cells learn to respond to particular functions over these inputs, functions that identify prominent causal factors operating in the environment. Pyramidal cells then send their outputs to the next cortical area, where the same two-step process of (1) enriching local layer 4 neighborhoods with related sensory information and (2) tuning pyramidal cells of the upper and deep layers to higher-order causal factors is repeated, and so on in all somatosensory cortical areas.

With the prominent causal factors involved in body/object interactions represented explicitly by their pyramidal cells, the somatosensory cortical areas can capture the functional relations among the educed causal factors in the patterns of their ascending, lateral, and feedback connections and can develop an internal working model of mechanical interactions of the body with the outside world. Such an internal model can endow the somatosensory cortex with powerful interpretive and predictive capabilities, crucial for haptic perception of proximal surroundings and for control of object manipulation.

# Somatotopy: Plasticity of Sensory Maps

*Sherre L. Florence and Jon H. Kaas*

## Introduction

*Somatotopy*, a dominant feature of subdivisions of the somatosensory system, is defined by a topographic representation, or map, in the brain of sensory receptors on the body surface (see SOMATOSENSORY SYSTEM for a review of cortical somatosensory receptive fields and their development). In the mammalian brain, there are orderly representations of cutaneous receptors at various levels: in the spinal cord, lower brainstem, thalamus, and neocortex. In the past, these sensory maps were considered relatively permanent point-to-point representations, with little or no changes in internal organization once the mature patterns had developed. Over the past two decades, however, evidence for plastic changes at all levels of the adult somatosensory system accumulated in a wide range of mammalian species. It is now clear that the somatotopic organization of sensory maps represents both the peripheral distribution of receptors and the dynamic aspects of brain function. Most of the evidence for somatosensory plasticity has accrued from studies of cortical reorganization after peripheral injury; however, changes in the relative levels of sensory stimulation as a result of training can also produce reorganization. Additionally, modifications can occur in sensory maps at all levels of the pathway, including subcortical and cortical somatosensory stations. This article emphasizes work on plasticity in the primate somatosensory system. The following issues are discussed: What features of somatotopic maps change, and under what conditions are the changes produced? How do subcortical changes contribute to cortical plasticity? What mechanisms account for these changes? What are the functional consequences of sensory map changes?

## Somatotopic Plasticity in Cortex

The large representation of the hand in the somatosensory cortex of primates is particularly suitable for studies of cortical plasticity, since some of the plastic changes involve small topographic shifts that are harder to detect in the compact representations that exist subcortically. The approach typically is to eliminate the relay of sensory information from a certain portion of the skin surface to the brain. A wide range of denervation procedures has been used, including nerve crush or cut, lidocaine injection, and amputation. The effects of the deprivation on the somatosensory pathway can be studied minutes, weeks, or even years later using microelectrode recording techniques that allow large regions of the nervous system to be sampled in each animal in a relatively limited span of time. In one of the first clear demonstrations of adult plasticity, Merzenich and colleagues (for a review, see Buonomano and Merzenich, 1998; Kaas and Florence, 2000) cut the median nerve that innervates the glabrous (palmar) surface of the thumb, index, and long fingers and the adjacent palmar pads in monkeys. Immediately after the nerve was cut, the majority of neurons in the large cortical zone where median nerve skin is represented were unresponsive. However, at a small number of recording sites, neurons had rapidly acquired new receptive fields on the dorsal rather than the glabrous surfaces of the digits. The immediate appearance of new receptive fields was detected at only a limited number of recording sites; the newly reactivated neurons were located in narrow zones along borders with adjacent intact representations. Thus the somatotopic extent of the change was quite small in scale.

The full potential for reorganization became apparent over an extended time course that required weeks and months after peripheral denervation. In some cases, much longer epochs, such as a year or more, seemed to be needed for all changes to emerge. In their initial studies of the effects of median nerve transection, Merzenich et al. (reviewed by Buonomano and Merzenich, 1998; Kaas and Florence, 2000) noted that more extensive map reorganization occurred in the weeks following denervation. They also determined that the source of the new activating inputs was somatotopically consistent. Neurons throughout much of the deprived median nerve territory had acquired new receptive fields on the hairy (dorsal) surfaces of the denervated digits or on the adjacent ulnar nerve–innervated hand, representations that are spatially adjacent to the deprived cortex. Subsequent investigations, involving a wide variety of sensory denervations, confirmed that alternative sources of activation to deprived representations typically were near neighbors in the sensory map (Figure 1). Thus, after amputation of only a portion of the index finger (digit 2, D2), neurons in the deprived zone closest to the border with D1 were reactivated by D1, and those closest to the intact representation of proximal D2 acquired new receptive fields on D2 (Figure 1*B*). If all the digits were lost, neurons in the deprived zone were reactivated by inputs from the palm (Figure 1*C*). If the hand was amputated, the deprived cortical representation was reactivated by inputs predominantly from the forearm (Figure 1*D*), although there may also have been some expansion of the face representation. Injuries that led to the loss or denervation of even larger extents of the arm resulted in progressively more takeover by inputs from the face (Figure 1*E*; see also Kaas and Florence, 2000).

Although few studies in primates have looked at the detailed time course of the slowly developing plasticity, it is assumed that reactivations of more than a few millimeters of cortical territory require many months before the full complement of changes could be expressed. For example, 3 weeks after complete cervical dorsal column section to eliminate all tactile inputs from the forelimb, cortical reorganization was still incomplete (reviewed in Jain and Kaas, 1998); however, by 6–8 months, hand cortex was fully reactivated by inputs from the face.

An important caveat of the studies that employ sensory deprivation to induce somatotopic plasticity is that outcomes may differ depending on the integrity of the denervation. For example, if even a few of the dominant inputs are spared, their influence is dramatically amplified and the skin surface that they innervate can take over considerable extents of deprived cortex. This was demonstrated compellingly by Jain and colleagues (see Jain and Kaas, 1998) in a study of the effects of dorsal column transection. In some cases the transection was incomplete and some of the sensory afferents from the hand that ascend in the dorsal columns were spared. At the level of cortex, these spared inputs activated only a small portion of the hand representation initially after the injury. However, over the course of about 5 weeks subsequent to the deprivation, the skin surface represented by the spared inputs expanded markedly and came to occupy the full extent of deprived cortex. Thus, the originally dominant sensory inputs appeared to have much more potency in denervated cortex than other, nondominant inputs.

Changes in cortical somatotopy have also been observed in intact individuals involved in behaviors that alter sensory stimulation patterns. For example, in monkeys trained in behavioral discrimination tasks, the cortical representation of the portion of the hand used to make the discrimination increased in representational area and the neurons in this representation had decreased receptive field sizes (for review, see Buonomano and Merzenich, 1998). Thus, more cortical space was devoted to the behaviorally important skin,

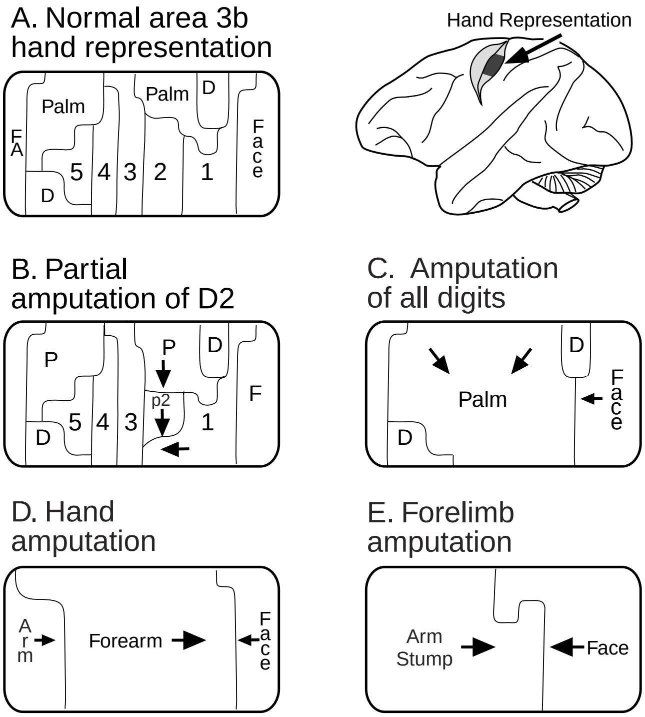

**Figure 1.** Patterns of topographic organization in area 3b of macaque monkeys after amputation of part or all of the forelimb. The location of cortical area 3b on the posterior bank of the central sulcus is shown in the figurine to the top right. The central sulcus (gray shading) has been opened to show the approximate location of the hand representation (dark gray shading). *A*, Topographic organization of the hand representation in area 3b in normal macaque monkeys. Large numerals 1–5 refer to the representations of digits 1–5, and thin lines indicate borders between representations. *B*, The pattern of reorganization that emerged in the hand representation of a monkey that lost the middle and distal phalanges of digit 2. Arrows indicate that adjacent representations expanded into the deprived zone (reviewed in Jones, 2000). *C*, After loss of all digits on one hand, the region of area 3b where the digits are normally represented is taken over by a large representation of the palm (reviewed in Kaas and Florence, 2000). *D*, After amputation at the level of the wrist, the hand representation is taken over by representations of the forearm (reviewed in Kaas and Florence, 2000). *E*, After amputation at the mid-humeral level of the arm, the deprived region is taken over by an expanded representation of the stump of the arm medially and the face laterally (reviewed in Kaas and Florence, 2000). D, Dors, dorsum of the hand; F, face; FA, forearm; P, palm; p2, proximal phalanx of digit 2.

and at the same time the "grain" of the representation became more refined. The impact of sensory training on cortical somatotopy was similar in humans. Recordings of somatosensory-evoked potentials in hand cortex of blind subjects who learned to read using the Braille method demonstrated that the area of activation for the reading (right index) finger was larger than that for other fingers (Pascual-Leone and Torres, 1993).

## Subcortical Contributions to Plasticity

Cortex typically is considered to have more adaptive potential than the subcortical relays; however, there is ample evidence for subcortical plasticity (reviewed by Kaas, Florence, and Jain, 1999; Jones, 2000; Kaas and Florence, 2000). Moreover, subcortical remodeling may be a substrate for some of the plasticity observed in cortex. Immediately after median nerve transection in monkeys, deprived neurons in the cuneate nucleus of the brainstem acquire new receptive fields on the dorsal skin of the hand, the same types of receptive fields shifts as described in cortex (Xu and Wall, 1999). This suggests that the reorganization observed in cortex is initiated by plasticity mechanisms in the cuneate nucleus.

Also, in monkeys that had undergone forelimb amputation, the pattern of reorganization observed in somatosensory cortex, reactivation of deprived cortex by expanded representations of the stump of the arm and the face, was consistent with changes observed at the level of the brainstem and thalamus. In the cuneate nucleus, the primary sensory afferents from the skin of the forearm adjacent to the amputation, which normally terminate dorsally in the cuneate nucleus, sprouted ventrally to occupy the region where hand inputs normally prevail (Figure 2). Similarly, inputs from the chin of the face, which normally project to the trigeminal nucleus, sprouted into the cuneate nucleus and infiltrated the deprived hand representation (Figure 2; see also Jain et al., 2000). Assuming that the new inputs were functionally potent, their impact would be even more evident at the next levels in the processing sequence, in the ventroposterior nucleus (VP) and consequently in somatosensory cortex (Figure 2), as a result of diverging projections. Indeed, recent studies of the functional organization of VP in monkeys that had sustained forelimb loss demonstrated new patterns of organization in the hand representation of VP (Florence, Hackett, and Strata, 2000) that were consistent with the interpretation that reorganization in the cuneate nucleus leads to map changes at higher-order stations. Other studies in monkeys as well as in humans documented somatotopic changes in the thalamus that mirror those reported in cortex (reviewed in Kaas and Florence, 2000).

## Mechanisms Underlying Map Plasticity

Multiple mechanisms contribute to somatotopic plasticity (reviewed in Buonomano and Merzenich, 1998; Kaas and Florence, 2000). Immediate changes have been attributed to an unmasking of existing excitatory connections through a reduction of afferent-driven activation of GABAergic inhibitory neurons (called *disinhibition*). The extent of this immediate reorganization is limited by the amount of overlap of the central projections from different skin regions. Thus, the spatial extent of changes mediated by disinhibition is small in scale. Nonetheless, the accumulation of small changes across subcortical levels of processing could yield a larger cortical reorganization. Changes that take place over a longer time course likely result from a combination of events, with disinhibition accounting for only a proportion of the reorganization. Some of the more slowly developing changes are presumed to involve Hebbian-type mechanisms. A model of cortical plasticity based on Hebbian-like synaptic modifications replicates most of the more limited somatotopic map changes (Sklar, 1991). For example, the model can account for changes in cortical organization after peripheral nerve injury and regeneration, the expansion of representations after the removal of competing inputs (such as after digit amputation), and expansions after overstimulation of a digit. This model is based on the theory that a neuron possesses a synaptic modification threshold that dictates whether the efficacy of synapses impinging on the neuron is strengthened or weakened. The threshold changes in relation to the neuron's recent average postsynaptic activity, so that synapses potentiate when postsynaptic activity is greater than the synaptic modification threshold and weaken when activity is less than the threshold.

Currently, the strongest candidate for the neural mechanism that underlies the Hebbian-type modification is the *N*-methyl-D-aspartate (NMDA) receptor mechanism (see NMDA RECEPTORS: SYNAPTIC, CELLULAR, AND NETWORK MODELS). The NMDA receptor is thought to coexist with other receptors for excitatory amino acids and to mediate synaptic transmission jointly. To test the role of the NMDA receptor mechanism in the reorganization

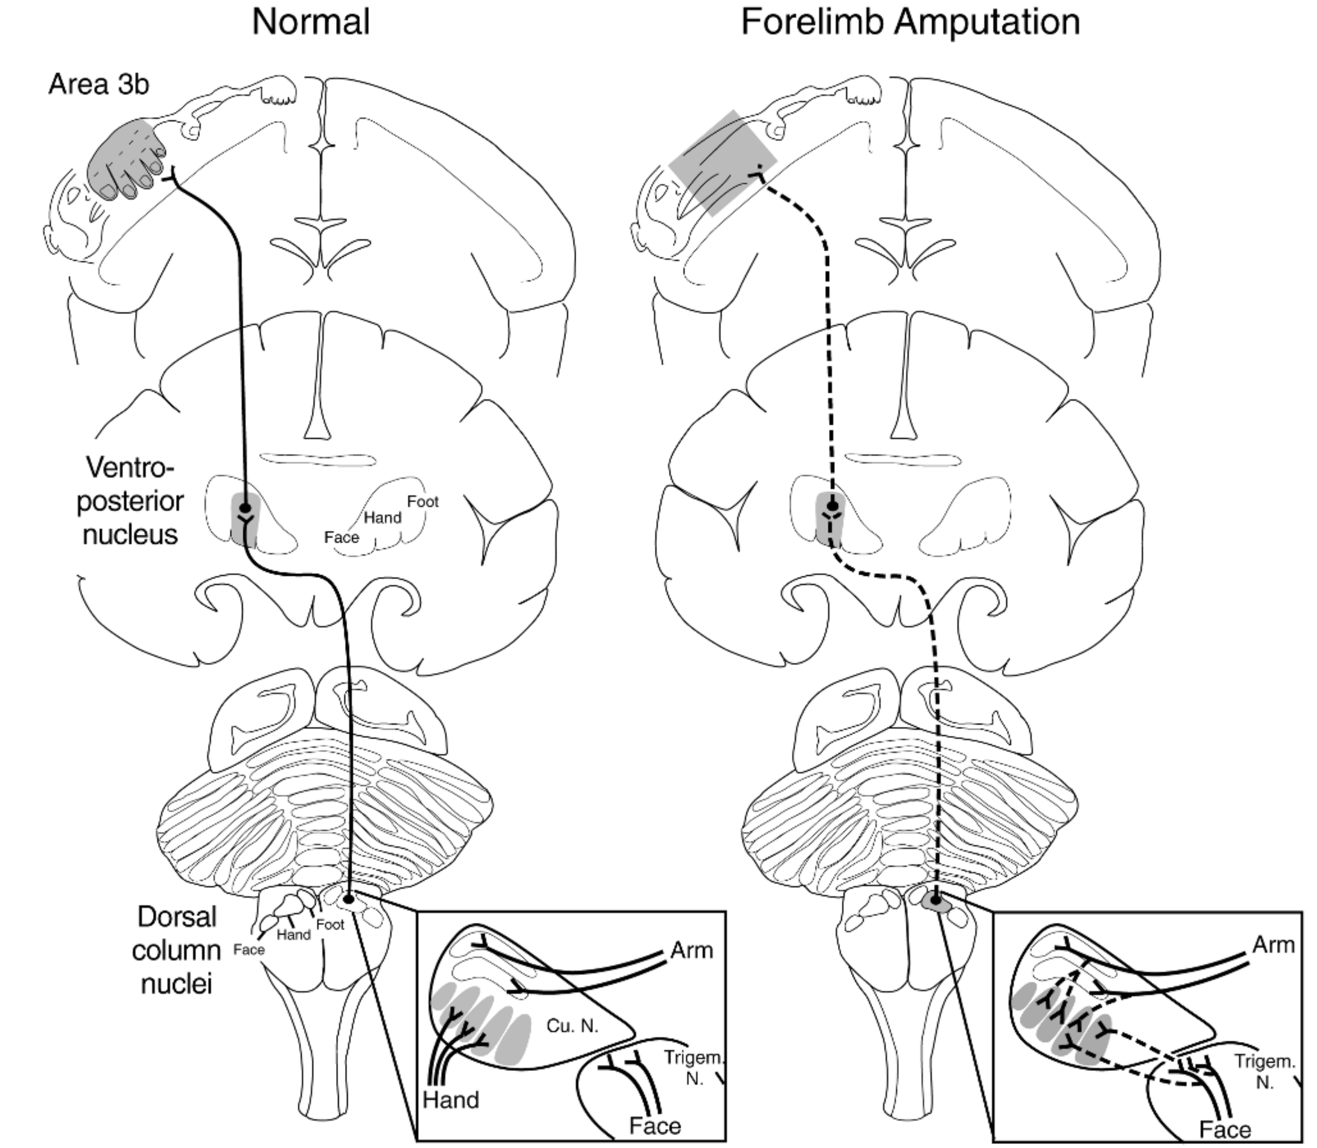

**Figure 2.** Schematic showing that changes in the dorsal column nuclei produced by longstanding forelimb amputation can lead to reactivations of the hand representations in the ventroposterior nucleus (VP) of the thalamus and cortical area 3b. In normal macaque monkeys (series of cross-sections on the left), only projections from the skin of the hand target the ventralmost cell clusters in the cuneate nucleus (gray shading). These inputs initiate a relay of activation to the hand representations (gray shading) in VP and in area 3b. In monkeys that lost part or all of the forelimb (series of cross-sections on the right), new connections from the arm and from the face (dashed lines in the enlarged image of the cuneate nucleus) sprout into the region of the cuneate nucleus where the hand is normally represented. These new activating inputs alter the maps projected to VP and area 3b (dashed lines), where neurons that normally respond to the hand (gray shading) come to respond to stimulation of the remaining stump of the arm or to the face (see Florence et al., 2000, for a discussion).

of hand cortex after median nerve transection in monkeys, NMDA antagonists were delivered systemically for weeks after the injury (reviewed in Myers et al., 2000). The reactivation of denervated cortex that typically emerged during that time course was blocked, indicating that the NMDA receptor mechanism was essential for the plasticity.

An important distinction of NMDA receptor–mediated plasticity is that it is *not* responsible for the reorganization that occurs immediately after sensory deprivation. As mentioned above, the rapid release of GABA inhibition was thought to be responsible for the plastic changes that appear immediately after a sensory denervation. To confirm that two mechanisms explain the distinct epochs in the time course of somatosensory plasticity, Myers and colleagues (2000) examined the immediate effects of median nerve transection in monkeys that had undergone systemic blockade of NMDA receptors. If NMDA receptors were required for the rapid appearance of new cortical receptive fields after nerve transection, then NMDA receptor blockade would prevent immediate plastic changes from occurring. However, this was not the case; immediate reorganization was observed in treated monkeys, just as in the control group. Thus, the NMDA receptor mechanism apparently played no role in the rapid phase of the somatotopic plasticity.

Over very long time courses, map reorganizations probably involve additional plasticity mechanisms. The growth of new connections probably accounts for some of the slowly developing changes. New growth, or *sprouting*, was thought to be limited in the mature brain so that the stability of brain function could be preserved. However, over the last decade, sprouting in the adult nervous system has been documented repeatedly. For example, in the spinal cord and lower brainstem, the central processes of both injured and uninjured peripheral nerve axons sprout when nearby synaptic territories are vacated by the removal of other peripheral nerve inputs (reviewed in Mendell and Lewin, 1992). Other evidence for sprouting is the finding of new inputs to the hand representation in the cuneate nucleus of monkeys that had forelimb amputation (described above). Finally, local-circuit neurons in primary somatosensory cortex have the potential for considerable new growth. In monkeys with longstanding forelimb injuries, injections of anatomical tracers into the deprived hand representation resulted in much more extensive zones of label than in normal monkeys (reviewed in Kaas and Florence, 2000). The data suggested that neurons in the deprived region of cortex had extended new connections to nondeprived portions of the sensory representation. The functional impact of the new connections was unclear; however, they may have provided an additional source of activation for the deprived neurons.

## Functional Consequences of Sensory Map Changes

It has been commonly assumed that large sensory representations relate to superior sensory abilities, since skin zones with good tactile acuity, such as the hands and lips, have large representations in the somatosensory pathway. To some extent, these large representations reflect a high density of peripheral receptors; however, it also appears that adding neurons to a processing circuit enhances the performance of that circuit. For example, after monkeys were trained in a tactile discrimination task using a specific finger, the cortical representation of that finger expanded and performance improved. Also, human amputees often demonstrated increased tactile acuity for skin zones adjacent to the site of amputation, the same skin whose cortical representation was expanded. In contrast, no improvement in the sensory performance of the reading finger was detected in Braille readers, even though the cortical representation of that finger was expanded (Pascual-Leone and Torres, 1993). Thus, the consequence of the expansion of the sensory representations in cortex remains unclear.

Some cortical reorganization may contribute to sensory mislocalizations. For example, some patients with forelimb amputations reported that tactile stimuli applied to the face produced sensations of touch on both the face and on the missing forelimb (Ramachandran and Hirstein, 1998). These mislocalizations have been attributed to reactivation of the denervated forelimb representation by face inputs, observed using noninvasive imaging techniques (see Elbert and Flor, 1999). The clinical findings suggest that, at least for the case of limb amputation, expanded representations do not lead to better performance. Thus, there must be limits to the extent to which processing circuits can benefit from increasing neuron number. Beyond that limit, additional neurons appear to be a detriment to sensory abilities.

For such profound changes in the topographic organization of the somatosensory cortex to affect the behavior of the individual, the use-driven alterations almost certainly must be relayed through higher-order sensory cortical areas into the motor pathway. Motor cortex appears to be equally as plastic as somatosensory cortex (reviewed by Sanes and Donoghue, 2000), and the interrelationship between the two has been shown in monkeys that develop a task-specific dystonia (abnormal and often painful muscular contractions) after intensive sensory training. The dystonia has been attributed to alterations in the sensory representations of skin surfaces that are overstimulated during training (Byl, Merzenich, and Jenkins, 1996). Sensory maps appear to be important for sensory control of fine motor skills; thus, it is argued that when the sensory maps are disrupted, sensorimotor feedback is affected and abnormal motor behaviors can emerge. A model of the relationship between the sensory and motor systems predicts that certain plastic changes in somatosensory cortex may exacerbate abnormal motor behaviors, such as dystonias (Sanger and Merzenich, 2000).

## Discussion

The reviewed findings show that both peripheral injury and altered sensory experience result in modifications of the body representation in the somatosensory cortex of primates. Current models of cortical function can account for many of the observed changes in somatotopic organization, but no models exist to account for the extensive reorganizations that occur long after massive sensory deprivation. This is largely because such massive reorganizations depend on the growth of new connections, and not only on changing synaptic weights. To successfully explain the types of topographic changes that have been found with large-scale reorganizations, models may need to estimate the role of new growth, and the accumulation of reorganizations relayed from subcortical levels of the somatosensory system.

# Sound Localization and Binaural Processing

*Yehuda Albeck*

## Introduction

In the most general sense, the term *sound localization* means the vivid perception of the location of an object that emits sound. In the more restricted context of psychophysics and neurophysiology, the term denotes the precision with which a subject can point at a sound source and the computational algorithm that the brain uses to complete such tasks. Psychologists can infer the characteristics of the human sound localization system by tuning their models to describe the performance of human subjects. These models emphasize performance: how well people localize sounds and what parameters affect this ability.

Neurobiologists study the underlying neural processing, focusing on neural characteristics and patterns of connectivity such as tuning curves, axonal conduction latencies, and inhibitory or excitatory projections. They use behavioral studies in normal and lesioned animals to study the role and significance of different groups of neurons for sound localization. The two disciplines produce similar but distinct models.

In this article, I concentrate on one aspect of sound localization: the use of the interaural time difference (ITD) to estimate the azimuthal angle of a sound source. I describe one biological model—the ITD detection in the barn owl's brainstem—and two psychological models—the cross-correlation (CRC) model extended by inhibition and monaural processors and the straightness model. These models have much in common. The biological model is well understood in terms of information processing. The psychological models are defined in realistic biological terms, and both contain elements that are present in the biological system. The binaural time pathway in the cat is also well understood (for reviews and references to more biological models, see Yin and Chan, 1988; Casseday and Covey, 1987).

More specifically, these models have a common theoretical foundation, the CRC model. This model suggests that the brain attempts to match the sounds in the two ears by shifting one sound relative to the other. To estimate the match, the brain averages the multiplication of the instantaneous amplitudes. This operation is similar to computing the CRC function of the sounds in the two ears. The shift that produces the best match is assumed to be the one that just balances the *real ITD*. However, the models differ in the detailed composition of the binaural cross-correlator and the way it is interpreted by higher systems. By comparing the models, I intend to highlight the merits of each approach and advocate the need for a unified theory that can satisfy the requirements of both fields.

Models of binaural interaction are founded on a simple logic. The mathematical description, however, is tedious. Thus, the description is only a qualitative introduction. Detailed mathematical formulation, simulation procedures, and experimental paradigms can be found in the original articles (for review, see Yin and Chan, 1988; Yost and Hafter, 1987; and other chapters in these books).

## The Cross-Correlation Model

Figure 1 shows a possible implementation of the CRC model (Jeffress, 1948). The ears decompose the sounds to their spectral components using a bank of bandpass filters. Each output line conveys the waveform in a specific spectral channel. Each spectral channel interacts with the corresponding channel from the other ear. The representation of information in distinct spectral channels is called *tonotopic organization*. Each binaural neuron multiplies the signals

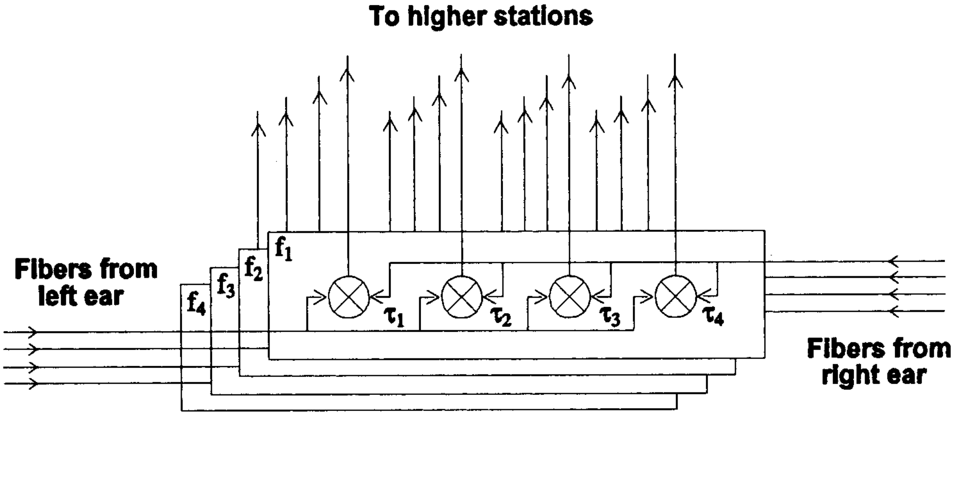

**Figure 1.** Schematic diagram of the cross-correlation model. The binaural processor has two dimensions, frequency and interaural time difference. In this example, each of the four spectral channels, $f_1$–$f_4$, has four coincidence detectors. The signals from each ear pass along delay lines on the way along the nucleus toward the contralateral side. Each detector provides an estimate of the cross-correlation of the signals at a specific band $f_i$ for a specific time shift $\tau_i$.

from both sides and averages the signal over the recent past. The inputs from the ears to each binaural neuron are identical; only the relative time shift is different. The signal from the left side reaches the leftmost unit before the signal from the right side does. The opposite is true for the neuron in the right border of the processor. Between these two extremes, the signals are shifted relative to each other by many intermediate values.

The model uses three important features. First, the input signal must represent the temporal structure of the sound. This representation is achieved by phase locking the spikes in the auditory nerve to the signal. In other words, the instantaneous likelihood of observing a spike in the auditory nerve is approximately proportional to the amplitude of the half-wave rectified sound at that time. The barn owl's auditory nerve phase locks to frequencies as high as 9 kHz. Second, the signal has to be accurately delayed to each binaural neuron by selecting the length of the axons from each side to provide the exact amount of conduction delay. The relevant range of ITDs for barn owls is ±170 $\mu$s (the size of the head divided by the speed of sound). Finally, neurons in the binaural processor must effectively multiply the signals. The neural system employs coincidence detectors to mimic the multiplication. These neurons respond only when spikes from the two sides arrive simultaneously, or at least within a fraction of a millisecond. Mathematically, this operation is equivalent to multiplication because the likelihood of a coincidence is the product of the likelihoods of the single independent events (see review in Yin and Chan, 1988). The biophysics of the coincidence detection are not clear (see discussion in Yin and Chan, 1993).

This binaural processor contains a map that *place codes* the azimuth of the target. The neuron for which the axonal interaural delay balances the acoustic interaural delay becomes most active. Its place along the array codes the real ITD. The ITD response of a single cell is usually wider than the behavioral acuity; thus, the brain must use global coding to read the map. The nature of this mechanism is not known.

## The Time Pathway in Barn Owls

Barn owls use hearing to locate their prey. When an owl hears a sound, it quickly turns its head to gaze directly at the sound source. The head-turning behavior involves auditory, visual, and motor systems. The auditory system's role is to provide a two-dimensional map of the space. In this map, the location of the target is coded by the firing of a group of neurons. The neurons in the map are organized in a two-dimensional array that resides in the external nucleus of the inferior colliculus. The location of the activity along one axis codes the azimuthal angle of the target. Along the perpendicular axis, the *interaural intensity difference* is represented, which codes the elevation of the target. This map projects to a motor map that controls the owl's neck muscles.

The creation of the ITD map occurs in four computational steps. The brain divides this task among at least eight structures on each side of the brain. A block diagram of the network is shown in Figure 2. The sound is bandpass filtered and transduced to a series of phase-locked spikes in the ears. These series are relayed through the auditory nerve to the nucleus magnocellularis, one of the cochlear nuclei. Each nucleus magnocellularis projects to a nucleus laminaris on both sides. Each nucleus laminaris, in turn, projects to the core of the contralateral inferior colliculus. All of these nuclei are tonotopically organized. The contralateral inferior colliculus projects to the lateral shell of the inferior colliculus on the contralateral side, and the lateral shell projects to the homolateral inferior colliculus. Note that the pathway crosses the midline back and forth three times, but binaural interactions take place only in the nucleus laminaris (see review in Konishi et al., 1988).

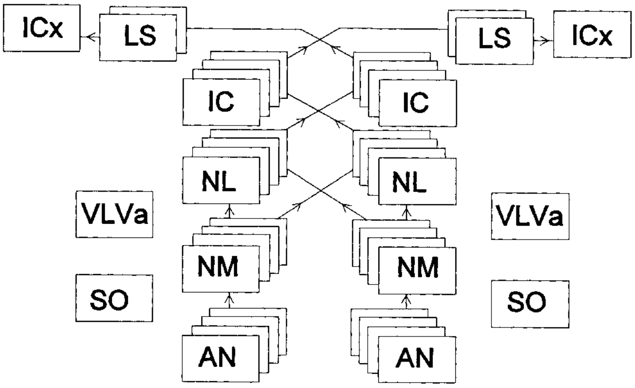

**Figure 2.** Block diagram of the barn owl's binaural time pathway. The nucleus magnocellularis (NM) relays the auditory nerve (AN) spikes to the nucleus laminaris (NL) on both sides. The NL projects to the core of the inferior colliculus (IC) on the contralateral side. The IC innervates the lateral shell (LS) of the IC, and the LS in turn projects to the inferior colliculus (ICx). Other nuclei, such as the superior olive (SO) and ventral lateral anterior lemniscus (VLVa), also participate, but are not discussed here. Tonotopic organized nuclei are shown in a cascade.

Typical ITD response curves of neurons from the nucleus laminaris, lateral shell, and inferior colliculus are plotted in Figure 3. Recordings in the nucleus laminaris confirm the predictions of the CRC model. The nucleus contains a systematic map of frequencies and ITDs (Carr and Konishi, 1990). In the nucleus laminaris and the contralateral inferior colliculus, the curve is periodic; this phenomenon is called *phase ambiguity*. A typical ITD response in the lateral shell shows a central dominant peak and smaller secondary peaks. In many inferior colliculus neurons, the secondary peaks disappear. This type of neuron is called *space specific*. Note also that the width of the ITD response decreases from approximately 70 $\mu$s in the nucleus laminaris to less than 30 $\mu$s in the inferior colliculus.

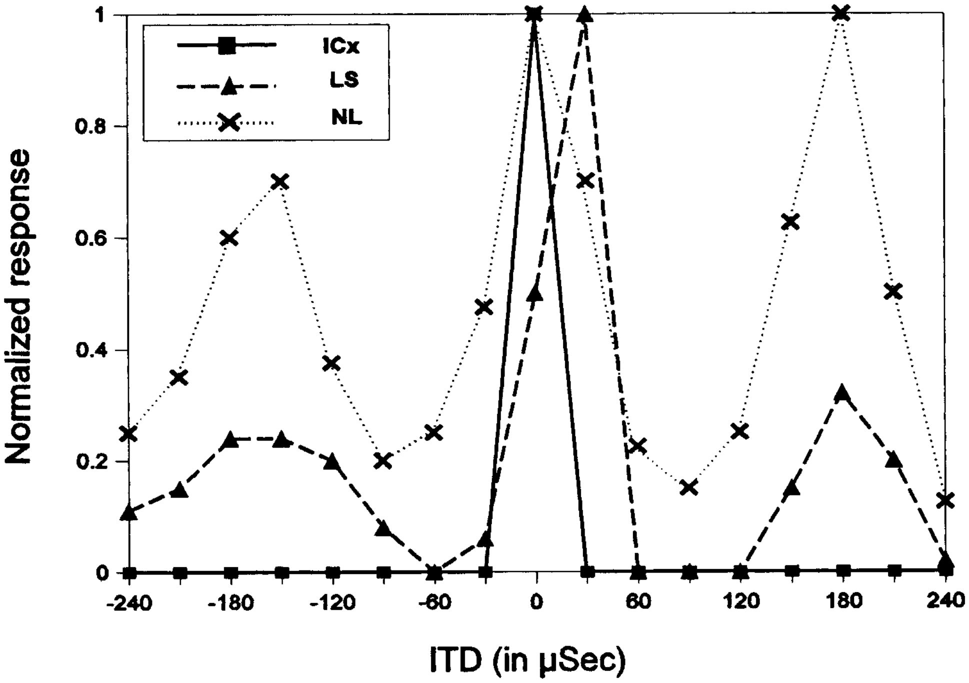
How does the phase-ambiguous curve transform into a space-specific response? It takes a combination of two processes, which are illustrated in Figure 4. The tonotopically organized nucleus laminaris is depicted as a matrix of binaural neurons. Each neuron has its own characteristic frequency and ITD. All neurons that have the same ITD, from all frequency channels, converge in the lateral shell. The convergence creates a composed ITD response curve, with partial suppression of secondary peaks. The real ITD appears in the same location across all of the spectral channels. The secondary peaks are separated from the primary peak by one period of the characteristic frequency; therefore, they have different locations for different frequencies. Thus, the contribution of the secondary peaks is spread out and cannot create a sharp, distinct peak in the composed ITD curve. Consequently, space-specific neurons cannot localize pure-tone stimuli (Takahashi and Konishi, 1986).

The second step involves inhibition (Fujita and Konishi, 1991). Neurons in the lateral shell project to inferior colliculus neurons with the same ITD. Simultaneously, they inhibit other inferior colliculus neurons with different ITDs. The inhibition, along with a high threshold, suppresses the activity in all neurons except those that receive a projection from the central ITD peak.

## Psychophysical Models

The CRC model provides a basic mechanism that explains how a neural network can extract the ITD of a binaural signal. Early theoretical approaches used this mechanism to calculate the theoretical

Figure 3. Normalized interaural time difference (ITD) response curves from the barn owl's brainstem. The nucleus laminaris (NL) response is phase ambiguous and has a high baseline. In the lateral shell (LS), the secondary peaks are suppressed. In the external nucleus of the inferior colliculus (ICx), only a narrow range of ITD evokes some response.



limits on the network's performance derived from the amount of noise in the system (see review in Colburn and Durlach, 1978).

More recent studies focused on how the binaural processor is used to estimate sound locations and enhance detection in a noisy environment (see review in Stern and Trahiotis, 1995). The basic CRC mechanism explains the lateralization experiments. *Lateralization* refers to the perception of an image inside the head that occurs in earphone experiments. *Localization* refers to external perception. The model does not explain how and why the interaural intensity difference can affect lateralization (see, e.g., Yost and Hafter, 1987). This effect is called *time-intensity trading*. The interaural intensity difference cannot change the CRC predictions because the signals from both sides are simply multiplied. Lindemann (1986) suggested that the signal traveling along the binaural processor has two components. The sound-evoked signal attenuates as it travels along the delay line, and it is replaced by a second independent signal. If the sound in the right ear is faint, the binaural units on the right of the processor will multiply it by the left signal and produce a small response. On the other hand, the units on the left multiply the strong signal from the left ear by the independent signal and produce a higher response. The peak of the response is then shifted leftward, and a time-intensity trade results. In addition, Lindemann suggested that each unit in the binaural processor inhibits the input to the other units (for more details, including the distinction between static and dynamic inhibition, see Lindemann, 1986). This inhibition sharpens the ITD peaks and enhances the stronger peak when another peak appears.

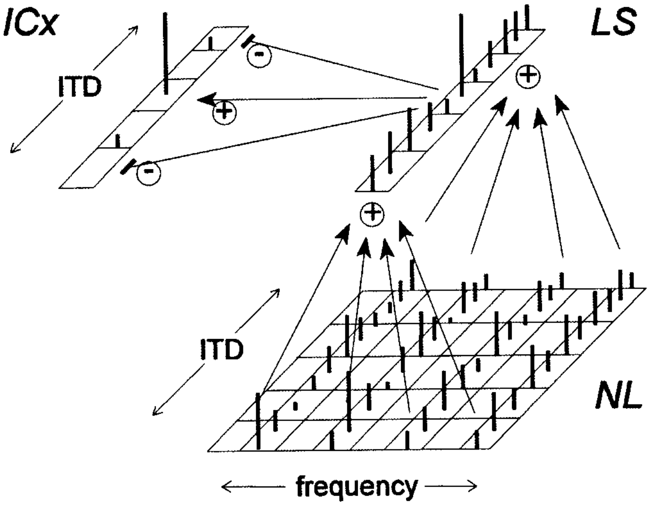


Figure 4. The nucleus laminaris (NL) can be viewed as a matrix of neurons. Each row in this matrix represents a group of neurons with the same characteristic frequency and different ITDs. Columns represent neurons with the same ITD and different characteristic frequency. All the neurons in a specific row excite a single neuron in the lateral shell (LS). The excitation is denoted by an arrow and a plus sign. This projection transforms the NL matrix into a one-dimensional array of ITD-sensitive neurons and destroys the frequency tuning. LS neurons supply excitation to inferior colliculus (ICx) neurons with the same ITD and inhibition to other ICx neurons with ITDs larger or smaller than their own. The inhibition is denoted by an arrow with a minus sign. These ICx neurons show a sharp tuning to the sound location and a broad tuning to frequency.

These extensions to the CRC model elegantly explain the time-intensity interaction. The model does not explain the interaction between different spectral channels. A pure 500-Hz tone with an ITD of −1.5 ms sounds as if it has an ITD of +0.5 ms. Both solutions are identical for a pure CRC model, but human subjects always perceive the ITD that is smaller in absolute value. As the spectrum of the signal broadens, the perception crosses the midline and moves toward the location that corresponds to an ITD of −1.5 ms. To explain this finding and similar experiments, Stern, Zeiberg, and Trahiotis (1988) stated the *straightness principle*. They suggested that an intermediate mechanism assigns greater weight to units that are active in coincidence with units of different spectral channels but of the same ITD. The weighted image is further processed to lateralize the sound. Neither model provides a perfect fit for every psychophysical experiment (see the review on lateralization in Yost and Hafter, 1987). Each model captures some aspects and probably reflects some characteristics of the biological system.

## Discussion

It is instructive to compare the biological and psychophysical approaches. The most striking characteristic of the biological system is its modular structure. Each nucleus performs a limited task. For example, the nucleus laminaris seems to pay little attention to the interaural intensity difference. This feature is taken care of by another nucleus. Also, there is no evidence of monaural processing in the nucleus laminaris. A special pathway is devoted to the preservation of monaural characteristics. The separate pathways converge only in the inferior colliculus. Similar mechanisms exist in other animals (Casseday and Covey, 1987).

The models differ in a more subtle way in across-frequency interaction. The owl employs a two-step process involving excitation and inhibition over the coincidence mechanism suggested in the straightness model. From a computational point of view, the owl's process is a realization of the straightness principle. Lateral inhibition in the inferior colliculus is probable, but in a different context than that suggested by Lindemann.

An important distinction between the models is the purpose of the network. The owl's network is responsible for head turning toward a sound source. Psychophysical models deal with perception, which may involve different brain structures (see DISSOCIATIONS BETWEEN VISUAL PROCESSING MODES for a distinction between *what* and *where* systems in vision). I suggest that models of perception should integrate several modalities and abandon the effort to construct a single, super-binaural processor that accounts for all of the psychophysical data in a single step. A more realistic model should have two separate modules for the processing of ITD and interaural intensity difference as well as a third decision mechanism that weighs both. The decision mechanism should be able to change its strategy based on monaural information, such as spectral composition and envelope structure.

The CRC model is sufficiently detailed to allow a successful silicon implementation of sound localization (Lazzaro and Mead, 1989) that captures the essential features of the biological system. On the other hand, the details of ITD detection at the cellular level are still not known. Intracellular recording in the nucleus laminaris and in analog mammalian structures is difficult; therefore, little is known about its biophysics and pharmacology.

Other biological systems possess some similarity to the owl's time pathway. The jamming-avoiding behavior of the weak electric fish and the echolocation of the bat are well documented (see review in Carr, 1993). However, these models provide little information about the internal representation of the external environment in the brain. Usually, more information is extracted by studying neural pathways that lead to a motor response, such as head turning in owls or frequency adjustments in electric fishes and bats. A more holistic theory of sound localization should unify the biological and psychological models. Such a theory may explain psychophysical phenomena in terms of realistic biological structures and provide testable predictions for experimentalists in both fields.

# Sparse Coding in the Primate Cortex

*Peter Földiák*

## Introduction

Brain function can be seen as computation, i.e., the manipulation of information necessary for survival. While computation itself is an abstract process, it must be performed in a physical system. Any physical computing system, be it an electronic computer or a biological system consisting of neurons, must use some form of physical representation for the pieces of information that it processes.

Computations are implemented by the transformations of these physical representations of information. The brain receives information via the sensory channels and must eventually generate an appropriate motor output. But before we can even study the transformations that are involved, we need at least some fundamental understanding of the internal representation that these transformations operate on. Neurons represent and communicate information mainly by generating (or "firing") a sequence of electrical impulses. Electrophysiological techniques exist for the recording of these impulses from isolated single neurons in the living brain. Single-cell recording has revealed a remarkably close and highly specific relationship between sensory stimuli, neural activity, and behavioral reports of perceptual states. However, the encoding of events and states into a sequence of neural impulses in a large number of neurons can be highly complex, especially in the cerebral cortex, which contains an elaborate working model of the world. One of the basic questions about this neural code is whether an information item (e.g., a specific sensory stimulus caused by an object) is represented by the activity of a single, individually meaningful cell or is only the global activity pattern across a whole cell population that corresponds to interpretable states. There are now strong theoretical reasons and experimental evidence suggesting that the brain adopts a compromise between these extremes, using a relatively small (though in absolute number still substantial) subset of neurons to represent each item. This is often referred to as sparse coding (Dayan and Abbott, 2001).

## Sparse Coding

The brain must encode the state of the environment and its own internal states by the firing pattern of a large but fixed set of neurons. For simplicity, consider coding by units that are either "active" or "passive" where the code assigns states to the subsets of active units. An important characteristic of such a code is the *activity ratio*, the fraction of active neurons at any one time. At its lowest value is *local representation*, where each state is represented by a single active unit from a pool in which all other units are silent. For instance, letters on a computer keyboard (ignoring the Shift and Control keys) are locally encoded. In *dense distributed representations*, each state is represented on average by about half of the units being active. Examples of this are the binary (ASCII) encoding of characters used in computers or the coding of visual images by the retinal photoreceptor array. Codes with low activity ratios are called *sparse codes*.

The activity ratio affects several aspects of information processing, such as the architecture and robustness of networks, the number of distinct states that can be represented and stored, generalization properties, and the speed and rules of learning (Table 1).

The representational capacity of local codes is small: they can represent only as many states as the number of units in the population, which is insufficient for any but the most trivial tasks. Even when the number of units is as high as that in the primate cortex, the number of discriminable states of the environment well exceeds this number. Making associations between a locally encoded item and an output, however, is easy and fast. Single-layer networks can learn any output association in a single trial by local, Hebbian strengthening of connections between active representation units and output units, and the linear separability problem does not even arise. In such a *lookup table*, there is no interference between associations to other discriminable states, and learning information about new states does not interfere with old associations. This, however, also means that there will be no generalization to other discriminable states, which presents a serious problem. If the discrimination is poor, that is a problem in itself. Alternatively, if the discrimination is fine enough to make all the necessary distinctions, we can expect a system never to experience precisely the same pattern of stimulation twice, and so no past experience will ever be used in a new situation.

Dense distributed, or "holographic," codes, on the other hand, can represent a very high number (e.g., in binary codes, $2^N$) of different states by combinatorial use of ($N$) units. In fact, this power is largely superfluous, as the number of patterns ever experienced by the system will never approach this capacity, and therefore dense codes usually have high statistical redundancy. The price to pay for the potential (but unused) high information content of each pattern is that the number of such patterns that an associative memory can store is unnecessarily low. The mapping between a dense representation and an output can be complex (a linearly nonseparable function), therefore requiring multilayer networks and learning algorithms that are hard or impossible to implement biologically. Even efficient supervised algorithms are prohibitively slow, requiring many training trials and large amounts of the kind of training data that is labeled with either an appropriate output or reinforcement. Such data is often too risky, time consuming, or expensive to obtain in a real system. Distributed representations in intermediate layers of such networks ensure a kind of automatic generalization; however, this often manifests as unwanted interference between patterns. A further serious problem is that new associations usually cannot be added without retraining the network with the complete training set.

Sparse codes combine the advantages of local and dense codes while avoiding most of their drawbacks. Codes with small activity ratios can still have sufficiently high representational capacity, while the number of input-output pairs that can be stored in an associative memory is far greater for sparse than for dense patterns. This is achieved by decreasing the amount of information in the representation of any individual stored pattern. As a much larger fraction of all input-output functions are linearly separable using sparse coding, a single supervised layer trained by simple supervised or reinforcement learning methods, following perhaps several unsupervised layers, is more likely to be sufficient for learning target outputs, avoiding problems associated with supervised training in multilayer networks. As generalization takes place only between overlapping patterns, new associations will not interfere with previous associations to nonoverlapping patterns.

Distributed representations are tolerant to damage to the units or noise. However, redundancy far smaller than that in dense codes is sufficient to produce robust behavior. For instance, by simply duplicating units with 99% reliability (assuming independent failures), reliability increases to 99.99%. Sparse representations can be even more tolerant to damage than dense ones if high accuracy is required for a representation to be recognized or if the units are highly unreliable.

**Table 1.** Properties of Coding Schemes

| | Representational Capacity | Memory Capacity | Speed of Learning | Generalization | Interference | Fault Tolerance | Simultaneous Items |
|---|---|---|---|---|---|---|---|
| Local | Very low | Limited | Very fast | None | None | None | Unlimited |
| Sparse | High | High | Fast | Good | Controlled | High | Several |
| Dense | Very high | Low | Slow | Good | Strong | Very high | One |

Sparseness can also be defined with respect to components. A busy scene may be encoded in a distributed representation while, at the same time, object features may be represented locally. The number of simultaneously presented items decreases as the activity ratio increases because the addition of active units eventually results in the activation of so many units that the representation of unrelated items ("ghost" items) will be apparent in the set of active units.

To utilize the favorable properties of sparse representations, densely coded inputs must be transformed into sparse form. As the representational capacity of sparse codes is smaller, this cannot be achieved perfectly for all possible patterns on the same number of units. Information loss can be minimized by increasing the number of representation units or by losing resolution—but only in parts of pattern space that are usually not used. Both measures seem to be taken in the cortex. First, the number of neurons in the primary visual cortex is about two orders of magnitude higher than the number of optic nerve fibers that indirectly provide its input. Second, the natural sensory environment consists of patterns that occupy only a small fraction of pattern space; that is, it has large statistical redundancy. Barlow (1972) suggested that it is the nonaccidental conjunctions, "suspicious coincidences" of features, or "sensory clichés" that must be extracted that give good discrimination in populated regions of pattern space. By making explicit, local representations for commonly occurring features of the natural environment, such as facial features, our visual system is much better at discriminating natural images than, for instance, random dot patterns. As events are linked to the causes of sensory stimuli in the environment, such as objects, rather than arbitrary combinations of receptor signals, associations can be made more efficiently, based on such direct representations (Barlow, 1991). There is substantial evidence that the visual system is well adapted to the special statistical properties of the natural visual environment by utilizing sparse coding (Baddeley et al., 1997; Vinje and Gallant, 2000, Simoncelli and Olshausen, 2001).

A simple unsupervised algorithm for learning such representations in a nonlinear network using local learning rules has been proposed (Földiák, 1990) that uses Hebbian forward connections to detect nonaccidental features, an adaptive threshold to keep the activity ratio low, and anti-Hebbian, decorrelating lateral connections to keep redundancy low. Simulations suggest that these three constraints force the network to implement a sparse code with only little information loss. Another interesting effect can be observed: high probability (i.e., known or expected) patterns are represented on fewer active units, while new or low probability patterns get encoded by combinations of larger numbers of features. This algorithm is not limited to detecting only second-order correlations, so it seems suitable for multilayer applications. Other algorithms adjust connection weight by explicitly maximizing measures of sparseness, successfully producing V1 simple-cell-like receptive fields (e.g., Olshausen and Field, 1997), although the biological implementation here is less direct.

## Sparse Coding in the Cortex

It is easy to measure sparseness in network models, where the responses of all units can be observed. An idealized "wavelet" filter model of simple cell responses in primary visual cortex has shown that wavelet coefficients of natural images show high kurtosis; that is, for natural images, most wavelet units have outputs near zero and only a small subset of units gives large responses, there being a different subset for each image (Field, 1999). Evaluating the sparseness of coding in brains, however, is difficult: it is hard to record a set of neurons simultaneously across which sparseness could be measured. Techniques such as optical recording and multiple electrode recording may eventually yield data on the sparseness of coding, but there are presently formidable technical difficulties to overcome. We have more information about individual neurons' breadth of tuning across various stimulus sets than about sparseness per se. Coding across stimuli and coding across cells are, however, closely related (Table 2). For instance, the activity ratio (related to sparseness) averaged across stimuli and breadth of tuning (expressed as a ratio) averaged across units must be equal.

What evidence is there for sparse coding from single unit recordings in sensory cortex? The most immediate observation during physiological experiments is the difficulty of finding effective stimuli for neurons in most cortical areas. Each neuron appears to have specific response properties, typically being tuned to several stimulus parameters. In primary visual cortex, many neurons respond strongly only when an elongated stimulus, such as a line, edge, or grating, is presented within a small part of the visual field, and then only if other parameters, including orientation, spatial frequency (width), stereoscopic disparity, and perhaps color or length fall within a fairly narrow range. This suggests that at any moment during the animal's life, only a small fraction of these neurons will be strongly activated by natural stimuli. The problem of finding the preferences of cells becomes severe in higher visual areas, such as area V4, and especially in inferotemporal cortex (IT). Cells' preferences in IT are often difficult to account for by reference to simple stimulus features, such as orientation, motion, position, or color, and they appear to lie in the domain of shape (Perrett, Rolls, and Caan, 1982; Tanaka, 1996). Cells here show selectivity for complex visual patterns and objects, such as faces, hands, complex geometrical shapes, and fractal patterns, and the responses are usually not predictable from responses to simple stimuli. Cells responding to faces but not to a large collection of control stimuli could be considered, on the one hand, to be very tightly tuned cells in the space of all possible stimuli. On the other hand, they may have quite broad tuning and show graded responses to stimuli within the carefully selected specific categories for which they show selectivity. To estimate, therefore, how often these cells are activated in behaving animals would require much more accurate knowledge of the animals' natural visual environment and behavior, or access to the cell's response during normal behavior.

Cells with apparent selectivity for faces might be selective for the full configural and textural information present in a preferred face stimulus, or may be triggered simply by the presence of two roughly collinear bars (most faces have eyebrows) or by a colored ovoid. One of the possible approaches to explore IT cells' preferences has been employed as systematically as possible by Tanaka and colleagues (Tanaka et al., 1991). Using this approach, they try to determine preferred features of cells by simplifying the stimuli that excite them. This method begins by presenting many objects to the monkey while recording from a neuron to find objects that excite it. Component features of effective stimuli, as judged by the experimenters, are then presented singly or in combination. By assessing the cell's firing rate during the presentation of each sim-

**Table 2.** Sparseness Versus Breadth of Tuning

| | | Cell | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
| | 1 | | | 0 | | | | | | |
| | 2 | | | 0 | | | | | | |
| | 3 | 1 | 0 | 1 | 0 | 0 | 1 | 0 | 1 | 1 |
| Stimulus | 4 | | | 0 | | | | | | Sparseness |
| | 5 | | | 1 | | | | | | |
| | 6 | | | 0 | | | | | | |
| | 7 | | | 0 | Breadth of tuning | | | | | |

plified stimulus, the protocol attempts to find the simplest feature combination that maximally excites the cell. This approach suffers from the problem that even simple objects contain a rich combination of color, orientation, depth, curvature, texture, specular reflections, shading, shape, and other features that may not be obvious to the experimenters. As any feature combination may be close enough to the preferences of a cell for it to become excited, the simplified stimuli that are actually presented are only a small subset of all possible combinations, selected according to the experimenter's intuitions. Hence, it is not possible to conclude that the best simplified stimulus found using this method is optimal for the cell, only that it was the best of those presented. A possible improvement in this area may come from automated neurophysiological experimental stimulus optimization procedures, which use more objective on-line search algorithms in a closed-loop experimental design to find peaks of neural tuning curves in high-dimensional (e.g., image) spaces (Földiák, 2001). However, it may not always be safe to assume that cells code only one optimal set of features, since it is possible that they could exhibit two or more maxima, corresponding to quite different feature combinations (Young, 1993). Recent results from intermediate stages of visual processing, area V4, however, suggest that cells at these stages encode well-localized individual contour components independently of global shape configuration (Pasupathy and Connor, 2001). Even at higher stages, e.g., in IT, cells can show preferences for patterns that are simpler than real visual objects. One interpretation of these results is that IT might consist of a large number of detectors of pattern "partials," which together might constitute an "alphabet." The detection of such partials would seem to suggest that these cells will have broader tuning than cells with selectivity for the full configuration. The idea that an IT cell reliably signals the presence of the particular pattern "partial" seems not to be supported by the results of Tanaka et al. (1991), who showed that the presence of other visual features can disrupt the cell's response to its "partial," a result that is inconsistent with the visual alphabet concept. Hence, the simplification approach captures neither necessary nor sufficient descriptions of the behavior of IT cells, and does not yet present a clear message on the sparseness of representation.

Finally, we note a difficulty in all attempts to measure sparseness in the cortex. In the extreme case, a cell with tuning so precise that it responds only to a single object will sustain its firing near its background rate when shown anything else. Researchers have only limited time and stimuli available to explore the cell's preferences during an experiment, and invariably go on to the next unit if they cannot determine what it is that the cell prefers, which strongly biases estimates of the specificity distribution. So, if there are any cells with extremely high specificity (approaching the specificity of "grandmother cells"), we cannot expect to find them experimentally using current methods. On the other hand, a cell that appears to respond only to a very limited number of a set of stimuli, as, for example, some human medial temporal lobe cells shown in Heit, Smith, and Halgren (1988), cannot be interpreted as conclusive evidence for extremely narrow tuning because of uncertainty about their responses to untested stimuli.

## Beyond Sparseness

While breadth of tuning and sparseness are interesting issues both experimentally and theoretically, these issues cover only a minor aspect of neural representation. A much more significant question is what the components of a representation stand for. Imagine a sparse code, where each information item is represented by a randomly selected subset of n units from a pool of $N$ units (e.g., the ASCII code). Alternatively, each unit could represent some meaningful aspect or feature of the item, and each item would be encoded by the combination of meaningful properties or features that are applicable to the item (Barlow, 1972). This scheme could have the same sparseness as the random scheme, but the random scheme would only allow us to identify whether the item is present in the representation. The alternative scheme, however, allows much more than that. It allows us to attribute meaning to it. It allows us not only to determine the degree of similarity between items, but the representation of the items also implicitly contain the description of the kind of similarity present between the items. It also allows the system to deal with unknown or new items by generalizing along the relevant dimensions.

Much of the neurophysiological data from high-level visual cortex support Barlow's hypothesis that the neural code is not only sparse, but that the elements of the code stand for meaningful features of the world, such as complex shapes, object-components, and faces (Perrett et al., 1982; Tanaka, 1996), and that even intermediate stages of the ventral visual pathway show selective responses to interpretable shape primitives and contour features, such as angles and curves (Pasupathy and Connor, 2001).

## Discussion

The theoretical reasons and experimental evidence discussed here support the hypothesis that sparse coding is used in cortical computations, while the degree of sparseness is still a subject for future research. Even more important may be exploration of the relationship between the responses of single neurons and significant, meaningful features and aspects of the sensory world. The full description of high-level cells will require far more detailed knowledge of their anatomical connectivity and better understanding of the lower-level sensory neurons out of which their responses are constructed.

# Speech Processing: Psycholinguistics

*Nick Chater and Morten H. Christiansen*

## Introduction

*Psycholinguistics* refers to the empirical study of the human language processing system, typically using behavioral experiments. This article considers attempts to capture psycholinguistic data using connectionist models (Christiansen and Chater, 2001). We primarily focus on relatively "early" aspects of speech processing—speech segmentation and word recognition.

The article is in three sections. "Connectionist Modeling: A Bridge from Psycholinguistics and Brain Theory?" outlines the gulf between theories of brain function and traditional accounts of language processing. Connectionist modeling promises to help span this gulf, by attempting to ground speech processing in a connectionist processing architecture, a type of architecture initially inspired by attempts to model the computational properties of the brain. The section titled "Segmentation and Recognition: Two Processes or One?" asks how far the problem of segmenting speech into words occurs independently of word recognition—a critical question for computational modeling. The section "Competition and Interaction in Word Recognition" considers connectionist models of word recognition, and their interplay with empirical research and theory.

## Connectionist Modeling: A Bridge from Psycholinguistics to Brain Theory?

Both theoretical and empirical aspects of the psycholinguistics of speech processing seem, at first sight, rather distant from brain theory.

Theoretically, the starting point in psycholinguistics has been to take ideas from linguistics, the study of the abstract structure of language. But a theoretical vocabulary of "phonemes," or "nouns," to say nothing of the subtle notions of modern linguistic theory, seems difficult to relate to neural mechanisms. We shall see, though, that neural network models of aspects of speech processing may be viewed as building a bridge between the abstract domain of linguistic representation and processing and the computational architectures that may capture some general properties of neural machinery.

Empirically, data on psycholinguistics also seem distant from brain theory at an experimental level, because relatively little is known about the detailed structure and function of the rather diverse brain areas involved in processing speech. Partly this is because, in contrast to the study of perception or motor control, it is not possible to gather relevant information from detailed neurobiological studies of nonhuman animals, because natural language appears to be unique to humans. Perhaps more important, it seems unlikely that brain structures underlying speech processing will have a neurophysiological basis as readily interpretable as the topographic maps in the visual and motor cortex. This is because the computational problems of speech processing have no apparent spatial structure that might be expected to map onto cortex in a spatially coherent way. In any case, at present, neurobiological considerations impose relatively coarse constraints on computational models of speech processing. Although data from neuropsychology and functional imaging are becoming increasingly important, the main empirical constraints on psycholinguistic models are derived from the vast body of sophisticated, but often highly equivocal, laboratory studies of human language processing.

Perhaps the strongest constraint on such models is that language processing must somehow be implemented in neural hardware, rather than on a conventional symbolic machine. Conventional symbolic models of language processing in cognitive science and artificial intelligence have typically ignored this constraint, often on the assumption that the brain must be as powerful as a universal Turing machine, and hence able to implement any computable procedure. But this argument ignores the fact that language-processing operations must operate extremely rapidly, using large numbers of slow and simple neural components, and thus require a highly parallel, cooperative style of computation. This style of computation is not easy to reconcile with the very complex chains of sequential symbolic operations involved in most conventional language-processing models.

Connectionist modeling attempts to bridge the gulf between psycholinguistics and neuroscience by capturing detailed psycholinguistic data using computational models that embody at least some of the computational principles of the brain. It also has more general significance as a crucial test case for the viability of neural network models of cognition. Because conventional linguistic theory describes the structure of language in terms of a highly complex set of symbolic rules, language processing appears to represent a very difficult challenge for neural network modeling (see Constituency and Recursion in Language). At present, connectionist models of speech processing are only partially developed, but prospects are encouraging in a number of areas (Christiansen and Chater, 2001).

The problem of speech processing is, of course, extremely broad, ranging from acoustic processing to semantic analysis. Our discussion focuses on the middle-ground problem of understanding how the brain segments and recognizes individual words in continuous, fluent speech.

## Segmentation and Recognition: Two Processes or One?

In speech processing, as in perception, a fundamental question concerns the relationship between the segmentation of sensory input (e.g., the speech signal) into chunks and the recognition of those chunks. Segmentation and recognition appear to stand in a chicken-and-egg relation: it is simply not clear how one could precede the other. Unless the input is segmented, how do we know what chunks of speech we should even attempt identify as specific words (or other linguistic units)? Conversely, unless we know what linguistic unit has been said, how can we know where the boundaries between units lie?

One approach to resolving the paradox is to assume that segmentation and recognition are two aspects of a single process—that tentative hypotheses about each issue are developed and tested simultaneously, and mutually consistent hypotheses are reinforced. A second approach is to suppose that there are segmentation cues in the input that are used to give at least better-than-chance indications of what segments may correspond to identifiable words. So the question is: Does speech processing involve dedicated segmentation strategies prior to word recognition?

Developmental considerations suggest that there may be specialized segmentation methods. The infant, initially knowing no words, seems constrained to segment speech input using some method not requiring word recognition. Moreover, studies have shown that prelinguistic infants may use such methods and are sensitive to a variety of information that is available in the speech stream and potentially useful for segmentation, such as phonotactics and lexical stress—probably before cues based on the possible meaning of what is being said can be used by the child (Jusczyk, 1997).

How can children learn to segment speech? Cairns et al. (1997) note that language is less predictable across, rather than between, words. They trained a recurrent network on a large corpus of phonologically transcribed conversational speech, represented as a sequence of bundles of binary phonetic features. The network was trained to predict the next bundle of features along with the previous and current feature bundles, based on the current input material. Where prediction error was large, it was assumed that a word boundary had been encountered. This model captured some aspects of human segmentation performance. For example, it spontaneously learned to pay attention to patterns of strong and weak syllables as a segmentation cue. However, it was able to reliably predict only a relatively small proportion of word boundaries, indicating that other cues also need to be exploited. Christiansen, Allen, and Seidenberg (1998) showed how multiple, partial constraints on segmentation could yield much better segmentation performance. They trained a simple recurrent network to integrate sets of phonetic features with information about lexical stress (strong or weak) and utterance boundary information (encoded as a binary unit) derived from a corpus of child-directed speech. The network was trained to predict the appropriate values of these three cues for the next segment. After training, the network was able to integrate the input such that it would activate the boundary unit not only at utterance boundaries, but also at word boundaries inside utterances. The network was thus able to generalize patterns of cue information that occurred at the end of utterances to when the same patterns occurred *inside* an utterance. This model performed well on the word segmentation task while capturing additional aspects of infant segmentation, such as the bias toward the dominant trochaic (strong-weak) stress pattern in English, the ability to distinguish between phonotactically legal and illegal novel words, and having segmentation errors being constrained by English phonotactics.

Although it seems likely that segmentation cues are exploited to guide the process of word recognition, this can achieve only limited results. A definitive segmentation of speech can only occur after word recognition has occurred. Empirical evidence strongly indicates that, during word recognition in adulthood, multiple candidate words are activated, even if these correspond to different segmentation of the input. For example, Gow and Gordon (1995) found that adult listeners hearing sentences involving a sequence (e.g., *two lips*) that could also be a single word (*tulips*, in U.S. pronounciation) showed speeded processing of an associate of the second word (*kiss*) and an associate of the longer word (*flower*), indicating that the two conflicting segmentations were simultaneously entertained. This would not occur if a complete segmentation of the input happened before word recognition was attempted. On the other hand, it is not clear how these data generalize to word segmentation and recognition in infancy before any comprehensive vocabulary has been established. How the segmentation and recognition develop into the kind of integrated system evidenced by the Gow and Gordon data remains a matter for future research.

## Competition and Interaction in Word Recognition

Gow and Gordon's (1995) result also suggests that word recognition itself may be a matter of competition among multiple activated word representations, in which the activation of the word depends on the degree of match between the word and the speech input. Indeed, many studies, representing a range of experimental paradigms, point toward this conclusion. Such competition is typically implemented in neural networks by a localist code for words (the activation of a single unit represents the strength of evidence for that word, see LOCALIZED VERSUS DISTRIBUTED REPRESENTATIONS), with inhibitory connections between word units. Thus, when an isolated word is identified, a "cohort" of words consistent with that input is activated. As more of the word is heard, this cohort is rapidly reduced, perhaps to a single item.

Although competition at the word level has been widely assumed, considerable theoretical dispute has occurred over the nature of the interaction between different levels of mental representation. *Bottom-up* (or data-driven) models are those in which less abstract levels of linguistic representation feed into, but are not modified by, more abstract levels (e.g., the phoneme level feeds into the word level, but not the reverse). We note, however, that this does not prevent these models from taking advantage of suprasegmental information (an example is the inclusion of lexical stress in the Christiansen et al. segmentation model, described above), provided that this information is available in a purely bottom-up fashion (i.e., no lexical-level feedback). *Interactive* (also *conceptually driven* or *top-down*) models allow a two-way flow of information between levels of representation. Figure 1 shows in abstract form the differences in information flow between the two types of models of word recognition. Note that bottom-up models allow information to flow through the network in one direction only, whereas an interactive model allows information to flow in both directions.

The bottom-up versus interactive debate rages in all areas of language processing, and also in perception and motor control. Here we focus on putative interactions between information at the phonemic and the lexical levels in word recognition (i.e., between phonemes and words), where experimental work and neural network modeling have been intense.

The most obvious rationale for presuming that there are top-down information flows from the lexical to the phoneme levels stems from the effects of lexical context on phoneme identification. For example, Ganong (1980) showed that the identification of a syllable-initial speech sound that was constructed to be between /g/ and /k/ was influenced by lexical knowledge. This intermediate sound was predominantly heard as /k/ if the rest of the word was *-iss* (*kiss* was favored over *giss*), but it was heard as /g/ if the rest of the word was *-ift* (*gift* was favored over *kift*).

The TRACE model (McClelland and Elman, 1986) has an *interactive activation* architecture, with a sequence of layers of units. First-layer units correspond to phonetic features, second-layer units correspond to phonemes, and third-layer units correspond to words. Within and between layers there are fixed inhibitory bidirectional connections between units, which stand for incompatible states, and fixed bidirectional excitatory connections between units, which stand for mutually compatible states. TRACE also deals with the temporal dimension of speech: there are many copies of the entire

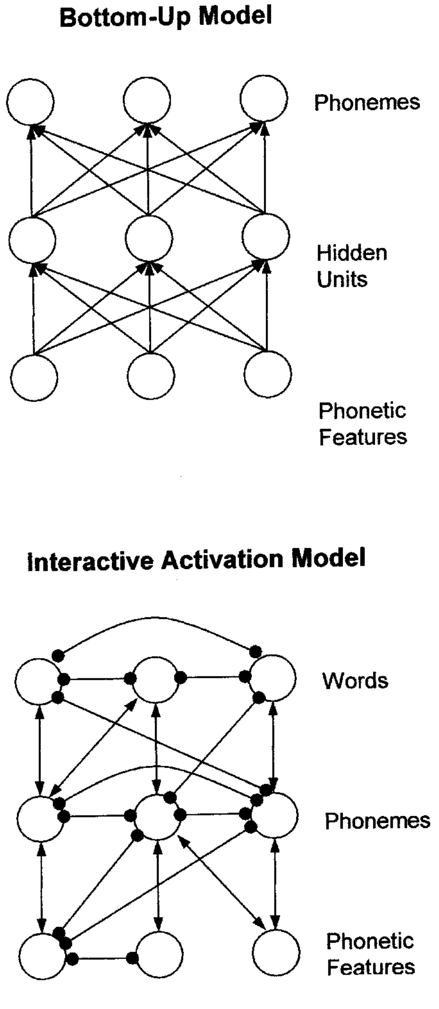

**Figure 1.** A bottom-up model of word recognition and an interactive model. The links in the bottom-up model can be either excitatory or inhibitory, and only allow information to flow upward from the phonetic features through the hidden units to the phonemes on the output. In the interactive activation model, the links are bidirectional and allow information to flow both bottom-up, from the phonetic features through the letter units to the word units, and top-down. Arrows denote excitatory links; solid circles denote inhibitory links.

network, standing for different points in time, with appropriate connections between the units in each copy. TRACE captures effects of lexical context because lexical units influence phonemic input. McClelland and Elman modeled a wide range of data, and their model has proved remarkably robust.

But "context" effects on phoneme recognition can also be explained in purely bottom-up terms. If a person's decisions about phoneme identity depend on both the phonemic and lexical levels, then phoneme identification will be lexically influenced, even though there need be no feedback from the lexical to the phoneme level. For example, the Ganong effect might be explained by assuming that the phoneme identification of an initial consonant that is ambiguous between /g/ and /k/ is directly influenced by the lexical level. Thus, if *gift* is recognized at the lexical level, this will influence the participant to respond that the initial phoneme was /g/; but if *kiss* is recognized, this will influence the participant to respond that the initial phoneme was /k/.

A substantial experimental literature has attempted to distinguish TRACE from bottom-up models, indicating the importance of connectionist modeling in inspiring experimental research. One experimental result (Elman and McClelland, 1988), derived as a novel prediction TRACE, appeared to be particularly persuasive evidence against bottom-up connectionist models. In natural speech, the pronunciation of a phoneme will to some extent be altered by the phonemes that surround it, in part for articulatory reasons. This phenomenon is known as *coarticulation*. Listeners should therefore adjust their category boundaries depending on the phonemic context. Experiments confirm that people do indeed exhibit this "compensation for coarticulation" (CFC; Mann and Repp, 1981). For example, given a series of synthetically produced tokens between /t/ and /k/, listeners move the category boundary toward the /t/ following an /s/ and toward the /k/ following a /sh/.

This phenomenon suggests a way of detecting whether lexical information really does feed back to the phoneme level. Elman and McClelland considered the case in which compensation for coarticulation occurs across word boundaries. For example, a word-final /s/ influences a word-initial phoneme ambiguous between /t/ and /k/ to be heard as a /k/ (as in *Christmas capes*). If lexical-level representations feeds back into phoneme-level representations, the compensation of the /c/ should still occur when the /s/ relies on lexically driven phoneme restoration for its identity (i.e., in an experimental condition in which the identity of /s/ in *Christmas* is obscured, the /s/ should be restored, and thus compensation for coarticulation should proceed as normal). Elman and McClelland confirmed TRACE's prediction experimentally. Recognition of the phoneme at the start of the second word was apparently influenced by CFC, as if the word-final phoneme in the first word had been "restored" by lexical influence.

Surprisingly, bottom-up connectionist models can also capture these results. Norris (1993) provided a small-scale demonstration, training a simple recurrent network to map phonetic input onto phoneme output, for a small (12-word vocabulary) artificial language. When the net received phonetic input with an ambiguous first word-final phoneme and ambiguous initial segments of the second word, an analogue of CFC was observed. The percentages of /t/ and /k/ responses to the first phoneme of the second word depended on the identity of the first word, as in Elman and McClelland (1998). But the explanation for this pattern of results cannot be top-down influence from word units, because there *are* no word units. Moreover, Cairns et al. (1995) scaled up these results using a similar network trained on phonologically transcribed conversational English.

How can an autonomous computational model, where there is no lexical influence on phoneme processing, mimic the apparent influence of word recognition on coarticulation? Cairns et al. (1995) argued that sequential dependencies between the phoneme sequences in spoken English can often "mimic" lexical influence. The idea is that the identification of the word-final ambiguous phoneme favored by the word level is also, typically, favored by transitional probability statistics across phonemes. Analyzing statistical regularities in the phoneme sequences in a large corpus of conversational English, Cairns et al. showed that this explanation applies to Elman and McClelland's (1988) experimental stimuli. If these transitional probabilities have been learned by the speech processor, then previous *phonemic* context might support the "restoration" of the ambiguous word final phoneme, with no reference to the word in which it is contained.

Pitt and McQueen (1998) tested between these two explanations experimentally. They carefully controlled for transitional probabilities across phonemes, and reran a version of Elman and McClelland's experiment: compensation for coarticulation was eliminated. Moreover, when transitional probabilities are manipulated in nonword contexts, compensation for coarticulation effects are observed. This pattern of results suggests that compensation for coarticulation is driven not by top-down lexical influence but by phoneme-level statistical regularities.

Against this, Samuel (1996) argues that the precise pattern of phoneme restoration does indicate the existence of small but discernible top-down effects. He conducted a statistical analysis of people's ability to discriminate whether a phoneme has been replaced by a noise in a word or nonword context, from the case where the phoneme and noise are both present. The logic is that to the extent that top-down factors restore the missing phoneme, it should be difficult to tell whether or not the phoneme is actually present, and hence people's discrimination between the two cases should be poorer. Hence, phoneme present/absent discrimination should be poorer in word contexts than in nonword contexts, because top-down factors should be stronger. This prediction was confirmed experimentally (Samuel, 1996). Predictably, however, purely bottom-up explanations of this finding have since been proposed (Norris, McQueen and Cutler, 2000).

The theoretical debate concerning segmentation and word recognition has been profoundly influenced by connectionism. Connectionist models are now the dominant style of computational account, even for advocates of very different positions (as we have seen in relation to the bottom-up/interactive debate). Attempts to test between the predictions of competing models have generated experimental advances, which in turn have informed how models develop.

## Discussion

Connectionist models can provide a rich framework for modeling important aspects of human speech recognition, and are now central to the theoretical and empirical literature in the psychology of language. Moreover, connectionist methods can also be applied both to early processes in speech recognition, concerned with the early analysis of what is a highly complex and variable acoustic stimulus (see READING), and to later aspects of language processing, where the main issues are syntactic and semantic (see CONSTITUENCY AND RECURSION IN LANGUAGE). A critical issue for connectionist modeling is how or whether accounts of different aspects of the speech processing problem might ultimately be integrated into an overall model of speech processing. Presently, such an integration is a long way off. Indeed, although progress has been substantial, connectionist and other models of speech perception are still some way from being able to identify words reliably in fluent continuous speech (and are not used, for example, in state-of-the-art automatic speech recognition), and work on syntactic and semantic analysis is still extremely preliminary.

Connectionist models do appear to provide a promising research direction, for a number of reasons. First, they provide a natural framework for modeling empirical psycholinguistic data. Second, learning is intrinsic to most connectionist networks, and hence the approach provides a natural source of developmental models (see COGNITIVE DEVELOPMENT). Third, connectionist models have provided a means of theoretical integration across different language-processing domains. For example, interactive and bottom-up models of speech recognition as described here are closely analogous to interactive and bottom-up models of single word reading. Fourth, it is widely argued that connectionist networks capture some aspects of the computational "style" of the brain, going at least some way to bridge between psycholinguistics and brain theory.

The potential implications of the connectionist approach to language processing are enormous, raising the possibility of a radical rethinking not just of language processing but of language structure itself. Perhaps the ultimate description of language resides in the structure of complex networks and can only approximately be expressed in terms of rigid, grammatical rules. Or perhaps connectionist models can only succeed to by building in standard linguistic constructs; or perhaps connectionist learning methods do not scale up at all (see Seidenberg's and Smolensky's contributions in Christiansen, Chater, and Seidenberg, 1999, for opposing perspectives). The future of connectionist models of language processing may therefore have important implications for the theory of language processing and language structure, and the neural machinery underlying speech processing.

# Speech Production

*Dani Byrd and Elliot Saltzman*

## Introduction

Understanding speech production requires a synthesis of perspectives found in physiology, motor control, cognitive science, and linguistics. This article presents work in the areas of motor control, dynamical systems and neural networks, and linguistics that is critical to understanding the functional architecture and characteristics of the speech production system.

Centuries of research in linguistics have provided considerable evidence that there are fundamental cognitive units that structure language. Spoken word forms are not unstructured wholes but rather are composed from a limited inventory of *phonological units* that have no independent meaning but can be (relatively freely) combined and organized in the construction of word forms. While languages differ in their selection of phonological units, within a given language there is a relatively small fixed set. Unlike certain other domains of human movement, in which the existence of component action units remains controversial (see Motor Primitives; Arm and Hand Movement Control), the production of speech by the lips, tongue, vocal folds, velum (the port to the nasal passages), and respiratory system can be understood as arising from choreographed linguistic action units.

A variety of micro- to macro-level units have been suggested as phonological units, among them features, gestures, phonemes (roughly, segments), moras, syllables, subsyllabic constituents (such as the syllable onset, nucleus, rime, and coda), gestural structures, and metrical feet (see Ladefoged, 2001). Some of these hypothesized units are mutually exclusive by definition (e.g., features and gestures); others have been assumed to coexist or to be hierarchically structured (e.g., feet and syllables and moras). For example, the word "phone" has three phonemes forming one syllable and could be transcribed /fon/, while the word "bone" (/bon/) contrasts in its initial unit and thereby in its meaning. (Two sounds are *contrastive* in a language if a change from one to the other can potentially change the meaning of a word.) Such pairs in a language are called minimal pairs and are appealed to as evidence for certain phonological units. Other types of evidence for phonological units can be gleaned from languages' word formation processes, language games, speech errors, diachronic language changes, and language acquisition. (And certain of these units, for example phonemes and syllables, form the basis of some orthographic systems.)

However, linguists and speech scientists have recognized that when phonological units are made manifest in word and sentence production, their spatiotemporal realization by the articulatory system, and consequent acoustic character presented to the auditory system, is highly variable and context dependent. In fact, the articulatory movements specific to adjacent units are not sequential in nature but are highly overlapped (i.e., co-articulated) and interactive. This has consequences that make the physical speech signal quite different from its familiar orthographic symbolic representation. In the acoustic domain, there is no invariant realization for a particular phonological unit across different contexts, an observation that has been termed *lack of invariance*. Additionally, the edges or boundaries between units are not implicit in the speech signal, a feature we can refer to as *lack of segmentability*. There are no pauses or "blank spaces" systematically demarcating phonological units—neither gestures, nor segments, nor words. (While there are amplitude and spectral discontinuities in the acoustic signal, they do not always indicate edges, although they may be indicative of certain important information regarding segment identity.) This *parallel transmission* of information in the acoustic signal due to co-articulated articulatory movements results in a highly efficient yet complex perceptual event that encodes and transmits information at high rates (see Motor Theories of Perception).

Efforts to understand the relationship between phonological units that structure words and their variable physical realization in fluent speech are an important component of speech production research. A common view is that certain linguistic information seems to be lexically specified (i.e., encoded in our stable knowledge of a particular word), whereas other aspects of word and phrase production seem best understood as resulting from principled modulations of phonological units in the performance of speaking and by peripheral properties of the physical speech production system. For this reason, the speech production system is sometimes viewed as having two components, one, traditionally referred to as *phonology*, concerned with categorical and linguistically contrastive information, and the other, traditionally referred to as *phonetics*, concerned with gradient, noncontrastive information. However, current work in connectionist and dynamical systems models blurs this dichotomy. Speech scientists' views on the cognitive organization of the speech production process are shaped by their hypotheses regarding:

- the coordinate systems in which controlled variables are defined,
- the dynamic versus symbolic nature of phonological units (i.e., primitives),
- the higher-level organization of these units,
- the role of the speaker-listener relationship in shaping speech behavior,
- child language acquisition yielding adult phonology.

We discuss some of the hallmarks of this research in the following sections.

## The Speech Production Apparatus

Speaking involves the orchestrated creation and release of constrictions in the supralaryngeal vocal tract (Figure 1). These constrictions are made by the lips and tongue (tip, body, and root) and serve to shape the resonance frequencies of the vocal tract tube. Many speech sounds are differentiated by the location and degree of these constrictions, and most speech sounds (though not all) are *pulmonic*; that is, they are generated using airflow from the lungs.

The sound excitation sources can be several but are primarily the vibratory airstream generated by rapid opening and closing of the vocal folds (*voicing*) and turbulence noise generated at narrow constrictions (*frication*). Vowels, which are voiced and produced with a relatively less constricted vocal tract than consonants, are differentiated in large measure by their first three resonance frequencies or *formants*, determined by the vocal tract shape. Consonants are differentiated largely by movement of the formant frequencies as constrictions at specific locations along the vocal tract are formed and released, by characteristic noise created at the constrictions themselves, and by the presence, absence, and timing of vocal fold vibration. Additionally, the vocal tract tube has a side branch to the nasal passageways that is opened for certain speech sounds by lowering the velum (soft palate). During speech, air may exit the vocal tract from the mouth (velum closed/raised) or from the nose (velum lowered and an anterior closure in the mouth), or from both (velum lowered and no oral closure). (Further information on the articulation and acoustics of speech can be found in

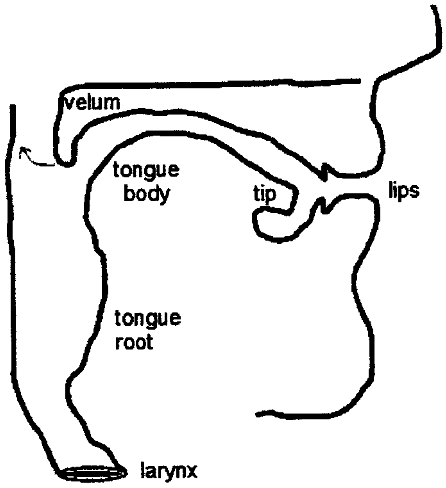

**Figure 1.** Schematic anatomy of the vocal tract showing the supralaryngeal constrictors (the upper and lower lips, the tongue tip, tongue body, and tongue root); the velum, which rises or lowers to prevent or allow airflow into the nasal passages; and the larynx, which houses the vocal folds that vibrate when adducted under appropriate aerodynamic conditions.

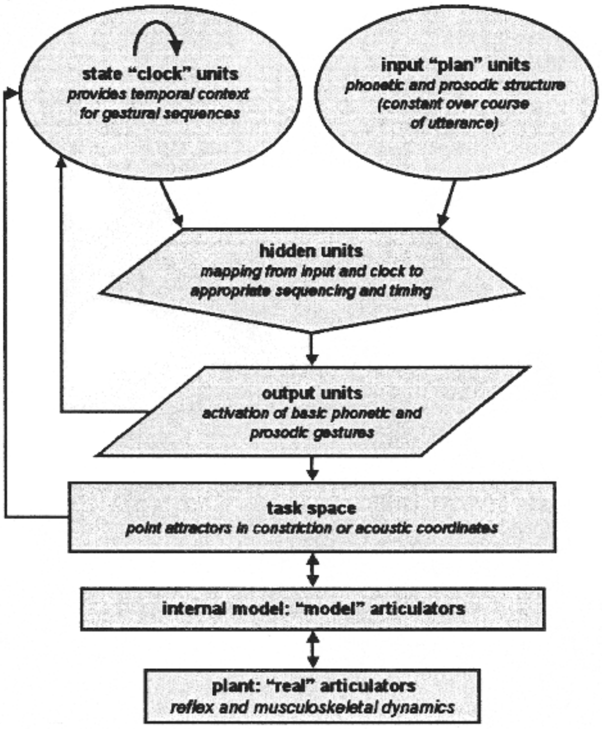
Ladefoged's [2001] *A Course in Phonetics*; for a more sophisticated account of the mapping between vocal tract shape and acoustics, see Stevens' [1998] *Acoustic Phonetics*.) A satisfactory account of human speech production abilities must encompass the great variety of speech sounds used contrastively in the world's languages, including those that contrast in aerodynamic mechanisms, tone, length, and phonation type (see Ladefoged, 2001, and citations therein, e.g., Ladefoged and Maddieson, 1996).

## Modeling the Speech Production Process

Linguists have generally adopted a symbolic representation of spoken language. This has proved to be useful in investigating the structure of words and higher-level grammatical processes. Scientists whose primary interest is speech motor control, however, have generally adopted the nonsymbolic formulations provided by dynamical systems and connectionist approaches. The research community interested in spoken language has begun to synthesize these approaches.

Many issues faced in the control and coordination of the speech articulators are the same as those faced in understanding nonspeech skilled actions. In both cases, the multilevel geometry of the system must be specified in terms of a set of appropriate reference frames (coordinate systems) and the set of mappings that is defined among them (see Geometrical Principles in Motor Control; Limb Geometry, Neural Control). Additionally, the appropriate dynamics must be specified within this set of coordinate systems. For speech production, at least four types of coordinate systems and associated dynamics are posited generically in many current models (Figure 2). At the most concrete peripheral level, the *plant* is defined by the actual articulators (e.g., jaw, upper lip) with their neuromuscular (reflexive and muscle activation) and biomechanical dynamics, and may be represented in a coordinate space defined, for example, according to muscle forces and/or equilibrium lengths (see, e.g., Sanguineti, Laboissière, and Ostry, 1998). Commands to this most peripheral level can be shaped with reference to the motions of an internal model of the plant (*model articulators*) (see Sensorimotor Learning), whose simulated neuromuscular and biomechanical behavior can provide significant constraints on the spatial patterning and relative timing (e.g., co-articulation) of movement commands. In turn, model articulator trajectories are shaped with reference to a set of task-space coordinates in which the goals of the language's phonological primitives are represented. Although there are differences in the exact nature of these coordinates among models—e.g., acoustic/auditory goals (Bailly, Laboissière, and Schwartz, 1991; Guenther, 1995) versus vocal tract constriction goals (Browman and Goldstein, 1995; Saltzman and Munhall, 1989)—models generally invoke static attractor dynamics to implement these goals. Thus, in all such models, when a particular phonological primitive is activated, the articulators will move in a coordinated manner to create a task-space *gesture* that attains the acoustic, auditory, or constriction targets and remains there until another primitive is activated or the current primitive is deactivated. In this sense, an *articulatory gesture* is a goal-directed movement of the vocal tract represented in a constriction task space and with an intrinsic duration reflecting the time constant of the attractor.

In order for this arrangement to work, a forward model must represent the mapping from current (model) articulator state to task-space state. A task-space dynamics must define the corresponding set of task-space state velocities ("forces"), and an inverse model must map these task-space state velocities to a corresponding set of (model) articulator state velocities. Finally, a set of activation (or "GO-signal"; e.g., Guenther, 1995) coordinates is required to orchestrate the patterning of these gestural units over time and vocal tract space.



state "clock" units
provides temporal context for gestural sequences
input "plan" units
phonetic and prosodic structure (constant over course of utterance)
hidden units
mapping from input and clock to appropriate sequencing and timing
output units
activation of basic phonetic and prosodic gestures
task space
point attractors in constriction or acoustic coordinates
internal model: "model" articulators
plant: "real" articulators
reflex and musculoskeletal dynamics

**Figure 2.** Schematic architecture of the speech production process. Gestural activations are viewed as outputs of a simple recurrent network that drive the articulatory plant through reference signal (model articulator) trajectories generated by task-space dynamics. Feedback connections from the task space and output units to the state unit "clock" modulate clock time flow, owing to the evolving state of the plant and gestural activations, respectively.

Although models generally have adopted connectionist dynamics to shape these activation trajectories, models can be distinguished on the basis of which of two approaches to intergestural timing is adopted. In *chain* models, gestural onsets are triggered whenever an associated preceding gesture either achieves near-zero velocity as it attains its target or passes through another kinematically defined critical point in its trajectory, such as peak tangential velocity (e.g., Guenther, 1995; see also Browman and Goldstein, 1995). In contrast, *clock* models have adopted architectures that are based on or similar to simple recurrent, sequential networks. In these models (e.g., Bailly et al., 1991; Saltzman and Munhall, 1989; see also SEQUENCE LEARNING and references therein), a network's *state unit* activity defines a dynamical flow with a time scale that is intrinsic to the intended sequence and that creates a temporal context within which gestural activations can be shaped by the network's output units. The resultant activation trajectories are determined by the manner in which a static input and the evolving state unit trajectories are mapped nonlinearly onto the output units (see Figure 2). Furthermore, it is noteworthy that many higher-level linguistic properties of both lexical and grammatical encoding can be captured using similar simple recurrent architectures (Dell, Chang, and Griffin, 1999).

## Dynamical Units (Gestures) as Phonological Primitives

In our own work we have adopted *articulatory phonology* as a formal account of phonological units and their organization (Browman and Goldstein, 1995, and references to Browman and Goldstein's work therein), and *task dynamics* (Saltzman and Munhall, 1989) as a quantitative model that implements these phonological units in the speech production system in a multilevel dynamical system defined across activation, task-space, and model articulator coordinates. Articulatory phonology views lexical representations as being composed of gestural primitives that act as combinatorial units. Gestures have two functions: they function as units of information (i.e., linguistic contrast) and as units of action (i.e., speech production) (Browman and Goldstein, 1995). The activation waveforms of the gestures in a given utterance are coordinated, or phased, with respect to one another in a highly temporally overlapped pattern that yields the coarticulatory effects that are ubiquitous in speech (Browman and Goldstein, 1995).

To this point, we have mainly discussed the dynamic gesture as the primitive unit of organization in speech production. But gestures can additionally cohere in macro-level structures. Studdert-Kennedy and Goldstein (2002) describe this using the metaphor of gestures as atoms that combine in regular patterns of coordination with one another to form molecules corresponding to larger phonological units such as segments and syllables. Segment-sized units can be viewed as coherent ions—combinations of gestural atoms (one or several) that recur in many different molecules (Studdert-Kennedy and Goldstein, 2002; see also Saltzman and Munhall, 1989). In this way, macro-level phonological structure can be viewed as emerging from micro-level gestural primitives.

Although underlyingly invariant (or at least relatively stable) control units have been postulated in speech production, and certainly for lexical representation, the exact spatiotemporal realization of these units varies according to both local and prosodic context. By way of example, consider the three /o/'s in the sentence "He said ***pho**ne* not f**o**lk on the teleph**o**ne": the [o] in "phone" will differ from the [o] in "folk" because of the different following consonantal context (e.g., there will be nasal airflow during the [o] in "phone," yielding different formant patterns). It will also differ from the [o] in "telephone" because of the emphatic stress placed on it in its first occurrence in the sentence. These are examples of co-articulatory variability and prosodic variability, respectively. Variation due to neighboring articulation (local context) is straightforwardly accounted for by the overlap of gestural units of action (e.g., Saltzman and Munhall, 1989; Browman and Goldstein, 1995, and references therein). However, variation due to prosody (e.g., phrasal position or informational prominence) requires the expression of the underlying primitives to be modulated for communicative ends in the production of a particular utterance. One approach we have pursued to implementing this modulation is via prosodic gestures that have no independent realization in vocal tract space but act vicariously to shape the time course of constriction (or auditory) gestures (Byrd et al., 2000). For example, a prosodic gesture at a phrase edge might slow the central clock (whose rate of time flow determines the local utterance rate), thereby time-stretching the gestural activations and inducing the articulatory slowing and acoustic lengthening that have been observed at phrase edges.

Although we and many in the speech production community adopt the general approach of articulatory phonology to linguistic representation, it is not without competition. A sense of this debate can be gleaned from a 1992 theme issue of the journal *Phonetica* on articulatory phonology (see Browman and Goldstein, 1992, cited in Browman and Goldstein, 1995). This view stands in contrast to a more traditional view among linguists that sees phonological primitives as symbolic (atemporal) elements such as features and segments rather than dynamic gestures. In the symbolic approach, the smallest units are typically binary features, such as [−continuant], [+aspirated], [+labial] (which could jointly describe the segment /p/ in /pat/), that are hierarchically incorporated into larger phonological units such as the syllable, (phonological) word, and phrase. These phonological units are then realized according to various and sundry phonetic implementation rules that mediate between lexical representation and physical realization.

## The Role of the Speaker-Listener Relationship in Performance

Speech behavior is adaptive to communicative and situational demands (Lindblom, 1990), and for this reason, listeners can play an important role in shaping the production of the speech signal. The speaker-listener interaction might affect word forms diachronically in the form of language change (see, e.g., Ohala, 1993; see also LANGUAGE EVOLUTION AND CHANGE) or synchronically as a function of the listener's abilities, the opaqueness of the signal, and the environment in which the communication task is taking place. Lindblom (1990) credits the speaker with a "tacit awareness of the listener's access to sources of information independent of the signal and his judgement of the short-term demands for explicit signal information" (p. 403). In Lindblom's view, it is crucial to characterize what constitutes sufficient discriminability in the signal for the listener and how speakers operate to balance the benefits of providing this discriminability against the costs of articulatory precision and effort. This viewpoint diverges from theories of speech production in which the listener plays little or no role in shaping on-line speaker behavior.

## The Organization of Speech: Adult Phonology

Whether the units of spoken language are symbolic or dynamic, they must be acquired in learning and utilized in behavior. The acquisition of the units of speech production and the organization of those units in the developing and adult lexicon into patterns appropriate to the language being acquired are broad topics that have just begun to be explored computationally.

While languages vary not only in their inventories of contrastive units but also in the structures (sequential, syllabic, rhythmic) into which those units are marshaled, they also show a large degree of agreement regarding the factors affecting the linguistic acceptability of word forms. A theoretical account of the bases for these cross-linguistic differences and similarities is provided by Prince and Smolensky's Optimality Theory (see, e.g., Prince and Smolensky, 1997; see also Optimality Theory in Linguistics). This approach to phonology (and, by extension, grammar in general) capitalizes on the idea that constraints determining well-formedness of linguistic structure are many but finite, universal (i.e., shared by all human languages), and in conflict within any particular language. The individual constraints are ranked differently from language to language and thereby yield observed cross-language typology. Constraints are thought to concern structural complexity (*markedness* constraints) (where complexity might be conceived, for example, in terms of production, perception [especially distinctiveness], and/or processing) and the relationship of a produced form to some underlying, analogous, or related form (*faithfulness* constraints). All constraints are violable (and indeed many constraints will be violated by any particular word form); however, the optimal candidate word form will be the one that avoids *any* violation of a higher-ranked constraint, regardless of the number of violations of lower-ranked constraints; that is, evaluation is via *strict domination* (Prince and Smolensky, 1997). Prince and Smolensky (1997) have described how the process of selecting optimal word forms might be modeled using connectionist networks in which (1) constraints are embodied in the network connection weights, and (2) optimality is defined according to Lyapunov function ("harmony") values corresponding to activation patterns of the network. Given a particular input, held fixed across a given set of network elements, the network will settle to a pattern that maximizes harmony and that corresponds to the most well-formed linguistic structure. The universality of constraints and the adequacy of particular evaluatory mechanisms for constraint satisfaction are topics of debate. For example, see Optimality Theory in Linguistics for a discussion of probabilistic and variable constraint ranking.

## The Organization of Speech: Child Language Acquisition

Finally, we wish to briefly mention the difficult problem of how phonological units emerge in child language production from a signal that clearly cannot be characterized as a sequence of discrete units but is best viewed as an intricately overlapping pattern of vocal tract or auditory goals. The child learner is thus faced with the challenges of *lack of invariance* and *lack of segmentability* in the continuous audiovisual signals with which she is confronted. (Of course, the adult perceiver is in a similar circumstance but brings a much richer semantic and syntactic knowledge, gained through years of experience, to the task.) Further, the child learner faces the additional difficulty of an immature vocal tract apparatus. The acoustics resulting from linguistically significant vocal tract actions of the child are, in certain respects, vastly different from the acoustic properties resulting from articulatorily parallel gestures of the adult (e.g., formant frequencies and fundamental [voicing] frequency are much higher), though their spectral and temporal *patterning* may, importantly, be similar. Further, the child's vocal tract is growing over time, resulting in ongoing changes in the relationship between the child's own articulatory gestures and their acoustic consequences, changes that must be reflected in adjustment to the production system's internal model during development. A recent special issue of the journal *Phonetica* on emergence and adaptation (2000) includes many illuminating articles relevant to the acquisition and development of linguistic systems. In one, Michael Studdert-Kennedy (2000) discusses the emergence of the gestural unit in the process of child language acquisition as occurring via an engagement of the child's own vocal apparatus and its behavioral consequences. He speculates that exemplar models of learning, facial imitation, and mirror neuron systems might have roles to play in elucidating how children form gestural units defined in terms of vocal tract constrictions in the language acquisition process (Studdert-Kennedy, 2000; see also Studdert-Kennedy and Goldstein, 2002).

Although computational modeling on the acquisition of speech production (i.e., articulation) is still in its infancy (but see Guenther, 1995, and several follow-up articles on his DIVA model for an illuminating treatment of the development of the production system), it is clear that there is an interdependent relationship between the codeveloping perceptual and production systems that relies on a perceptuomotor link (see Motor Theories of Perception), whether learned or innate, and on experience with the phonological and lexical patterning within the child's language. Marilyn Vihman's 1996 book, *Phonological Development*, is an ideal starting point for exploring this relationship, and Beckman and Edwards (2000) specifically address the importance of experience and lexical patterning in the acquisition of spoken language.

## Discussion

In order for an individual to articulate a language, she must know words of that language, know how to combine words into phrases, and be able to instantiate those phrases in the physical world through the use of body effectors. Furthermore, this act generally takes place socially in a communicative context involving a perceiver. All of these aspects of producing language shape the research agenda in the field of speech production. In this article we reviewed hypotheses regarding the nature of the units that serve to form words and the architecture of the production system that executes those units. We briefly touched on how the child learner might accomplish this, how the perceiver might play a role in shaping production, and how patterns of word forms within and among languages might be characterized. Although many challenges remain, not the least of which is connecting these insights to theories of brain, it is clear that an interdisciplinary approach involving motor control, cognitive and brain science, and linguistics is essential.

# Speech Recognition Technology

*Françoise Beaufays, Hervé Bourlard, Horacio Franco, and Nelson Morgan*

## Introduction

Automatic speech recognition, the technology that allows computer systems to transcribe speech waveforms into words, relies on digital signal processing and statistical modeling methods to analyze and model the speech signal. The core technology typically is not based on connectionist methods, even though neural network processing is commonly seen as a promising alternative to some of the current algorithms. Because of the maturity of the current technology, neural networks have to compete with high-performance algorithms to gain acceptance in the field, and it is only recently that researchers have obtained significant performance improvements by using neural networks in specific subsystems of the speech recognizer.

In this article, we review the main neural network approaches to speech recognition. To limit the scope of this review, we will focus on speech recognizers intended to process large-vocabulary continuous speech (as opposed to small-scale systems intended to be integrated into portable electronic devices and which recognize only a few command words), and we will limit the discussion to systems based on multilayer feedforward neural networks or multilayer perceptrons (MLPs).

## Automatic Speech Recognition

Traditional speech recognition systems follow a hierarchical architecture. A grammar specifies the sentences allowed by the application. (Alternatively, for very large vocabulary systems, a statistical language model may be used to define the probabilities of various word sequences in the domain of application.) Each word allowed by the grammar is listed in a dictionary that specifies its possible pronunciations in terms of sequences of phones (e.g., k O l for the word *call*). Phones are further decomposed into smaller units whose acoustic realizations are represented by statistical acoustic models.

When a speech waveform is input to a recognizer, it is first processed by a front-end unit that extracts a sequence of observations, or "features," from the raw signal. This sequence of observations is then decoded into the sequence of speech units whose acoustic models best fit the observations and respect the constraints imposed by the dictionary and language model (Figure 1).

## Front-End Processing

The purpose of the front end is to extract from the speech signal a set of features that are representative of the lexical content of the signal and invariant to acoustic variations such as those due to ambient noise. Typically, the waveform is divided in overlapping windows or "frames" of approximately 25 ms, over which the signal is assumed to be stationary. Each such frame then undergoes a spectral analysis, from which a feature vector is derived. Many variants of spectral analysis have been used, among them cepstral coefficients (which are the Fourier transform of the log spectrum) computed from a spectrum of the data integrated in a filterbank whose design emulates the auditory system. To model the time dynamics of the signal, the feature vector is augmented with the first and second time derivatives of its components.

## Acoustic Modeling

The models used to represent the acoustic realizations of the speech units are based on the underlying assumption that words consist of sequences of units that have varying length, and that each unit has constant spectral properties. The nonstationary characteristics of speech arise as the sequence of units is traversed in time. Although this is not an accurate model for many speech sounds, it is a simplifying assumption that allows powerful statistical techniques to be applied.

The tool most commonly used to model speech units is the hidden Markov model (HMM) (see Hidden Markov Models). HMMs assume that the sequence of feature vectors is a piecewise stationary process. Accordingly, an utterance is modeled as a succession of stationary states, with instantaneous transitions between these states (modeling the temporal structure of speech), and a set of state output processes, one output process associated with each state, that model the actual observed feature vectors (modeling the locally stationary character of the speech signal). This output process is typically represented by a Gaussian mixture model over the feature vectors.

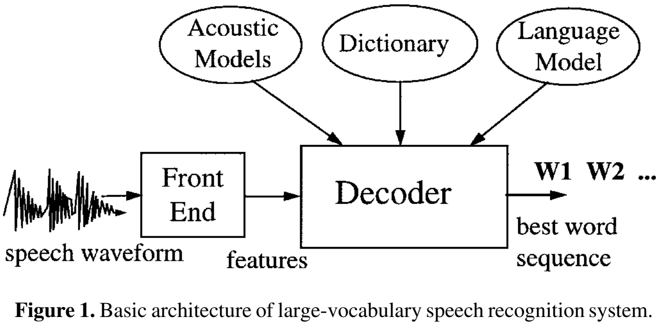

**Figure 1.** Basic architecture of large-vocabulary speech recognition system.

Although it is theoretically conceivable to have an HMM for every possible utterance, this is clearly unfeasible for all but extremely constrained tasks. Instead, a hierarchical scheme is typically adopted in which a sentence is modeled as a sequence of words and each word is modeled as a sequence of subword units. The units most commonly used are the phones, i.e., the acoustic realizations of phonemes.

A further refinement is the use of context-dependent phone units, usually referred to as triphones, which are the acoustic realizations of phonemes in the specific context defined by the previous and following phonemes. Typically, the phone or triphone HMMs have three states, with a left-to-right structure.

The simplest and most efficient algorithm to train the parameters of the HMMs (the parameters of the Gaussian mixture models as well as the interstate transition probabilities) is based on maximum likelihood techniques, that is, on finding the model parameters that maximize the likelihood of the training data. The most common of these is the forward-backward algorithm, a form of the well-known estimation maximization algorithm (see HIDDEN MARKOV MODELS).

## Discriminative Training

Some of the efforts aimed at improving speech recognition have focused on extending the model training paradigm beyond that of maximum likelihood, and on optimizing training criteria more closely related to the actual recognition metric, the recognition error rate.

It has been argued that maximum likelihood training has the potential for poor discrimination between phonetic units because it maximizes the likelihoods of individual models independently of the likelihoods of other (possibly competing) models. Discriminative training instead emphasizes contrasts between phonetic classes. Neural network classifiers based on MLPs provide the simplest architecture for discriminative training: feature vectors extracted from the data frame can be input to an MLP and classified into $N$ classes corresponding to the speech units to be modeled, phones or triphones. When appropriately trained, such an MLP classifier can be shown to minimize the classification error rate over the training data. This form of training explicitly maximizes the discrimination between the correct output class and its competitors. This approach underlies the hybrid MLP/HMM models (Bourlard and Morgan, 1993), which will be described in a later section.

This type of discrimination is local in the sense that it makes the models compete over a single frame of data at a time. Speech recognition, however, is not so much concerned with correctly recognizing individual frames of data as it is with correctly recognizing entire word sequences composed of many data frames. This observation calls for what is referred to as global discrimination, where the training algorithm attempts to increase the likelihood of the correct word string while decreasing the likelihoods of all other competing word strings.

A number of approaches to "global" discriminative training have been proposed. The first approach is that of maximum mutual information, which maximizes the mutual information between the spoken word sequence and its acoustic observations. As a consequence of this formulation, the training procedure maximizes the probability of the correct word sequence while minimizing the probability of all the other possible word sequences (Bahl et al., 1986).

Another popular training criterion is minimum classification error, where an approximation to the number of classification errors in the training data is computed and minimized. The approximation is based on computing the difference between a discriminant function for the correct class and a geometric average of the discriminants for the competing classes, and passing this difference through a nonlinearity that outputs 1 when any of the competing classes has a higher discriminant value than the correct class, and 0 otherwise (Juang and Katagiri, 1992). This method has been used initially to train neural network classifiers and later to train hybrid HMM/MLP hybrid systems.

Even though discriminative training was introduced early in the speech area, under the form of maximum mutual information, it is really the advent of neural networks that spurred the interest in discriminative approaches.

## Acoustic Modeling with MLPs

The idea of combining HMMs and MLPs for the acoustic modeling of speech signals was motivated by the observation that HMMs and MLPs have complementary properties: (1) HMMs are clearly dynamic and very well suited to temporal data, but several assumptions limit their generality; (2) MLPs can approximate any kind of nonlinear discriminant functions, are very flexible, and do not need strong assumptions about the distribution of the input data, but they cannot properly handle time sequences. However, HMMs are based on strict formalisms, making them difficult to interface with other modules in a heterogeneous system. The first such implementations were the so-called hybrid HMM/MLP models.

### *Context-Independent Hybrid HMM/MLP Models*

In hybrid models (Bourlard and Morgan, 1993), an MLP is used to evaluate the likelihoods of the observations given the phones, $p(\mathbf{x}_t|q_j)$, where $\mathbf{x}_t$ denotes the observation vector at time $t$, and $q_j$ denotes the $j$th phone state. The MLP is trained as a classifier that estimates phone-class posterior probabilities, $P(q_j|\mathbf{x}_t)$. The posteriors are then inverted with the Bayes rule, according to $p(\mathbf{x}_t|q_j) = P(q_j|\mathbf{x}_t)p(\mathbf{x}_t)/P(q_j)$. The resulting likelihoods are used in lieu of the Gaussian mixture model probabilities computed in a conventional HMM-based system. The rest of the HMM structure (transition probabilities, decoding procedure, etc.) is kept unchanged. Because the MLP learns the boundaries between the phone classes, the hybrid models show better phone discrimination characteristics than traditional ASR systems.

In order to provide the MLP with more contextual information, the phone posterior probabilities can advantageously be conditioned on a window of several consecutive observations (typically nine frames: $\mathbf{x}_{t-4}, \mathbf{x}_{t-3}, \ldots \mathbf{x}_t, \ldots \mathbf{x}_{t+4}$) rather than on a single frame of data.

### *Extension to Context-Dependent Hybrid Models*

In early implementations of hybrid models, the context of a phone, which is known to influence its acoustic realizations because of coarticulation effects, was ignored. This context, denoted here by $c_i$, can take the form of one or several phones to the right and/or to the left of the current phone, $q_j$. With context modeling, the likelihood of an observation $\mathbf{x}_t$ can be expressed as $p(\mathbf{x}_t|q_j, c_i) = P(q_j, c_i|\mathbf{x}_t) \cdot p(\mathbf{x}_t)/P(q_j, c_i)$, and, in the context of hybrid models, the posterior probability $P(q_j, c_i|\mathbf{x}_t)$ needs to be estimated by an MLP. Simply extending the context-independent approach to estimate biphone or triphone posteriors would greatly increase the number of outputs of the MLP, and thus the number of parameters to estimate. Because this is undesirable, factorization approaches were proposed in which the posterior probability of a phone and of its context, $P(q_j, c_i|\mathbf{x}_t)$, is decomposed into products of probabilities that can be estimated with smaller MLP classifiers. In Bourlard and Morgan (1993), this posterior is expressed as $P(q_j, c_i|\mathbf{x}_t) = P(c_i|q_j, \mathbf{x}_t)P(q_j|\mathbf{x}_t)$, where both terms on the right-hand side of the equation can be estimated by separate MLPs (further context factorization is possible in the case of left and right context modeling). In Franco et al. (1994), the phone and context posterior is factored as $P(q_j, c_i|\mathbf{x}_t) = P(q_j|c_i, \mathbf{x}_t)P(c_i|\mathbf{x}_t)$, where $p(q_j|c_i, \mathbf{x}_t)$ is estimated by a context-dependent MLP whose training data set contains only tokens whose context is $c_i$, and which is initialized as the context-independent MLP estimating $P(q_j|\mathbf{x}_t)$. $P(c_i|\mathbf{x}_t)$ is estimated by an MLP classifier similar to that estimating $P(q_j|\mathbf{x}_t)$.

### *Hierarchical Connectionist Acoustic Models*

In very large systems (tens of hours of training data, thousands of HMM states), context classifiers are difficult to train because of the nonuniform distribution of context classes for different phones, and because of the large amount of training data. To overcome this problem, Fritsch (1997) proposed clustering the HMM states in a tree-structured hierarchy and estimating the posterior probability of a given state as a product of the posteriors of the parent nodes in the tree. This approach is very modular and allows as many small MLPs as necessary to be trained for a given task. This was the first connectionist approach to outperform state-of-the-art standard HMM systems on the notoriously difficult Switchboard corpus, a large database of conversational telephone speech.

### *Recurrent Neural Networks*

Recurrent MLPs have been used to incorporate time dependencies in the computation of the HMM's state probabilities (Robinson, 1994). In recurrent MLP implementations of hybrid HMM/MLP recognizers, posterior phone probabilities are estimated based not only on the current observations but also on a set of state variables that are themselves functions of the observations and state variables at previous times. The recurrence built into the state variables allows the network to capture the dynamic evolution of the speech signal in a more principled and efficient way than by increasing the number of data frames in the input window, as in nonrecurrent hybrid systems. The weights of the recurrent MLP are typically trained with the backpropagation-through-time algorithm, a method for "unfolding" the recurrence and treating the time-expanded structure as a long multilayer feedforward MLP (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION).

This approach proved to be competitive with state-of-the-art HMM-based recognizers on large-vocabulary continuous speech recognition tasks (Hochberg et al., 1994).

### *Multiband Recognition*

Hybrid MLP/HMM systems were recently used in multiband recognition, a technique by which the speech frequency band is divided in several subbands that are recognized in parallel. The subband segments can be recombined at the frame, phone, or word level, either with an MLP combiner or with a simpler (nonadaptive) mechanism. This approach has shown great potential for speech environments with band-limited noise (by weighting the clean frequency bands more than the noisy bands) (Bourlard and Dupont, 1996).

## MLP Front-End Processing

The front-end unit, which is responsible for extracting feature vectors from the waveform, is probably the most critical component of a speech recognition system in that, ultimately, the performance of the system is limited by the amount of information contained in the speech features.

Although most of the early attempts at incorporating MLPs in recognition systems focused on the acoustic models rather than the front end, MLP-based feature extractors have progressively gained more interest in the speech community. There are several reasons for this.

First, traditional front-end units are designed based on classical signal processing principles, guided to some extent by our knowledge of the human hearing system. They have few parameters, and offer little room for optimization from observed data. The introduction of trainable elements in the front end opens the door to more data-driven designs. Second, MLP-based front ends can be jointly optimized with the acoustic models, thereby allowing a closer integration of the two modules. This is especially relevant in the context of discriminative training. Finally, MLPs are powerful tools for introducing new knowledge sources into the front-end unit, without having to make specific modeling assumptions. The following sections will give a few examples of these points.

### *Speaker Normalization and Adaptation*

Speaker recognition systems are typically trained from utterances spoken by different speakers. These are speaker-independent recognizers. Speaker-dependent recognizers, trained from a single speaker's data, typically outperform speaker-independent systems but are understandably harder to build, because of the difficulty of collecting massive amounts of speech from each user of the system. Part of the performance gap between speaker-dependent and speaker-independent recognizers can be regained with techniques such as speaker adaptation, or adjusting the speaker-independent models to fit a specific voice, and speaker normalization, or factoring out interspeaker differences.

There is a vast body of literature on this topic, most of which does not make use of MLPs. Model adaptation algorithms differ in terms of which parameters are adapted (e.g., Gaussian means only or means and variances), what criterion is used (maximum likelihood or maximum a posteriori), how the transformations are constrained, and so on. Similarly, feature transformations come in different flavors. A few examples of adaptation/normalization implementations using MLPs are given below.

In Neto et al. (1995), a single-layer MLP was inserted between the front end and a speaker-independent connectionist recognizer. It was trained from a small amount of data for each test speaker to normalize out speaker-specific characteristics from the feature stream. This layer was trained by freezing the parameters of the speaker-independent system after it had been trained and backpropagating errors through the recognizer, down to the MLP layer.

To improve the acoustic resolution of the feature transformation Abrash (1997) followed a mixture-of-experts approach. Instead of transforming the speech features with a global transformation according to $\mathbf{x}' = T(\mathbf{x})$, he considered a stack of transformation networks, $T_i(.)$, each specializing at a specific region of the acoustic space, $r_i$. The overall feature transformation is then expressed as a weighted sum of local transformations, $\mathbf{x}' = \Sigma_i P(r_i|\mathbf{x})T_i(\mathbf{x})$, where the posterior probabilities $P(r_i|\mathbf{x})$ are estimated by a so-called gating network. In particular, the acoustic regions can be defined to correspond to the different phonemes or groups of phonemes.

As mentioned previously, speaker adaptation can also be performed in the model domain by transforming the parameters of the speaker-independent acoustic models. In Abrash et al. (1996), a nonlinear model transformation was proposed to adapt the means of a standard Gaussian mixture–based HMM system. The MLP transformations were trained with a generalization of the Expectation-Maximization algorithm, but with the maximization step performed with a series of steepest ascent iterations, a technique inspired from backpropagation training.

### *Joint Feature Extraction and Model Training*

Steepest descent/ascent training and the concept of backpropagating error gradients throughout a given structure, as is commonly done in the field of MLPs, find applications in various aspects of speech recognition. For example, in Bengio et al. (1992), an MLP feature transformation was trained along with the HMM-based acoustic models to maximize the maximum mutual information criterion for a plosive consonant classification task. Here the feature transformation is speaker independent and is meant to increase acoustic discrimination rather than focusing on speaker variability. Jointly optimizing both sets of parameters gave higher recognition rates than optimizing the two modules separately.

Similarly, in Rahim, Bengio, and LeCun (1997), a feature transformation and a set of acoustic models were jointly trained to minimize the classification errors between subword units. The transformation and the acoustic models were iteratively trained by freezing one of the two modules, training the other one, and vice versa. The authors showed that multiple parallel transformations (one for each word class) gave better recognition results than a single transformation, and that a nonlinear MLP transformation performed better than an affine transformation.

### *Noise Robustness*

Speech recognition systems typically show lower performances when operated in noisy environments (e.g., speech transmitted through a hands-free telephone in a moving car). Noise corrupts the speech waveform and is often difficult to model because of the changing nature of the environment that produces it (speed of the car, quality of the road, etc.).

To help solve this problem, MLPs have been trained to extract clean speech from noisy input signals. In Sorensen (1991), a mapping was performed by presenting noisy speech feature vectors to an MLP and using the corresponding clean feature vectors as target outputs. Experiments were performed with cepstral and auditory features on an isolated word recognition task.

MLPs have also been used to combine knowledge sources, such as instantaneous and sentence-level measures of the signal-to-noise ratio, sentence-level estimates of the noise level, and noise-corrupted speech amplitude to compute an estimate of the noise, and subtract it from the noisy feature vector (Weintraub and Beaufays, 1999). This approach was tested on a large-vocabulary conversational speech database corrupted by additive car noise.

Such approaches resulted in impressive recognition improvement. Nonetheless, noise reduction remains an active research topic awaiting more developments, especially in applications where the noise is nonstationary or is correlated with the speech signal (e.g., speech reverberation in cars).

### *MLP Front Ends for Speaker Verification*

Speaker verification, the task of recognizing a person's identity from his/her voice, is similar in essence to speech recognition: a front-end unit extracts features from the test waveform, and a subsequent classifier uses statistical models of the users's voices to identify the speaker's identity. In Heck et al. (2000), an MLP was trained to perform frame-level classification of speakers. The inputs to the MLP are nine adjacent frames of cepstral features, and the outputs are speaker posterior probabilities. The MLP has four hidden layers, with a bottleneck in the middle. The first two layers can be seen as performing discriminative feature compression, whereas the last two layers perform speaker classification. After training of the MLP, the last two layers are chopped off, and the features computed by the remaining layers are fed into a traditional Gaussian mixture–based speaker classifier.

## Confidence in Recognition Results

Although speech recognition has made tremendous progress in the last decade, the technology is not faultless, and error correction mechanisms must be available for a deployed application to be successful. In particular, it is important to assess how confident the recognizer is in its understanding of the user's request before processing it. One way of implementing such a feature is to estimate the posterior probability that each word in the utterance was correctly recognized, and to decide, based on the word posteriors, whether to execute the request or reprompt the user.

MLPs have been used to implement such a mechanism (Weintraub et al., 1997). During recognition, the system collects a set of cues relative to the current word and to its decoding by the recognizer, e.g., how well the acoustic models match the data, whether there are other likely decodings of the spoken segment, how the durations of the subword segments fit their expected distributions, and so forth. These cues act as knowledge sources that are input to an MLP classifier. The MLP is trained with a target output equal to 1 (if the word was correctly recognized) or 0 (misrecognition). At run time, the MLP classifier will output the posterior probability that the word is correctly recognized, given the measured knowledge sources.

## Discussion

Speech recognition was already a very mature field by the time multilayer MLPs and the backpropagation algorithm gained general acceptance from the research community. As a consequence, MLPs were experimented with to replace specific components of a well-defined architecture, rather than as a way to solve a brand-new problem. A posteriori, the question is thus where and how MLPs have helped improve recognition systems.

Virtually every possible functionality of multilayer MLPs has been exploited: MLP classifiers were used for phone and triphone classification, MLP estimators proved to be useful in feature transformation and noise estimation, and MLP combiners helped in merging different knowledge sources to estimate confidence measures.

In all these applications, the main advantages of MLPs over other statistical modeling methods are (1) MLP implementations typically require fewer assumptions and can be optimized in a data-driven fashion, (2) backpropagation training can be generalized to any optimization criterion, including maximum likelihood and all forms of discriminative training, and (3) MLP modules can easily be integrated in nonadaptive architectures.

However, most industrial speech recognizers to date count very few MLP components. This can be attributed in part to historical reasons, but more fundamentally, MLPs have some limitations that still hamper their integration in recognition systems. In particular, their training time is typically much greater than that of nonconnectionist models for which closed-form or fast iterative solutions can be derived. This is problematic with a very large data sets, where weeks of training may be necessary to achieve the desired performance. It is even more critical when one considers that, somewhat disconcertingly, increasing the amount of training data and the number of parameters remains to date the best way to improve recognition performance! Nonetheless, MLPs have made great progress in the speech recognition field since the first edition of the *Handbook*: scalable implementations have started to appear in the literature, and MLP-based models have outperformed state-of-the-art traditional recognition systems on some of the most challenging recognition tasks.

# Spiking Neurons, Computation with

*Wolfgang Maass*

## Introduction

Most artificial neural network models are based on a neuron model (called perceptron or threshold gate) that McCulloch and Pitts proposed in 1943 as an abstraction of the computational function of a biological neuron. Today we know that there exist a number of fundamental differences between computations in such artificial neural networks and computations in circuits of biological neurons. One difference becomes obvious when one considers the output of a neuron. The output of a neuron in an artificial neural network is a bit (in the case of a perceptron) or a real-valued number (in the case of a sigmoidal gate). The output of a biological neuron consists of sharp potential increases (called action potentials, or *spikes*) that are initiated at the initial segment of its axons. These spikes, which last for 1–2 ms, are propagated through its axonal tree, with intermediate restoration of the shape of the spike at the nodes of Ranvier. Since this shape is rather stereotypical (there are no "half-spikes"), one may argue that it corresponds to the binary output of a perceptron: spike $=$ 1, no spike $=$ 0. But in contrast to artificial neural networks, which are usually driven in a synchronous mode, a generic biological neural circuit has no central clock. The times when a neuron fires depend on its current and preceding input. Hence, although at any instance in time the decision whether a neuron fires resembles the computational operation of a perceptron, and although the average number of spikes (with an average taken over time or space) emitted by neurons resembles the real-valued output of a sigmoidal neuron, the resource time plays a completely different role in the computation in a biological neural circuit. Whereas it is trivialized as a computational resource in most digital computers and artificial neural networks, because one takes care that the times at which a gate emits an output adhere to a rigid schedule that is largely input independent, a biological neuron can encode essential information about the input in the times when it fires. This facility can, for example, be used to transmit information very fast through small temporal differences between the spikes sent out by different neurons (see FAST VISUAL PROCESSING), and it can potentially be used to transmit information about relations between neurons through relations between their firing times (e.g., transient correlations between the firing times of a subset of neurons; see SYNCHRONIZATION, BINDING AND EXPECTANCY). Methods from information theory can be used to quantify how much more information about a stimulus can be extracted from spike trains if the precise spike times are taken into account (see SENSORY CODING AND INFORMATION TRANSMISSION). Finally, computing with an input-driven and flexible temporal organization of computational units is potentially beneficial for computing in an online manner on a continuous-input stream, since the computation speed can be instantly adjusted to the current input activity, and no energy is wasted by transmitting a central clock signal to all units even if there is nothing to compute. Apparently all of these aspects are essential for understanding biological neural computation. But they also present new ideas for the design of artificial computing machinery that can respond in real time to a complex input stream while spending just a fraction of the energy of a digital processor (see SILICON NEURONS; NEUROMORPHIC VLSI CIRCUITS AND SYSTEMS). Formal models for spiking neural networks are useful for investigating this strange new world of computing with spikes, both in order to formulate reasonable hypotheses about the organization of biological neural computation and to provide an abstract platform for exploring the possible use of spikes and temporal coding in novel artificial computing machinery. These networks of spiking neurons may be viewed as a third generation of neural network models, after perceptrons and sigmoidal neural networks.

## A Formal Spiking Neural Network Model

A biological neuron $j$ fires at certain time points $t_j^{(1)}, t_j^{(2)}, \ldots$, each time sending a stereotyped spike down its axonal tree. At the synapses that connect these axonal branches with other neurons, the spike triggers the emission of neurotransmitter, thereby causing positive pulses (excitatory postsynaptic potentials, EPSPs) or negative pulses (inhibitory postsynaptic potentials, IPSPs) on the membrane potential of the postsynaptic neurons $i$ (Figure 1). The time course of these EPSPs and IPSPs resulting from a firing of neuron $j$ at time $t_j^{(f)}$ can be described by terms of the form $w_{ij}(t) \cdot \varepsilon(t - t_j^{(f)})$, where the function $\varepsilon(t - t_j^{(f)})$ describes a potential hill that has value 0 if $t - t_j^{(f)}$ is less than the transmission time $\Delta_{ij}$ from the soma of neuron $j$ to the soma of neuron $i$, then increases almost linearly and finally decays exponentially back to 0 (typically within 20–80 ms). The factor $w_{ij}(t)$, which describes the efficacy of the synaptic connection from neuron $j$ to neuron $i$ at time $t$, is positive in the case of an EPSP and negative in the case of an IPSP.

There exist various mathematical models that predict the firing times $t_i^{(1)}, t_i^{(2)}, \ldots$ of a biological neuron $i$ in dependence on the firing times $t_j^{(f)}$ of "presynaptic" neurons $j$. Because of its mathematical simplicity, the most useful model for a computational analysis is the *spike response model* (see Integrate-and-Fire Neurons and Networks). Here the membrane potential $u_i(t)$ at time $t$ at the trigger zone of neuron $i$—i.e., that location on the soma of neuron $i$ where its spikes are initiated—is represented by a sum $\Sigma_{j,f}\, w_{ij}(t) \cdot \varepsilon(t - t_j^{(f)})$ consisting of EPSPs and IPSPs that were caused by firings of presynaptic neurons $j$ at preceding times $t_j^{(f)}$, and a refractory term $\eta(t - \hat{t}_i)$ that depends on the last time $\hat{t}_i$ when neuron $i$ has fired before time $t$. If $t - \hat{t}_i$ is positive but very small (less than 2 ms) then $\eta(t - \hat{t}_i)$ is strongly negative, whereas for larger values of $t - \hat{t}_i$, its value returns back to 0. According to the spike response model the neuron $i$ fires whenever the resulting term for its membrane potential $u_i(t) = \eta(t - \hat{t}_i) + \Sigma_{j,f}\, w_{ij}(t) \cdot \varepsilon(t - t_j^{(f)})$ reaches a certain firing threshold $\vartheta$ from below.

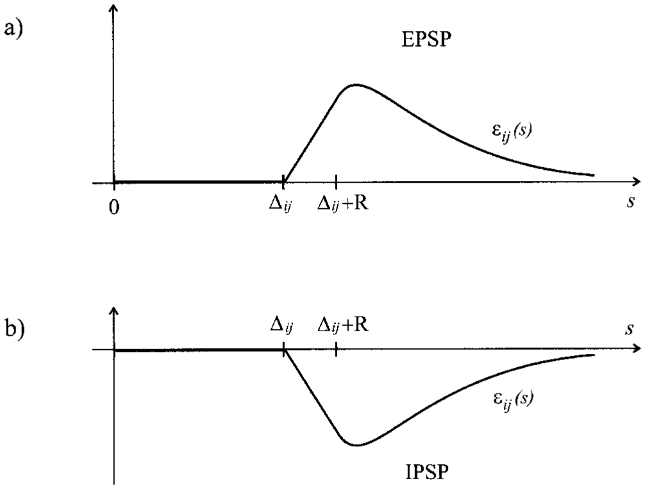

**Figure 1.** *A*, Typical shape of an excitatory postsynaptic potential (EPSP). *B*, Typical shape of an inhibitory postsynaptic potential (IPSP).

In comparison with the Hodgkin-Huxley model and the standard equations for integrate-and-fire neurons, this spike response model is much easier to handle for the purpose of analyzing computations, since its formulation does not involve differential equations. On the other hand, with suitable choices of the response functions $\eta$ and $\epsilon$ (which may depend on the neurons $i$ and $j$) and the functions $w_{ij}(t)$ (which may depend on the specific temporal dynamics of the synaptic connection between neurons $i$ and $j$), this model is able to capture quite well the dynamics of a biological neural circuit.

## Computing with One Spike per Neuron

In order to analyze the computational power of this formal spiking neural network model, one needs in an addition a convention for translating between their inputs and outputs, which are vectors of sequences of spikes ("spike trains") in continuous time, and the types of inputs and outputs of other computational models (which typically are vectors of binary or real-valued numbers). Of particular interest are translations between binary and analog numbers and spike trains that are biologically realistic in the sense that they match translation schemes employed by sensory neurons to encode external stimuli. Several such potential "neural codes" are discussed in Integrate-and-Fire Neurons and Networks. One of the most intriguing one, which has no analogon in artificial neural network models, is the time-to-first-spike code (also called delay code), where one assumes that the times of the first spikes in each of $n$ incoming spike trains encode $n$ real-valued numbers. Since stronger stimuli tend to produce shorter latencies, one might assign the largest value 1 to the input channel with the earliest first spike, the smallest value 0 to the input channel with the latest first spike, and to the other input channels real values between 0 and 1, corresponding to the position of their first spike relative to the others.

The first interesting observation is that for such code, a spiking neuron can carry out computational operations that have no counterpart in the computational units of traditional neural network models: a spiking neuron can act as *coincidence detector* for incoming pulses by firing only if a certain number of EPSPs arrive almost simultaneously at its soma (Abeles, 1982). Hence if the arrival times of the incoming pulses (EPSPs) encode *analog numbers* $x_j$, a spiking neuron can detect whether some of these numbers $x_j$ have (almost) equal value. Thus, a spiking neuron can also decide whether the numbers $x_j$ in a vector $\langle x_1, \ldots, x_n\rangle$ are all different, which happens to be a well-known benchmark problem in computer science. It is usually referred to as the element distinctness problem (ED). Since the formal version of this problem requires hair-trigger decisions, one can expect from a physical implementation of a spiking neuron only that it computes a closely related partial function $ED_n : \mathbb{R}^n \rightarrow \{0, 1\}$, where for some parameter $c > 0$ (that is related to the amount of imprecision or noise) the output $ED_n(x_1, \ldots, x_n)$ satisfies the equation

$$ED_n(x_1, \ldots, x_n) = \begin{cases} 1, & \text{if there are } j \neq j' \text{ so that } x_j = x_j' \\ 0, & \text{if } |x_j - x_j'| \geq c \text{ for all } j \neq j' \end{cases}$$

A single spiking neuron, modeled according to our formal model, can compute this function $ED_n$ (Figure 2). This is remarkable, since artificial neural networks need a substantial amount of hardware for computing $ED_n$ (even if the network is allowed to give any output it wants if neither of the two cases in the definition of $ED_n$ apply). It was shown in Maass (1997b) that any threshold circuit (i.e., any layered feedforward circuit consisting of McCulloch-Pitts neurons) that computes $ED_n$ needs to have at least $n/2 \log n$ perceptrons on its first hidden layer, and that any feedforward analog neural net (i.e., any multilayer perceptron consisting of sigmoidal neurons) that computes $ED_n$ needs to have at least $n - 6/2$ sigmoidal gates as hidden units.

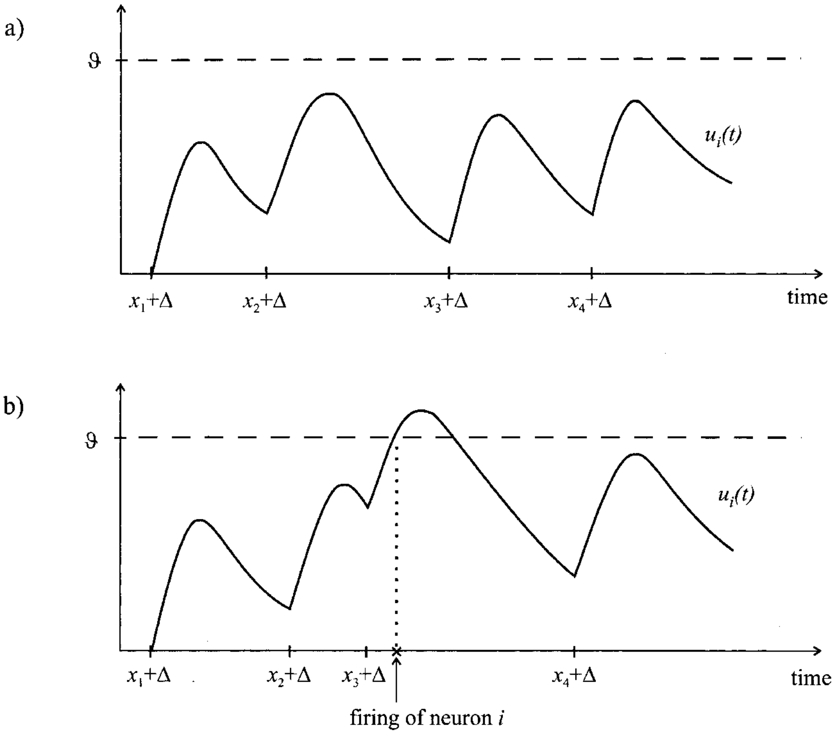

**Figure 2.** *A*, Typical time course of the state variable $u_i(t)$ if $ED_4(x_1, x_2, x_3, x_4) = 0$. *B*, Time course of $u_i(t)$ in the case where $ED_4(x_1, x_2, x_3, x_4) = 1$ because $|x_3 - x_2| \leq c$.

One can exploit the coincidence detection capability of a spiking neuron $i$ even further and raise its firing threshold $\vartheta$ so high that EPSPs caused by firings of *all* presynaptic neurons have to arrive nearly simultaneously at the soma of $i$ to make it fire. In this case the spiking neuron implements a variation of an RBF unit (radial basis function unit) in the temporal domain (Hopfield, 1995). If the transmission delays $\Delta_{ij}$ from the trigger zone of neuron $j$ to the trigger zone of neuron $i$ all have the same value, then such a neuron with a high threshold $\vartheta$ fires if and only if the firing times $t_j$ of all presynaptic neurons $j$ have almost the same value. If these transmission delays $\Delta_{ij}$ vary for different $j$, then the same neuron $i$ will fire if and only if the firing times $\langle t_j \rangle_j$ of the presynaptic neurons $j$ form a specific temporal pattern: $t_j \approx T - \Delta_{ij}$ for all $j$, where $T$ is some number that is independent of $j$. In Natschläger and Ruf (1998), the previous construction has been extended to self-organizing RBF networks with the help of lateral inhibition between RBF units.

In the approach for computing with spiking neurons that we have sketched so far, the input consisted of a vector of analog numbers, encoded through temporal delays between the first spikes, but the output of the spiking neuron was binary, encoded through firing or nonfiring of that neuron. Obviously, for multilayer or recurrent computations with spiking neurons, it is desirable to *output* a vector of analog numbers that is encoded in the same way as the input. For that purpose one needs a mechanism for *shifting* the firing time of a spiking neuron $i$ in dependence on the firing times $t_j$ of presynaptic neurons. Such mechanism is provided by the fact that advancing $t_j$ in time tends to advance the firing time of neuron $i$, and it advances it even more if the intermediate synaptic weight $w_{ij}$ has a large value. This can be used to compute a weighted sum for analog values in such a way that the same temporal code is used for inputs and outputs. Since it is straightforward to simulate the nonlinear activation function of a sigmoidal neuron through the firing mechanism of a spiking neuron, one can simulate in this way any sigmoidal neuron by a spiking neuron where each analog input or output is encoded by the temporal position of a spike. Hence, one can rigorously prove (Maass, 1997a) that any continuous function $F : [0, 1]^n \rightarrow [0, 1,]^m$ can be approximated arbitrarily closely by a network of spiking neurons with inputs and outputs encoded by temporal delays.

As an alternative, Thorpe and co-workers have proposed viewing the *order* of the firing times $t_j$ of different neurons $j$ as the relevant signal conveyed by these neurons, and have explored mechanisms for computing in terms of such code (see Thorpe and Gautrais, 1997, and Fast Visual Processing). One may view this firing order code as a digitalized version of the previously discussed delay code.

An interesting general question concerns the theoretical limits of the computational power of spiking neurons, regardless of specific assumption about neural coding. It turns out that if the firing times of spiking neurons were not affected by noise, one could theoretically simulate any Turing machine by some finite network of spiking neurons (Maass, 1996); hence any digital computation could be carried out by such a network. This implies that in order to evaluate the actual computational power of a concrete biological or artificial spiking neural network, one needs to know something about the noise that affects it.

## Computing on Spike Trains

In the preceding section we focused on computations where inputs and outputs consisted of a single spike per channel. In this section we will look at the case where inputs and outputs consist of *spike trains*. This can be used for computations on analog variables that are represented in a highly noise-robust manner, or for computations on time series. A simple scheme for converting spike trains into time series of numbers and vice versa is the well-known *firing rate code*, where one interprets the number of times that a neuron $i$ fires (during some sliding time window of a certain length) as the current output of neuron $i$. Another scheme, this one for interpreting spike trains as codes for analog time series, which requires many fewer spikes but greater precision in the timing of the spikes, results from convolving each spike with a suitable smooth kernel function (see Rieke et al., 1997). In this way each spike train can be viewed as a code for a smooth time-varying function. Possible methods for computing on input functions that are represented in this way by spike trains are discussed in Temporal Integration in Recurrent Microcircuits (q.v.). A third option for neural coding is the *space-rate code* or *population code*, where the fraction of neurons within a certain pool that fire during a specific short time interval (say, 5 ms) encodes an analog number. It is shown in Maass and Natschläger (2000) that networks of spiking neurons can approximate any given continuous multivariable function if the network inputs and outputs are assumed to encode analog numbers through such a space-rate code. It turns out that the unreliability of synaptic transmission in biological systems (see Synaptic Transmission) is quite useful for such analog computing in terms of a space-rate code. Furthermore, one can prove that networks of spiking neurons can in principle carry out with regard to a space-rate code more complex operations, where the current output depends not just on the current input but also on previous inputs. One usually refers to such computations as operators or filters, since they map functions of time onto functions of time, rather than mapping numbers on numbers. In this context one can utilize the tails of EPSPs and IPSPs (i.e., their exponentially decaying segments) to implement linear filters via networks of spiking neurons (Maass and Natschläger, 2000). All computations in formal models of spiking neural networks that we have discussed so far can be implemented with static synapses, i.e., with synapses where each synaptic weight $w_{ij}(t)$ has a time-invariant fixed value. In reality, the efficacy of a biological synapse changes on a fast time scale, depending on the frequency and temporal pattern of previous spike arrivals at the synapse (see Temporal Dynamics of Biological Synapses). If one takes this into account, then a feedforward network of spiking neurons can approximate with regard to space-rate coding of time-varying analog inputs and outputs a very large class of nonlinear filters: any nonlinear filter that is time invariant and has fading memory (Maass and Sontag, 2000).

Because of their coincidence-detection capabilities, spiking neurons are quite sensitive to statistical correlations in the firing times of presynaptic neurons (often referred to as *synchronization*). Furthermore, computer simulations suggest that biologically supported learning rules enhance this capability. Since the number of possible relations among presynaptic neurons that can be encoded in this way is exponential, a coding mechanism that involves correlations in firing times may substantially enlarge the expressive capabilities of neural networks. The precise computational operations that can be carried by spiking neurons in the presence of a larger number of competing "relations" encoded through firing correlations of presynaptic neurons has remained elusive (see Milner, 1974; von der Malsburg, 1981; Eckhorn et al., 1988; Maass, 1998).

Synfire Chains (q.v.) represent yet another approach for information processing in networks of spiking neurons (Abeles, 1991). Each synfire chain consists of a layered feedforward circuit of spiking neurons, where a wavefront of firing activity is propagated from layer to layer. From the point of view of computation, a single synfire chain just implements a binary register (through its two states, active/nonactive), and hence is not a computational model in a strict sense. But if several synfire chains are superimposed on a spiking neural network, the activity of one or several synfire chains may ignite activity in yet another synfire chain. In this fashion one can, for example, implement an AND gate via a (fairly large) network of spiking neurons. Analog versions of such computations are discussed in Maass and Natschläger (2000).

## Discussion

Networks of spiking neurons represent a third generation of neural network models that are biologically more realistic, since they allow that the timing of individual computation steps may transfer salient information. Rigorous proofs imply that formal models for spiking neural networks can carry out all computations that standard neural network models can handle, some of them with substantially fewer gates. In addition, networks of spiking neurons are particularly well suited for carrying out computations on analog time series (see Temporal Integration in Recurrent Microcircuits). Since spiking neural networks can compute in an input-driven mode without any central synchronization, hardware implementations of such networks offer new ways for real-time sensory processing at the microwatt level (see Analog VLSI Implementations of Neural Networks). Surveys on biology-oriented models for computations with spiking neurons can be found in Abeles (1991), Rieke et al. (1997), and Cariani (2001). More detailed survey articles on the theory and hardware for implementing computing with spiking neurons are contained in Maass and Bishop (1999). Research papers on the current state of the art can be found in Grossberg, Maass, and Markram (2001).

# Spinal Cord of Lamprey: Generation of Locomotor Patterns

*James T. Buchanan*

## Introduction

The successes in revealing the structure and function of rhythm-generating networks in invertebrates led to the insight that although there are recurring "building blocks" in the evolution of neuronal networks, there is also a great deal of variation in the details of network construction between different classes of organisms (Getting, 1989). Thus, to understand vertebrate neuronal networks, one must study vertebrate nervous systems, and this realization has led to a proliferation of vertebrate models for investigating the cellular and synaptic mechanisms of locomotor rhythm generation (Pearson and Gordon, 2000) (see LOCOMOTION, VERTEBRATE). One of the most favorable adult vertebrate preparations is the lamprey, a jawless fish with close ties to the earliest vertebrates of the fossil record. Significant progress has been made toward revealing features of the lamprey locomotor network, and this preparation has been the focus of numerous modeling studies.

## The Lamprey Spinal Cord

The adult lamprey spinal cord has numerous advantages for neurophysiological studies aimed at understanding the cellular and synaptic mechanisms of rhythmic locomotor activity. In overall structure and organization, the lamprey spinal cord resembles the spinal cords of higher vertebrates. For example, the spinal cord consists of a core of nerve cell bodies surrounded by axon tracts, and there are dorsal and ventral roots of sensory and motor functions, respectively. However, when compared with other adult vertebrates, the lamprey spinal cord contains relatively few nerve cells (ca. 1,000 per segment), and the cell bodies of many of these neurons are clearly visible in the thin (ca. 0.3 mm), transparent spinal cord. In addition, the lamprey spinal cord survives and functions well when isolated and can be readily manipulated by adding pharmacological agents to the bathing fluid. This is particularly important in the study of locomotor activity because one can activate the spinal swimming network by adding the excitatory neurotransmitter, glutamate, to the bathing fluid. One disadvantage to using the lamprey nervous system is the lack of uniquely identifiable cells in the spinal cord, a feature that made invertebrate preparations, such as the crustacean stomatogastric ganglion, so successful in the study of network structure and function (see CRUSTACEAN STOMATOGASTRIC SYSTEM). In the lamprey spinal cord we must characterize classes of nerve cells rather than unique individuals, and thus we face the uncertainties associated with defining cell classes.

## Fictive Swimming

Like most fish, lampreys swim with lateral body undulations that propagate from head to tail (Figure 1*A*). These body waves are created by contractions of muscles that alternate between the two sides and propagate down the body. The speed of wave propagation is scaled to the swim frequency so that as the animal swims faster, the propagation speed of the waves increases. In this way, the lamprey maintains about one full wave of body curvature over the length of its body for a wide range of swimming speeds. When the spinal cord is isolated and exposed to glutamate, similar rhythmic activity can be recorded from the ventral roots, the nerves that contain the axons of the motor neurons innervating the body muscles (Figure 1*B*). As the motor neurons fire action potentials, their spikes are recorded as rhythmic bursts (ca. 0.5–4 bursts/s) that alternate with ventral roots on the opposite side of the spinal cord (Figure 1*B*). Ventral roots located more distant from the head show a progressive delay in burst onset. Again, this delay is scaled to the swim frequency, so that there is a constant phase lag in the head-to-tail propagation of the ventral root bursts. This phase lag is about 1% of a cycle period per segment (ca. 100 spinal segments total). Thus, there is a close match between the pattern of muscle electrical activity in the swimming lamprey and the pattern of ventral root bursting in the isolated spinal cord, indicating that the latter represents the neuronal correlate of swimming and is therefore referred to as fictive swimming.

## The Lamprey Locomotor Network

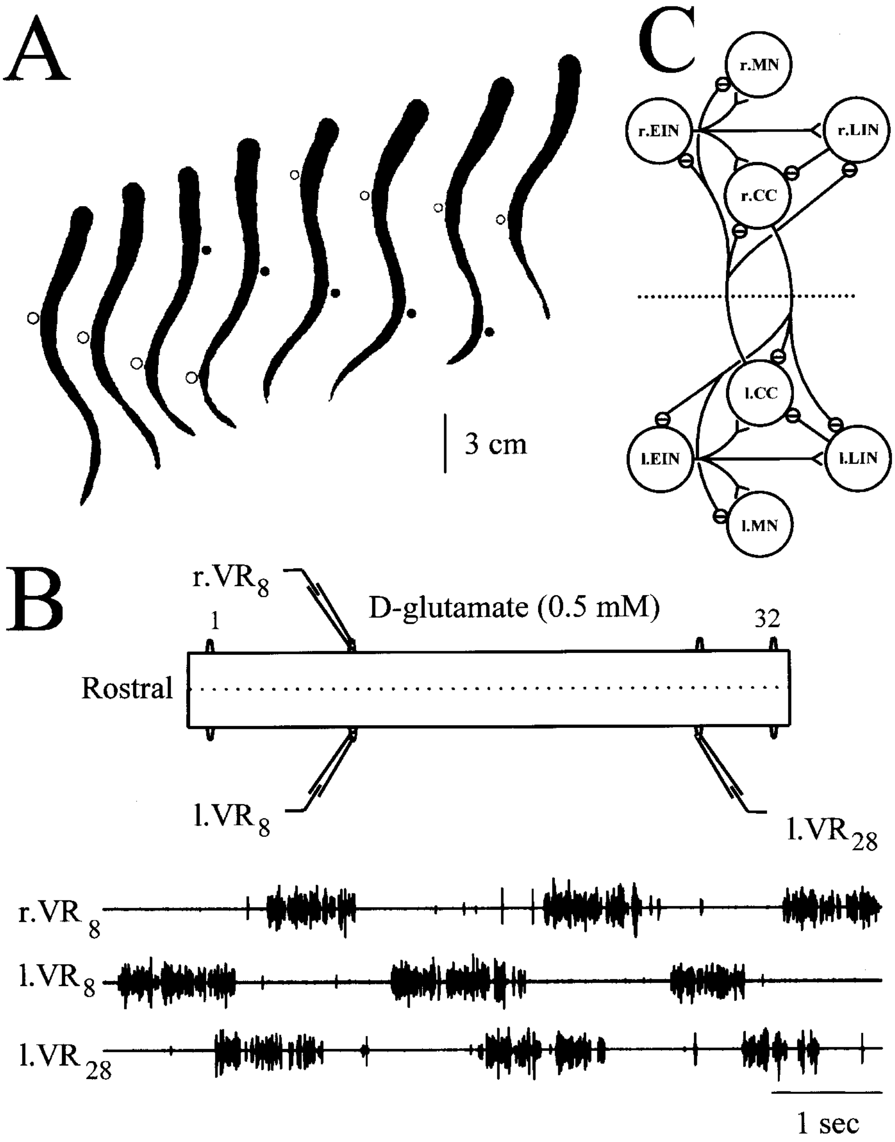
The presence of swimming activity in the isolated spinal cord demonstrates that, like other vertebrate and invertebrate preparations, the lamprey spinal cord contains a central pattern generator for locomotion. That is, the neuronal machinery required to produce the detailed locomotor pattern is an emergent property of spinal nerve cells and their synaptic interactions.

One goal of locomotor studies is to understand the structure and function of the locomotor central pattern generator. What do we know about the cells comprising this network and their synaptic interactions? Although uniquely identifiable neurons have not been found in the lamprey spinal cord, several classes of spinal neurons have been characterized on the basis of physiological and anatomical criteria (Figure 1*C*) (Buchanan, 2001). The alternating pattern of rhythmic activity between the two sides of the spinal cord and the disruption of rhythmic activity by midline cuts suggest that cells with midline-crossing axons (commissural interneurons) are important for locomotor activity (Buchanan, 1999). Therefore, commissural interneurons (CCINs) have been a focus of intracellular studies. One class of CCINs has been shown to make inhibitory glycinergic synapses on motor neurons and interneurons on the opposite side of the spinal cord. These inhibitory CCINs are thought to provide a mechanism for alternation between the two sides and for basic rhythm generation via their reciprocal inhibitory interactions (see HALF-CENTER OSCILLATORS UNDERLYING RHYTHMIC MOVEMENTS). In addition to the inhibitory CCINs, there is a class of small excitatory interneurons (EINs) with short axons confined to the same side of the spinal cord. The EINs provide rhythmic excitation of nearby motor neurons and interneurons via glutamatergic excitatory synapses. Finally, there is a third class of interneurons that are active during fictive swimming, the lateral interneurons (LINs). The LINs inhibit CCINs on the same side of the spinal cord via glycinergic synapses. The LINs have been proposed to provide the early inhibition that is observed in the CCINs and thus to terminate the firing of the CCINs on one side of the cord, allowing the inhibitory CCINs on the opposite side to begin firing.

## Modeling Lamprey Locomotion

The lamprey locomotor network has been simulated with a variety of models, from connectionist-style to more detailed biophysical models. These simulations have demonstrated the feasibility of the proposed circuit (Figure 1*C*), have helped to assess the importance of various electrophysiological parameters in the function of the

Images are separated by 67 msec. *B*, Fictive swimming in a 32-segment length of isolated spinal cord exposed to 0.5 mM of D-glutamate. Ventral roots (VR) were recorded with extracellular electrodes. *C*, The proposed lamprey locomotor network consists of three types of interneurons. Each cell represents many neurons. Open triangles indicate excitatory synapses, circles indicate inhibitory synapses, and the dashed line indicates the midline. MN, motor neuron; CC, commissural interneuron; EIN, excitatory interneuron; LIN, lateral interneuron.



network, and have provided insights into various network issues.

Detailed biophysical models typically use Hodgkin-Huxley (HH)-style kinetic modeling of ion channels that are incorporated into compartmental models of neuronal electrotonic structure. Such models of the lamprey locomotor network suffer from the problem of an overabundance of unspecified and unconstrained parameters because we do not have good voltage-clamp characterizations of the HH parameters for lamprey neurons. An alternative to detailed voltage-clamp analysis has been to use white noise analysis (Murphey, Moore, and Buchanan, 1995). The magnitude and phase responses of lamprey neurons to small-amplitude, subthreshold white noise current or voltage signals have been used to fit model neurons containing voltage-dependent conductances and electrotonic structure. This approach provides a stronger data-based modeling of the nonlinear voltage dependencies and the contributions of dendritic electrotonic structure, but a systematic characterization of the various lamprey spinal neuron classes using this technique has not yet been done.

Although detailed HH-style modeling currently has limitations when applied to lamprey neurons, these or similar detailed biophysical models are essential for a full understanding of any neuronal network. For example, neuromodulators often act by subtly altering the activity of voltage-gated or ligand-gated channels, and detailed biophysical models are required to explore the consequences of these ion channel changes on network activity (see NEUROMODULATION IN INVERTEBRATE NERVOUS SYSTEMS). There are a number of neuromodulators present in the lamprey spinal cord that alter the output of the locomotor network, with serotonin, dopamine, and the tachykinins being among the best studied. These substances offer good opportunities to test our knowledge of the locomotor system by combining the cellular and synaptic actions of the modulators into detailed network models.

Interesting new work involving neuromodulators in the lamprey has come from Parker and Grillner (2000). They have been investigating the effects of substance P, a tachykinin neuropeptide. The tachykinins have been well studied in the mammalian spinal cord, where they are involved in pain processing. In the lamprey, application of substance P to the isolated spinal cord has an extremely powerful effect on fictive swimming, increasing the swim burst frequency by three to five times. What is most remarkable is that after only a 10-minute exposure to substance P, the increase in the fictive swimming frequency persists for at least the next 24 hours. This essentially permanent alteration in the locomotor network requires protein and RNA synthesis for its maintenance. Tachykinins are present in the lamprey spinal cord in ventral midline cells located below the central canal, where they coexist in neurons with serotonin and dopamine. At the synaptic level, substance P and serotonin both have strong effects on activity-dependent plasticity at the synapses involved in generating the locomotor rhythm. This type of modulation of activity-dependent synaptic plasticity is referred to as metaplasticity. Not only are serotonin, dopamine, and substance P colocalized in spinal neurons, but their actions on the locomotor network are interdependent. Serotonin can block the effects of substance P on swim frequency and on synaptic metaplasticity. Detailed biophysical models of the lamprey network have demonstrated that metaplasticity can have significant effects on network behavior that are consistent with those observed experimentally (Kozlov et al., 2001). A major challenge for lamprey neurobiology will be to determine when these various neuromodulators are released. Are they coreleased or differentially released in a context-dependent manner?

Given the lack of detailed biophysical information about lamprey locomotor neurons, models that do not depend on details of individual cells have proved useful in advancing our understanding of lamprey locomotion. For example, simplified rhythm generators have been employed to look at larger-scale issues, such as the control of turning (McClellan and Hagevik, 1997). Techniques of bifurcation analysis have been used to examine the dynamic behavior of the network (Figure 1*C*), especially with regard to its interactions with the brain (Jung, Kiemel, and Cohen, 1996). Efforts have also been made using simpler locomotor networks to expand the levels of modeling to take into account the properties of the muscles, movement through water, and sensory feedback during movement (Ekeberg and Grillner, 1999).

Another application of models with less neuronal detail has been in investigations aimed at understanding the nature of the coupling among the rhythm generators. This is an interesting problem because the speed of the head-to-tail propagation of the rhythmic activity down the spinal cord varies with the speed of swimming, yet conduction delays in axons are fixed. Experimental tests of a model of coupled oscillators (Cohen et al., 1992) (see CHAINS OF OSCILLATORS IN MOTOR AND SENSORY SYSTEMS) led to the conclusion that ascending intersegmental coupling signals have a stronger influence over oscillator coupling in the lamprey spinal cord than do descending signals (Sigvardt and Williams, 1996). Williams (1992) explored coupling using connectionist-style modeling to link chains of unit locomotor networks using the same neurons that generate the rhythmic activity. By adjusting the synaptic strengths of the coupling signals, it was possible to achieve constant phase lags with values similar to that of fictive swimming. While these studies demonstrated the feasibility of this mechanism, we do not yet know sufficient details of the intersegmental connectivity to verify the mechanism experimentally.

## Discussion

An underlying motivation for studying the lamprey locomotor network is to learn about vertebrate locomotor networks in general. Does the lamprey tell us anything about higher vertebrates? There is certainly reason for hope that the lamprey network shares some fundamental properties with the locomotor networks of higher vertebrates because of the striking similarities between the lamprey network and that of the frog tadpole spinal cord (Roberts et al., 1998). These two animals swim with similar patterns, so it may not be unexpected that the networks are similar, yet the organisms are evolutionarily quite distant. We would like to believe that the lamprey locomotor network has been conserved to some extent in higher vertebrates as a core rhythm-generating network, and evolution has provided coupling among these core oscillators to generate the more complex sequences of muscle activation required in fins and limbs. In this regard, the salamander offers a promising preparation for studying the interaction of swimming and walking networks because this animal performs both. Connectionist-style modeling has recently been used to explore how a neural circuitry can produce and modulate the two locomotor programs of swimming and walking (Ijspeert, 2001), and several laboratories are beginning to explore these issues experimentally.

Where do we go from here in our attempts to understand the generation and control of vertebrate locomotion? A major limitation to understanding the lamprey locomotor network is the large numbers of nerve cells and the inability to uniquely identify them or even to classify them with confidence. Experimentally, we need to employ techniques that will allow characterization of populations and the synaptic interactions of many cells. Optical imaging of calcium signals or of voltage-sensitive dyes offers some hope in this direction. Further exploration of neuromodulators of the locomotor network will continue to provide opportunities to test our models as we try to account for the network effects of modulators on the basis of their demonstrated cellular and synaptic actions. Modeling of the locomotor network must proceed in parallel with the experimental data; and ultimately, large-scale and detailed biophysical modeling will be necessary. However, given the current limitations in our knowledge about the lamprey locomotor network, modeling that relies less on the details of individual cells will continue to be useful in understanding how locomotion is organized within the lamprey nervous system. Finally, comparisons with other vertebrates will be important for determining what aspects of the locomotor network have been conserved and how the core rhythm-generating network of swimming was modified for walking with limbs.

## Introduction

The theory of learning in artificial neural networks has benefited from various different fields of research. Among these, statistical physics has become an important tool for understanding a neural network's ability to generalize from examples. This article explains some of the basic principles and ideas of this approach.

In the following, we assume a feedforward network of $N$ input nodes, receiving real-valued inputs, summarized by the vector $\mathbf{x} = (x(1), \ldots, x(N))$. The configuration of the network is described by its weights and will be abbreviated by a vector of parameters $\mathbf{w}$. Using $\mathbf{w}$, the network computes a function $F_{\mathbf{w}}$ of the inputs $x$ and returns $\sigma = F_{\mathbf{w}}(\mathbf{x})$ as its output.

In the simplest case, a neural network should learn a binary classification task. That is, it should decide whether a given input $\mathbf{x}$ belongs to a certain class of objects and respond with the output: $F_{\mathbf{w}}(\mathbf{x}) = +1$, or, if the input does not belong, it should answer with $\sigma = -1$ (the choice $\sigma = \pm 1$, rather than, for example, 0, 1, is arbitrary and has no consequence for the learning curves). To learn the underlying classification rule, the network is trained on a set of $m$ inputs $\mathbf{x}^m = \{\mathbf{x}_1, \ldots, \mathbf{x}_m\}$ together with the classification labels $\sigma^m = \{\sigma_1, \ldots, \sigma_m\}$, which are provided by a trainer or *teacher*. Using a *learning algorithm*, the network is adapted to this *training set* $D_m = (\sigma^m, \mathbf{x}^m)$ by adjusting its parameters $\mathbf{w}$ such that it responds correctly on the $m$ examples.

How well will the trained network be able to classify an input that it has not seen before? In order to give a quantitative answer to this question, a common model assumes that all inputs, those from the training set and the new one, are produced independently at *random* with the same probability density from the network's environment. Fixing the training set for a moment, the *probability* that the network will make a mistake on the new input defines the generalization error $\varepsilon(D_m)$. Its *average*, $\varepsilon$, over many realizations of the training set, as a function of the number of examples gives the so-called *learning curve*. This will be the main quantity of interest in the following.

Clearly, $\varepsilon$ also depends on the specific algorithm that was used during the training. Thus, the calculation of $\varepsilon$ requires knowledge of the network weights generated by the learning process. In general, these weights will be complicated functions of the examples, and an explicit form will not be available in most cases.

The methods of statistical mechanics provide an approach to this problem, which often enables an *exact* calculation of learning curves in the limit of a very large network, i.e., for $N \to \infty$. It may seem surprising that a problem will simplify when the number of its parameters is increased. However, this phenomenon is well known for physical systems like gases or liquids which consist of a huge number of molecules. Clearly, there is no chance of estimating the complete *microscopic* state of the system, which is described by the rapidly fluctuating positions and velocities of all particles. On the other hand, the description of the *macroscopic* state of a gas requires only a few parameters, like density, temperature, and pressure. Such quantities can be calculated by suitably *averaging* over a whole ensemble of microscopic states that are compatible with macroscopic constraints.

Applying similar ideas to neural network learning, the problems that arise from specifying the details of a concrete learning algorithm can be avoided. In the statistical mechanics approach, one studies the ensemble of *all* networks that implement the same set of input/output examples to a given accuracy. In this way the typical generalization behavior of a neural network (in contrast to the worst or optimal behavior) can be described.

## The Perceptron

In this section I will explain this approach for one of the simplest types of networks, the *single-layer perceptron* (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION). A study of this network is not of purely academic interest, because the single-layer architecture is a substructure of multilayer networks, and many of the steps in the subsequent calculations also appear in the analysis of more complex networks. Furthermore, by replacing the input vector $\mathbf{x}$ with a suitable vector of nonlinear features, the perceptron (equipped with a specific learning algorithm) becomes a *support vector machine*, an extremely powerful learning device introduced by V. Vapnik and his collaborators (see SUPPORT VECTOR MACHINES).

The adjustable parameters of the perceptron are the $N$ weights $\mathbf{w} = (w(1), \ldots, w(N))$. The output is a weighted sum

$$\sigma = F_{\mathbf{w}}(\mathbf{x}) = \operatorname{sign}\left(\sum_{i=1}^{N} w(i)x(i)\right) = \operatorname{sign}(\mathbf{w} \cdot \mathbf{x}) \tag{1}$$

of the input values. Since the length of $\mathbf{w}$ can be normalized without changing the performance, we choose $\|\mathbf{w}\|^2 = N$.

The input/output relation in Equation 1 has a simple geometric interpretation. Consider the *hyperplane* $\mathbf{w} \cdot \mathbf{x} = 0$ in the $N$-dimensional space of inputs. All inputs that are on the same side as $\mathbf{w}$ are mapped onto $+1$, those on the other side onto $-1$. Perceptrons realize *linearly separable* classification problems. In the following, we assume that the classification labels $\sigma_k$ are generated by some other perceptron with weights $\mathbf{w}_t$, the "teacher" perceptron. (A simple case of a student/teacher mismatch is discussed later.)

The geometric picture immediately gives us an expression for the generalization error. A misclassification of a new input $\mathbf{x}$ by a "student" perceptron $\mathbf{w}_s$ occurs only if $\mathbf{x}$ is between the separating planes defined by $\mathbf{w}_s$ and $\mathbf{w}_t$. If the inputs are drawn randomly from a spherical distribution, the generalization error is proportional to the angle between $\mathbf{w}_s$ and $\mathbf{w}_t$. We obtain

$$\varepsilon(D_m) = \frac{1}{\pi} \arccos (R) \qquad (2)$$

where the "overlap" $R \doteq N^{-1}\mathbf{w}_s \cdot \mathbf{w}_t$ measures the similarity between student and teacher.

Following the pioneering work of Elizabeth Gardner (1988), we assume that $\mathbf{w}_s$ was chosen *at random* with equal probability from all student perceptrons that are consistent with the training set, thereby avoiding the introduction of a concrete learning algorithm. In computational learning theory, the space of consistent vectors has been termed the *version space*. The corresponding probability density is $p(\mathbf{w}_s|D_m) = 1/V(D_m)$ if $\mathbf{w}_s$ is *in* the version space, and $p(\mathbf{w}_s|D_m) = 0$ if it is outside. $V(D_m)$ is the volume of the version space given by

$$V(D_m) = \int d\mathbf{w} \prod_{k=1}^{m} \Theta(\sigma_k \mathbf{w} \cdot \mathbf{x}_k) \qquad (3)$$

Here, the Heaviside step function $\Theta(x)$ equals 1 if $x$ is positive and 0 otherwise. Thus, only coupling vectors for which the outputs $\sigma_k$ are correct, i.e., $\sigma_k \mathbf{w}_s \cdot \mathbf{x}_k > 0$, contribute.

$V(D_m)$ is related to *Shannon's entropy* $\mathcal{S}$ of the distribution $p(\mathbf{w}|D_m)$ by $\mathcal{S} = -\int d\mathbf{w}\, p(\mathbf{w}|D_m) \ln p(\mathbf{w}|D_m) = \ln V(D_m)$. Similarly, in statistical mechanics the entropy measures the logarithm of the volume of microscopic states that are compatible with given values of macroscopic constraints, such as the total energy of a system. In fact, the constraint of perfect learning of all examples is equivalent to the condition of a minimal "training energy." The learning of an increasing number of examples reduces the set of consistent vectors $\mathbf{w}_s$ and leads to a decrease of the entropy $\mathcal{S}$, i.e., of our uncertainty about the unknown teacher $\mathbf{w}_t$. As we will see, by calculating the entropy one will get the generalization error $\varepsilon$ for free.

## Entropy and Replica Method

Although $V(D_m)$ fluctuates with the random training set, for large $N$, the quantity $N^{-1}\mathcal{S}$ will be, with high probability, close to its *average* value $\mathcal{S}_{av}$. This results from the fact that the entropy is roughly additive in the degrees of freedom (which would be exactly true if the components of the weight vector $\mathbf{w}$ were statistically independent). Hence, the fluctuations of $N^{-1}\mathcal{S}$ will be averaged out by the many additive random contributions. A similar argument applies to $R = N^{-1}\mathbf{w}_s \cdot \mathbf{w}_t$.

The calculation of $\mathcal{S}_{av}$ requires another tool of statistical physics, the *replica method*. It is based on the identity

$$\mathcal{S}_{av} = \langle\langle \ln V(D_m) \rangle\rangle = \lim_{n \to 0} n^{-1}(\langle\langle V^n(D_m) \rangle\rangle - 1) \qquad (4)$$

The brackets denote the average over the examples. Often, the average of $V^n(D_m)$, which is the volume of the version space of $n$ perceptrons (replicas) $\mathbf{w}_a$, $a = 1, \ldots, n$, being trained on the same examples, can be calculated for *integers n*. At the end, an analytical continuation to real $n$ is necessary. The calculation of the high-dimensional integral over weight vectors is enabled by two ideas: Since the labels are produced by the teacher perceptron $\mathbf{w}_t$, and the input distribution is *spherical*, the integrand will depend *only* on the angles between the vectors $\mathbf{w}_a$, $a = 1, \ldots, n$, and $\mathbf{w}_t$, i.e., on the overlaps

$$\begin{aligned} q_{ab} &= N^{-1}\mathbf{w}_a \cdot \mathbf{w}_b,\ a < b \\ R_a &= N^{-1}\mathbf{w}_a \cdot \mathbf{w}_t \end{aligned} \qquad (5)$$

The result can be written in the form

$$\langle\langle V^n(D_m) \rangle\rangle = \int \prod_a dR_a \prod_{a<b} dq_{ab} \exp[N\mathcal{G}(n, \{q_{ab}, R_a\})] \qquad (6)$$

The explicit form of $\mathcal{G}$ has been given in Györgyi and Tishby (1990); see also Engel and Van den Broeck (2001).

The limit $N \to \infty$ (to get a nontrivial result, the number of examples is scaled like $m = \alpha N$, with $\alpha$ fixed) provides a second simplification: The integrals in Equation 6 are dominated by values $R_a(n)$ and $q_{ab}(n)$, for which the exponent $\mathcal{G}(n, \{q_{ab}, R_a\})$ is maximal. Other values have an (in $N$) exponentially smaller weight. The continuation of these most probable values to noninteger $n \simeq 0$ is by far nontrivial: The symmetry of $\mathcal{G}(n, \{q_{ba}, R_a\})$ under permutation of indices $a$, $b$, suggests the *replica symmetric* ansatz $q_{ab}(n) = q(n)$ and $R_a(n) = R(n)$, which is correct for the present perceptron problem. A more complicated scheme called *replica symmetry breaking* (Mézard, Parisi, and Virasoro, 1987) for continuing the matrices $q_{ab}$ to noninteger dimensions can be necessary if the version space of the learning problem is, for example, disconnected or not convex (Monasson and Zecchina, 1995).

Within replica symmetry, the analytic continuation $R = R(n = 0)$ coincides with the average teacher-student overlap needed for the generalization error (Equation 2), and $q = q(n = 0)$ gives the average overlap between two random student vectors in the version space. The resulting learning curve $\varepsilon$ as a function of the relative number of examples $\alpha$ is shown as the solid line in Figure 1. For a small size of the training set ($\alpha \to 0$), $q$ and $R$ are close to zero and $\varepsilon \approx 1/2$, which is not better than random guessing. To ensure good generalization, $m$, the size of the training set must significantly exceed $N$, the number of couplings. Finally, when the ratio $\alpha = m/N$ grows large, $q$ and $R$ approach 1, and the error decreases slowly to 0 as $\varepsilon \simeq 0.62\alpha^{-1}$.

The shrinking of the space of network couplings resembles a similar result obtained for the learning in attractor neural networks,

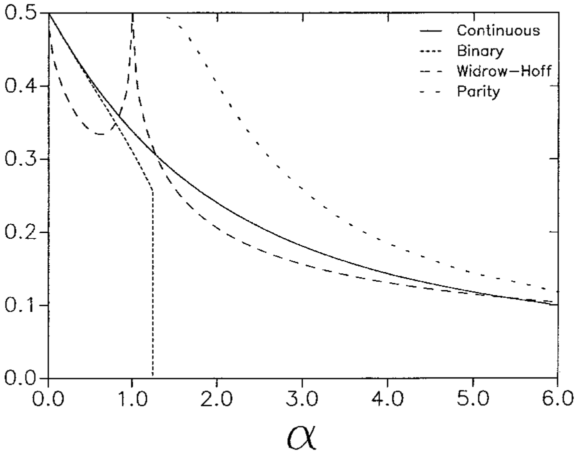

**Figure 1.** Generalization errors $\varepsilon$ for a typical continuous (solid curve) and a typical binary perceptron (dotted curve) as a function of the relative size $\alpha = m/N$ of the training set. For $\alpha = 1.24$, the generalization error drops discontinuously to zero. The dashed curve refers to the linear network formulated in Equation 9. For $\alpha \approx 1$, the mismatch between the nonlinear teacher and the linear student becomes apparent: although all examples are perfectly learned, generalization becomes impossible ($\varepsilon \approx ½$). This overfitting phenomenon diappears for $\alpha > 1$, when the algorithm learns with training errors. The curve with small dashes shows the learning curve for a parity tree machine with two hidden units. Nontrivial generalization ($\varepsilon <$ ½) is impossible for $\alpha < 1.2337$.

as presented in STATISTICAL MECHANICS OF GENERALIZATION (q.v.). For the latter case, however, the output bits of the corresponding perceptron are completely random (given by the random patterns to be stored), instead of being defined by a teacher network. As the number of patterns grows, the volume of couplings decreases to zero already at a non-zero critical capacity $\alpha = 2$.

So far we have discussed the *typical* generalization ability of a perceptron learning a linear separable rule. Is it possible to generalize faster, by using more sophisticated learning strategies? The answer is, not much, if we are restricted to random training examples. Studies of the asymptotics for optimal Bayes classifiers (Opper and Haussler, 1995) yield a generic $\alpha^{-1}$ decay for broad classes of learning models. For linear separable rules and spherical input distribution, the optimal decay is $\varepsilon \simeq 0.44\ \alpha^{-1}$, only slightly better than the typical error (Watkin, Rau, and Biehl, 1993; Opper and Kinzel, 1995).

The situation changes if the learner is free to ask the teacher questions (Watkin et al., 1993), because she can choose highly informative inputs. Then the decrease in the generalization error $\varepsilon$ can be exponentially fast in $\alpha$.

The approach of statistical mechanics is able to provide information about generalization abilities even in situations where, at present, no efficient learning algorithms are known. Assume, for example, that the perceptron weights are constrained to binary values $w(j)\ \varepsilon\ \{+1, -1\}$. This may give a crude model for the effects of a finite weight precision in digital network implementations. For this binary perceptron, perfect learning is equivalent to a hard combinatorial optimization problem, which in the worst case is believed to require a learning time that grows exponentially with $N$. Using the replica method, the dotted learning curve in Figure 1 is obtained. For sufficiently small $\alpha$, the discreteness of the version space has only minor effects. However, since there is a minimal volume of the version space when only one coupling vector is left, the generalization error $\varepsilon$ drops to zero at a finite value $\alpha_c = 1.24$. Remarkably, this transition is discontinuous. This means that for $\alpha$ slightly below $\alpha_c$, the few coupling vectors $\mathbf{w}$ that are consistent with all examples typically differ in a finite fraction of bits from the teacher (and from each other).

## Phase Transitions and Symmetry Breaking

In statistical mechanics, the overlaps $q$ and $R$ are examples of *order parameters*, which measure the degree of ordering of a system toward an external influence. In our case, the labels, which are provided by the teacher, make the typical student vector more and more aligned with the teacher. This is reflected by the increase in $q$ and $R$ from the minimal values 0 (when there are no examples) to their maximal values 1, when student and teacher align perfectly.

In statistical physics, a variety of systems show *phase transitions*, i.e., ordering sets in *spontaneously* when a control parameter exceeds a critical value. Surprisingly, such phase transitions can also be observed for *multilayer networks*. I will illustrate such a behavior for a simple toy multilayer network with a drastically simplified architecture, the *parity tree*. Here, the set of $N$ input nodes is equally divided into $K$ nonoverlapping groups, each of which is connected to one of $K$ hidden units by $N/K$ adjustable weights, as in a perceptron. The output node computes the parity of the hidden outputs; i.e., a $-1$ output results from an odd number of negative hidden units and a $+1$ output results from an even number. For $K = 2$, we obtain the learning curve (Hansel, Mato, and Meunier, 1992) with the small dashes shown in Figure 1. Below $\alpha = 1.2337$, the network perfectly memorizes the training examples without being able to generalize at all ($\varepsilon = 1/2$). Above this critical value, generalization sets in, and the generalization error decays smoothly. For $K > 2$, the transition is discontinuous (Engel and Van den Broeck, 2001).

This and similar phase transitions are related to *spontaneous symmetry breaking*. Although a statistical ensemble is invariant under a symmetry transformation, the typical, macroscopically observed state of the system may not show this symmetry. For the parity machine, the symmetry transformation is the inversion of the signs of the couplings corresponding to a pair of different hidden units. For example, for $K = 2$, a network with couplings all equal to, say, $+1$ implements exactly the same classification task as a network with all couplings equal to $-1$. For small $\alpha$, the typical student networks trained by a "$+1$" teacher will reflect this ± symmetry. Their coupling vectors consist of an equal fraction of positive and negative weights without any preference for the teacher (or the reversed teacher), and generalization is impossible. If $\alpha$ exceeds the critical value, the symmetry is broken, and we have *two* possible types of typical students, one with a majority of positive couplings, the other one with a majority of negative couplings. Both types of typical students now display some similarity with the teacher or its negative image, and generalization sets in. A related type of *retarded generalization* can be found in models of *unsupervised learning*, where the learner has to infer an unknown symmetry axis of a high-dimensional probability distribution (Engel and Van den Broeck, 2001). When the number of data is less than a critical value, the estimated direction of the axis will typically be orthogonal to the true one.

Phase transitions for multilayer networks with fully connected architectures are related to the breaking of the permutation symmetry between hidden units (Schwarze and Hertz, 1993; Engel and Van den Broeck, 2001). They can already be observed for *on-line learning* algorithms. Since the change in weights depends on the most recently presented example only, and since each example is seen only once, a detailed study of the dynamics of learning is possible (see STATISTICAL MECHANICS OF ON-LINE LEARNING AND GENERALIZATION).

## Algorithms and Overfitting

The statistical mechanics approach can also be applied to the performance of concrete algorithms, if the algorithm minimizes a *training energy*, such as the quadratic deviation

$$E(\mathbf{w}_s|\sigma^m, \mathbf{x}^m) = \sum_{k=1}^{m} (\sigma_k - F_{\mathbf{w}_s}(\mathbf{x}_k))^2 \qquad (7)$$

between the network's and the teacher's outputs (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION).

The ensemble of students is now defined by all vectors $\mathbf{w}_s$ that achieve a certain accuracy in learning, i.e., that have a fixed training energy. We may as well fix the *average* energy, allowing for small fluctuations. Such fluctuations also occur for physical systems in thermal equilibrium, which can exchange energy with their environment. The *Gibbs distribution*

$$p(\mathbf{w}_s|D_m) \propto e^{-\beta E(\mathbf{w}_s|D_m)} \qquad (8)$$

provides the proper probability density for such a case, where the parameter $\beta$ has to be adjusted such that the average energy achieves the desired value. In physics, $T = 1/\beta$ plays the role of the temperature. For the relation of this concept to the stochastic dynamics of networks, see STATISTICAL MECHANICS OF GENERALIZATION.

For $\beta = \infty$, the distribution $p$ is concentrated at the vector $\mathbf{w}_s$, for which $E$ is minimal, corresponding to a learning algorithm that achieves the total minimum of the training energy. An application to the generalization performance of *support vector machines* can be found in Dietrich, Opper, and Sompolinsky (1999).

Let me briefly illustrate the results of this method for a single-layer perceptron where, during the training phase, the student is replaced by a simple *linear* function

$$F_{\mathbf{w}_s}(\mathbf{x}) = \mathbf{w}_s \cdot \mathbf{x} \tag{9}$$

in Equation 7. For a teacher of the same linear type, the classification rule is learned completely with $m = N$ examples. A different behavior occurs if the teacher is the *nonlinear* rule (Equation 1), and, for generalization, the student's output is also given by Equation 1. Although all examples are still perfectly learned up to $\alpha = m/N = 1$, the generalization error increases to the random guessing value $\varepsilon = 1/2$ (Figure 1, dashed line), a phenomenon termed *overfitting*.

If $m > N$, the minimal training error $E$ is *greater than zero*. Nevertheless, $\varepsilon$ decreases again and approaches 0 asymptotically for $\alpha \to \infty$. This shows that one can achieve good generalization with algorithms that allow for learning errors.

The introduction of a temperature is not merely a formal trick. Stochastic learning with a non-zero temperature may be useful to escape from local minima of the training energy, enabling a better learning of the training set. Surprisingly, it can lead to *better generalization abilities* if the classification rule is not completely learnable by the net. In the simplest case, that happens when the rule contains a degree of noise (Györgyi and Tishby, 1990; Opper and Kinzel, 1995; see also Simulated Annealing and Boltzmann Machines).

The replica method enables us to study the properties of networks at their minimal training energy. However, a real learning algorithm may not reach such a state when local minima are present.

## Discussion

The statistical mechanics approach to learning and generalization allows us to understand the typical generalization behavior of large neural networks. Its major tool, the replica method, has been illustrated in this article for simple neural networks like the perceptron. Even for simple models, interesting and unexpected phenomena, such as discontinuous and retarded generalization, can be observed.

The statistical mechanics approach allows us to perform controlled analytical experiments on very large networks. In contrast to real experiments, which will produce an enormous amount of microscopic data that must be evaluated, this analytical method provides us with a small set of order parameters that are directly interpretable in terms of the network's macroscopic performance. Concentrating on typical behavior, the statistical mechanics analysis can complement other theoretical approaches to generalization, such as the worst case PAC bounds (see Engel and Van den Broeck, 2001; Urbanczik, 1996; see also Learning and Generalization: Theoretical Bounds).

Presently, the approach is being applied to both novel learning concepts in neural computing, such as support vector machines, and to a variety of other problems in information science, such as error-correcting codes and hard combinatorial optimization problems (see, e.g., Nishimori, 2001). Siginificant progress has also been made in understanding the *dynamical* properties of concrete algorithms (see Heimel and Coolen, 2001, and Statistical Mechanics of On-Line Learning and Generalization).

New and challenging applications are also found in other fields where learning and adaptation in large populations of entities play a role. These fields include ecological systems and economical markets.

# Statistical Mechanics of Neural Networks

*Annette Zippelius and Andreas Engel*

## Introduction

Statistical mechanics describes the collective properties of systems composed of many interacting elements on the basis of the individual behavior and mutual interaction of these elements. The term "collective" refers here to properties that result substantially from the interaction of the constituents and which show up only if the whole system contains a sufficient number of elements. In physics, statistical mechanics bridges the gap between microscopic structure and macroscopic properties of matter. A basic example is the calculation of the equation of state for a gas—i.e., the law according to which pressure changes with temperature—from the equation of motion governing the dynamics of the molecules. Numerous detailed investigations of physical systems have revealed two remarkable features of this approach:

1. The collective properties of a system can be more complex than the simplicity of its constituents seems to allow. This feature is a consequence of the phenomenon of spontaneous *symmetry breaking*, which means that a macroscopic system can be in a state of lesser symmetry (i.e., higher complexity) than the underlying microscopic dynamics. For example, the statistical distribution of atomic *spins* in an unmagnetized bar of iron is symmetrical, but once the iron is magnetized the mean direction of the spins is constrained to lie in a specific direction—the symmetry has been broken. Such symmetry breaking is often the sign of a *phase transition* during which matter changes from one state of organization to another.
2. Very few of the details characterizing the elements of a macroscopic system are essential for the qualitative collective properties. In the example of the gas, an attractive interaction between the molecules results in a condensation point, such that for temperatures below this point there is a phase transition from gas to liquid. Practically any law of mutual attraction would give qualitatively the same transition, just changing the specific value for the transition temperature. The same is true for the characterization of spins in models of magnetization. Consequently, extremely simplified models for the microscopic elements can be used. To find out which microscopic properties are *relevant* is, of course, the first step of the program, usually a nontrivial and decisive one.

Biological as well as technical neural networks are, in many, but not all, cases, made up of a large number of elements (neurons or electronic circuits) strongly interacting through connections (synapses or wires). They can perform information processing of amazing complexity. Although the elements are themselves already rather complicated systems which, at least in the case of biological neurons, are still far from being completely understood, it is generally believed that these abilities for information processing are far beyond the possibilities of a single or a few units and are therefore in some sense collective properties. It is then tempting to assume that, as in complex physical systems, these collective properties are again fairly independent of many of the microscopic details. The aim of a statistical mechanics of neural network models is hence to investigate to what extent the models of physics can be applied to show how, in a large system of simple interacting units reminiscent of biological neurons, there can emerge collective properties for complex information processing comparable to those found in real neural networks.

Within the approach of statistical mechanics, we define a neural network as an ensemble of $N$ neurons of activity $S_i$, $i = 1, \ldots, N$, which interact via synaptic couplings $J_{ij}$, $i, j = 1, \ldots, N$. Both the activity and the couplings can be real valued or restricted to a discrete set, and in general evolve dynamically. However, most studies assume a separation of time scales, such that either

- the neurons evolve dynamically, $S_i = S_i(t)$, for a fixed set of couplings $J_{ij}$, or
- the couplings evolve dynamically, $J_{ij} = J_{ij}(t)$, for a given activity state $\{S_i\}$ or a set of $p$ such states $\{\xi_i^\nu\}$, numbered by $\nu = 1, \ldots, p$.

In the first case the focus is on processing of information. Problems of this kind will be discussed in this article. In the second case the important question is how to adapt the couplings to a particular processing task. Questions concerning this type of learning dynamics are dealt with in other articles in this book (see Statistical Mechanics of On-Line Learning and Generalization).

Statistical mechanics provides a quantitative analysis of the properties of a very large network (mathematically in the limit $N \to \infty$). A large class of models can be solved exactly. Examples such as the Hopfield model and strongly diluted networks are discussed below.

Many of the information processing tasks that a neural network can perform involve a set of special configurations $\{\xi_i^\nu\}$ of neuron activity, called *patterns*. Generally, the performance depends on the detailed realization of this pattern set. The focus of statistical mechanics is then on the *typical* behavior of the network, i.e., one wants to know how it performs typically for a given problem rather than to pinpoint the properties specific to one particular pattern set $\{\xi_i^\nu\}$. An effective way to mathematically describe such a typical performance is to generate the pattern set at random according to a given probability distribution (e.g., $\xi_i^\mu = \pm 1$ with equal probability) and to determine averages of the quantities of interest. As it turns out, many interesting quantities are self-averaging, which means that for $N \to \infty$ the performance on a special random pattern set is identical to the average performance. Calculating the average of the relevant quantities, one can hence make reliable predictions for the results of a real or numerical experiment involving just one realization of the pattern set. This approach has been very successful in the theory of disordered physical systems as noncrystalline solids or random magnets, and many of the mathematical techniques developed there have been proven to be adequate for the statistical mechanics of neural networks.

## Neuron Dynamics

An extremly simplified model of the individual neurons suitable for a statistical mechanics analysis was introduced in 1943 by Warren McCulloch and Walter Pitts. They devised a neuron as a bistable threshold unit, which is either active (firing) or passive (quiescent). The state of neuron $i$ can therefore be described by a binary variable $S_i = 0, 1$ or equivalently, $S_i = \pm 1$. The former choice was used by McCulloch and Pitts, whereas the latter became standard in statistical mechanics due to its formal similarity with magnetic ("spin") systems, many of which have been studied by physicists under the general heading of *spin glasses*. The interaction between $N$ such neurons takes place via real-valued couplings $J_{ij}$. More precisely, a neuron $S_j$ contributes to the (postsynaptic) potential of neuron $S_i$ with the value $J_{ij}S_j$ depending on its own activity state. Neuron $S_i$ in turn sums up all these contributions and compares the sum with a neuron-specific threshold $\theta_i$. If the accumulated potential $\Sigma_j J_{ij} S_j$ exceeds this threshold, neuron $S_i$ becomes (or remains) active, otherwise it remains (or becomes) passive. The discrete-time dynamics of the whole network is therefore given by

$$S_i(t+1) = \operatorname{sign}(h_i(t)) = \operatorname{sign}\left(\sum_j J_{ij} S_j(t) - \theta_i\right) \qquad (1)$$

where $\operatorname{sign}(x) = +1$ for $x > 0$ and $\operatorname{sign}(x) = -1$ otherwise, and where $t = 0, 1, 2, 3, \ldots$ denotes the discrete-time steps.

The collective behavior of an ensemble of such neurons is often understood in the context of associative memory, i.e., the recall of information on the basis of partial knowledge of its content. The use of neural networks as associative memories is built on three main principles (see Computing with Attractors):

- The information, which is to be stored and retrieved in the system, is represented as one or many configurations of neuronal activity, called patterns $\{\xi_i^\nu\}$ ($i = 1, \ldots, N$; $\nu = 1, \ldots, p$).

- The couplings are designed to make the patterns attractors of the neuron dynamics.
- Association is the dynamic evolution of an arbitrary initial state into one of these attractors.

In this section we discuss the performance of the network for a given set of couplings that we assume to be adapted to a set of patterns $\{\xi_i^\nu\}$. Some of the relevant questions are:

- What are the attractors of the neuron dynamics and how well are they correlated with the patterns?
- What is the capacity, i.e., what is the maximal number of patterns that can be stored and retrieved?
- What are the basins of attraction, i.e., what is the maximal amount of noise permissible in the initial stimulus?
- How long does it take the network to reach an attractor?

Of particular interest are the stationary states of the dynamics, for which $S_ih_i > 0$ for all $i = 1, \ldots, N$ (see Equation 1). If the coupling constants are symmetric, i.e., $J_{ij} = J_{ji}$, and if there are no self-interactions, i.e., $J_{ii} = 0$, then an *energy function*

$$E(\{S_i\}) = -\frac{1}{2}\sum_{i\neq j} J_{ij}S_iS_j + \sum_i \theta_iS_i \tag{2}$$

exists and is monotonically decreasing for the *asynchronous* dynamics of Equation 1. The stationary states of the dynamics must then coincide with the minima of this energy, which in turn can be analyzed with the methods of equilibrium statistical mechanics.

Before embarking on that analysis, however, it is useful to slightly generalize this approach. By describing the neurons in terms of binary activity variables, we ignored almost all microscopic details of the network. The influence of the neglected microscopic degrees of freedom on the dynamics of the activity states can be modeled by a random noise term changing the deterministic updating process (Equation 1) into a probabilistic one:

$$S_i(t + 1) = \operatorname{sign}(h_i(t) + \varphi_i(t)) \tag{3}$$

The probability distribution $P(\varphi)$ of the noise is not very critical. A simple choice would be a Gaussian $P(\varphi) = 1/\sqrt{\pi T}$ $\exp(-\varphi^2/T)$, which would imply that neuron $i$ will be firing (quiescent) at time $(t + 1)$ with probability

$$p_\pm = \frac{1}{2}\left(1 \pm \frac{2}{\sqrt{\pi}}\int_0^{h_i(t)/T} dx\, e^{-x^2}\right) \tag{4}$$

The strength of the noise is denoted by $T$, such that for $T = 0$ we recover the deterministic dynamics of Equation 1. By analogy with physical systems we will often refer to the noise strength $T$ as the temperature, keeping in mind, however, that it is usually different from the (thermodynamic) temperature of the neural network under consideration. The stochastic process (Equation 3) is also the basic dynamics of Monte Carlo Simulations, which can be used efficiently to *simulate* the dynamics of artificial neural nets. In that context a different choice,

$$P(\varphi) = \frac{1}{2T}\left[\cosh\left(\frac{\varphi}{T}\right)\right]^{-2} \tag{5}$$

is quite common. It gives rise to a firing probability $p_\pm = (1/2)(1 \pm \tanh(h_i(t)/T)$, which differs only slightly (at most 1%) from Equation 4. Both firing probabilities are such that the system will ultimately converge to a steady-state probability distribution. The macroscopic properties of the system are then given as averages with this distribution. (see Reif, 1982, for a textbook account of relevant results from "ordinary" statistical mechanics).

In deterministic neural networks (see COMPUTING WITH ATTRACTORS), the state of the neural networks will tend toward a single attractor. Once noise is included, no such determinism is possible. Instead, statistical mechanics provides tools to find an *equilibrium distribution* in which each state has a probability of occurrence for which the probability of leaving a state is exactly balanced by the probability of entering it. If we choose the noise statistics of Equation 5, we end up in the equilibrium distribution in which states are distributed according to the Boltzmann distribution in which the probability of a state is given by

$$P(\{S_i\}) = \exp(-\beta E(\{S_i\}))/Z \tag{6}$$

where $\beta = 1/T$ and $Z$ is a normalization factor, $Z = \Sigma_{\{S_i\}}$ $\exp(-\beta E(\{S_i\}))$. All equilibrium expectation values can then be calculated by summing over all configurations, weighted with their Boltzmann factor. For example, the mean activity of neuron $k$ is given by

$$\langle S_k\rangle_{th} = \frac{\sum_{\{S_i\}} S_k \exp(-\beta E(\{S_i\}))}{\sum_{\{S_i\}} \exp(-\beta E(\{S_i\}))} \tag{7}$$

where the notation $\langle\cdot\rangle_{th}$ means "average over all states at thermal equilibrium." Note that equivalently we could write

$$\langle S_k\rangle_{th} = \frac{1}{\beta}\frac{\partial F}{\partial \theta_k} \tag{8}$$

with the free energy $F(\beta, \theta_i)$ defined by

$$F(\beta, \theta_i) = -\frac{1}{\beta}\log\sum_{\{S_i\}} \exp(-\beta E(\{S_i\})) \tag{9}$$

It is a standard result of statistical mechanics that all averages with the Boltzmann distribution, i.e., all macroscopic quantities, can be calculated similarly by appropriate derivatives of the free energy. The main task within a statistical mechanics analysis is hence the calculation of the free energy.

The inclusion of noise has the effect that many configurations—and not just the minima of $E$—contribute to the expectation values. In other words, a much larger part of configuration space can be explored. A similar approach has been put forward in optimization theory to include nearly optimal solutions (see SIMULATED ANNEALING AND BOLTZMANN MACHINES and OPTIMIZATION, NEURAL).

In statistical mechanics, powerful methods have been developed to calculate the free energy Equation 9. Most of them, however, only apply in the thermodynamic limit $N \to \infty$. In physics we have abundant experimental evidence that this limit exists. Quantities such as the energy (Equation 2) and the free energy (Equation 9) are expected to be *extensive* variables, increasing linearly with $N$. Hence the corresponding *intensive* quantities, e.g., the free energy per neuron $f = F/N$ have a well-defined limit as $N \to \infty$. Furthermore, fluctuations of extensive quantities are generally negligible in the thermodynamic limit. Typically the variance relative to the mean decreases like $N^{-1/2}$. Therefore the results obtained theoretically employing the limit $N \to \infty$ very accurately describe real systems with finite but large $N$. This is a characterictic feature of statistical distributions involving very many degrees of freedom. In a typical neural network application the $N \to \infty$ results of statistical mechanics characterize systems with $N = 100 - 1000$ with an accuracy of a few percent.

## Statics of the Hopfield Model

The following choice of couplings was used in early studies of ASSOCIATIVE NETWORKS (q.v.) by Hopfield (1982) and extensively thereafter (see Amit, 1989)

$$J_{ij} = \frac{1}{N} \sum_{\nu=1}^{p} \xi_i^\nu \xi_j^\nu \tag{10}$$

The patterns are random variables and the synaptic couplings of Equation 10 correspond to one realization of the random process. In the simplest case all $\xi_i^\nu$ are statistically independent, identically distributed and equally likely to be $\pm 1$. To further simplify the analysis we set $\theta_i = 0$.

There is no limit on the range of interaction for the coupling matrix of Equation 10, instead each neuron interacts with every other neuron. Hence the *local field*, i.e., the "force" exerted on a single neuron by the activity of all other neurons

$$h_i = \sum_{j=1}^{N} J_{ij} S_j = \frac{1}{N} \sum_{j=1}^{N} \sum_{\nu=1}^{p} \xi_i^\nu \xi_j^\nu S_j \tag{11}$$

is a large sum of many random numbers, which are only weakly correlated. As long as the number $p$ of patterns remains finite as $N \to \infty$ we can neglect these correlations and replace $h_i$ by its thermal average:

$$h_i \cong \sum_{\nu=1}^{p} \xi_i^\nu \frac{1}{N} \sum_{j=1}^{N} \xi_j^\nu \langle S_j \rangle_{th} \tag{12}$$

The most important characteristic of an associative memory is the overlap

$$m^\nu = \frac{1}{N} \sum_{j=1}^{N} \xi_j^\nu \langle S_j \rangle_{th} \tag{13}$$

It describes the average alignment of the stationary states with the patterns. The overlap (as well as the free energy) is self-averaging, i.e., its fluctuations from pattern set to pattern set go to zero in the thermodynamic limit. It is hence equal to its average over the pattern statistics with probability 1: $m^\nu = \langle\langle \xi_i^\nu \langle S_j \rangle_{th} \rangle\rangle_\xi$. In terms of the local field $h_i$ (Equation 12) the activity is given by $\langle S_i \rangle_{th} = \tanh(\beta h_i)$ so that the overlap vector $\boldsymbol{m} = (m^1, m^2, \ldots, m^p)$ is the solution of

$$\boldsymbol{m} = \langle\langle \boldsymbol{\xi}^\mu \tanh \beta \boldsymbol{m} \cdot \boldsymbol{\xi}^\mu \rangle\rangle_\xi \tag{14}$$

In the context of associative memory we are interested in states $\{S_i\}$, which are correlated with one pattern only, i.e., $m^\nu = m\delta_{\nu\nu_0}$. Such states are called *Mattis* or *retrieval states* and are indeed solutions of Equation 14 below a critical noise level $T_c = 1$. These retrieval states are the global minima of $E$ for $T \simeq T_c$ and for $T \to 0$ and presumably for all $T$ in between. The failure of this property for $T > T_c$ is an example of a *phase transition* in neural networks. Equation 14 also has solutions with several non-zero components of $\boldsymbol{m}$. They correspond to network configurations that resemble mixtures of stored patterns. Such states clearly disturb the retrieval process. One of the surprising results of the statistical analysis is the fact that noise actually improves the efficiency of the network as a an associative memory by eliminating these *spurious states* for $T \geq .5$.

It is also possible to store an extensive number of patterns, i.e., $p \to \infty$ with $N \to \infty$ such that $\alpha = p/N$ finite (Amit, Gutfreund, and Sompolinsky, 1987). This approach gives rise to a *static* random contribution $z$ in the local field $h$:

$$\begin{aligned} \langle S_i \rangle_{th} &= \tanh \beta h(z) \\ h(z) &= \boldsymbol{m} \cdot \boldsymbol{\xi}^\mu + \sqrt{\alpha r} z \end{aligned} \tag{15}$$

The overlap $\boldsymbol{m}$ and the variance $r$ of the new noise term have to be calculated from the coupled equations

$$\begin{aligned} \boldsymbol{m} &= \int \frac{dz}{\sqrt{2\pi}} e^{-z^2/2} \langle\langle \boldsymbol{\xi}_i \langle S_i \rangle_{th} \rangle\rangle_\xi \\ q &= \int \frac{dz}{\sqrt{2\pi}} e^{-z^2/2} \langle\langle \langle S_i \rangle_{th}^2 \rangle\rangle_\xi \\ r &= \frac{1}{1 - \beta(1 - q))^2} \end{aligned} \tag{16}$$

Thermal noise ($T$) as well as the static noise (cross-talk, $z$) resulting from many other stored patterns destroy the retrieval states above a critical line in the ($T$, $\alpha$) plane. In the absence of thermal noise ($T = 0$), retrieval states can only exist up to $\alpha_c \simeq 0.14$. This result is in very good agreement with extensive computer simulations of the model. The transition is discontinuous with a sudden jump of the overlap from $m(\alpha \to \alpha_c) \simeq .97$ to $m = 0$ for $\alpha > \alpha_c$. Hence when overloading the network the retrieval quality abruptly changes.

For $\alpha < \alpha_c$ retrieval states coexist with so-called spin glass states. In the latter the neurons build up static random configurations almost uncorrelated with the stored patterns. They can be understood as descendents of the mixture states encountered for finite $p$ now mixing very many patterns. The retrieval states are global minima of the energy $E$ for $\alpha \leq .05$ only.

Numerous extensions and generalizations of the Hopfield model have been discussed. They include the following:

- *Robustness*. It has been shown that the Hopfield model is surprisingly robust with respect to various perturbations, such as synaptic noise or synaptic dilution. Even synaptic clipping, i.e., retaining only the sign of $J_{ij}$, just reduces the capacity from $\alpha_c \sim 0.14$ to $\alpha_c \sim 0.1$.
- *Forgetting and unlearning*. In the Hopfield model, all memories are destroyed completely upon overloading the network. This distruction can be avoided by using special learning rules that weigh patterns differently thereby forgetting older items in favor of newer ones. It has also been suggested that "unlearning," a procedure to weaken bonds in a specific way, can improve the performance of the network (Hopfield, Feinstein, and Palmer, 1983).
- *Other pattern statistics*. The assumption of uncorrelated patterns in the Hopfield model does not apply to many situations of practical interest. An explicit construction of the coupling matrix for patterns with arbitrary correlations is provided by the pseudo-inverse rule. If the patterns are linearly independent, it is given by

$$J_{ij} = \frac{1}{N} \sum_{\nu,\mu}^{p} \xi_i^\nu (C^{-1})_{\nu\mu} \xi_j^\mu \quad \text{with} \quad C_{\nu\mu} = \frac{1}{N} \sum_{i=1}^{N} \xi_i^\nu \xi_i^\mu \tag{17}$$

This coupling matrix is nothing but a projector $\Sigma_j J_{ij} \xi_j^\nu = \xi_j^\nu$, which implies that the patterns are stationary states because

$$h_i \xi_i^\nu = \xi_i^\nu \sum_j J_{ij} \xi_j^\nu = 1 \tag{18}$$

It has been widely used in the context of self-organizing maps (Kohonen, 1984) as well as attractor neural networks. The storage capacity is $\alpha_c = 1$ and a local learning rule was given to construct the couplings in an iterative scheme. Special cases of correlated patterns include hierarchical correlations, which may be important for the organization of human memory, and biased patterns, which have non-zero average mean activity.

## Dynamic Properties

Several interesting questions concern the dynamic behavior of neural networks during retrieval, as, for example:

- How long does it take the system to retrieve a pattern?
- Which initial conditions are iterated into a particular attractor?

If the couplings are asymmetric $J_{ij} \neq J_{ji}$, as in the majority of biological systems, then a neural network is only defined as a dynamic process (Equation 1). Such models have in general no energy function, and complex, time-dependent attractors may occur. Even if one is only interested in stationary states or distributions, these can in general only be obtained as the long time limit of the dynamics. Since the methods of nonequilibrium dynamics are much less developed than those of equilibrium statistical mechanics, it is no surprise that genuine dynamic problems, like the basins of attraction, are much less understood than the stationary properties of neural networks. Nevertheless, nontrivial dynamic behavior is of great importance in biological as well as technical neural networks.

One motivation to study cyclic attractors is the abundant appearance of temporal sequences in cognition and of rhythmic motion in motor control tasks. Hopfield suggested a network, which was designed to store and retrieve a sequence $\boldsymbol{\xi}^{1}, \boldsymbol{\xi}^{2}, \ldots, \boldsymbol{\xi}^{q}$, such that the system, if initialized in pattern $\boldsymbol{\xi}^{1}$, makes a collective transition to $\boldsymbol{\xi}^{2}$, then from $\boldsymbol{\xi}^{2}$ to $\boldsymbol{\xi}^{3}$ and so on.

The following set of couplings

$$J_{ij} = \frac{1}{N}\sum_{\nu=1}^{q} \xi_i^{\nu}\xi_j^{\nu} + \frac{\lambda}{N}\sum_{\nu=1}^{q-1} \xi_i^{\nu+1}\xi_j^{\nu}, \quad \lambda > 1 \tag{19}$$

generate such a temporal sequence of states, provided the neurons are updated synchronously and without any noise, either in the dynamics or in the initial state. Noise tolerance or recall of sequences with asynchronous dynamics can be achieved with delayed synapses, which induce transitions only after the system has been stabilized for a time $\tau$ in one of the patterns. The synaptic delay does not have to match the period of the sequence exactly. In fact a broad distribution of synaptic delays is well suited for learning of sequences, whose relevant time scale is represented in the spectrum (see Sequence Learning). Connections that match the timescale of the sequence approximately will be enforced, a process which can be seen as learning by selection.

Complex dynamical behaviour naturally occurs in asymetrically *diluted networks*. The assumption of complete connectivity in the Hopfield model is implausible for biological systems and unacceptable for technical implementations. Hence we are led to consider diluted networks, e.g., a diluted Hopfield model

$$J_{ij} = \frac{c_{ij}}{K}\sum_{\nu=1}^{p} \xi_i^{\nu}\xi_j^{\nu} \tag{20}$$

The $c_{ij} \in \{0, 1\}$ are independent random variables and $c_{ij} = 1$ with probability $K/N$. In the limit of strong dilution $\log K \ll \log N$ the dynamic model defined by Equations 1 and 20 is exactly solvable (Derrida, Gardner, and Zippelius, 1987). Specializing to retrieval states with overlap $m(t)$ with, e.g., pattern $\boldsymbol{\xi}^{1}$ one finds for synchronous updating

$$m(t + 1) = f(m(t)) = \int \frac{dy}{\sqrt{2\pi}} e^{-y^2/2} \tanh \beta(m(t) - \sqrt{\alpha}\, y) \tag{21}$$

Here we have taken the limit $K \to \infty$ (after $N \to \infty$) and anticipated a finite capacity $\alpha = P/K$ per synapse. Retrieval states correspond to stable fixed points $m_s^* = f(m_s^*) \neq 0$. They exist up to $\alpha \leq \alpha_c = 2/\pi$. As $\alpha \to \alpha_c$, $m_s^*$ decreases continuously to zero, in marked contrast to the discontinuous behavior of $m$ at $\alpha_c$ found in the last section for the fully connected Hopfield model. Note also that the retrieval states $m_s^* \neq 0$ do not correspond to fixed points in phase space. Although the overlap $m$ is constant in time, there is substantial dynamic activity on the microscopic level. This can be seen from the fact that two states with the same overlap have in general a Hamming distance different from zero and the time delayed autocorrelation function exhibits dynamic noise even at zero temperature.

The size of the basins of attraction is determined by an *unstable* fixed point $m_u^*$ of Equation 21 with $0 \leqslant m_u^* < m_s^*$. If the system is started in a configuration with initial overlap $m(t = 0)$ larger than $m_u^*$ it will be iterated into $m_s^*$. If $m(t = 0) < m_u^*$ the dynamics will evolve the state toward $m^* = 0$. The basins of attraction have been calculated in this way for a variety of learning rules in the limit of strong dilution.

## Discussion

This article attempts to elucidate how the concepts and methods of statistical mechanics can be successfully applied to understand certain aspects of large neural networks. It has emphasized the goals of statistical mechanics more than the abundance of results. A specific example, namely the Hopfield model for associative memory, has been discussed in detail to show what kind of quantitative result can be expected from a statistical mechanical analysis. To put this model in a more general context, this article has indicated how it can be extended to more complex tasks, and has focused on the dynamics of neurons in the presence of fixed synaptic couplings. The inverse problem—the adaptation of the couplings to given neuronal activity states—has also been analyzed very sucessfully with the methods of statistical mechanics (see Statistical Mechanics of On-Line Learning and Generalization). Statistical mechanics of neural networks is a rapidly developing field with widespread research activity. For more information the interested reader is referred to textbooks (Amit, 1989; Domany, van Hemmen, and Schulten, 1991; Hertz, Krogh, and Palmer, 1991; Engel and Van den Broeck, 2001) and the contributions in this *Handbook*.

# Statistical Mechanics of On-Line Learning and Generalization

*Michael Biehl and Nestor Caticha*

## Introduction

In trying to understand how artificial neural networks (ANNs) learn from examples, researchers ask a variety of questions whose answers may require very different approaches. For questions about the typical properties of large ANNs, statistical mechanics (SM) provides a set of tools which was first developed to discern macroscopic properties emerging from microscopic interactions among a large number of units.

The aim of this article is to introduce the reader to the SM theory of on-line training of feedforward neural networks and their generalization ability. The main characteristic of on-line learning is that training examples are dealt with one at a time, as opposed to off-line or memory-based methods, where learning is guided by the minimization of a cost function that incorporates possibly all of the data. In the language of statistical physics, the distinction is between systems that can be thought of as in a state of thermal equilibrium, and off-equilibrium situations in which the network is not allowed to extract all possible information from a set of examples. The equilibrium SM of off-line learning and generalization is reviewed in Statistical Mechanics of Generalization and Statistical Mechanics of Neural Networks (q.v.).

Although on-line learning is an intrinsically stochastic process, the restriction to large networks, togther with assumptions that are made about the statistical properties of the inputs, permits a concise description of the dynamics in terms of coupled ordinary differential equations. These deterministic equations govern the average evolution of quantities that completely define the macroscopic state of the ANN. The average is taken with respect to the data—an operation that is straightforward if the presented examples are statistically independent.

This off-equilibrium situation can be analyzed for a variety of network architectures and environments. The types of problems that can be investigated in this framework include (1) determining the learning curves for a large class of models, (2) deriving the upper bounds of the typical performance and determining how these bounds might be approached, (3) dynamical symmetry breaking in hidden-layer neurons, which can model rapid transitions to new levels of generalization ability, and (4) analyzing the effects of different types of noise, or changes in the environment. The last issue in particular arises in real-world applications and is an area in which on-line learning is to be preferred. The performance of on-line algorithms compares well with that of sophisticated off-line prescriptions. However, the computational cost and memory requirements of on-line algorithms are significantly lower. Off-line training is not capable of dealing with environmental drift or sudden changes, because no distinction is made between old, possibly irrelevant data and more recent data. This is treated most naturally by on-line methods (see Vicente, Kinouchi, and Caticha, 1998, and references therein).

## The Dynamics of On-Line Learning

For illustrative purposes, we will show the theoretical treatment of on-line learning in terms of a specific class of neural networks. It should be noted that many of the restrictions introduced in the discussion can be relaxed without complicating the analysis very much.

We consider student networks with $N$ real-valued inputs, $K$ units in a hidden layer, and one single output. Denote by $\mathbb{J} = (\mathbf{J}_1, \mathbf{J}_2, \ldots \mathbf{J}_K)$ the set of adaptive student weights that connect the input layer to the hidden units. Here and in the following, boldface vectors are in $\mathbb{R}^N$. The state of a hidden unit is taken to be a function $\sigma_j^k = f_{\text{hid}}(x_k)$ of the projection $x_k = \mathbf{J}_k \cdot \xi$, and the total output is given as $\Sigma_J(\xi) = f_{\text{out}}(\sigma_J^1, \sigma_J^2, \ldots, \sigma_J^K)$. All units may have Boolean $(\pm 1)$ or continuous (e.g., linear or sigmoidal) transfer functions.

In general, the functions $f_{\text{hid}}, f_{\text{out}}$ can be specified through a set of additional adaptive parameters. For simplicity we will concentrate here on cases where only $\mathbb{J}$ is to be determined in the course of learning and $f_{\text{out}}$ is fixed a priori. Learning a finite number of second-layer weights or thresholds is easier and faster than adaptating the $K\,N$ first-layer weights $\mathbb{J}$ (Riegler and Endres, 1999).

The student network is to learn a rule from examples. For the purpose of modeling it is convenient to parameterize the unknown rule in terms of a teacher network. Let $\mathbb{B} = (\mathbf{B}_1, \mathbf{B}_2, \ldots, \mathbf{B}_M)$ denote its $M$ hidden-unit weight vectors with $y_m = \mathbf{B}_m \cdot \xi$. This teacher net implements the mapping $\Sigma_B(\xi) = f_{\text{out}}(\sigma_B^1, \sigma_B^2, \ldots, \sigma_B^M)$, where $\sigma_B^m = f_{\text{hid}}(y_m)$. For simplicity we will assume that the activation functions are the same in student and teacher. We also restrict our attention to the thermodynamic limit, where $N \to \infty$, but $K$ and $M$ remain finite. Note that in this simplified scheme it is still possible to model a variety of scenarios, including the case of matching complexity ($K = M$), where the rule is perfectly learnable. Obviously, the student can only approximate the rule for $K < M$, whereas the network is *oversophisticated* if $K > M$.

The learning of a linearly separable rule with a so-called single-layer perceptron has served as a prototype model in the development of the entire field (see Statistical Mechanics of Generalization). This scenario is recovered for $K = M = 1$ with threshold hidden activation $f_{\text{hid}}(\,) = \text{sign}(\,)$ and with the output transfer function $f_{\text{out}}$ being the identity.

A set of weights $\mathbb{J}^\mu$ is chosen after presentation of $\mu - 1$ examples of the form $(\xi_\nu, \Sigma_\nu)$. Here $\xi_\nu$ is the input vector drawn at discrete-time $\nu$ from a distribution $P(\xi_\nu)$, and $\Sigma_\nu$ is the corresponding training label. The latter can coincide with the true rule output $\Sigma_B(\xi_\nu)$ if reliable example data are available, or it is a noisy version thereof in the presence of stochastic corruption. The aim of learning is to determine $\mathbb{J}^\mu$ such that the teacher and student outputs are close in some respect for a novel, random input $\xi$. A quite natural choice of an error measure is the quadratic deviation from the correct rule output $e(\xi) = (\Sigma_J(\xi) - \Sigma_B(\xi))^2/2$. The expected value of this quantity with respect to $P(\xi)$ is termed the generalization error $e_G = \langle e(\xi) \rangle_\xi$. Achieving small values of $e_G$ is aimed at by making small changes in $\mathbb{J}^\mu$ at each time step.

Although there is considerable liberty in the choice of a training prescription, some common features are shared by all reasonable algorithms. Here we will consider updates of the student vectors that can be written in the form

$$\mathbf{J}_k^\mu = \mathbf{J}_k^{\mu-1} + \frac{1}{N} F_k \cdot \xi_\mu \tag{1}$$

on presentation of example $(\xi_\mu, \Sigma_\mu)$. The central quantities in defining the algorithm are the *modulation functions* $F_k$, which determine the amount of correction in the direction of the latest example. Often, the update term $F_k \xi_\mu$ can be written as the gradient with respect to $\mathbf{J}_k$ of an instantaneous cost function defined for the latest example. Because of the similarity to pioneering ideas about learning in biological neural networks, algorithms of the type shown in Equation 1 have been termed (generalized) *Hebbian learning*. Modulation functions that vary between different components of the student vectors (*matrix update*) can also be considered (see, e.g., Murata in Saad, 1998; Bös and Amari in Saad, 1998).

The modulation $F_k$ can be a function of several quantities. It utilizes information about the current example and actual student weights. More sophisticated algorithms may depend on several other variables that play the role of hyperparameters. In general, they reflect the fact that the amount of information contained in an example depends strongly on the state of the student network. Learning can introduce so-called hyperparameters to the algorithm that estimate, among other things, the performance of the network, noise levels affecting the data, or parameters that describe the input distribution. Learning will then be efficient, in some cases even as fast as optimal off-line training.

In order to obtain a macroscopic description of the dynamics, we can project the iteration equation (Equation 1) onto $\mathbb{J}$ and $\mathbb{B}$, which immediately yields a set of equations for the overlaps

$$Q_{ij} = \mathbf{J}_i \cdot \mathbf{J}_j \quad \text{and} \quad R_{\text{in}} = \mathbf{J}_i \cdot \mathbf{B}_n \tag{2}$$

The set of (usually) nondynamical parameters $T_{mn} = \mathbf{B}_m \cdot \mathbf{B}_n$ is also introduced here for future reference. In the simplest models, all considered inputs are independent random vectors with uniform density on the sphere $\xi^2 = N$ (referred to as isotropic data in the following discussion). Then, no further directions in $\mathbb{R}^N$ and therefore no other projections are relevant.

Performing the projections brings up great simplifications. First, the number of equations drops from $N\,K$ to only $(K^2 + K)/2 + K\,M$. Second, by the law of large numbers, the overlaps in Equation 2, but not their changes, become *self-averaging* quantities in the thermodynamic limit for a large class of algorithms and input distribution. Mean values, as observed in a computer simulation, for instance, will approach the theoretical prediction with increasing $N$. In many example scenarios, the deviation is found to be on the order $1/N$, yielding excellent results for fairly small systems with, say, $N \sim 100$ already. At the same time, the width of the distribution of quantities in Equation 2, emerging from the randomness in the data, tends to zero with $N \to \infty$. This property is a common feature of so-called order parameters describing disordered systems in SM. A more detailed discussion of self-averaging in on-line learning is given in Reents and Urbanczik (1998).

Finally, the iteration equations for the overlaps reduce to first-order ODE, where the continuous parameter $\alpha = \mu/N$ measures the learning time. Averaging over the last example input $\xi_\mu$ and the possibly noisy label $\Sigma_\mu$ leads to the set (indices $\mu$ omitted)

$$\dot{R}_{in} = \langle y_n F_i \rangle, \quad \dot{Q}_{ij} = \langle x_i F_j + x_j F_i + F_i F_j \rangle \tag{3}$$

where the dot denotes a derivative with respect to $\alpha$. The right-hand side reduces to multidimensional Gaussian integrals if the dependence of $F_k$ on $\xi_\mu$ is only through the projections $x_k^\mu = \mathbf{J}_k^{\mu-1} \cdot \boldsymbol{\xi}_\mu$ and $y_m^\mu = \mathbf{B}_m \cdot \boldsymbol{\xi}_\mu$. By means of the central limit theorem, these quantities become correlated Gaussian random numbers in the thermodynamic limit. Hence, their statistics are completely determined by first and second moments, which in the case of isotropic data read

$$\langle x_i \rangle = \langle y_m \rangle = 0, \quad \langle x_i x_j \rangle = Q_{ij}, \quad \langle y_m\, y_n \rangle = T_{mn}, \quad \text{and} \quad \langle x_i\, y_n \rangle = R_{in} \tag{4}$$

The set of differential equations (Equation 3) can now be integrated, at least numerically, and yields the evolution of $R_{ij}$, $Q_{mn}$ from arbitrary initial conditions at $\alpha = 0$. Another advantage of the projection is that the generalization error $e_G = \langle e(\xi) \rangle_\xi$ can be written as a function of the overlaps in Equation 2. The particular form depends on the transfer functions, distribution of examples, and the architectures considered.

The formalism outlined here allows one to address a variety of problems: What is the typical behavior of standard algorithms, such as Rosenblatt's perceptron prescription or backpropagation in the soft committee? Which is the best possible decrease of the generalization error, and by what choice of $F$ is it achieved?

In the next section we discuss a few selected results. The following section addresses the learning of classification schemes. Then, regression by means of on-line gradient descent and related methods is discussed, and in closing we summarize some of the many other topics that have been investigated.

## Learning of Classification Schemes

The study of binary classifiers presents one of the simplest approaches to categorization. On-line learning of classifications has been investigated for several architectures, ranging from the single-layer perceptron learning a linearly separable rule to fully connected feedforward machines with $(K, M > 1)$, but also for density estimation and unsupervised learning. We will restrict ourselves to the case of supervised learning of a Boolean rule in student-teacher scenarios.

For binary outputs $\Sigma_{J,B} = \pm 1$, it is natural to choose the measure $e(\xi) = (\Sigma_J - \Sigma_B)^2/4 \in \{0, 1\}$, which differs from that introduced above by only a factor ½. Its expected value $e_G$ is the probability of disagreement between student and teacher with respect to a novel random input. As an example, for the single-layer perceptron ($K = M = 1$), one obtains $e_G = \arccos(R/\sqrt{Q})/\pi$ for isotropic inputs.

Instead of a detailed review of results for each particular network architecture and learning scenario, we will describe the properties that are common to successful learning algorithms in terms of the single-layer perceptron. The modulation function $F$, the central quantities in this analysis, serves as an estimate of the value of the information carried by the example. Different algorithms make different attributions to this value, which leads to differences in performance.

The simplest choice is pure *Hebbian learning*, where $F = \Sigma$ is given by the training label, independent of the actual student weights. This recipe seems to work in the sense that for isotropic inputs, the generalization error decreases as $e_G \propto \alpha^{-1/2}$ if the rule is linearly separable. This hides the fact that it will fail to learn completely for nonuniform distributions. The reason can be tracked to the equal treatment of correctly and incorrectly predicted examples. Rosenblatt's perceptron rule, by paying attention only to errors and disregarding correctly predicted examples, goes further. The resulting algorithm, $F\Sigma_B(\xi) = \Theta(-x\Sigma(\xi))$, i.e., 1 (if wrong) or 0 (if correct), is able to deal with nonuniform distributions, although in the singular isotropic case it is not as fast—$e_G \propto \alpha^{-1/3}$ for large $\alpha$—as the pure Hebbian prescription (Biehl and Riegler, 1994).

The perceptron rule can be improved by noting two facts. First, not all errors are equally important. Those made on examples far from the decision border should be penalized more than those made on examples near it. The on-line relaxation algorithm with $F = -x\Theta(-x\Sigma(\xi))$ leads to a dramatic improvement with $e_G \propto \alpha^{-1}$ (Biehl and Riegler, 1994). Second, correctly predicted examples may also contain useful information. Their inclusion, however, is not always desired. At the beginning of a learning session, they carry useful information and lead to improved performance; however, their importance decreases as the student net starts to approach the rule. The lesson is that successful algorithms $F$ should be performance dependent.

The effect of noise in the data has been intensely investigated (see Copelli and Caticha in Saad, 1998, for references). The foregoing analysis suggests that algorithms work by constructing a modulation function from information about the *surprise* carried by an incorrectly predicted example and by deciding whether that surprise is expected or not, given the state of the learning process. This strategy is most useful if determined by an estimate of the performance. In the presence of noise, a new ingredient enters: the suspicion that a misclassification is due to noise in the data should suppress large modulations. There is, therefore, the need for a crossover from a regime of surprise to one of *student confidence*, where blame attribution for prediction errors shifts to the data. This idea is implemented, for example, in the on-line Gibbs algorithm (Kim and Sompolinsky, 1996) through a cutoff of the function $F$ at large absolute values of $x$.

For those cases where learning conditions permit the use of queries, Kinzel and Rujan (1990) have shown that improved performance is achieved by selecting examples at the very edge of the student decision border. To our knowledge, their work constitutes the first description of on-line learning and generalization by means of ODE. Appropriate choices of the actual algorithm $F$ lead their query method to an exponential decay of $e_G$.

All of these ingredients have been used in building algorithms. They can also be obtained from first principles for a set of model problems by the variational optimization of $e_G$ with respect to the modulation function. The variational method was introduced in Kinouchi and Caticha (1992) with an application to the pure perceptron problem, where $|de_G/d\alpha|$ is to be maximized. It has been extended by several authors but is restricted to working in the limit $N \to \infty$. The obtained optimal modulation function depends typically on the actual performance $e_G$ of the student. Further, it may require knowledge of other unavailable quantities describing the noise or the input distribution, for instance. Obviously, this limits the direct applicability of the prescription in practice. However, the procedure does suggest which are the relevant features of a successful algorithm, and enables establishing lower bounds to $e_G(\alpha)$ in model situations.

The key result in this context is that on-line learning of classifications can be as efficient as the much more involved memory-based training (Kinouchi and Caticha, 1992; Opper, 1996; Van den Broeck and Reimann, 1996). For the single-layer perceptron, e.g., the asymptotic decay of $e_G \infty 1/\alpha$ with $\alpha \to \infty$ differs only by a factor of 2 from the result for optimal off-line learning if examples are noiseless or corrupted by random inversion of the labels. In the case of continuous corruption, such as through additive noise in the inputs, the optimal performances of off-line and on-line training coincide exactly, and $e_G \propto \alpha^{-1/2}$ (see Statistical Mechanics of Generalization). Recently the relation of the variational approach with Bayesian analysis was clarified (Opper, 1996; Opper in Saad, 1998; Solla and Winther in Saad, 1998).

## Learning in Continuous Networks

In applications, ANNs with continuous activation are frequently used to solve regression problems. But it is also common practice in classification to approximate the rule with a *soft* or *probabilistic* version thereof. One reason for doing so is that appealing, simple training schemes are available for multilayered architectures. In networks with differentiable activations, the error measure itself is a differentiable function of the network parameters. Therefore, off-line training can be based on gradient descent or similar minimization procedures. The most popular prescription of this kind has been termed *backpropagation of error*, and its success has boosted interest in ANN applications.

As an example architecture, the so-called soft-committee machine has been considered (Saad and Solla, 1995), with sigmoidal $f_{\text{hid}}(x) = \text{erf}(x/\sqrt{2})$ and a single linear output with weights fixed to 1. Training is based on the quadratic error for the latest example, i.e.,

$$F_k \xi_\mu = -\eta \Delta_{J_k} e(\xi_\mu)|_{(\mu-1)}$$

in Equation 1, where the gradient is evaluated with the weights at time $\mu - 1$. The dynamics (Equation 3) as well as the generalization error can be worked out analytically for arbitrary $K$ and $M$ (but with $K, M \ll N$).

The learning rate $\eta$ appears quadratically in the equations of motion (Equation 3); hence its nontrivial influence on the behavior of the system. For example, a critical value $\eta_c$ exists in matching scenarios, above which the perfect solution $\mathbb{J} = \mathbb{B}$ becomes unstable and even very small deviations from the perfect solution would increase in the training process. For $K < M$ the asymptotic value $e_G(\alpha \to \infty)$ depends explicitly on $\eta$, and only in the limit $\eta \to 0$ is the optimal approximation of the rule achieved.

One of the most interesting phenomena in on-line gradient descent is the breaking of permutation symmetry during learning. It can be observed for $K = M = 2$ already: Figure 1 shows a typical learning curve obtained in this scenario when training is based on reliable examples with isotropic inputs. Obviously, the learning process is dominated by a pronounced plateau state in which very little progress is made while the number of examples increases. Only after an extended period of time does the system leave the plateau and approach its asymptotic state exponentially fast.

The occurrence of plateaus can be related to fixed points of the ODE (Equation 3). In the case displayed in Figure 1, the system is very close to a perfectly symmetric configuration with $\mathbf{J}_1 = \mathbf{J}_2$, i.e., $R_{ij} = R$ and $Q_{ij} = Q$ for all $i,j$. The existence of such a stationary state reflects an underlying symmetry of the problem: the student output and hence the error measure is invariant under permutations of hidden units. Whereas this property leads to phase transitions in equilibrium off-line training (see Statistical Mechanics of Generalization), the effect here is that the system approaches a symmetric state from generic initial conditions.

Properties of such plateaus can be investigated in detail by linearizing the dynamics close to the fixed point. The configuration is unstable, that is, weakly repulsive in a few directions in overlap space. Consequently, the system stays in its vicinity for a long time before eventually leaving the plateau. The observed plateau length depends on the corresponding eigensystem and, in a subtle way, on the initial state. If the student weights are uncorrelated with the teacher before training, one expects random $R_{ij}(0) = \mathbb{O}(N^{-1/2})$ in a finite system. As a consequence, the plateau length and hence the

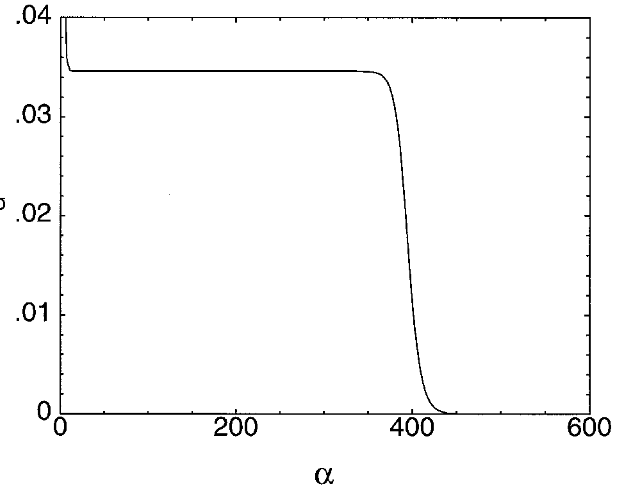

**Figure 1.** The learning curve of the $K = M = 2$ soft-committee scenario (as described in the text) with $T_{mn} = \delta_{mn}$, $\eta = 1.5$, and initial values $Q_{ii}(0) = 0.5$. All $R_{\text{in}}(0)$ as well as $Q_{12}(0)$ were different numbers of order $\mathbb{O}(10^{-12})$.

characteristic learning time will be $\alpha \propto \ln N$, demonstrating the relevance of the phenomenon to the practical treatment of high-dimensional data (Biehl, Riegler, and Wöhler, 1996).

The occurrence of plateaus in learning curves is by no means a feature of the particular scenario considered here. Weakly repulsive fixed points are found for any $K \geq 2$, independent of $M$. They exist also in systems where the invariance with respect to permutations is replaced by more complicated symmetries. Further, the number of fixed points increases with both $K$ and $M$, while only the most symmetric states seem to dominate the dynamics from generic initial conditions (Saad and Solla, 1995; Biehl et al., 1996). An interesting observation is the possible existence of attractive fixed points with $e_G > 0$ when $K > M$. Successful training can be impossible if the student is highly oversophisticated for the task to learn.

The deeper reason for the occurence of plateaus is the fact that learning requires the specialization of hidden units. After presentation of only a few examples, it is only reasonable that the student's hypothesis about the rule be as simple as possible. In this sense, unspecialized plateaus can be considered a necessary phase of learning and should be expected quite generally. However, from a practical point of view the question arises as to how the length of this phase can be reduced, potentially to its minimum. To this end, variational methods have been applied to the soft-committee machine as well. Note that the situation is more complicated here than it is in the perceptron or nonoverlapping architectures: $e_G$ is a function of many order parameters and it is not a priori clear that the local maximization of $|de_G/d\alpha|$ yields a successful strategy. Alternatively, the global optimization of $e_G$ achieved after presentation of a certain number of examples has been considered. Both approaches predict that an efficient decrease in plateau length should be possible (Saad and Rattray, 1997; Vicente and Caticha, 1997). The latter is also true for methods that explicitly incorporate curvature information into the learning algorithm. The so-called natural gradient method of Amari deserves particular attention in this context (see Amari, 1967; Rattray and Saad in Saad, 1998; Bös and Amari in Saad, 1998). Its main idea is to base learning on a distance measure that is invariant under reparameterization of the student output.

## Discussion

The statistical mechanics approach to on-line learning has allowed for a theoretical understanding of the dynamics of various adaptive systems. In this article we considered selected examples of the success of this method. For a more complete overview of the field and recent developments, see Saad (1998).

The question of on-line learning in systems with discrete degrees of freedom was recently addressed (Solla and Winther in Saad, 1998). A treatment of network parameters that can be trained on different time scales is provided in Riegler and Endres (1999).

The framework of on-line learning and many of the phenomena discussed here carry over immediately to unsupervised learning in high-dimensional spaces (see Biehl et al. in Saad, 1998, for further references).

In a related, alternative approach to on-line learning one preserves the stochastic nature of the Markov process and refrains from taking $N \rightarrow \infty$ beforehand (see, e.g., Heskes and Wiegerinck in Saad, 1998; Leen in Saad, 1998). By means of appropriate expansions and approximations one can then, for example, investigate the dynamics of finite systems. The convergence of on-line algorithms is discussed in the framework of stochastic approximation theory by Bottou (in Saad, 1998).

A question of great importance is that of correlations among the training examples and their influence on the learning dynamics. In this context, training from a limited pool of fixed examples (see chapters by Barber and Sollich, Coolen and Saad, and Heskes and Wiegerinck in Saad, 1998) remains one of the theoretical challenges with great practical relevance.

# Statistical Parametric Mapping of Cortical Activity Patterns

*Karl J. Friston*

## Introduction

This article addresses the experimental design and analysis of functional brain imaging studies. It considers the neurobiological motivations for different designs and describes some standard approaches that have been developed to analyze the ensuing data. Functional neuroimaging (positron emission tomography, or PET, and functional magnetic resonance imaging, or fMRI) is generally used to make inferences about functional anatomy on the basis of evoked patterns of cortical activity. Functional anatomy refers to the anatomical organization of the brain as it relates to function. It involves an understanding of what each part of the brain does and how different brain systems interact to support various sensorimotor and cognitive functions. Large-scale organization can be inferred using techniques that image the hemodynamic and metabolic sequelae of evoked neuronal responses. PET measures regional cerebral blood flow (rCBF), and fMRI measures oxygenation changes. Their spatial resolution is on the order of a few millimeters. Because PET uses radiotracers, its temporal resolution is limited by the half-life of the tracers employed (usually a minute or so). However, fMRI is limited only by the biophysical time constants of hemodynamic responses themselves (a few seconds).

An important issue in the design and analysis of functional anatomical experiments is the relationship between conceptual models of brain organization and neurophysiological responses, and how this relationship is realized in the statistical models used in analysis. This article begins by reviewing the distinction between *functional specialization* and *integration* and how these principles serve as the motivation for most analyses.

Statistical parametric mapping (SPM) is used to identify functionally specialized brain regions. Specialized regions respond selectively to experimental cognitive or sensorimotor changes. SPM is used to detect these responses anywhere they occur, irrespective of changes elsewhere. The alternative perspective, that provided by functional integration, requires a different set of (multivariate) approaches that examine the relationship between changes in one area and changes in another. SPM is a voxel-based approach (a voxel is a volume element of an image) that employs standard inferential statistics to make some comment about regionally specific responses to experimental factors at each voxel. In contradistinction to the alternative approach, based on prespecified regions of interest (ROI), SPM examines every part of the brain at the highest resolution afforded by the data. SPM has now almost universally superseded ROI approaches because it avoids preconceptions about evoked responses and avoids many forms of bias. Technically, SPM is a *mass-univariate* approach, in the sense that each data sequence from every voxel is treated as a univariate response. The massive number of voxels is analyzed in parallel, and dependencies among them are dealt with using random field theory at the point of inference. The alternative to a mass-univariate approach is a *multivariate* analysis that considers images as a multidimensional observation with as many components as there are voxels. The general ideas behind statistical parametric mapping are described and illustrated with the different sorts of inferences that can be made with different experimental designs. The article concludes by reviewing multivariate analyses and effective connectivity.

## Functional Specialization and Integration

The brain appears to adhere to two fundamental principles of functional organization, functional integration and functional specialization, with the integration within and among specialized areas mediated by *effective connectivity*. This distinction relates to that between *localizationism* and (*dis*) *connectionism* that dominated thinking about cortical function in the nineteenth century. Since the early anatomical theories of Gall, the identification of a particular brain region with a specific function has become a central theme in neuroscience. However, functional localization per se was not easy to demonstrate. For example, a meeting that took place on August 4, 1881, addressed the difficulties of attributing function to a cortical area, given the dependence of cerebral activity on underlying connections (Phillips, Zeki, and Barlow, 1984). The topic of the meeting was “Localization of function in the cortex cerebri.” Goltz, although accepting the results of electrical cortical stimulation, considered that the excitation method was inconclusive, in that movements elicited might have originated in related pathways, or current could have spread to distant centers. In short, the excitation method could not be used to infer functional localization because localizationism discounted interactions, or functional integration, among different brain areas. It was proposed that lesion studies could supplement excitation experiments; ironically, it was observations on patients with brain lesions some years later that led to the concept of *disconnection syndromes* and the refutation of localizationism as a complete or sufficient explanation of cortical organization. Functional localization implies that a function can be localized in a cortical area, whereas specialization suggests that a cortical area is specialized for some aspect of perceptual, motor, or cognitive processing, and that this specialization is anatomically segregated within the brain. The neuronal infrastructure supporting a single function may then involve many specialized areas whose union is mediated by the functional integration among them. In this view, functional specialization is only meaningful in the context of functional integration, and vice versa. Certain patterns of cortical projections are so common that they could amount to rules of cortical connectivity. “These rules revolve around one, apparently, overriding strategy that the cerebral cortex uses—that of functional segregation” (Zeki, 1990). This is the model upon which the search for regionally specific effects is based.

The analysis of functional neuroimaging data involves many steps, which can be broadly divided into (1) spatial preprocessing, (2) estimating the parameters of a statistical model, and (3) making inferences about modeled effects using the parameter estimates and their associated statistics (Figure 1). We will focus on model estimation and inference.

## Statistical Parametric Mapping

Functional mapping studies are usually analyzed with some form of *statistical parametric mapping*, or SPM. SPM refers to the construction of statistical maps to test hypotheses about regionally specific effects like “activations” (Friston et al., 1995). The maps are image processes with voxel values that, under the null hypothesis, are distributed according to a known probability density function (usually Student’s $T$ or $F$ distributions). The success of SPM is largely due to the simplicity of the idea. Namely, one analyzes each and every voxel using any standard (univariate) statistical test. The resulting statistical parameters are assembled into an image, the SPM map. SPM$\{T\}$ refers to a map comprising $T$ statistics; similarly, SPM$\{F\}$ denotes a map of $F$ statistics. SPMs are interpreted as spatially extended statistical processes by referring to the probabilistic behavior of stationary Gaussian fields (Friston et al., 1995; Worsley et al., 1996). Stationary fields model both the univariate probabilistic characteristics of an SPM and any spatial covariance structure. “Unlikely” excursions of the SPM are interpreted as regionally specific effects, attributable to the sensorimotor or cognitive process that has been manipulated experimentally. Statistical analysis corresponds to modeling the data in order to partition observed neurophysiological responses into components of interest, confounds, and error. Almost universally, the models employed are general linear models.

### *The General Linear Model*

The general linear model is an equation, $y = X\beta + \varepsilon$, that expresses the observed *response variable* $y$ in terms of a linear combination of explanatory variables $X$ plus a well-behaved error term (see Friston et al., 1995). The general linear model is variously known as

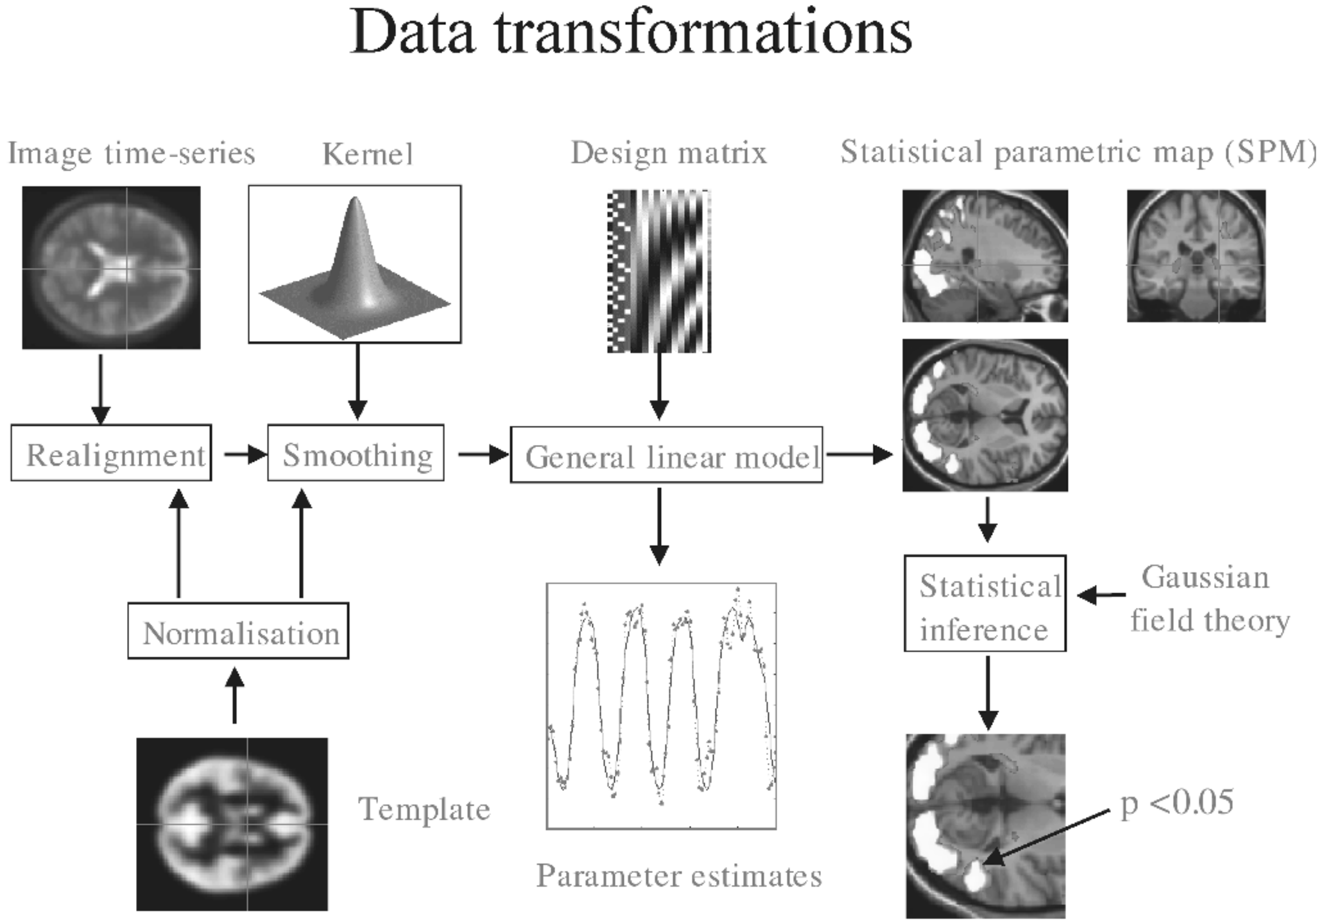

**Figure 1.** Schematic depicting the transformations that start with the imaging time series and end with a statistical parametric map (SPM). SPMs can be thought of as x-rays of the significance of an effect. Voxel-based analyses require the data to be in the same anatomical space: realigning the data to remove the effects of subject movement effects this. After realignment the images are subject to nonlinear warping so that they match a template that already conforms to a standard anatomical space. After smoothing, the general linear model is employed to (1) estimate the parameters of the model and (2) derive the appropriate univariate test statistic at each voxel. The test statistics that ensue (usually, $T$ or $F$ statistics) constitute the SPM. The final stage is to make statistical inferences on the basis of the SPM and characterize the responses observed using the fitted responses or parameter estimates. The display format is sometimes a maximum intensity projection (MIP) of the SPM$\{T\}$ from three views of the brain. The anatomical space conforms to that of the Talairach and Tournoux atlas. This MIP display format in this figure is a thresholded SPM, superimposed on slices through the brain depicting anatomical structures. Such a display format is sometimes preferred when the structure-function relationship is important and can be summarized by reporting a single slice of the SPM.

analysis of covariance or multiple regression analysis, and subsumes simpler variants, like the two-sample $T$ test for a difference in means, to more elaborate linear convolution models such as finite impulse response models for time series. The matrix $X$ that contains the explanatory variables (e.g., designed effects or confounds) is called the design matrix. Each column of the design matrix corresponds to some effect the investigator has built into the experiment or that may confound the results. These are variously referred to as *explanatory variables*, covariates, regressors, or, in fMRI, stimulus functions. The example in Figure 1 relates to an fMRI study of visual stimulation under four conditions. The effects on the response variable are modeled in terms of functions of the presence of these conditions (i.e., boxcars smoothed with a hemodynamic response function) and constitute the first four columns of the design matrix. There follows a series of terms designed to remove or model low-frequency variations in signal due to artifacts such as aliased biorhythms. The final column is whole-brain activity. The relative contribution of each of these columns is assessed using generalized least-squares estimates. These are the estimates of $\beta$, the parameters of the model. Inferences about parameter estimates are made using $T$ or F statistics, depending on whether one is looking at a particular linear combination or several.

The error or noise in neuroimaging has a number of sources and is generally about the same size as the evoked responses themselves. Scan-to-scan error is due to technical measurement noise and neurophysiological noise, inherent in ongoing brain activity. In multisubject designs, between-subject variability in responses is another important error variance component and can sometimes be greater than within-subject or scan-to-scan variability. In fMRI, aliased biorhythms and drifts in the measurement device induce correlations among the errors. This is known as *nonsphericity* and is accommodated in generalized linear models (e.g., Worsley and Friston, 1995). The nonsphericity corrections used to deal with temporal correlations in fMRI are the same as those adopted in conventional analysis of variance.

Generalized linear models can be used to implement a vast range of statistical analyses. The issue is therefore not so much the mathematics but the formulation of a design matrix $X$ appropriate to the study design and inferences that are sought. The design matrix can contain both covariates and indicator variables. Each column of $X$ has an associated unknown parameter. Some of these parameters will be of interest (e.g., the effect of a particular sensorimotor or cognitive condition, or the regression coefficient of hemodynamic responses on reaction time). The remaining parameters will be of no interest and pertain to nuisance or confounding effects (e.g., the effect of being a particular subject, or the regression slope of voxel activity on global activity). Inferences about the parameter estimates are made using their estimated variance. This allows one to test the null hypothesis that all the estimates are zero, using the $F$ statistic to give an SPM$\{F\}$, or that some particular linear combination (e.g., a subtraction) of the estimates is zero, using an SPM$\{T\}$. The $T$ statistic obtains by dividing a *contrast* or linear combination (specified by contrast weights) of the ensuing parameter estimates by its standard error. The latter is estimated using the variance of the residuals about the least-squares fit. An example of contrast weights would be $[-1\ 1\ 0\ 0\ \ldots]$ to compare the differential responses evoked by the two conditions, modeled by the first two condition-specific regressors in the design matrix. In summary, the $T$ statistic can be regarded as the size of a response, or activation estimate, divided by its variability or standard error. The square of this statistic is the ratio of the sum of squares or variance of interest divided by error variance. This is the F statistic, which can be computed for several linear combinations or *contrasts* of estimated responses at once. This is useful when several parameter estimates are potentially interesting (e.g., using polynomial expansions [Büchel et al., 1996] or basis functions of some parameter of interest).

### Statistical Inference and the Theory of Gaussian Fields

Inferences using SPMs can be of two sorts, depending on whether one knows where to look in advance. With an anatomically constrained hypothesis about effects in a particular brain region, the *uncorrected P* value associated with the height or extent of that region in the SPM can be used to test the hypothesis. With an anatomically open hypothesis (i.e., a null hypothesis that there is no effect anywhere in the brain), a correction for multiple dependent comparisons is necessary. The theory of Gaussian fields provides a way of computing this *corrected P* value that takes into account the fact that neighboring voxels are not independent by virtue of smoothness in the original data. This *Gaussian field correction* (GFC) plays the same role for continuous, multidimensional statistical processes like SPM$\{T\}$ as the *Bonferroni correction* plays in multiple discrete $T$ tests. Provided the data are sufficiently smooth, the correction based on Gaussian field theory is much less severe (i.e., is more sensitive) than a Bonferroni correction for the number of voxels. This is simply because the GFC ensures that the rate of false positive "clusters" is maintained as a nominal level (usually 0.05). The rate of false positive voxels can therefore be much larger, e.g., 0.05 times the expected number of voxels per cluster. The difference between a Gaussian field and a Bonferroni correction increases with smoothness, or expected voxels per cluster.

## Experimental Design

### Categorical Designs, Cognitive Subtraction, and Conjunctions

The tenet of cognitive subtraction is that the difference between two tasks can be formulated as a separable cognitive or sensorimotor component and that regionally specific differences in hemodynamic responses identify the corresponding functionally specialized area. Early applications of subtraction range from the functional anatomy of word processing (Petersen et al., 1989) to functional specialization in extrastriate cortex (Lueck et al., 1989). The latter studies involved presenting visual stimuli with and without some sensory attribute (e.g., color, motion). The areas highlighted by subtraction were identified with homologous areas in monkeys that showed selective electrophysiological responses to equivalent visual stimuli.

Cognitive conjunctions (Price and Friston, 1997) can be thought of as an extension of the subtraction technique, in the sense that they combine a series of subtractions. In subtraction, one tests a hypothesis pertaining to the activation in one task relative to another. In conjunction analyses several hypotheses are tested conjointly, with the investigator asking whether all the activations, in a series of task pairs, are jointly significant. Conjunction analyses allow one to demonstrate any context-insensitive component of regional responses.

### Parametric Designs

The premise behind parametric designs is that regional physiology will vary systematically with the degree of cognitive or sensorimotor processing or deficits thereof. Examples of this approach include the PET experiments of Grafton et al. (1992), which demonstrated significant correlations between hemodynamic responses and the performance of a visually guided motor tracking task. These relationships, or "neurometric functions," may be linear or nonlinear. Using polynomial regression, in the context of the general linear model, one can identify nonlinear relationships between stimulus parameters (e.g., stimulus duration or presentation rate) and evoked responses. To do this one usually uses an SPM{F} (Büchel et al., 1996).

The example provided in Figure 2 illustrates subtraction, conjunction, and parametric approaches to design and analysis. These data were obtained from an fMRI study of visual motion processing using radially moving dots. The stimuli were presented over a range of speeds using isoluminant and isochromatic stimuli. To identify areas involved in visual motion, a stationary dots condition was subtracted from the moving dots conditions (see contrast weights on the upper right). To ensure significant motion-sensitive responses using both color and luminance cues, a conjunction of the equivalent subtractions was assessed under both viewing contexts. Areas V5 and V3a are seen in the SPM$\{T\}$. The responses in left V5 (lower panel) speak to a compelling inverted-U relationship between speed and evoked response that peaks at around 8°/s. It is this sort of relationship that parametric designs try to characterize. Interestingly, the form of these speed-dependent responses was similar using both stimulus types, although luminance cues elicited a greater response. From the point of view of a factorial design, there is a *main effect* of cue (isoluminant *vs.* isochromatic) and a main (nonlinear) effect of speed, but no speed by cue *interaction*.

### Factorial Designs

At its simplest, an interaction represents a change in a change. Interactions are associated with factorial designs where two or more factors are combined in the same experiment. The effect of one factor on the effect of the other is assessed by the interaction term. Factorial designs have a wide range of applications (e.g., assessing physiological adaptation with time by condition interactions). Psychopharmacological activation studies are examples of factorial designs. In these studies, cognitively evoked responses are assessed before and after the subject is given a drug. The interaction term reflects the modulatory drug effect on the task-dependent activation. Factorial designs have an important role in the context of cognitive subtraction and additive factors logic by testing for context-sensitive activations, to demonstrate the fallacy of pure in-

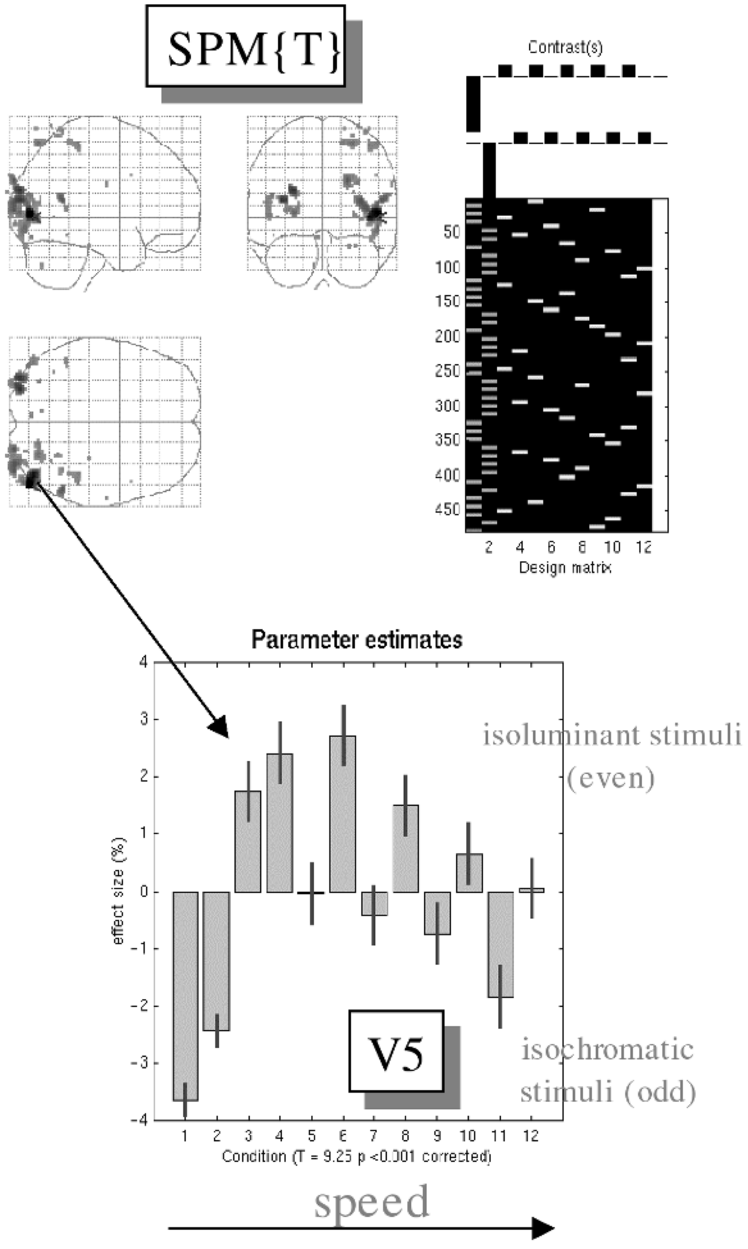

**Figure 2.** Shown at upper right is an image representation of the design matrix. Contrasts are the vectors of contrast weights defining the linear compounds of the parameters tested. The contrast weights are displayed over the column of the design matrix that corresponds to the effects in question. The design matrix here includes condition-specific effects (boxcars convolved with a hemodynamic response function). Odd columns correspond to stimuli shown under isochromatic conditions, and even columns model responses to isoluminant stimuli. The first two columns are for stationary stimuli and the remaining columns are for conditions of increasing speed. The final column is a constant term. At upper left is a maximum-intensity projection of the SPM{$T$} conforming to the standard anatomical space of Talairach and Tournoux. The $T$ values here are the minimum $T$ values from both contrasts, thresholded at $P = 0.001$ (uncorrected). The most significant conjunction is seen in left V5. In the lower panel is a plot of the condition-specific parameter estimates for this voxel. The $T$ value was 9.25 ($P < 0.001$ corrected).

sertion. Pure insertion refers to the assumption that the difference between one task and another is completely specified by the difference in task demands. In other words, the difference is inserted without *interacting* with the context established by the extant task components (see Friston et al., 1996). These interaction effects can sometimes be interpreted as (1) the integration of the two or more (cognitive) processes or (2) the modulation of one process by another.

## Effective Connectivity and Functional Integration

There is a necessary relationship between functional integration and multivariate analyses because the latter models interactions among brain regions. Multivariate approaches can be divided into those that are inferential in nature and those that are data led or exploratory. Most are based on the singular value or eigen decomposition of the between-voxel covariances in a neuroimaging time series.

### *Eigenimage Analysis and Related Approaches*

Friston et al. (1993) introduced voxel-based principal component analysis (PCA) of neuroimaging time series to characterize distributed brain systems implicated in sensorimotor, perceptual, or cognitive processes. These distributed systems are identified with principal components or eigenimages that correspond to spatial modes of coherent brain activity. This approach represents one of the simplest multivariate characterizations of functional neuroimaging time series and falls into the class of exploratory analyses. Eigenimage analysis generally uses singular value decomposition (SVD) to identify a set of orthogonal spatial modes that capture the greatest amount of variance, expressed over time. As such, the ensuing

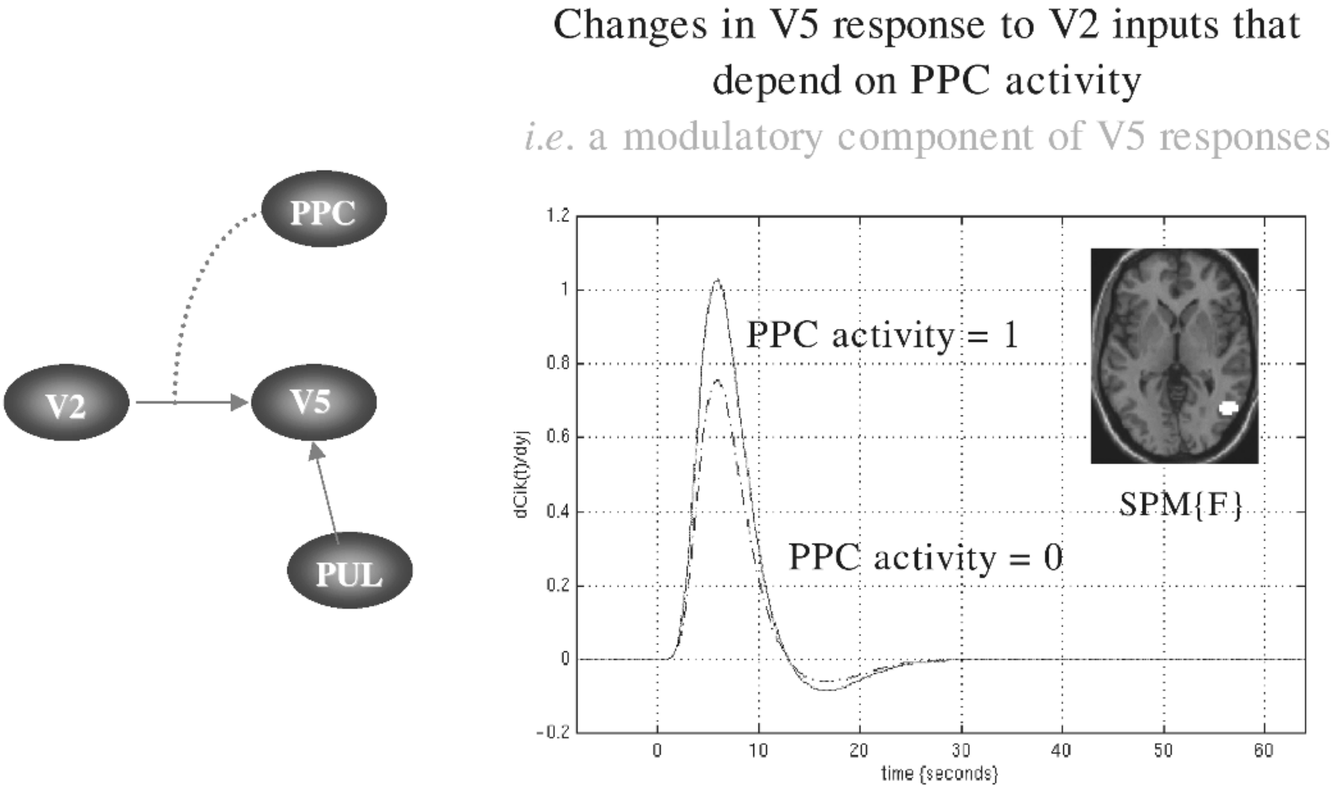

**Figure 3.** Characterization of effects of V2 inputs on V5 and the modulation of these effects by posterior parietal cortex (PPC). The broken lines represent estimates of V5 responses when PPC activity $= 0$ according to a second-order Volterra model with inputs based on the activity in V2, PPC, and the pulvinar (all normalized to zero mean and unit standard deviation). The input from V2 corresponded to a square wave of 500 ms duration convolved with a hemodynamic response function. The solid curves represent the same response when PPC activity $= 1$. It is evident that V2 has an activating effect on V5 and that PPC increases the responsiveness of V5 to these inputs. The insert shows all the voxels in V5 that evidenced a modulatory effect ($P < 0.05$ uncorrected). These voxels were identified by thresholding SPMs of the F statistic testing for the contribution of second-order effects involving V2 and PPC while treating all other components as confounds. Results for one subject are shown. Subjects were studied with fMRI under identical stimulus conditions (visual motion subtended by radially moving dots) while the attentional component of the task (the detection of velocity changes) was manipulated.

modes embody the most prominent aspects of the variance-covariance structure of a given time series. Noting that the covariances among brain regions are equivalent to functional connectivity (see below) renders eigenimage analysis particularly interesting, because it was among the first ways of addressing functional integration in the human brain.

### Functional and Effective Connectivity

Imaging neuroscience has firmly established functional specialization as a principle of brain organization in humans. The functional integration of specialized areas has proved more difficult to assess. Functional integration is usually inferred on the basis of correlations among measurements of neuronal activity. Functional connectivity has been defined as *correlations between remote neurophysiological events*. However, correlations can arise in a variety of ways. For example, in multiunit electrode recordings they can result from stimulus-locked transients evoked by a common input, or they may reflect stimulus-induced oscillations mediated by synaptic connections (Gerstein and Perkel, 1969). Integration within a distributed system is usually better understood in terms of effective connectivity. Effective connectivity refers explicitly to *the influence that one neural system exerts over another*, either at a synaptic (i.e., synaptic efficacy) or at a population level. Effective connectivity is dynamic, i.e., activity and time dependent, and it depends on a model of the interactions. Key here is that effective connectivity may vary from task to task (see next section), even though anatomical connections remain the same. The models employed in functional neuroimaging can be classified as (1) those based on regression models (see next section) or (2) structural equation modeling (McIntosh and Gonzalez-Lima, 1994; see also COVARIANCE STRUCTURAL EQUATION MODELING).

### Characterizing Nonlinear Coupling among Brain Areas

Linear models of effective connectivity assume that the multiple inputs to a region are linearly separable. This precludes activity-dependent connections that are expressed in one sensorimotor or cognitive context and not in another. The resolution of this problem lies in adopting nonlinear models that include interactions among inputs. These interactions can be construed as a context- or activity-dependent modulation of the influence that one region exerts over another, where that context is instantiated by activity in other brain regions exerting modulatory effects. These nonlinearities are important in modeling and understanding task-specific changes in effective connectivity. From the point of view of regression models, modulatory effects can be modeled with nonlinear input-output models and in particular a Volterra series formulation (this formulation can be thought of as a polynomial regression on the activity of areas providing inputs, both now and in the recent past).

Because the kernels are high-order, they embody interactions over time and among inputs. The influence of one region *j* on another *i* can therefore be divided into two components: (1) the direct influence of *j* on *i*, irrespective of activity elsewhere, and (2) an activity-dependent component that represents an interaction with inputs from the remaining regions. The example provided in Figure 3 addresses the modulation of visual cortical responses by attentional mechanisms and the mediating role of activity- or context-sensitive changes in effective connectivity. Figure 3 shows a characterization of this modulatory effect in terms of the increase in V5 responses to V2 input when posterior parietal activity is zero (broken line) and when it is high (solid lines). This sort of result suggests that parietal activity may be a sufficient explanation for attentional modulation of visually evoked extrastriate responses.

## Discussion

Functionally specialized brain areas can be identified by some form of statistical parametric mapping. The nature of the specialization and the interactions between various cognitive or sensorimotor factors in engendering a brain response can be established using simple subtraction, parametric, or multifactorial designs. Functional integration is usually assessed using some form of multivariate analysis framed in terms of effective connectivity. Recent advances in modeling effective connectivity emphasize nonlinear interactions among inputs to an area in "causing" its response.

# Stereo Correspondence

*John P. Frisby*

## Introduction

Stereoscopic vision exploits the fact that points in a three-dimensional (3D) scene will in general project to different positions in the images formed in the left and right eyes. These differences are termed *retinal disparities*. They can be analyzed as vectors with horizontal and vertical components. Horizontal retinal disparities are determined both by 3D scene structure and by the positions of eyes in the head, whereas vertical retinal disparities, to first order, contain only information on eye positions (i.e., the prevailing gaze, elevation, and vergence angles of the eyes; Mayhew and Longuet-Higgins, 1982). This geometrical fact allows data from vertical disparities on eye positions to be used for disambiguating the information in horizontal disparities by way of recovering 3D scene structure.

The stereo correspondence problem is, how can a pair of stereo images be mapped into a single representation, called a *disparity map*, that makes explicit the disparities of all points common to both images? A great deal of computer vision research has addressed this problem because a disparity map is a useful first step toward building a representation of 3D scene structure. The problem is illustrated in Figure 1, which shows that the image locations of both correct and false matches fall on geometrical constructs called epipolar lines. The importance of this geometrical constraint is that it makes the stereo matching problem a one-dimensional (1D) search. Without it, the stereo problem becomes formally identical to the two-dimensional (2D) optic flow motion correspondence problem.

Most claims made in this article that are not accompanied by explicit citations are supported by references in Frisby and Pollard (1991) and Howard and Rogers (2002).

## Matching Primitives

The first issue in designing any stereo algorithm is deciding what image features should serve as the points to be matched. Edge points are the most common choice because they usually stand in reasonably close correspondence to scene entities and hence they seem a sensible choice, as the ultimate goal is to deliver 3D information about scene structures (Marr, 1982). That property is not

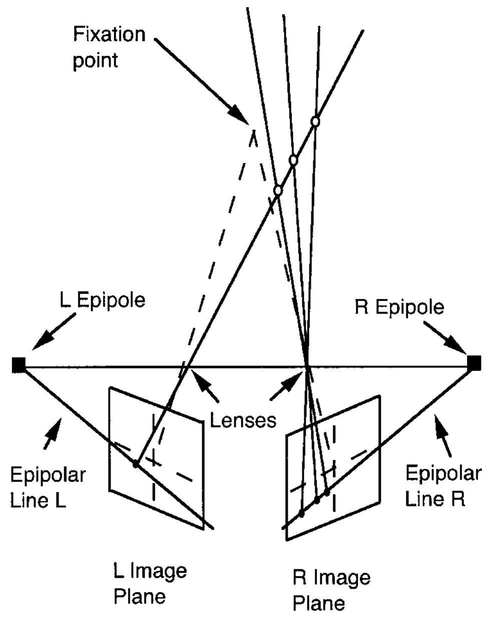

**Figure 1.** Epipolar geometry and the stereo correspondence problem. A line of sight is shown extending from a left (L) image point through the optic center of the lens out into the world. A sample of the possible locations in the world that could have given rise to that point are shown as unfilled circles. These are imaged in the right (R) image on a geometrical construct known as an epipolar line, thereby reducing to a single dimension the stereo correspondence problem, which is the task of deciding which points in the L and R images are to be matched.

possessed by image point intensities because a given scene entity often produces different pixel/receptor values in the left and right images. Other possible matching primitives that have been tried include image regions, for example in stereo algorithms relying on area cross-correlation (sometimes implemented with coarse-to-fine Fourier filter pyramids), and "corner points," usually defined as image features possessing a sharply peaked autocorrelation function.

Edge and corner points produce sparse disparity maps. It is possible to interpolate a dense disparity surface using processes that lend themselves readily to implementations in neural nets (Blake and Zisserman, 1987). Texture boundary cues help shape such interpolation processes in human vision.

Human stereo vision uses a diverse set of matching primitives, including dots, edges, regions, lines, and texture boundaries. It is clear that stereo matching can be achieved without recourse to matching primitives at the level of objects (chairs, faces, etc.), because human stereo vision can find correctly matching points even when no high-level objects are discernible in each stereo half-image. This is demonstrated by random-dot stereograms, made by taking two copies of a noise field, one for each stereo half-image, and then shifting chosen regions to create disparate zones, but hiding these shifts monocularly by filling in the gaps so generated with new random noise texture, a technique first richly exploited by Julesz.

## Exploiting the Epipolar Constraint

Taking advantage of the 1D search characteristic of the stereo correspondence problem requires knowing the location of the right image epipolar line for a given left image primitive, or vice versa. This in turn requires a solution to the nontrivial problem of knowing the spatial relationships between the two cameras/eyes, as well as facts about focal length, image aspect ratios, etc. This is the business of camera calibration, as it is termed in the computational literature. Before it has been solved, images are said to be "uncalibrated." For a stereo camera rig it typically involves solving at least 12 free parameters. To find these using image data requires knowledge of at least some matching points, which sets up a vicious circle: matched points are needed to find epipolar lines, so that epipolar lines can be used to find matching points. The circle can be broken using unambiguous corner features as the inputs for an optimal least-squares fit of the various camera parameters.

The calibration problem for human stereovision is usually discussed in the psychophysical literature as a problem in stereoscopic depth constancy. Somehow human vision manages to support a stable or "constant" 3D percept (if the scene itself is unchanging), despite eye movements that radically alter retinal disparities. Therefore, it must have some way of allowing for the effects of changes in fixation position on the disparity vector field. One way to do this is to use vertical disparities to compute eye positions (see the Introduction). Another is to use oculomotor information (inflow and/or outflow) about eye positions. The relative weights given to these two cues, a topical cue integration research issue, may depend on the size of the field of view, the task, the nature of the vertical disparity cues present, and so on.

The stereo calibration problem is less severe if relief rather than metric 3D scene properties are to be recovered. The regional disparity correction theory of Gårding, Porrill, Mayhew, and Frisby (see Frisby et al., 1999) uses vertical disparities to recover 3D surface relief properties (such as planarity, collinearity, etc.) from horizontal disparities by fitting a three-parameter polynomial to regions of the vertical disparity field and then using the coefficients so obtained to correct horizontal disparities to values from which relief properties are easily obtained. Frisby et al. (1999) reported evidence that human vision implements a theory of this type even for small fields of view. Porrill et al. (1999) have shown, using robust Bayesian statistics, that the coefficients used by the regional disparity correction theory have attractive computational properties for pooling vertical disparity measurements to obtain estimates of eye positions. Their scheme is suitable for a simple Hough parameter estimation algorithm that lends itself readily to implementation in a biologically plausible neural network. This pooling scheme is remarkably robust to noise from outliers: using even ten times more incorrect than correct matches still yielded good eye position estimates. It thus allows the epipolar geometry to be recovered without having matched points (see also Zhang et al., 1995). Once epipolar geometry is recovered, it can be exploited in solving the stereo correspondence problem. However, Schreiber et al. (2001) have created stereograms suggesting that human vision does not in fact exploit the epipolar constraint. They conclude that it uses retina-fixed search zones whose size is large enough to cover all locations of the epipolar lines for the usual range of fixation positions. The size of these zones, they suggest, is minimized by the eyes twisting around their lines of sight in a way that reduces the motion of the epipolar lines as the fixation position is changed.

The fact that we can adjust, given time, to perturbations imposed by various distorting lenses shows that the "eye/head calibration" mechanisms in human vision are adaptive in character, suggesting that processes of continual recalibration are at work. These are of obvious benefit in coping with head growth during maturation, as head growth alters the important calibration parameter of interocular separation.

## Constraints for Resolving the Matching Problem

Even if used, the epipolar constraint is not sufficient for solving the stereo correspondence problem because several potentially correct matching primitives will often fall on any given epipolar line. Hence other constraints are required, and these must be derived from aspects of the viewed world and its projection into stereo images. From these constraints can be inferred binocular matching rules capable of eliminating false matches while preserving correct ones.

### *The Constraint of Compatibility of Matching Primitives*

The size of the ambiguity problem can be substantially reduced, although not altogether eliminated, by matching features of similar shape and contrast. Marr's (1982) way of expressing this constraint, which he dubbed the compatibility constraint, was to match only left and right features that could have arisen from the same scene entity. To implement this constraint requires careful attention to how scene features appear in stereo projections. This is necessary to determine bounds on the ranges of, for example, size (spatial frequency) and orientation differences allowed between left and right image features if they are to form potential matches.

### *The Cohesivity Constraint*

Marr and Poggio argued that it is reasonable to assume the visual world is made up of matter separated into objects whose surfaces are generally smooth compared with their overall distances from the viewer (see Marr, 1982). In other words, the visual world is not usually made up only of clouds of dust particles or snowflakes. They termed this the cohesivity constraint, and they used it to underpin their continuity binocular matching rule: prefer possible matches that could have arisen from smooth surfaces. This is an example of a smoothness constraint being used as a "regularizer" for solving ill-posed vision problems, so termed because they are either under- or overdetermined (see PROBABILISTIC REGULARIZATION METHODS FOR LOW-LEVEL VISION).

### *The Uniqueness Constraint*

Marr and Poggio also noted that a scene entity cannot be in two places at the same time, from which they derived the binocular matching rule: each matching primitive from each image may be assigned at most one disparity value.

### *The Figural Continuity Constraint*

Mayhew and Frisby in 1981 used the cohesivity constraint to justify a different matching rule: cohesive objects generate surface edges and surface markings that are spatially continuous and therefore prefer matches which preserve figural continuity. That is, give preference to point-for-point matches that are part of an edge whose other component points also have matches, such that the whole forms a figurally continuous structure of matched points. Mayhew and Frisby found psychophysical evidence suggesting that human stereovision exploits this constraint and developed a correspondence algorithm, STEREOEDGE, based on it.

### *The Ordering Constraint*

If opaque surfaces can be assumed, then it is possible to exploit the fact that the order of primitives along an epipolar line in one image is preserved in the other image.

## Neural Network Stereo Correspondence Algorithms

Much research has attempted to solve the stereo correspondence problem by implementing one or more of the above constraints with processes of excitation and inhibition in networks of elements that represent competing (usually edge-based) matches. Few network modelers have taken seriously the problem of camera calibration, often seeking to solve the (often trivially easy) problems posed by random-dot stereograms, for which rasters are assumed to be the appropriate epipolar lines. Networks differ both in the constraints they try to implement and in the details of how they do so. They will be described with reference to the diagram shown in Figure 2.

### *Dev's Stereo Neural Network*

In 1975, Dev described a stereo algorithm using a neural network in which excitation was exchanged (giving mutual support) between elements representing potential matches with the same disparity (hence lying on the diagonals of Figure 2). The support window was in fact two-dimensional (not shown in Figure 2) because excitation was exchanged between potential matches of the same disparity lying on different epipolar lines within a local neighborhood. This use of excitation implements the cohesivity constraint because it favors matches with roughly the same depth. Inhibition was passed between elements lying on lines orthogonal to the diagonals (lines not shown in Figure 2). Marr (1982) severely criticized that way of using inhibition, arguing that it amounts to the unjustifiable constraint of forbidding double matches along radial lines extending from the viewer.

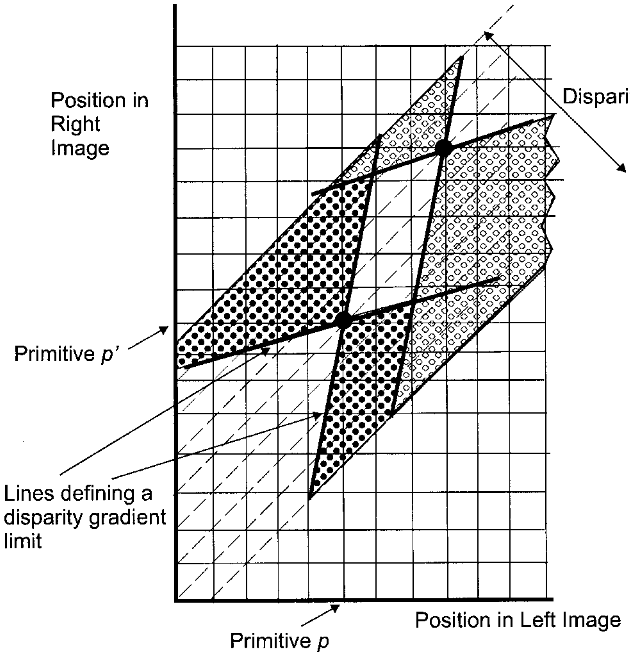

**Figure 2.** The axes represent the locations of matching primitives on a corresponding pair of left and right epipolar lines. The lines perpendicular to each axis represent lines of sight extending from each primitive, and their intersections represent potential matches. Primitives with zero disparity would fall on the diagonal passing through the origin. Other isodisparity planes lie parallel to that diagonal. The potential match *pp′* formed from the primitives *p* and *p′* and lying in a non-zero disparity plane is shown at the intersection of two bold lines whose slope reflects a particular disparity gradient. The shaded areas on one side of these lines depict, for the region of disparity space shown, zones in which neighbours of *pp′* would have too steep a disparity gradient with *pp′* to be allowed to support that match in the PMF stereo algorithm. Gradient limit lines extending from a second match are also shown to emphasize that all matches have their own region of support in disparity space.

### *Marr and Poggio's Stereo Neural Network*

Marr and Poggio's 1976 algorithm was similar to Dev's. The difference lay in the inhibitory connections. These were between elements lying on the same line of sight, shown as the vertical and horizontal lines passing through each potential match in Figure 2. This scheme implements the uniqueness constraint properly. Mathematical analyses showed that states satisfying the cohesivity and uniqueness constraints were stable states of the network, and that the network converges for a wide range of parameter values (Marr, 1982).

### *PMF and the Disparity Gradient Limit Constraint*

A limitation of the Dev and Marr/Poggio algorithms is that they impose a very restricted version of the cohesivity constraint, one that favors isodisparity surfaces. Yet it is evident from inspection of table tops, floors, etc., that human stereo vision copes readily with scenes with a variety of slants. Even locally isodisparity surface patches are far from being a universal characteristic of our visual world. The key idea in Pollard, Mayhew, and Frisby's stereo algorithm, called PMF (Frisby and Pollard, 1991), is that neighboring potential matches exchange support (mutual excitation) if their disparities are similar, not just if they are the same. Similarity is defined in terms of the disparity between potential matches not exceeding a disparity gradient (DG) limit. The butterfly shapes in Figure 2 illustrate the bounds on neighboring matches falling within and outside this limit. DG is defined in PMF as the difference in disparities divided by feature separation.

The use of a disparity gradient limit in PMF was prompted by human psychophysical experiments by Burt and Julesz which showed that if two disparate dots are brought closer and closer together while their disparity is kept unaltered, there comes a point (DG about 1.0) at which binocular fusion breaks down into diplopia.

The Dev and Marr/Poggio algorithms essentially imposed a DG limit of zero, by allowing only matches with the same disparity to exchange support. Using a DG limit greater than zero is much less restrictive: DGs of 1.0 arise from a planar surface with a slant of 84° for a viewing distance of 65 cm and interocular separation of 6.5 cm. One way to view the use of a DG limit is as a means of parameterizing the binocular matching rule of seeking matches that preserve surface smoothness. Perhaps it is better to say parameterizing surface jaggedness, because potential matches falling within the DG limit do not need to arise from smooth surfaces, if by that is meant adopting a selection procedure equivalent to fitting locally planar or curved surfaces. If the DG limit is set close to zero, then the disambiguating power is great, but the range of surfaces that can be dealt with is correspondingly small. This power reduces as the DG limit is increased toward the theoretical limit of 2.0 for opaque surfaces, the value obtained when the viewing direction from one eye to an opaque surface lies in that surface.

The matching strength of each potential match in PMF is computed as the sum of the strengths of all potential matches in a local image neighborhood that satisfy a moderate DG limit with respect to it. The limit used varies as the algorithm proceeds, from an initially prudent 0.5 to a finally generous 1.5. Because the probability of a neighboring match's falling within the DG limit by chance increases (almost linearly) with its distance away from the match under consideration, the contribution of each match in the neighborhood is weighted inversely by its distance away. PMF exploits the uniqueness constraint by selecting the best supported matches using winner-take-all discrete relaxation. To the basic PMF algorithm was added procedures implementing the figural continuity constraint, the use on startup of a set of strong "seed point" matches to speed up selection of subsequent matches, and an explicit use of the ordering constraint at a late stage to resolve remaining ambiguities. This blend of good ideas, each based solidly on a good constraint, may be in keeping with the style of computation evolved by robust biological vision systems.

### *Surface Discontinuities and Uncorrelated Points*

Even if the cohesivity constraint is utilized in a form that treats the world as "locally not very jagged," it is nevertheless true that many common scenes contain surface discontinuities that are very jagged indeed. For example, tufts of grass or hair are full of discontinuities in depth that exceed a DG limit of 1.0 in almost all directions, yet they give excellent stereo percepts. Any algorithm modeling human stereovision must be able to cope with such objects.

Within the framework of the neural net models being reviewed here, one means for doing this is to compute only the quantity of *support* that exists for a particular match, and not to exact a penalty for neighboring matches that do not satisfy the particular definition of smooth surface being implemented. For example, the extent to which the DG limit is offended by other potential matches in the neighborhood of a candidate match does not directly affect the selection procedure of PMF. The advantage of this design feature can be appreciated by considering a large step between two planar surfaces. This will create steep DGs across it but not necessarily along it. Within-DG-limit support exchanged between neighboring matches will pick out matches lying on one or the other side of the step. This will help their correct selection without introducing inappropriate evidence from the other surface, as would happen if penalties were imposed from neighbors lying outside the DG limit.

Discontinuities from opaque surfaces will usually create features in one image that do not appear in the other image because they are hidden from view. Human vision is remarkably fast at detecting uncorrelated image regions. This suggests they are utilized in some way, not just treated as noise left over after stereo matching has been completed.

### *The Problem of Transparency*

Human stereo vision can deal successfully with points arising from overlapping transparent surfaces. The difficulty they pose is avoiding computations associated with points from one surface becoming entangled with those from other surfaces. Neural network algorithms can solve this problem in the way just described for dealing with discontinuities, namely, by computing the support for any given potential match without imposing a penalty for neighbors that do not satisfy the support rule. For a recent review, experiments, and a neural model, see Gephstein and Cooperman (1998).

## Neurophysiological Studies of Disparity Mechanisms

G. F. Poggio's classification scheme for disparity-tuned V1 neurons places them into three broad types, defined in terms of whether they are tuned to disparities close to the fixation point, or to "far," or to "near" disparities. It is controversial whether these are distinct classes or whether they are better regarded as points on a continuum. Cumming and DeAngelis (2001) consider this question in a wide-ranging review of the disparity neuron literature. They note that the signals of V1 neurons differ in many ways from the perception of depth; e.g., they respond to false matches in their receptive fields. They conclude that V1 neurons probably measure binocular correlation over a range of vertical and horizontal disparities, with their outputs exploited in extrastriate cortex for a number of different tasks: stereopsis, vergence control, scene segmentation, and 3D heading judgments. Jannssen, Vogels, and Orban (2000) found that more than one-third of inferior temporal lobe neurons in rhesus monkey were selective for complex surfaces portrayed in random-dot stereograms. This implies that they must be at or after the level at which the stereo correspondence problem is solved. Backus et al. (2001) provide an example of fMRI being used to find brain regions mediating stereopsis in humans. An interesting question stimulated by neurophysiology is whether human vision relies on oriented channels for its matching primitives. Mayhew and Frisby drew a negative conclusion in 1978, based on both psychophysical and logical considerations. Farell (1998), however, reports evidence from an adaptation study suggesting that 2D (non-oriented) matches are derived from 1D (oriented) stimulus components in human stereopsis. To sum up this section, despite much progress in studying neurons linked to stereopsis, an understanding of brain mechanisms that solve the stereo correspondence problem is not yet available.

## Learning Algorithms

The neural networks described in this article were hand-crafted by their originators. A topic of considerable interest is how to create networks able to learn their own constraints. O'Toole has described a stereo network model that developed connection weights implementing the smoothness constraint following associative learning of a large number of example mappings from disparity data to surface depth data. Becker and Hinton described a network that replaces an external teacher with internally derived teaching signals generated by the assumption that neighboring parts of the input have common causes in the external world. Small modules look at separate but related parts of the input and discover these common causes by striving to produce outputs that agree with each other, thereby learning to exploit the smoothness constraint. Stone (1996) has devised a learning scheme based on the general principle that perceptually salient visual invariances, such as surface depth, vary smoothly over time. His algorithm uses a learning rule that maximizes the long-term variance of the state of a model neuron and simultaneously minimizes its short-term variance. This approach proved sufficient for estimating subpixel stereo disparities from random-dot stereograms.

## Discussion

The main point emphasized throughout has been that neural network approaches to the stereo correspondence problem (as indeed any others) need to be firmly grounded in an analysis of the task to be solved by way of discovering constraints to be implemented in the network. It is also worth emphasizing that solving the stereo correspondence problem as it has been posed here produces a disparity map that is simply another iconic (image-like) representation that itself needs to be interpreted if the information it contains is to be used, for example, for controlling visually guided behavior. Thus there is much more to stereo vision than solving the stereo correspondence problem. A further limitation of the models described here is that they do not meet the challenges posed by eye movements. In this connection, it is worth noting the potential importance of seeking to establish stereo correspondence in the context of binocular image flows over time.

# Stochastic Approximations and Efficient Learning

*Léon Bottou and Noboru Murata*

## Introduction

Many learning algorithms work by repeatedly picking one example and updating the learning system parameters on the basis of this example only. The evolving state of the parameters is the only trace of the previously seen examples. These algorithms, called *stochastic algorithms* or *on-line algorithms*, date back to early work on recursive identification and learning systems (Robbins and Monro, 1951; Widrow and Hoff, 1960; Amari, 1967; Tsypkin, 1971). This was the dawn of the computer age. Algorithmic simplicity was a practical requirement.

The analysis of on-line algorithms is much more difficult than that of ordinary optimization algorithms. Practical successes in signal processing (Widrow and Stearns, 1985) motivated the creation of sophisticated mathematical tools known as *stochastic approximations* (Ljung and Söderström, 1983; Benveniste, Metivier, and Priouret, 1990).

On-line algorithms are still extremely useful because they enjoy significant performance advantages for large-scale learning problems (Le Cun et al., 1998). This article describes their properties using the stochastic approximation theory as a very broad framework, and provides a brief overview of newer insights obtained using information geometry (see NEUROMANIFOLDS AND INFORMATION GEOMETRY) and replica calculations (see STATISTICAL MECHANICS OF ON-LINE LEARNING AND GENERALIZATION).

The first section describes and illustrates a general framework for neural network learning algorithms based on stochastic gradient descent. The second section presents stochastic approximation results describing the *final phase*. The third section discusses the conceptual aspects of the *search phase* and comments on some of the latest results.

## Stochastic Gradient

This section presents a simplified version of the general framework for stochastic gradient learning algorithms introduced in Tsypkin (1971). Several examples of neural network learning algorithms are discussed in this context.

### *Stochastic Gradient and Backpropagation*

Let us introduce the necessary concepts using the well-known example of multilayer networks (see PERCEPTRONS, ADALINES, AND BACKPROPAGATION). Each example $z$ is a pair composed of an input pattern $x$ and a desired output $y$. The output of a multilayer network is a differentiable function $f(x, w)$ of the input pattern $x$ and the network weight vector $w$. The performance of the network on a particular example $z = (x, y)$ is measured by a *loss function* $Q(z, w)$. In the multilayer network case, the loss function usually is the square of the distance between the desired output $y$ and the network output $f(z, w)$:

$$Q_{\mathrm{mse}}(z, w) \overset{\Delta}{=} ½ \,(y - f(x, w))^2 \tag{1}$$

One seeks a weight vector $w$ that minimizes the loss function averaged over the examples. There is, however, a subtlety in how we define this average. Do we average over the few examples available in the training set, or over all the examples that nature cares to produce? The first average is named *empirical risk* and measures only the training set performance. The second average is called the *expected risk* and measures the much more interesting generalization performance (Vapnik, 1998).

Both empirical and expected risk can be written as:

$$C(w) \overset{\Delta}{=} \mathbf{E}_z Q(z, w) \overset{\Delta}{=} \int Q(z, w) dP(z) \tag{2}$$

where $dP(z)$ represents a probability distribution of examples and $\mathbf{E}_z$ represents the expectation with respect to this distribution. In the case of the expected risk, $dP(z)$ is an unknown *ground truth distribution* representing the laws of nature. In the case of the empirical risk, $dP(z)$ is a discrete distribution defined by the training set examples $z_{(1)} \ldots z_{(L)}$. The expectation in Equation 2 then reduces to a simple average, $1/L\Sigma_i Q(z_{(i)}, w)$.

It has often been suggested (e.g., Rumelhart, Hinton, and Williams, 1986) to minimize the risk in Equation 2 by using a gradient descent algorithm. Each iteration of the algorithms moves the weights along the steepest descent direction,

$$w_{t+1} = w_t - \gamma_t \int \nabla_w Q(z, w_t) dP(z) \tag{3}$$

where $\gamma_{\mathrm{t}}$ is an adequately chosen positive learning rate and $\nabla_w Q$ denotes the gradient of the loss function $Q$ with respect to the weight vector $w$. This optimization algorithm cannot be used to optimize the expected risk case because the ground truth distribution is unknown. One must optimize the empirical risk instead and hope that the training set performance is a good predictor of the generalization performance. Each iteration of this *batch gradient descent* involves visiting all of the training examples in order to compute the average gradient.

The *stochastic gradient descent* algorithm is a drastic simplification of the above algorithm. Each iteration consists of picking a single random example $z_t$, and updating the weight vector $w$ according to the following rule:

$$w_{t+1} = w_t - \gamma_t \nabla_w Q(z_t, w_t) \tag{4}$$

This algorithm illustrates the concept of *stochastic approximation*. It is hoped that iterating Equation 4 behaves like iterating its mean (Equation 3), despite the noise introduced by this simplified procedure.

The stochastic gradient descent does not need to remember which examples were visited during the previous iterations. This makes this algorithm suitable for the on-line adaptation of deployed systems. In such a situation, the stochastic gradient descent directly optimizes the expected risk, since the examples are randomly drawn from the ground truth distribution.

The stochastic gradient descent can also pick examples from a finite training set. This procedure optimizes the empirical risk. The number of iterations is usually larger than the size of the training set. The examples are therefore presented multiple times to the network.

### *General Stochastic Gradient Descent*

The preceding example suggests a more general framework:

Let us consider a learning system whose goal consists in minimizing a cost function (Equation 2) that can be expressed as the expectation of a loss function, $Q(z, w)$. Each iteration of the *generalized stochastic gradient descent algorithm* consists in picking a random example $z_t$ and updating the parameter vector $w$ using the update rule in Equation 4.

A number of well-known learning algorithms can be viewed as particular cases of the generalized stochastic gradient descent algorithm. A few examples are presented in the following discussion. Additional examples can be found in Bottou (1998). Most results discussed in this contribution are based on the general framework and therefore apply to all of these learning systems alike.

*Adaline.* The early neural network learning algorithms adapt the parameters of a single threshold unit. Input patterns $x$ are recognized as members of class $y = \pm 1$ according to the sign of dot product $w'x$. Each iteration of the adaline learning algorithm (Widrow and Hoff, 1960) takes one training example $z_t = (x_t, y_t)$ and applies the *delta rule*:

$$w_{t+1} = w_t + \gamma_t(y_t - w'_t x_t)x_t \tag{5}$$

This is nothing more than an iteration of the stochastic gradient descent algorithm in Equation 4 with the following loss function:

$$Q_{\mathrm{adaline}}(z, w) \overset{\Delta}{=} ½ \,(y - w'x)^2 \tag{6}$$

The adaline loss function does not take the discontinuity of the threshold unit into account. It is much more difficult to optimize the apparently more natural loss function $(y - \mathrm{sign}(w'x))^2$ because its gradient is null almost everywhere.

*Perceptron.* The perceptron algorithm provides a slightly different solution. The weights are updated according to the following rule if and only if the current example, $z_t = (x_t, y_t)$, is misclassified:

$$w_{t+1} = w_t + \gamma_t y_t x_t \tag{7}$$

This learning algorithm can be derived as an on-line gradient descent applied to the following loss function:

$$Q_{\text{perceptron}}(z, w) \triangleq ½ \,(\text{sign}(w'x) - y)w'x \tag{8}$$

The loss function is not differentiable when $w'x$ is null. It has been shown that the average behavior of the stochastic gradient algorithm is not affected by such mild nondifferentiabilities (Bottou, 1998).

*Unsupervised clustering.* The $k$-means algorithm is a popular clustering method that dispatches $K$ centroids $w(k)$ in order to find clusters in a set of points $x_1, \ldots, x_L$. This algorithm can be derived by performing the on-line gradient descent with the following loss function:

$$Q_{\text{kmeans}}(x, w) \triangleq ½ \min_k \,(x - w(k))^2 \tag{9}$$

This loss function measures the average error achieved when each point $x$ is replaced by the nearest centroid $k^*(x)$. The mild nondifferentiability of this loss function on the cluster region boundaries are handled as in the perceptron case. Equation 4 then yields the $k$-means algorithm:

$$w_{t+1}(k) = w_t(k) + \gamma_t \begin{cases} x_t - w_t(k) & \text{if } k = k^*(x_t) \\ 0 & \text{otherwise} \end{cases} \tag{10}$$

### Stochastic Gradient Dynamics

Given a suitable choice of the learning rates $\gamma_t$, the ordinary gradient descent algorithm (Equation 3) is known to converge to a local minimum of the cost function. This local minimum is a function of the initial parameters $w_0$. The parameter trajectory follows the meanders of the local attraction basin and eventually reaches the corresponding minimum.

The random noise introduced by stochastic gradient descent (Equation 4) disrupts this deterministic picture. The parameter trajectory can jump from basin to basin. One usually distinguishes a *search phase*, which explores the parameter space, and a *final phase*, which takes place in the vicinity of a minimum.

## Final Phase

### Convergence

The final convergence phase takes place in the vicinity of a single minimum $w^*$. The following results rely on the *general convexity* hypothesis:

$$\forall \varepsilon > 0, \quad \inf_{(w - w^*)^2 > \varepsilon} \,(w - w^*)\nabla_w C(w) > 0 \tag{11}$$

This hypothesis simply states that the opposite of the gradient always points toward the minimum $w^*$. This hypothesis usually holds within the final convergence region because the cost function is locally convex.

In order to obtain convergence, the parameter updates $\gamma_t \nabla_w Q(z, w)$ must become smaller and smaller when the parameter vector approaches the optimum $w^*$. This implies that either the gradients or the learning rates must vanish in the vicinity of the optimum.

The size of the gradients can be described with a first-order expansion of $\nabla_w Q$ in $w^*$. There usually are constants $A, B \geq 0$ such that the following bound holds within the final convergence region:

$$\begin{aligned} \mathbf{E}_z(\nabla_w Q(z, w)^2)) &\approx \mathbf{E}_z(\nabla_w Q(z, w^*)^2) + \mathbf{E}_z((w - w^*) \ldots) \\ &< A + B(w - w^*)^2 \end{aligned} \tag{12}$$

The constant $A$ must be greater than the residual variance of the gradients at the optimum $\mathbf{E}_z(\nabla_w Q(z, w^*)^2)$. This residual variance can be zero for certain rare noiseless problems where $w^*$ simultaneously optimizes the loss for every example. It is strictly positive in most practical cases. The average norm of the gradients then does not vanish when the parameter vector $w$ approaches the optimum. Therefore, one must use *decreasing learning rates*, e.g.:

$$\sum \gamma_t^2 < \infty \tag{13}$$

The presence of constant $A$ in Equation 12 marks a critical difference between stochastic gradient descent and ordinary gradient descent. There is no such constant in the case of the ordinary gradient descent. A simple analysis then yields an expression for the maximal constant learning rate (Le Cun et al., 1998). In the stochastic gradient case, this analysis suggests that the parameter vector eventually hovers around the minimum $w^*$ at a distance roughly proportional to $\gamma_t$. Quickly decreasing the learning rate is therefore tempting. Suppose, however, that the learning rates decrease so fast that $\Sigma\gamma_t = R < \infty$. This would effectively maintain the parameters within a certain radius of their initial value. It is therefore necessary to enforce the following condition:

$$\sum \gamma_t = \infty \tag{14}$$

The general convexity hypothesis (Equation 11) and the three conditions given in Equations 12, 13, and 14 are sufficient conditions for the almost sure convergence of the stochastic gradient descent (Equation 4) to the optimum $w^*$ (Bottou, 1998).

### Second-Order Methods

Significant speed-ups of the final phase can be achieved using second-order methods (Le Cun et al., 1998). The simplest second-order method rescales the gradient vector using the inverse of the Hessian matrix $H(w_t)$ in a manner analogous to Newton's algorithm:

$$w_{t+1} = w_t - \gamma_t H(w_t)^{-1} \nabla_w Q(z_t, w_t) \tag{15}$$

It is, however, preferable to use instead the Gauss-Newton matrix (Le Cun et al., 1998) or the Fisher information matrix (described later under Natural Gradient). These matrices asymptotically behave like the Hessian matrix and also provide superior performance during the search phase.

State-of-the-art batch optimization algorithms (Dennis and Schnabel, 1983) reach so-called superlinear convergence speed *on the training set* using such second-order methods. Such speeds are not possible with stochastic gradient because the convergence speed is determined by the learning rate schedule, which is limited by the condition in Equation 14. This speed limit has often been presented as a severe drawback. However, training algorithms are about the generalization of performance. Well-designed second-order stochastic algorithm have been shown to saturate the Crámer-Rao bound (Murata, 1998). This result means that batch algorithms that converge faster on the training set are merely overtraining.

## Search Phase

Although our understanding of the search phase is still very incomplete, empirical and theoretical evidences indicate that stochastic gradient algorithms enjoy significant advantages over batch algorithms.

Stochastic gradient descent can take advantage of the redundancies of the training set. Consider the extreme case, where a training set of size 1,000 is inadvertently composed of 10 identical copies of a set with 100 samples. Averaging the gradient over all 1,000 patterns gives exactly the same result as computing the gradient based on just the first 100. Batch gradient descent is wasteful because it recomputes the same quantity 10 times before one parameter update occurs. On the other hand, stochastic gradient descent will see a full epoch as 10 iterations through a 100-long training set.

The stochastic approximation tools provide only weak results on the search phase (e.g., Bottou, 1998). Stronger results have been obtained using information geometry (see NEUROMANIFOLDS AND INFORMATION GEOMETRY) and statistical mechanics (see STATISTICAL MECHANICS OF ON-LINE LEARNING AND GENERALIZATION). This section reviews what new information has been brought by these new approaches.

### *Information Geometry*

Describing the geometry of the cost function is paramount to understanding the convergence of a training algorithm. The final phase results, for instance, are built on two hypotheses (Equations 11 and 12) that adequately summarize the geometry of the cost function in the final convergence region. This is much more difficult to achieve for the search phase because the parameter vector can explore every aspect of the cost function.

Information geometry provides an elegant description of the global geometry of the cost function. It is best introduced by casting the learning problem as a density estimation problem. A multilayer perceptron $f(x, w)$, for instance, can be regarded as a parametric regression model $y = f(x, w) + \varepsilon$, where $\varepsilon$ represents an additive Gaussian noise. The network function $f(x, w)$ then becomes part of the Gaussian location model:

$$p(z, w) = C \exp\left(-\frac{(y - f(x, w))^2}{2\sigma^2}\right) \tag{16}$$

The optimal parameters are found by minimizing the Kullback-Leibler divergence between $p(z, w)$ and the ground truth $P(z)$. This is equivalent to the familiar optimization of the mean square loss in Equation 1:

$$\mathbf{E}_z \log \frac{P(z)}{p(z, w)} = \frac{1}{\sigma^2}\mathbf{E}_z Q_{mse}(z, w) + \text{Constant} \tag{17}$$

The essential idea consists of endowing the space of the parameters $w$ with a distance that reflects the proximity of the distributions $p(z, w)$ instead of the proximity of the parameters $w$. Multilayer networks, for instance, can implement the same function with very different weight vectors. The new distance distorts the geometry of the parameter space in order to represent the closeness of these weight vectors.

The infinitesimal distance between distributions $p(z, w)$ and $p(z, w + dw)$ can be written as follows:

$$D(w \| w + dw) \approx dw'J(w)dw \tag{18}$$

where $J(w)$ is the Fisher information matrix:

$$J(w) \triangleq \int (\nabla_w \log p(z, w) \nabla_w \log p(z, w'))p(z, w)dz \tag{19}$$

The determinant $|J(w)|$ of the Fisher information matrix usually is a smooth function of the parameter $w$. The parameter space is therefore composed of *Riemannian domains* where $|J(w)| \neq 0$, separated by *critical subspaces* where $|J(w)| = 0$.

### *Natural Gradient*

Natural gradient (see NEUROMANIFOLDS AND INFORMATION GEOMETRY) provides an almost ideal way to search a Riemannian domain. The gradient $\nabla_w C(w)$ defines the steepest descent direction in the Euclidian space. The steepest descent direction in a Riemannian domain differs from the Euclidian one. It is defined as the vector $dw$ that maximizes $C(w) - C(w + dw)$ in the $\delta$-neighborhood:

$$D(w \| w + dw) \approx dw'J(w)dw \leq \delta \tag{20}$$

A simple derivation then shows that multiplying the gradient by the inverse of the Fisher information matrix yields the steepest Riemannian direction. The natural gradient algorithm applies the same correction to the stochastic gradient descent algorithm in Equation 4:

$$w_{t+1} = w_t - \gamma_t J^{-1}(w_t)\nabla_w Q(z, w_t) \tag{21}$$

The similarity between the update rules in Equations 15 and 21 is obvious. This link becomes clearer when the Fisher information matrix is written in Hessian form:

$$J(w) \triangleq \int -(\nabla_w^2 \log p(z, w))p(z, w)dz \tag{22}$$

where $\nabla_w^2$ denotes a second derivative. When the parameter approaches the optimum, distribution $p(z, w)$ becomes closer to the ground truth $dP(z)$, and the Fisher information matrix aligns with the Hessian matrix $\nabla_w^2 \mathbf{E}_z Q(z, w)$. The natural gradient asymptotically behaves like the Newtonian algorithm.

### *Critical Subspaces and Symmetries*

Consider a neural network with two fully connected layers and $n$ hidden units. The weight space contains at least $n!$ symmetric Riemannian domains corresponding to all permutations of the hidden units and delimited by critical subspaces. The cost landscape in the vicinity of a critical subspace contains multiple directions along which no first-order change of the cost can be detected. Such critical subspaces create considerable problems for gradient descent algorithms. Batch gradient descent often remains trapped in these extremely flat regions of the cost landscape, because the gradient $\nabla_w C(w)$ is zero along those directions that would allow the algorithm to escape the critical subspace.

These problems arise because the gradient vector no longer carries enough information to describe the local cost geometry. Unlike their batch counterpart, stochastic gradient algorithms have a random component and therefore can resort to luck in picking each training example $z_t$. A lucky pick sometimes transports the parameter vector into a more interesting area of the cost landscape.

Critical subspaces have both a hierarchical and a symmetric structure (Fukumizu and Amari, 2000). Replica calculations (see STATISTICAL MECHANICS OF ON-LINE LEARNING AND GENERALIZATION) have brought new insights into the symmetry-breaking properties of on-line algorithms. The natural gradient algorithm in Equation 21 seems to perform remarkably well (Rattray and Saad, 1999) in this context too.

## Discussion

On-line learning algorithms were introduced early in the computer age because of their low computational requirements. Today, on-line learning algorithms enjoy significant performance advantages for large-scale learning problems (large dimension, millions of examples). On-line algorithms are also mandatory when a system must continuously adapt while being used.

A large number of common learning algorithms can be understood as instances of the general stochastic gradient descent algorithm. The stochastic approximation theory provides a general analysis of the convergence of these algorithms. This analysis describes very accurately the behavior of on-line algorithms in the vicinity of a local solution. Second-order on-line algorithms provide asymptotically optimal convergence speed.

The behavior of on-line algorithms during the search phase is much less understood. Information geometry pictures the search space as an ensemble of Riemannian manifolds separated by critical subspaces. Critical subspaces cause considerable problems to all gradient algorithms. On-line gradient algorithms can overcome these problems, thanks to noise introduced by the random example selection process. Methods from statistical mechanics have recently brought new insights to this topic. These results might be the precursors of vastly more efficient on-line learning algorithms.

# Stochastic Resonance

*Frank Moss*

## Introduction

### *Definition of Stochastic Resonance*

Stochastic resonance (SR) is an essentially nonlinear phenomenon whereby the addition of a random process, or noise, to a weak incoming signal can enhance the probability that it will be detected by a system. Information about the signal transmitted through the system is also enhanced. An optimal intensity of noise results in maximal enhancements. The information content or detectability of the signal is degraded for noise intensities that are either smaller or larger than the optimal value. The phenomenon is exhibited in Figure 1*A* where the system can be thought of as a "black box."

*Only three ingredients are necessary.* The actions within our black box are diagrammed in Figure 1*A*. The threshold is shown by the dashed line and the subthreshold signal, $A$ sin($\omega t$), by the heavy solid line. The magnitude of the threshold, measured from the mean of the subthreshold signal, is designated $\Delta_0$. A noise (random process), as shown by the gray, irregular line, has been added to the subthreshold signal. Positive-going threshold crossings of the combined signal plus noise are marked above by the train of standard-shaped (narrow) pulses. The noise can be external, for example, environmental noise (perhaps including thermal fluctuations) that adds to the signal to be detected by a sensory neural modality; or it could be internal, for example, deterministic noise generated by dynamical processes within the sensory neurons or even in the brain where the sensory signal is interpreted.

As we can see, it is noise that causes the threshold crossings and hence the output marker pulses above. In the absence of noise there would be no threshold crossings and consequently no output. Thus it is the noise that makes the subthreshold signal detectable in our paradigm. Although the marker pulses, analogous to neural action potentials, seem randomly spaced in time, they carry a surprising amount of information about the subthreshold signal. This is because the probability of threshold crossing is much larger at the locations of the maxima of the signal than at the minima. In sensory neuroscience this is called "rate coding," the mean rate of firings being determined by how close the membrane potential is to the threshold. We can see that the noise serves as a sampling function of the signal, but each sample carries only one bit of information—the time of the threshold crossing. Signal amplitude information is encoded only in the mean rate of threshold crossings.

Thus, only three ingredients are necessary for SR: a threshold, a subthreshold signal, and noise. These three ingredients are ubiquitous in both natural and in manmade systems, so it is not surprising that SR has been found in many of them (Moss, Pierson, and O'Gorman, 1994; Anishchenko et al., 1999).

*The threshold: A fundamentally simple nonlinear system.* Stochastic resonance appears only in a class of *nonlinear* systems, the simplest examples of which are those systems characterized by a "hard" threshold. Let us consider the input-output characteristic of such a system. If the amplitude of the input is smaller than (or equal to) the threshold, the output is zero. If the amplitude of the input is larger than the threshold, the output equals the input multiplied by some gain factor. Thus, no signal (input) can be detected or transmitted through the system to the output unless the threshold is exceeded.

Thresholds and noise are ubiquitous in both manmade and natural systems; indeed, SR is found in diverse areas. But here we focus on SR as it appears in several biological settings (Moss and Wiesenfeld, 1995): the mechanosensory system of the crayfish, the

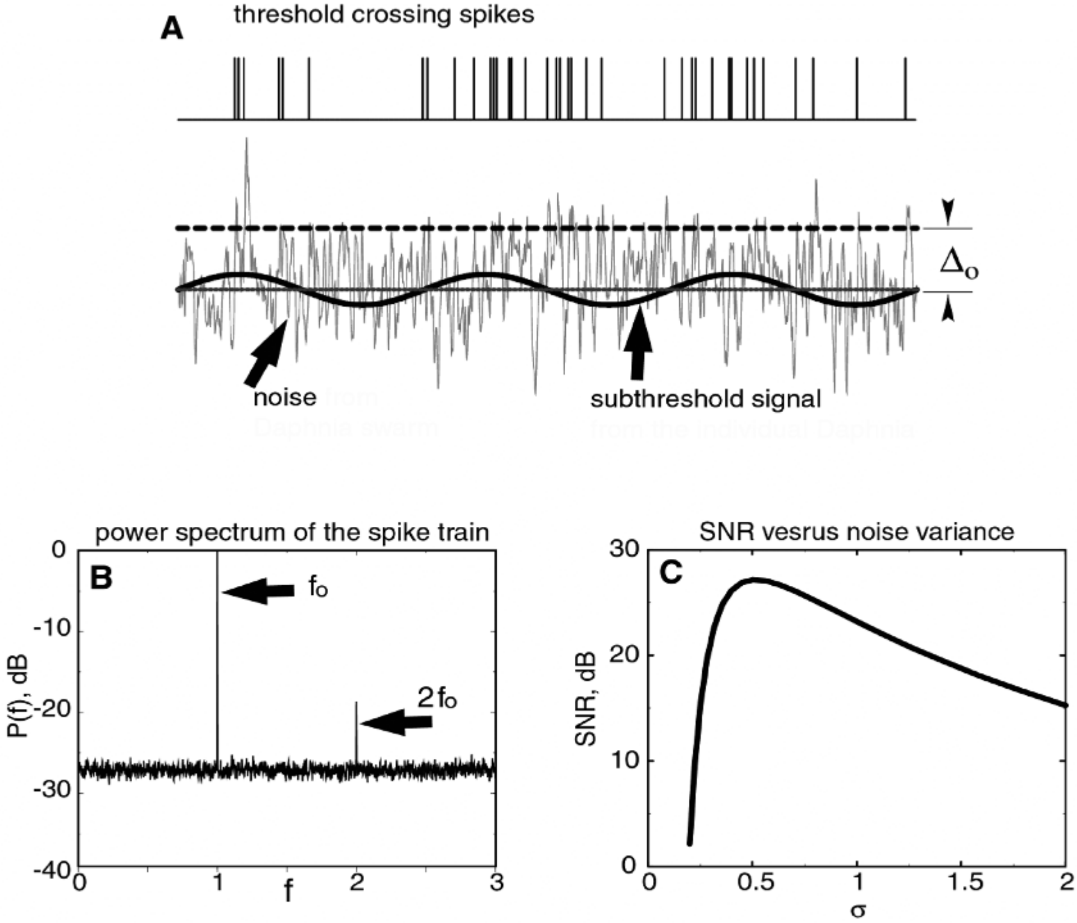

**Figure 1.** *A*, The three ingredients necessary for stochastic resonance (SR): a threshold (dashed line), a subthreshold signal (solid sinusoidal line), and noise (irregular shaded line). Threshold crossings of the combined (sinusoid + noise) induce standard responses, or outputs, shown by the train of spikes above. *B*, The power spectrum of the spike train, showing strong evidence of the subthreshold signal as the sharp peaks at $f_0$ and $2f_0$ riding on a broadband noise background (horizontal irregular line). *C*, The signal-to-noise ratio versus the standard deviation of the noise added to the subthreshold signal in Figure 1*A*. The presence of a maximum at an optimal noise intensity is the signature of SR.

electrosensory system of the paddlefish, human cognition and perception, and the human baroreflexive system. And for simplicity we consider only hard thresholds, though soft thresholds (typically sigmoidal), which abound in neuroscience, also show SR. We consider a simple paradigm: a black box containing the threshold, with an input and output. If the threshold is crossed in the positive-going direction under the influence of an input signal (of sufficient amplitude), the black box outputs a single pulse of standard shape, for example, a narrow pulse of unit amplitude. Otherwise it outputs nothing. This seems somewhat abstract, but it was the earliest model to account for the generation of action potentials by sensory neurons. When a threshold (typically around −50 mV for mammals) is crossed from below by the membrane potential, the neuron "fires," or generates an action potential of standard amplitude and shape that propagates along the axon.

## *The Signature of Stochastic Resonance*

The signature of SR is that some measure of the information content of the marker pulse train shown in Figure 1*A* passes through a maximum at some optimal value of the noise intensity. Considering the noise as a sampling function, we can see that if the noise intensity is too small, the signal is undersampled and information about it is lost. If the noise intensity is too large, the samples become randomized and information about the signal is masked by the large noise. Thus the information is a maximum at an optimal noise intensity.

One measure, commonly used by communications engineers, is the signal-to-noise ratio (SNR) based on measures of the power spectrum. The power spectrum shows the amount of power contained in the signal on a scale of frequency. Figure 1*B* depicts the power spectrum of the marker pulse train shown in Figure 1*A*. We note sharp peaks (indicating large power) at the signal frequency, $f_0$, and its second harmonic, $2f_0$. The horizontal irregular line marks the background randomness of the marker train induced by the noise added to the signal. The SNR is the ratio of the power contained within the peak to the power (in a unit bandwidth) of the noise background at the signal frequency. Figure 1*C* shows a graph of the SNR versus the noise intensity, $\sigma$. (In this simulation the noise is Gaussian distributed with standard deviation $\sigma$.) The graph shows that the SNR passes through a maximum at optimal noise intensity.

Sensory biologists are more familiar with the probability distributions of the time intervals between spikes. A related topic is called "skipping." Skipping occurs when no, one, or just a few spikes are generated near the signal maxima. As can be seen from

Figure 1*A*, the time between spikes at every maximum should be close to the period *T* of the signal. Skipping is represented by time intervals of 2*T*, 3*T*, etc. Thus we expect to see a sequence of maxima in the probability distribution of interspike intervals; indeed, such distributions have been observed in sensory biology for a very long time. Only recently have we achieved a quantitative understanding that such multimodal distributions with exponentially decreasing peak amplitudes are the result of our three ingredients (Longtin, Bulsara, and Moss, 1991). Skipping is related to SR in the sense that there is a maximum of information about the subthreshold signal contained in the multimodal distribution at optimal noise intensity.

## Stochastic Resonance in Cell Membrane Ion Channels

Our outline of the development of SR in biology is not chronological; rather, it commences with the application of smallest physical size—a single protein molecule—and proceeds up the scale of size and complexity to whole-animal behavior and human psychophysics.

A few years ago, Bezrukov and Vodyanoy (1995) published the results of a remarkable experiment. They measured the current through an array of artificial, voltage-dependent ion channels, each a single alamethicin molecule embedded in a lipid bilayer. The individual ion channels may open to allow a through-flow of positive ions or close to terminate the current. The probability of opening or closing is determined by the potential. The array is characterized by a sigmoidal threshold curve that is essentially a measure of the mean opening probability of the ion channels as a function of the potential across the bilayer. The key is to modulate the bilayer potential with a weak signal that is a near-subthreshold, periodic potential plus noise, precisely as shown in Figure 1*A*. Then the current through the array, though noisy, carries information about the subthreshold signal. Figure 2*A* shows a power spectrum of the current transmitted through the array. The signal feature shows as a sharp spike at $f_0 = 0.5$ Hz, and its second harmonic at $2f_0 = 1$ Hz is also visible, much like the threshold simulation shown in Figure 1*B*. Figure 2*B* shows that although the amplitude of the signal transduction through the array as a function of the bilayer noise voltage (triangles) increases by about four orders of magnitude, the SNR (circles) passes through but a modest maximum at an optimal noise voltage of approximately 10 mV. The SNR effect is small; nevertheless, this experiment was the first to demonstrate SR at the molecular level.

## Stochastic Resonance in Sensory Biology

### *The Crayfish Mechanoreceptor*

In biology, stochastic resonance was first observed in the mechanoreceptor system located on the tailfan of the crayfish (Douglass et al., 1993). This system is adapted for predator avoidance. An array of hydrodynamically sensitive hairs on the crayfish tailfan senses a weak, nearly periodic water motion (8 to 12 Hz) that signals the approach of a predatory fish. Each hair is innervated by an afferent sensory neuron that converges on a ganglion (the sixth, or caudal, ganglion) located just anterior to the tailfan. In their experiment, Douglass and colleagues applied periodic and random hydrodynamic motions simultaneously to the tailfan while recording the spike train from a single afferent sensory neuron identified with its individual hair. The afferents studied were chosen to have low internal noise, allowing the researchers to perform a clean experiment with a single noise source. Power spectra assembled from the spike trains revealed the familiar signature of the three ingredients—a sharp signal feature and its smaller amplitude second harmonic riding on a broadband noise background. The SNRs computed from these power spectra indicated a clear maximum at an optimal noise intensity. The data are shown in Figure 3*A*. They demonstrate SR at the level of single sensory neurons.

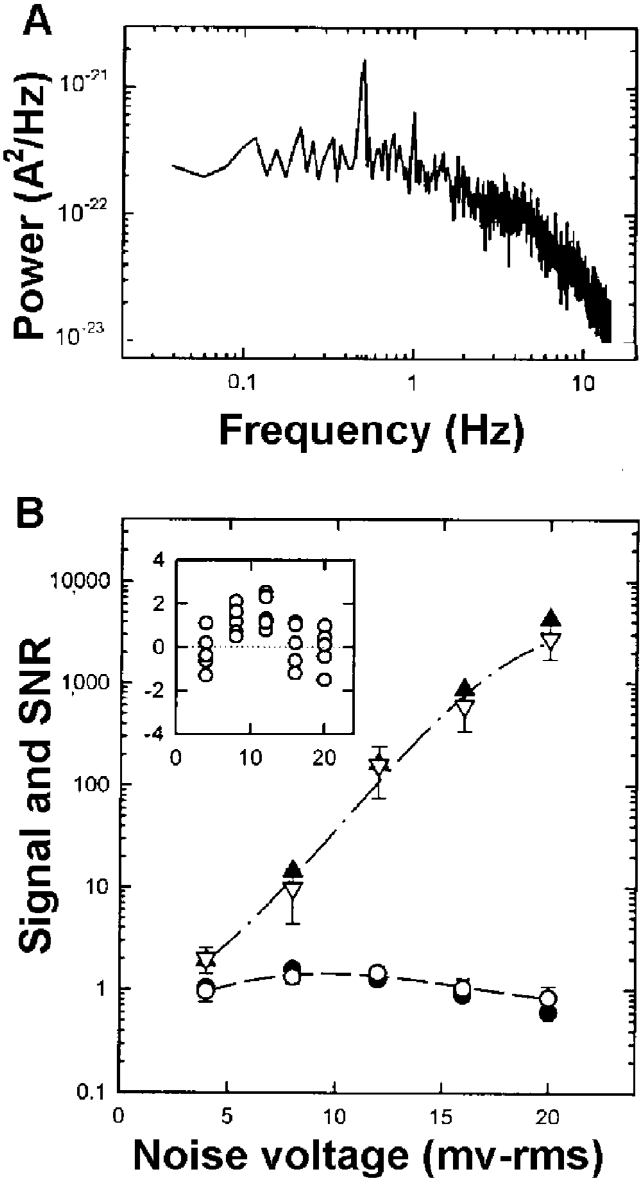

**Figure 2.** *A*, An experimentally obtained power spectrum from the current transmitted by an array of ion channels through a lipid bilayer (membrane). Note the sharp peak, evidence of the subthreshold periodic signal applied to the bilayer. *B*, The signal amplitude and the signal-to-noise ratio measured as functions of the applied noise intensity. The inset shows a magnified view of the SNR data plotted below with the closed and open circles. The data show a maximum at the optimal noise voltage of approximately 10 mV (rms), thus demonstrating SR. The dashed and dash-dot curves are a guide to the eye. (Reproduced with permission from Bezrukov, S. M., and Vodyanoy, I., 1995, Noise-induced enhancement of signal transduction across voltage-dependent ion channels, *Nature*, 378:362–364.)

### *The Cricket Cercal System*

Levin and Miller (1996) reported a remarkable experiment—similar to that described above but with many improvements and

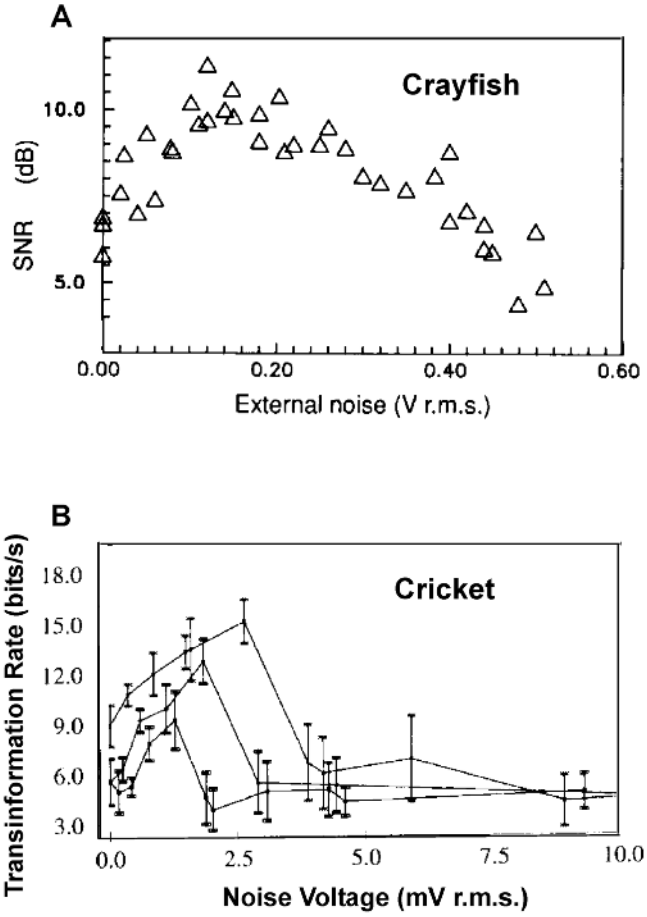

**Figure 3.** Stochastic resonance in the crayfish and cricket. *A*, signal-to-noise ratio versus noise intensity for the crayfish. (Reproduced with permission from Douglass, J. K., et al., 1993, Noise enhancement of information transfer in crayfish mechanoreceptors by stochastic resonance, *Nature*, 365:337–340.) *B*, Transinformation rate versus noise intensity for the cricket. The curves correspond to three different signal amplitudes increasing from left to right. (Reproduced with permission from Levin, J. E., and Miller, J. P., 1996, Broadband neural encoding in the cricket cercal sensory system enhanced by stochastic resonance, *Nature*, 380:165–168.)

one level up in complexity—using a different animal: the cricket. Their experiment is especially interesting because both the cricket and the crayfish are arthropods and have very similar sensory neural architectures for predator avoidance. The cricket is, however, a land animal; its medium is the air, and its main predator is a specific type of wasp. The flight of the approaching wasp causes perturbations of the air similar to the hydrodynamic perturbations generated by the swimming fish, but the frequency is higher (125 to 150 Hz). The tail of the cricket has two appendages that are covered with hairs adapted to sense nearly periodic weak air motions. As in the crayfish system, each hair is innervated by an afferent sensory neuron, and the neurons converge on a ganglion, collectively called the cercal system. The experiment was performed by applying periodic plus random air motions to the appendages while recording spike trains from within the ganglion. In addition to other improvements, Levin and Miller computed the Shannon transinformation between the stimulating air currents and the neural spike trains instead of the SNR of the spike trains alone. This information measure clearly demonstrates SR at the level of the ganglion in the cricket cercal system as shown by the data in Figure 3*B*.

## Stochastic Resonance in Human Psychophysics and Animal Behavior

### *SR in Human Psychophysics*

Stochastic resonance has made its way into human psychophysics. Can the addition of a random process to an applied stimulus enhance the ability of a human subject to perceive the stimulus accurately? An excellent tutorial on protocol design, statistical accuracy, and theoretical interpretations of psychophysics experiments has been provided by Norwich (1993). An early numerical experiment with a neural network model examined the role of the internal noise characteristic of the human brain. The model considered an energy potential with two minima (i.e., stable states) representing the two human perceptions of Necker's famous cube (Riani and Simonotto, 1994). The human percept of the perspective of the cube alternates randomly, and experiments with this percept provided the first quantitative measurements of noise within the brain.

But can noise added to an external stimulus enhance perception? For human hearing, this question has been addressed and answered affirmatively by two experimental groups (Zeng, Fu, and Morse, 2000; Ward et al., 2001). The effect is small (only about 3 dB), and the experiments are difficult owing to the extreme sensitivity of the human ear. It is hard to devise a reliably subthreshold stimulus—one of the three essential ingredients. Nevertheless, both groups have obtained positive results with statistical significance. In their experiment, Zeng and colleagues simply added auditory noise to a weak periodic stimulus; Ward and co-workers, however, made use of the higher perceptive threshold for a beat note from two periodic stimuli of slightly different frequencies, again with added noise.

A suitable protocol has also been devised using noise added to visual stimuli (Ward et al., 2001). In this experiment a well-known visual contrast threshold was exploited. The addition of noise distributed over all pixels in a computer-generated scene displayed on a fast monitor was found to enhance the subject's perceptive ability.

But even earlier, SR had been demonstrated in human tactile sensation (Collins, Imhoff, and Grigg, 1996). In this experiment, an indenter applied a subthreshold "touch" to the skin of a finger. In separate experiments, both mechanical noise and electrical noise were added to the stimulus, and both yielded positive results.

Usher and Feingold (2000) have recently reported an interesting and suggestive experiment on SR in human cognitive ability. They found that the addition of auditory noise can enhance the speed of memory retrieval for arithmetic multiplication rules. This is the first, and to date the only experiment showing SR in a human cognitive function (in contrast to sensory perception).

In a somewhat different approach, the human baroreflexive system was used to demonstrate "functional" SR (Hidaka, Nozaki, and Yamamoto, 2000). This application made use of the coupling between the cardiac and blood pressure regulatory functions. A weak periodic signal was applied to the venous blood pressure and noise to the arterial blood pressure receptor. The noise-enhanced signal was observed in cardiac response, which in turn could compensate for changes (drops) in blood pressure. Stochastic resonance in this application thus mediates an essential physiological function.

Finally, it is worth noting that, in parallel to the human psychophysics experiments, animal behavior experiments (with an electrosensitive fish) have also demonstrated SR as a behavioral perceptive phenomenon (Russell, Wilkens, and Moss, 1999).

## Discussion

Stochastic resonance has been demonstrated at several levels in biology: from ion channels in cell membranes to animal and human cognition, perception, and ultimately behavior. The behavioral effects are small, since SR lurks at the edge of human and animal perceptive thresholds. Nevertheless, over evolutionary time scales, SR may have endowed its beneficiaries with a selective advantage. Thus, today we can see its effects in widely diverse living creatures. Such speculations are stimulating and will undoubtedly lead to further study.

# Structured Connectionist Models

*Lokendra Shastri*

## Introduction

Research in *structured connectionism* is motivated by the twin beliefs that understanding the computational properties of the brain is essential for understanding human cognition, and that insights acquired by disciplines such as computer science, artificial intelligence (AI), psychology, linguistics, and learning theory are crucial for understanding the neural basis of cognition.

Structured connectionist models are networks of nodes and links that are intended to be computational abstractions of neurons and synapses, respectively. Although the structured connectionist approach shares many features with the *distributed* connectionist approach, it differs from the latter in significant ways. The fully distributed approach assumes that each "item" (a concept or mental object) is represented as a pattern of activity distributed over a *common* pool of nodes (van Gelder, 1992). This notion of representation suffers from several fundamental limitations. Consider the representation of *John and Mary*. If *John* and *Mary* are each represented as patterns of activity over the entire network such that each node in the network has a specific value in the patterns for *John* and *Mary*, respectively, then how can the network represent *John* and *Mary* at the same time? The situation gets even more complex if the system has to represent relations such as *John loves Mary* or *John loves Mary but Tom loves Susan*. In contrast to the distributed approach, the structured approach holds that small clusters of nodes can have distinct representational status (for simplicity, structured connectionist models often equate a small cluster of nodes with a single *idealized* node). In particular, there exist small clusters of nodes that act as *focal nodes* or *focal clusters* of learned concepts and provide access to more elaborate structures that make up the detailed encoding of concepts. Such a detailed encoding might include various features of the concept as well as its relationship to other concepts (see Shastri in Barnden and Pollack, 1991; Shastri, 2001b). The nodes comprising the focal cluster of a concept may be physically distributed, and the focal clusters of two concepts may overlap, although the extent of this overlap is expected to be small.

Another difference between the structured and the fully distributed approaches concerns learning. The latter underplays the importance of prior structure and assumes that the required structure emerges as a result of general purpose learning processes operating on relatively unstructured hidden layers. The structured approach holds that such a tabula rasa view is untenable on the grounds of computational complexity; training unstructured networks using general purpose-learning techniques is not a feasible way to obtain scalable solutions to complex problems. The structured approach emphasizes the importance of prior structure for effective learning and requires that the initial network architecture—for example, the number of layers and the interconnections within and between layers—reflect the structure of the problem.

The structured connectionist approach is sometimes wrongly equated with a narrow interpretation of the grandmother cell approach in which each concept is assumed to be represented by a single neuron. This misunderstanding stems from an incorrect interpretation of the representational role of focal nodes (Page, 2000; see also LOCALIZED VERSUS DISTRIBUTED REPRESENTATIONS).

## Some Neural Constraints on Cognitive Models

### *Representational Constraints*

With more than $10^{11}$ computing elements and $10^{15}$ interconnections, the human brain's capacity for encoding, communicating, and processing information seems awesome. But if the brain is extremely powerful, it is also extremely limited. First, neurons are slow computing devices. Second, although the spatiotemporal integration of inputs performed by neurons is quite complex, it is unlikely that this integration can encode and decode symbolic structures. Third, neurons communicate via "messages" that encode only a few bits of information. Hence, a neuron's output cannot be expected to encode complex structures.

A specific limitation of neurally plausible systems is that they have difficulty representing composite structures in a dynamic fashion (see COMPOSITIONALITY IN NEURAL SYSTEMS). Consider the representation of the event, *John gave Mary a book*. This event cannot be represented dynamically by activating the conceptual roles *giver, recipient*, and *given-object* and the entities *John, Mary*, and *a book*. Such a representation would be indistinguishable from that of *Mary gave John a book*. The problem is that an unambiguous representation of an event requires the representation of *bindings* between the roles of an event (e.g., *giver*) and the entities that fill these roles in the event (e.g., John). It is easy to represent long-term bindings using dedicated "binder" nodes (such a binder node can be viewed as a conjunction of a bound role and filler pair). But whereas it is feasible to use binder nodes for encoding long-term knowledge, it is implausible to assume that binder nodes can be recruited for representing numerous dynamic bindings arising rapidly during language understanding and visual processing. Binding techniques based on von Neumann architecture cannot be used, since the storage capacity of nodes and the resolution of their outputs are insufficient for storage and communication of names and pointers.

### *Scalability in Time and Space*

We can visually recognize commonplace items in about 100 ms, and we can understand language at the rate of several hundred words per minute, even though doing so involves perceptual processing and the integration of syntactic, semantic, contextual, and pragmatic knowledge. This indicates that the brain can perform a wide range of complex visual, linguistic, and inferential tasks within a few hundred milliseconds. This observation provides a powerful constraint that can inform our search for cognitive models (Feldman and Ballard, 1982; Shastri and Ajjanagadde, 1993).

Although the number of neurons in the brain is large, it is not too large, given the types of problems it must solve. Consider vision. The retinal output consists of a million signals, and hence the "size" of the input processed by the visual system is about a million. Consequently, any model of vision whose node requirement is quadratic (or higher) in the number of inputs cannot be neurally plausible. A similar argument can be made for commonsense reasoning, which occurs with respect to a very large knowledge base.

## Examples of Structured Connectionist Models

### *Early Work*

An early structured connectionist model was the interactive activation model for letter perception proposed by McClelland and Rumelhart (1981). The model consisted of three layers of nodes corresponding to visual letter features, letters, and words. Nodes representing mutually exclusive hypotheses within the letter and word layers inhibited each other. For example, all nodes representing letters in the same position inhibited each other. A node in the feature layer was connected via excitatory connections to nodes in the letter layer representing letters containing that feature. Similarly, a node in the letter layer was connected via excitatory connections to nodes in the word layer representing words containing that letter in the appropriate position. Additionally, there were reciprocal connections from the word layer to the letter layer. The interconnection pattern allowed bottom-up perceptual processing to be guided by top-down expectations. The model could explain a number of psychological findings about the preference of words and pronounceable nonwords over other nonwords and isolated letters.

Other examples of early structured connectionist models were word sense disambiguation models developed by Cottrell and Small (1983) and Waltz and Pollack (1985). Most words have multiple senses, but we are able to exploit contextual and syntactic information to rapidly disambiguate their meanings. These models demonstrated how such disambiguation might occur. Cottrell and Small's model consisted of a three-level network consisting of the word level, the word sense level, and the case level. There were inhibitory links between mutually exclusive senses of a word. A node at the lexical level was connected via excitatory links to all its senses at the word sense level. Connections between the word sense level and the case level expressed all feasible bindings between case roles and objects. As a sentence was input by activating the appropriate lexical items in a sequence, the combination of lexical items, word senses, and case assignments that best fit the input formed a stable coalition.

Another example of an early structured connectionist model was Shastri's (1988) connectionist semantic network (CSN) model. CSN viewed semantic memory (see SEMANTIC NETWORKS) as concepts organized in an IS-A hierarchy (e.g., "Bird IS-A Animal"). Moreover, each concept was assumed to be a collection of property-value pairs. The property-value information consisted of distributional information, such as how many apples are red, green, and yellow, respectively. CSN could infer the most likely value of a specified property for any concept. Furthermore, given a partial description of a concept, CSN could find the concept that best matched the description. CSN found answers by combining available distributional information using the principle of maximum entropy. CSN could deal with partial, exceptional, and conflicting information and disambiguate "multiple inheritance" situations that could not be handled by extant AI models. CSN encoded concepts, properties, and values using focal nodes and IS-A relations as links. Property values were attached to concepts via binder nodes, with link weights capturing distributional information.

### *Solution to the Binding Problem*

A crucial limitation of the structured connectionist models mentioned above was that they could not express dynamic bindings. For example, the McClelland and Rumelhart model could not dynamically bind a letter to a position in a word and required an *n*-fold repetition of letter and feature layers to deal with words of length *n*. Subsequent structured connectionist models have made significant progress in solving the binding problem. These models include CONPOSIT (see Barnden and Srinivas in Barnden and Pollack, 1991), ROBIN (see Dyer in Barnden and Pollack, 1991), SHRUTI (Shastri and Ajjanagadde, 1993), CONSYDERR (Sun, 1992), and LISA (Hummel and Holyoak, 1997). ROBIN and CONSYDERR assign a unique pattern of activity (i.e., a signature) to each concept and propagate signatures to establish bindings. CONPOSIT creates bindings by virtue of the relative position of active nodes and the similarity of patterns. In contrast, SHRUTI and LISA use synchronous firing of nodes to represent and propagate dynamic bindings.

The possible role of synchronous activity in neural representations and feature binding had been suggested by several researchers (see DYNAMIC LINK ARCHITECTURE; SYNCHRONIZATION, BINDING AND EXPECTANCY; SYNFIRE CHAINS; SPIKING NEURONS, COMPUTATION WITH), but SHRUTI was the first model to offer a detailed computational account of how such activity could be harnessed to solve problems in the representation and processing of high-level conceptual knowledge and to support inference.

SHRUTI can encode a large body of semantic and causal knowledge, and yet perform inferences required to establish referential and causal coherence within several hundred milliseconds (Shastri and Ajjanagadde, 1993). For example, given the story fragment "John fell in the hallway. Tom had cleaned it," SHRUTI can rapidly infer that *it* refers to the hallway, the hallway floor was wet because Tom had cleaned it, and John probably fell because he slipped on the wet floor.

SHRUTI encodes relational knowledge (e.g., event frames and action schemas) using neural circuits composed of focal clusters. The focal cluster of a relation $P$ consists of a node $+:P$ whose activity indicates that the system is making an assertion about an instance of $P$, a node $?:P$ whose activity indicates that the system is seeking an explanation about an instance of $P$, and role nodes, one for each role associated with $P$. A dynamic binding between a role and an entity filling that role in a given situation is represented by the synchronous firing of the role and entity nodes. For example, the event "John fell in the hallway" is represented by a *rhythmic* pattern of activity wherein the node $+$:*fall* fires, the node $+$:*John* fires in synchrony with the role node *fall-patient*, and the node $+$:*hallway* fires in synchrony with the role node *fall-location*. A systematic mapping between relations (and other rule-like knowledge) is encoded by high-efficacy links between focal clusters. For example, the knowledge "falling can lead to getting hurt" is encoded by directed links from $+$:*fall* to $+$:*hurt* and ?:*hurt* to ?:*fall*, and by two-way links between *fall-patient* and *hurt-patient* and between *fall-location* and *hurt-location*. Given the above connectivity, the state of activation encoding "John fell in the hallway" evolves so that the role *hurt-patient* starts firing in synchrony with the role *fall-patient* (and hence, with $+$:*John*), and the role *hurt-location* starts firing in synchrony with the role *fall-location* (and hence, with $+$:*hallway*). The resulting firing pattern represents not only the event "John fell in the hallway," but also the *inferred* event "John got hurt in the hallway." Thus SHRUTI is able to infer that John got hurt in the hallway, given that John fell in the hallway.

As illustrated by this simple example, inference in SHRUTI results from the propagation of rhythmic activity across interconnected focal clusters. In general, SHRUTI combines predictive inferences with explanatory (or abductive) inferences, exhibits priming, instantiates new entities during inference (if John ran, there must be a path along which he ran), and unifies multiple entities by merging their phases of firing (if John got hurt and if there is a man who got hurt, then the man is likely to be John). These features of SHRUTI allow it to rapidly draw a wide range of inferences within a few hundred milliseconds. The time taken to generate an inference is simply $l * \alpha$, where $l$ is the length of the chain of inference and $\alpha$ is the time required for connected nodes to synchronize.

The use of temporal synchrony for encoding dynamic bindings leads to the prediction that a large number of items may be active at the same time, and a large number of rules may fire simultaneously, provided the number of distinct entities occurring as role fillers in these items remains small (ca. 7). This constraint is motivated by biological considerations; each entity participating in dynamic bindings occupies a distinct phase, and hence the number of distinct entities that can occur as role fillers in dynamic facts cannot exceed $\lfloor \pi_{\max}/\omega \rfloor$. Here $\pi_{\max}$ is the maximum delay between consecutive firings of synchronous cell clusters (about 25 ms, assuming that $\gamma$ band activity underlies the encoding of dynamic bindings), and $\omega$ equals the allowable jitter in synchrony (ca. ±2 ms).

Henderson (1994) has developed an on-line parser for English using a SHRUTI-like architecture. The parser shows that constraints on working memory help explain several properties of human parsing pertaining to long-distance dependencies, garden path effects, and our limited ability to deal with center embedding.

## Learning in Structured Networks

Regier's (1996) model for learning the lexical semantics of spatial terms provides an early example of learning within structured connectionist models. The model observes movies of simple two-dimensional objects moving relative to one another, in which each movie is labeled as an example of some spatial term, and learns the association between the label (word) and the event/relation it describes. The model successfully learned several spatial terms for natural languages. The model includes structured network components that reflect prior constraints about the task as well as the usual hidden layers, and demonstrates how structured connectionist models can incorporate flexible learning ability and at the same time leverage prior structure to achieve tractability.

In addition to incremental learning driven by repeated exposure to training data, structured connectionist models have also made use of one-shot learning using *recruitment* learning (see Feldman, 1982; Shastri, 1988, 2001b; Page, 2000). Recruitment learning can be described as follows. Learning occurs within a partially structured network containing a large number of randomly interconnected nodes. Recruited nodes are nodes that have acquired a distinct "meaning" (or functionality) by virtue of their strong interconnections to other recruited nodes and/or sensorimotor (i.e., input/output) nodes. Nodes that are not yet recruited can be viewed as "free" nodes. Such nodes are connected via weak links to a large number of nodes. Free nodes form a primordial network from which suitably connected nodes may be recruited for representing new items. Consider a novel concept $y$ that can be expressed as a conjunct of existing concepts $x_1$ and $x_2$. This concept can be learned by (1) identifying free nodes that receive links from nodes representing $x_1$ and nodes representing $x_2$ and (2) recruiting one or more such free nodes by strengthening the weights of links incident on these nodes from $x_1$ and $x_2$ nodes. Shastri (2001a) has shown that recruitment learning algorithms can be grounded in the biological phenomena of *long-term potentiation* (LTP) and *long-term depression* (LTD), which involve rapid, long-lasting, and highly specific changes in synaptic strength.

The crucial role of structure in neural systems is highlighted by SMRITI, a computational model of episodic memory formation via corticohippocampal interactions (Shastri, 2001a, 2001b). Episodic memory refers to our ability to remember events in our daily lives. A wide array of neuropsychological and imaging data suggests that the hippocampal system, consisting of the entorhinal cortex, the dentate gyrus, the hippocampus proper, and the subicular complex, serves an essential role in the formation of episodic memories. The hippocampal system is known to have a complex and idiosyncratic architecture, and this raises the following question: Does the idiosyncratic architecture of the hippocampal system reflect the functional requirements of the task it is known to subserve? SMRITI suggests that the answer to this question is yes.

Several models have been proposed to explain how the hippocampal system supports episodic memory function, but several key representational problems associated with the encoding of episodic memory remain unsolved. In particular, most existing models view an item in episodic memory as a feature vector or a conjunction of features. But as discussed in Shastri (2001b), a functionally adequate memory trace of an event must be capable of viewing an event as a collection of bindings. Furthermore, the memory trace of an event should be responsive to partial cues, and at the same time, it should be capable of distinguishing between the memorized event and other highly similar events. These requirements suggest that an event's memory trace should be a complex circuit incorporating functional units that serve as binding detectors, binding-error detectors, binding-error integrators, relational-match indicators, and binding reinstators.

SMRITI demonstrates that the idiosyncratic architecture and local circuitry of the hippocampal system is ideally suited for the recruitment of the functional units enumerated above. Specifically, it shows that the propagation of rhythmic activity representing an event can automatically lead to the rapid recruitment of a functionally adequate memory trace within the hippocampal system as a result of LTP. The fine-grained mapping between form and function provided by SMRITI offers the potential for detailed modeling of memory function in normal and patient populations.

## Advantages of Structured Connectionism

The structured connectionist approach promotes the development of network models containing different types of nodes, involving different forms of learning, and incorporating anatomical and physiological constraints—although at an abstract computational level. This has led to the development of sophisticated and large-scale models of cognitive function such as memory, reasoning, and language understanding. The representational and expressive power of these models usually exceeds that of parallel distributed networks developed for modeling similar cognitive phenomena. Moreover, instead of viewing networks as black boxes that serve as function approximators for modeling highly circumscribed data sets, the structured connectionist approach attempts to develop networks that model broadly defined cognitive functions (e.g., episodic memory). Finally, the structured connectionist approach explicates the correspondence between structure and function, and this can lead to a better understanding of the neural basis of cognition.

## Discussion

Structured connectionism offers a rich framework for developing models of cognition guided by biological, behavioral, and computational constraints. The approach has been productive and has resulted in a number of models informed by insights from such diverse disciplines as computer science, AI, psychology, linguistics, and neuroscience. With some difficult representational problems resolved, the focus of work is shifting toward the study of structured adaptive networks that are grounded in perception and action (Feldman and Bailey, 2000; see Schema Theory) and tightly constrained by biology (Shastri, 2001b).

# Support Vector Machines

*Bernhard Schölkopf and Alexander J. Smola*

## Introduction

One of the fundamental problems of learning theory is the following: suppose we are given two classes of objects. We are then faced with a new object, and we have to assign it to one of the two classes. This problem, referred to as (*binary*) *pattern recognition*, can be formalized as follows: we are given empirical data

$$(x_1, y_1), \ldots, (x_m, y_m) \in \mathscr{X} \times \{\pm 1\} \tag{1}$$

and we want to estimate a *decision function* $f: \mathscr{X} \to \{\pm 1\}$. Here, $\mathscr{X}$ is some nonempty set from which the *patterns* $x_i$ are taken, usually referred to as the *domain*; the $y_i$ are called *labels* or *targets*.

A good decision function will have the property that it *generalizes* to unseen data points, achieving a small value of the *risk*

$$R[f] = \int \tfrac{1}{2}|f(x) - y| \, dP(x, y) \tag{2}$$

In other words, on average over an unknown distribution P which is assumed to generate both training and test data, we would like to have a small error. Here, the error is measured by means of the *zero-one loss function* $c(x, y, f(x)) := (\tfrac{1}{2})|f(x) - y|$. The loss is 0 if $(x, y)$ is classified correctly, and 1 otherwise.

It should be emphasized that so far, the patterns could be just about anything, and we have made no assumptions on $\mathscr{X}$ other than it being a set endowed with a probability measure P (note that the labels $y$ may, but need not, depend on $x$ in a deterministic fashion). Moreover, Equation 2 does not tell us how to *find* a function with a small risk. In fact, it does not even tell us how to *evaluate* the risk of a given function, since the probability measure P is assumed to be unknown.

We therefore introduce an additional type of structure, pertaining to what we are actually given—the training data. Loosely speaking, to generalize, we want to choose $y$ such that $(x, y)$ is in some sense similar to the training examples (Equation 1). To this end, we need notions of *similarity* in $\mathcal{X}$ and in $\{\pm 1\}$.

Characterizing the similarity of the outputs $\{\pm 1\}$ is easy. In binary classification, only two situations can occur: two labels can be either identical or different. The choice of the similarity measure for the inputs, on the other hand, is a deep question that lies at the core of the problem of machine learning.

One of the advantages of kernel methods is that the learning algorithms developed are quite independent of the choice of the similarity measure. This allows us to adapt the latter to the specific problems at hand without the need to reformulate the learning algorithm itself.

## Kernels as Similarity Measures

Let us consider a symmetric similarity measure of the form

$$\begin{aligned} k : \mathcal{X} \times \mathcal{X} &\to \mathbb{R} \\ (x, x') &\mapsto k(x, x') \end{aligned} \tag{3}$$

that is, a function that, given two patterns $x$ and $x'$, returns a real number characterizing their similarity. The function $k$ is often called a *kernel.*

General similarity measures of this form are rather difficult to study. Let us therefore start from a particularly simple case and generalize it subsequently. A simple type of similarity measure that is of particular mathematical appeal is a *dot product.* For instance, given two vectors $\mathbf{x}, \mathbf{x}' \in \mathbb{R}^N$, the *canonical dot product* is defined as

$$\langle \mathbf{x}, \mathbf{x}' \rangle := \sum_{i=1}^{N} [\mathbf{x}]_i [\mathbf{x}']_i \tag{4}$$

Here, $[\mathbf{x}]_i$ denotes the $i$th entry of $\mathbf{x}$.

The geometric interpretation of the canonical dot product is that it computes the cosine of the angle between the vectors $\mathbf{x}$ and $\mathbf{x}'$, provided they are normalized to length 1. Moreover, it allows computation of the *length* (or *norm*) of a vector $\mathbf{x}$ as

$$\|\mathbf{x}\| = \sqrt{\langle \mathbf{x}, \mathbf{x} \rangle} \tag{5}$$

Being able to compute dot products amounts to being able to carry out all geometric constructions that can be formulated in terms of angles, lengths, and distances.

Note, however, that the dot product approach is not really sufficiently general to deal with many interesting problems.

- First, we have deliberately not made the assumption that the patterns actually exist in a dot product space. So far, they could be any kind of object. In order to be able to use a dot product as a similarity measure, we therefore first need to represent the patterns as vectors in some dot product space $\mathcal{H}$, called the *feature space.* To this end, we use a map

$$\begin{aligned} \Phi : ;\mathcal{X} &\to \mathcal{H} \\ x &\mapsto \mathbf{x} := \Phi(x) \end{aligned} \tag{6}$$

  Note that we use a boldface $\mathbf{x}$ to denote the vectorial representation of $x$ in the feature space.
- Second, even if the original patterns lie in a dot product space, we may still want to consider more general similarity measures obtained by applying a nonlinear map (Equation 6). An example that we will consider below is a map that computes products of entries of the input patterns.

Embedding the data into $\mathcal{H}$ via $\Phi$ has two main benefits. First, it allows us to deal with the patterns geometrically, and thus lets us study learning algorithms using linear algebra and analytic geometry. Second, it lets us define a similarity measure from the dot product in $\mathcal{H}$,

$$k(x, x') := \langle \mathbf{x}, \mathbf{x}' \rangle = \langle \Phi(x), \Phi(x') \rangle \tag{7}$$

The freedom to choose the mapping $\Phi$ enables us to design a large variety of similarity measures and learning algorithms.

## A Simple Pattern Recognition Algorithm

We now design a simple pattern recognizer. We make use of the structure introduced in the previous section; that is, we assume that our data are embedded in a dot product space $\mathcal{H}$. The basic idea of the algorithm is to assign a previously unseen pattern to the class with closer mean. We thus begin by computing the means of the two classes in feature space:

$$\mathbf{c}_+ = \frac{1}{m_+} \sum_{\{i \mid y_i = +1\}} \mathbf{x}_i \tag{8}$$

$$\mathbf{c}_- = \frac{1}{m_-} \sum_{\{i \mid y_i = -1\}} \mathbf{x}_i \tag{9}$$

where $m_+$ and $m_-$ are the number of examples with positive and negative labels, respectively, with $m_+, m_- > 0$. We assign a new point $\mathbf{x}$ to the class whose mean is closest (Figure 1). This geometric construction can be formulated in terms of the dot product $\langle \cdot, \cdot \rangle$, leading to

$$\begin{aligned} y &= \operatorname{sgn} \langle (\mathbf{x} - \mathbf{c}), \mathbf{w} \rangle \\ &= \operatorname{sgn} \langle (\mathbf{x} - (\mathbf{c}_+ + \mathbf{c}_-)/2), (\mathbf{c}_+ - \mathbf{c}_-) \rangle \\ &= \operatorname{sgn} (\langle \mathbf{x}, \mathbf{c}_+ \rangle - \langle \mathbf{x}, \mathbf{c}_- \rangle + b) \end{aligned} \tag{10}$$

Here, we have defined the offset

$$b := \tfrac{1}{2} (\|\mathbf{c}_-\|^2 - \|\mathbf{c}_+\|^2) \tag{11}$$

which vanishes if the class means have the same distance to the origin.

It is instructive to rewrite Equation 10 in terms of the input patterns $x_i$, using the kernel $k$ to compute the dot products. To this

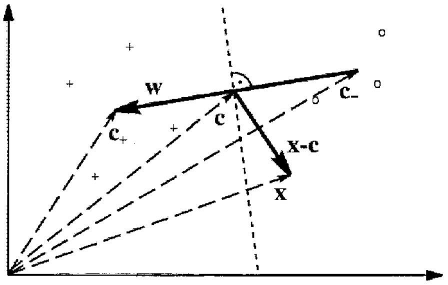

**Figure 1.** A simple geometric classification algorithm: given two classes of points (depicted by o and +), compute their means $\mathbf{c}_+$, $\mathbf{c}_-$ and assign a test pattern $\mathbf{x}$ to the one whose mean is closer. This can be done by looking at the dot product between $\mathbf{x} - \mathbf{c}$ (where $\mathbf{c} = (\mathbf{c}_+ + \mathbf{c}_-)/2$) and $\mathbf{w} := \mathbf{c}_+ - \mathbf{c}_-$, which changes sign as the enclosed angle passes through $\pi/2$ (From Schölkopf, B., and Smola, A. J., 2002, *Learning with Kernels*, Cambridge, MA: MIT Press. Reprinted with permission.)

end, substitute Equations 8 and 9 into Equation 10 to get the *decision function*

$$\begin{aligned} y &= \operatorname{sgn}\left(\frac{1}{m_+}\sum_{\{i|y_i=+1\}}\langle \mathbf{x}, \mathbf{x}_i\rangle - \frac{1}{m_-}\sum_{\{i|y_i=-1\}}\langle \mathbf{x}, \mathbf{x}_i\rangle + b\right) \\ &= \operatorname{sgn}\left(\frac{1}{m_+}\sum_{\{i|y_i=+1\}}k(x, x_i) - \frac{1}{m_-}\sum_{\{i|y_i=-1\}}k(x, x_i) + b\right) \end{aligned} \tag{12}$$

Similarly, the offset can be expressed in terms of the kernel. Surprisingly, it turns out that this rather simple-minded approach contains a well-known statistical classification method as a special case. Assume that the class means have the same distance to the origin (hence $b = 0$, cf. Equation 11), and that $k$ can be viewed as a probability density when one of its arguments is fixed.

In this case, Equation 12 takes the form of the so-called Bayes classifier separating the two classes, subject to the assumption that the two classes of patterns were generated by sampling from two probability distributions that are correctly estimated by the *Parzen windows* estimators of the two class densities,

$$p_+(x) := \frac{1}{m_+}\sum_{\{i|y_i=+1\}} k(x, x_i)$$

and (13)

$$p_-(x) := \frac{1}{m_-}\sum_{\{i|y_i=-1\}} k(x, x_i)$$

where $x \in \mathscr{X}$.

The classifier in Equation 12 is quite close to support vector machines (SVMs). In both cases, the decision function is a kernel expansion corresponding to a separating hyperplane in a feature space.

SVMs deviate from Equation 12 in the selection of the patterns on which the kernels are centered and in the choice of weights that are placed on the individual kernels in the decision function. It will no longer be the case that *all* training patterns appear in the kernel expansion, and the weights of the kernels in the expansion will no longer be uniform within the classes.

## Examples of Kernels

So far, we have used the kernel notation as an abstract similarity measure. We now give some concrete examples of kernels, mainly for the case where the inputs $x_i$ are already taken from a dot product space. The role of the kernel then is to implicitly change the representation of the data into another (usually higher-dimensional) feature space. One of the most common kernels used is the polynomial one,

$$k(x, x') = \langle x, x'\rangle^d, \quad \text{where } d \in \mathbb{N} \tag{14}$$

It can be shown to correspond to a feature space spanned by *all* products of order $d$ of input variables, i.e., all products of the form $[x]_{i_1} \cdot \ \ldots \cdot [x]_{i_d}$. The dimension of this space is of the order $N^d$, but, using the kernel to evaluate dot products, this does not affect us. Another popular choice is the Gaussian

$$k(x, x') = \exp\left(-\frac{\|x - x'\|^2}{2\sigma^2}\right) \tag{15}$$

with a suitable width $\sigma > 0$. Likewise the function

$$k(x, x') = \mathbf{E}[f(x)f(x')] = \int f(x)f(x')d\mathrm{P}(x, x') \tag{16}$$

is a kernel. Such functions are typically used in Gaussian process estimation (see Williams, 1998, for further details). Examples of more sophisticated kernels, defined not on dot product spaces but on discrete objects such as strings, are the string matching kernels proposed by Watkins (2000) and Haussler (1999).

In general, there are several ways of deciding whether a given function $k$ qualifies as a valid kernel. One way is to appeal to *Mercer's theorem.* This classical result of functional analysis states that the kernel of a positive definite integral operator can be diagonalized in terms of an eigenvector expansion with nonnegative eigenvalues. From the expansion, the feature map $\Phi$ can explicitly be constructed. Another approach exploits the fact that the class of admissible kernels coincides with the class of *positive definite* kernels, i.e., functions $k$ such that $\Sigma_{ij}a_ia_jk(x_i, x_j) \geq 0$ for all $a_i$, $x_i(i = 1, \ldots, m)$. For positive definite kernels, the feature space can be constructed as the associated *reproducing kernel Hilbert space*.

## Hyperplane Classifiers

Statistical learning theory, or Vapnik-Chervonenkis (VC) theory, shows that it is imperative to restrict the set of functions from which $f$ is chosen to one that has a *capacity* suitable for the amount of available training data. VC theory provides *bounds* on the test error, depending on both the empirical risk and the capacity of the function class. The minimization of these bounds leads to the principle of *structural risk minimization* (Vapnik, 1995).

SVMs can be considered an approximate implementation of this principle, by trying to minimize a combination of the *training error* (or *empirical risk*),

$$R_{\text{emp}}[f] = \frac{1}{m}\sum_{i=1}^{m} \tfrac{1}{2}\, |f(x_i) - y_i| \tag{17}$$

and a capacity term derived for the class of hyperplanes in a dot product space $\mathscr{H}$ (Vapnik, 1995),

$$\langle \mathbf{w}, \mathbf{x}\rangle + b = 0 \text{ where } \mathbf{w} \in \mathscr{H}, b \in \mathbb{R} \tag{18}$$

corresponding to decision functions

$$f(\mathbf{x}) = \operatorname{sgn}\,(\langle \mathbf{w}, \mathbf{x}\rangle + b) \tag{19}$$

Consider first problems that are separable by hyperplanes. Among all hyperplanes separating the data, there exists a unique *optimal hyperplane* (Vapnik, 1995), distinguished by the maximum margin of separation between any training point and the hyperplane. It is the solution of

$$\underset{\mathbf{w}\in\mathscr{H}, b\in\mathbb{R}}{\text{maximize}} \min \{\|\mathbf{x} - \mathbf{x}_i\| | \mathbf{x} \in \mathscr{H}, \langle \mathbf{w}, \mathbf{x}\rangle + b = 0, i = 1, \ldots, m\} \tag{20}$$

Moreover, the capacity of the class of separating hyperplanes can be shown to decrease with increasing margin. The latter is the basis of the *statistical* justification of the approach; in addition, it is *computationally* attractive, since we will show below that it can be constructed by solving a quadratic programming problem for which efficient algorithms exist.

Note that although the form of the decision function (Equation 19) is similar to our earlier example (Equation 10), the training is different. In the earlier example, the normal vector of the hyperplane was trivially computed from the class means as $\mathbf{w} = \mathbf{c}_+ - \mathbf{c}_-$. In the present case, we need to do some additional work. To construct the optimal hyperplane, we have to solve

$$\underset{\mathbf{w}\in\mathscr{H}, b\in\mathbb{R}}{\text{minimize}}\ \tau(\mathbf{w}) = \tfrac{1}{2}\, \|\mathbf{w}\|^2 \tag{21}$$

$$\text{subject to } y_i(\langle \mathbf{w}, \mathbf{x}_i\rangle + b) \geq 1 \text{ for all } i = 1, \ldots, m \tag{22}$$

Note that the constraints in Equation 22 ensure that $f(\mathbf{x}_i)$ will be $+1$ for $y_i = +1$, and $-1$ for $y_i = -1$. Now, one might argue that for this to be the case, we don't actually need the "$\geq 1$" on the right-hand side of Equation 22. However, without it, it would not be meaningful to minimize the length of **w**: to see this, imagine we wrote ">0" instead of "≥1." Now assume that the solution is (**w**, $b$). Let us rescale this solution by multiplication with some $0 < \lambda < 1$. Since $\lambda > 0$, the constraints are still satisfied. Since $\lambda < 1$, however, the length of **w** has decreased. Hence (**w**, $b$) cannot be the minimizer of $\tau(\mathbf{w})$.

Let us now try to get an intuition for why we should be minimizing the length of **w**, as in Equation 21. If $\|\mathbf{w}\|$ were 1, then the left-hand side of Equation 22 would equal the distance from $\mathbf{x}_i$ to the hyperplane (cf. Equation 20). In general, we have to divide $y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b)$ by $\|\mathbf{w}\|$ to transform it into this distance. Hence, if we can satisfy Equation 22 for all $i = 1, \ldots, m$ with a **w** of minimal length, then the overall margin will be maximized (Figure 2).

The constrained optimization problem (Equation 21) is dealt with by introducing *Lagrange multipliers* $\alpha_i \geq 0$ and a *Lagrangian*

$$L(\mathbf{w}, b, \boldsymbol{\alpha}) = \tfrac{1}{2} \|\mathbf{w}\|^2 - \sum_{i=1}^{m} \alpha_i (y_i(\langle \mathbf{x}_i, \mathbf{w} \rangle + b) - 1) \quad (23)$$

We use boldface Greek letters as a shorthand for corresponding vectors $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_m)$. The Lagrangian $L$ has a *saddle point* in **w**, $b$ and $\boldsymbol{\alpha}$ at the optimal solution of the primal optimization problem. This means that it should be minimized with respect to the *primal variables* **w** and $b$ and maximized with respect to the *dual variables* $\alpha_i$. Note that the constraints appear in the second term of the Lagrangian.

Let us try to get some intuition for this way of dealing with constrained optimization problems. If a constraint (Equation 22) is violated, then $y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) - 1 < 0$, in which case $L$ can be increased by increasing the corresponding $\alpha_i$. At the same time, **w** and $b$ will have to change such that $L$ decreases. To prevent $\alpha_i(y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) - 1)$ from becoming an arbitrarily large negative number, the change in **w** and $b$ will ensure that, provided the problem is separable, the constraint will eventually be satisfied. Similarly, one can understand that for all constraints that are not precisely met as equalities (that is, for which $y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) - 1 > 0$), the corresponding $\alpha_i$ must be 0: this is the value of $\alpha_i$ that maximizes $L$. The latter is the statement of the *Karush-Kuhn-Tucker (KKT) complementarity conditions* of optimization theory.

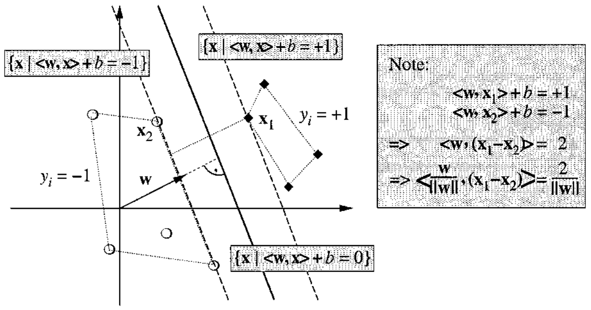

**Figure 2.** A binary classification toy problem: separate balls from diamonds. The *optimal hyperplane* (Equation 20) is shown as a solid line. The problem being separable, there exists a weight vector **w** and a threshold $b$ such that $y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) > 0$ ($i = 1, \ldots, m$). Rescaling **w** and $b$ such that the point(s) closest to the hyperplane satisfy $|\langle \mathbf{w}, \mathbf{x}_i \rangle + b| = 1$, we obtain a *canonical* form (**w**, $b$) of the hyperplane, satisfying $y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) \geq 1$. Note that in this case, the *margin* (the distance of the closest point to the hyperplane) equals $1/\|\mathbf{w}\|$. This can be seen by considering two points $\mathbf{x}_1$, $\mathbf{x}_2$ on opposite sides of the margin, that is, $\langle \mathbf{w}, \mathbf{x}_1 \rangle + b = 1$, $\langle \mathbf{w}, \mathbf{x}_2 \rangle + b = -1$, and projecting them onto the hyperplane normal vector $\mathbf{w}/\|\mathbf{w}\|$. (From Schölkopf, B., and Smola, A. J., 2002, *Learning with Kernels*, Cambridge, MA: MIT Press. Reprinted with permission.)

To minimize with respect to the primal variables, we require

$$\frac{\partial}{\partial b} L(\mathbf{w}, b, \boldsymbol{\alpha}) = 0 \quad \text{and} \quad \frac{\partial}{\partial \mathbf{w}} L(\mathbf{w}, b, \boldsymbol{\alpha}) = 0 \quad (24)$$

leading to

$$\sum_{i=1}^{m} \alpha_i y_i = 0 \quad (25)$$

and

$$\mathbf{w} = \sum_{i=1}^{m} \alpha_i y_i \mathbf{x}_i \quad (26)$$

The solution thus has an expansion (Equation 26) in terms of a subset of the training patterns, namely, those patterns with nonzero $\alpha_i$, called *support vectors* (SVs). Often, only few of the training examples actually end up being SVs. By the KKT conditions,

$$\alpha_i[y_i(\langle \mathbf{x}_i, \mathbf{w} \rangle + b) - 1] = 0 \text{ for all } i = 1, \ldots, m \quad (27)$$

the SVs lie on the margin (see Figure 2), and this can be exploited to compute $b$ once the $\alpha_i$ have been found. All remaining training examples $(\mathbf{x}_j, y_j)$ are irrelevant: their constraint $y_j(\langle \mathbf{w}, \mathbf{x}_j \rangle + b) \geq 1$ (cf. Equation 22) could just as well be left out, and they do not appear in the expansion in Equation 26. This nicely captures our intuition of the problem: as the hyperplane (see Figure 2) is completely determined by the patterns closest to it, the solution should not depend on the other examples.

By substituting Equations 25 and 26 into the Lagrangian Equation 23, one eliminates the primal variables **w** and $b$, arriving at the so-called *dual optimization problem*, which is the problem that one usually solves in practice:

$$\underset{\boldsymbol{\alpha} \in \mathbb{R}^m}{\text{maximize}} \; W(\boldsymbol{\alpha}) = \sum_{i=1}^{m} \alpha_i - \tfrac{1}{2} \sum_{i,j=1}^{m} \alpha_i \alpha_j y_i y_j \langle \mathbf{x}_i, \mathbf{x}_j \rangle \quad (28)$$

subject to

$$\alpha_i \geq 0 \text{ for all } i = 1, \ldots, m \text{ and } \sum_{i=1}^{m} \alpha_i y_i = 0 \quad (29)$$

Using Equation 26, the hyperplane decision function (Equation 19) can thus be written as

$$f(\mathbf{x}) = \operatorname{sgn}\left( \sum_{i=1}^{m} y_i \alpha_i \langle \mathbf{x}, \mathbf{x}_i \rangle + b \right) \quad (30)$$

where $b$ is computed by exploiting Equation 27. For details, see Vapnik (1995), Burges (1998), Cristianini and Shawe-Taylor (2000), Schölkopf and Smola (2002), and Herbrich (2002).

## Support Vector Classification

We now have all the tools to describe SVMs (Figure 3). Everything in the last section was formulated in a dot product space, which we think of as the feature space $\mathcal{H}$ (see Equation 6). To express the formulas in terms of the input patterns in $\mathcal{X}$, we employ Equation 7. This substitution, which is sometimes referred to as the *kernel trick*, was used by Boser, Guyon, and Vapnik (1992) to develop nonlinear SVMs. It can be applied since all feature vectors only occurred in dot products (see Equations 28 and 30). We obtain decision functions of the form (cf. Equation 30)

$$\begin{aligned} f(x) &= \operatorname{sgn}\left( \sum_{i=1}^{m} y_i \alpha_i \langle \Phi(x), \Phi(x_i) \rangle + b \right) \\ &= \operatorname{sgn}\left( \sum_{i=1}^{m} y_i \alpha_i k(x, x_i) + b \right) \end{aligned} \quad (31)$$

and the following quadratic program (cf. Equation 28):

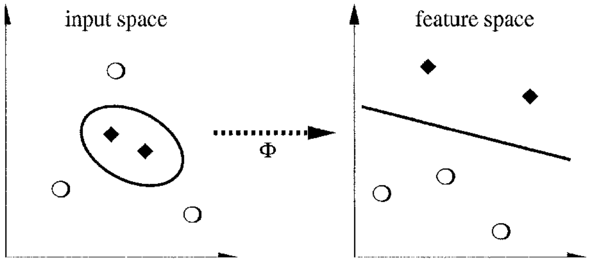

**Figure 3.** The idea of SVMs: map the training data into a higher-dimensional feature space via Φ, and construct a separating hyperplane with maximum margin there. This yields a nonlinear decision boundary in input space. By the use of a kernel (Equation 3), it is possible to compute the separating hyperplane without explicitly carrying out the map into the feature space. (From Schölkopf, B., and Smola, A. J., 2002, *Learning with Kernels*, Cambridge, MA: MIT Press. Reprinted with permission.)

$$\underset{\boldsymbol{\alpha}\in\mathbb{R}^m}{\text{maximize}}\ W(\boldsymbol{\alpha}) = \sum_{i=1}^{m} \alpha_i - ½ \sum_{i,j=1}^{m} \alpha_i\alpha_j y_i y_j k(x_i, x_j) \tag{32}$$

subject to

$$\alpha_i \geq 0 \text{ for all } i = 1, \ldots, m, \text{ and } \sum_{i=1}^{m} \alpha_i y_i = 0 \tag{33}$$

Figure 4 shows a toy example.

In practice, a separating hyperplane may not exist, e.g., if a high noise level causes a large overlap of the classes. To accommodate this case, one introduces slack variables

$$\xi_i \geq 0 \text{ for all } i = 1, \ldots, m \tag{34}$$

in order to relax the constraints of Equation 22 to

$$y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) \geq 1 - \xi_i \text{ for all } i = 1, \ldots, m \tag{35}$$

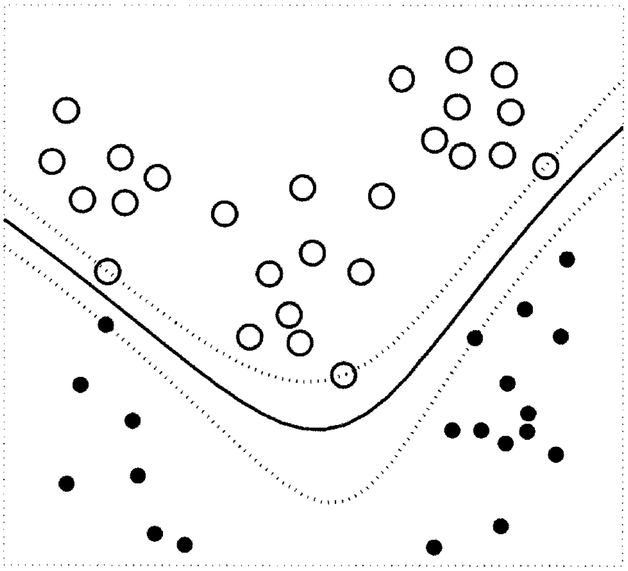

**Figure 4.** Example of an SV classifier found using a radial basis function kernel $k(x, x') = \exp(-\|x - x'\|^2)$. Circles and points are two classes of training examples; the middle line is the decision surface; the outer lines precisely meet the constraint formulated in Equation 22. Note that the SVs found by the algorithm (sitting on the constraint lines) are not centers of clusters but examples that are critical for the given classification task.

A classifier that generalizes well is then found by controlling both the classifier capacity (via $\|\mathbf{w}\|$) and the sum of the slacks $\Sigma_i \xi_i$. The latter can be shown to provide an upper bound on the number of training errors.

One possible realization of such a *soft margin* classifier is obtained by minimizing the objective function

$$\tau(\mathbf{w}, \xi) = ½ \|\mathbf{w}\|^2 + C \sum_{i=1}^{m} \xi_i \tag{36}$$

subject to the constraints in Equations 34 and 35, where the constant $C > 0$ determines the trade-off between margin maximization and training error minimization. This again leads to the problem of maximizing Equation 32, subject to modified constraint where the only difference from the separable case is an upper bound $C$ on the Lagrange multipliers $\alpha_i$.

Another realization uses the more natural $\nu$-parametrization. In it, the parameter $C$ is replaced by a parameter $\nu \in (0, 1)$, which can be shown to provide lower and upper bounds for the fraction of examples that will be SVs and those that will have non-zero slack variables, respectively. Its dual can be shown to consist in maximizing the quadratic part of Equation 32, subject to $0 \leq \alpha_i \leq 1/(\nu m)$, $\Sigma_i \alpha_i y_i = 0$ and the additional constraint $\Sigma_i \alpha_i = 1$.

## Support Vector Regression

Rather than dealing with outputs $y \in \{\pm 1\}$, *regression estimation* is concerned with estimating real-valued functions using $y \in \mathbb{R}$.

To generalize the SV algorithm to the regression case, Vapnik (1995) proposed the *ε-insensitive loss function* (Figure 5),

$$c(x, y, f(x)) := |y - f(\mathbf{x})|_\varepsilon := \max\{0, |y - f(\mathbf{x})| - \varepsilon\} \tag{37}$$

To estimate a linear regression

$$f(\mathbf{x}) = \langle \mathbf{w}, x \rangle + b \tag{38}$$

one minimizes

$$½ \|\mathbf{w}\|^2 + C \sum_{i=1}^{m} |y_i - f(\mathbf{x}_i)|_\varepsilon \tag{39}$$

Here, the term $\|\mathbf{w}\|^2$ is the same as in pattern recognition (cf. Equation 36). We can transform this into a constrained optimization problem by introducing slack variables, akin to the soft margin case.

An analysis similar to the one above leads to the dual (for $C$, $\varepsilon \geq 0$ chosen a priori):

$$\begin{aligned}\underset{\boldsymbol{\alpha},\boldsymbol{\alpha}^*\in\mathbb{R}^m}{\text{maximize}}\ W(\boldsymbol{\alpha}, \boldsymbol{\alpha}^*) = &-\varepsilon \sum_{i=1}^{m} (\alpha_i^* + \alpha_i) + \sum_{i=1}^{m} (\alpha_i^* - \alpha_i) y_i \\ &- ½ \sum_{i,j=1}^{m} (\alpha_i^* - \alpha_i)(\alpha_j^* - \alpha_j) k(x_i, x_j)\end{aligned} \tag{40}$$

subject to

$$0 \leq \alpha_i, \alpha_i^* \leq C \text{ for all } i = 1, \ldots, m, \text{ and } \sum_{i=1}^{m} (\alpha_i - \alpha_i^*) = 0 \tag{41}$$

The regression estimate takes the form

$$f(x) = \sum_{i=1}^{m} (\alpha_i^* - \alpha_i) k(x_i, x) + b, \tag{42}$$

where $\alpha_i^* - \alpha_i$ is zero for all points that lie inside the ε-tube (Figure 5). Note the similarity to the pattern recognition case (cf. Equation 31 and Figure 6).

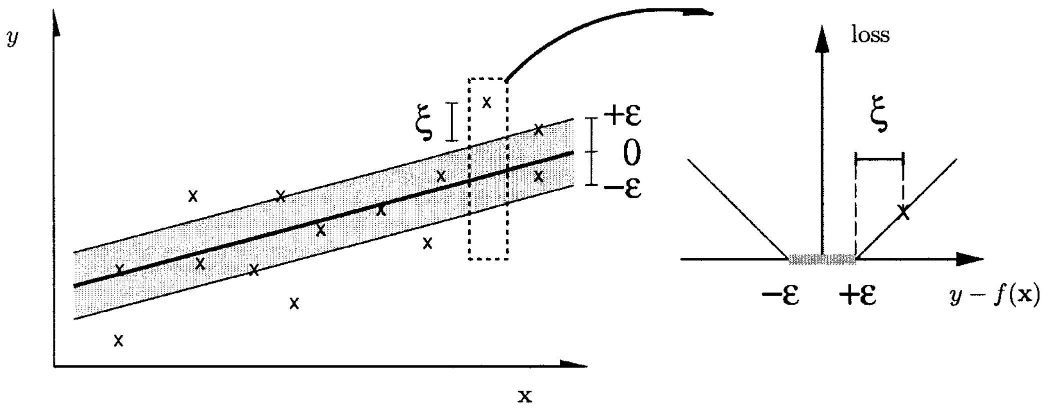

**Figure 5.** In support vector regression, a tube with radius $\varepsilon$ is fitted to the data. The trade-off between model complexity and points lying outside of the tube (with positive slack variables $\zeta$) is determined by minimizing Equation 39. (From Schölkopf, B., and Smola, A. J., 2002, *Learning with Kernels*, Cambridge, MA: MIT Press. Reprinted with permission.):

## Kernel Principal Component Analysis

The kernel trick can be used to develop nonlinear generalizations of any algorithm that can be cast in terms of dot products, such as Principal Component Analysis (PCA) (q.v.).

PCA in feature space leads to an algorithm called *kernel PCA*. It is derived as follows. We wish to find eigenvectors **v** and eigenvalues $\lambda$ of the so-called *covariance matrix* **C** in the feature space, where

$$\mathbf{C} := \frac{1}{m} \sum_{i=1}^{m} \Phi(x_i)\Phi(x_i)^{\top} \tag{43}$$

In the case when $\mathcal{H}$ is very high-dimensional, the computational costs of doing this directly are prohibitive. Fortunately, one can show that all solutions to

$$\mathbf{C}\mathbf{v} = \lambda \mathbf{v} \tag{44}$$

with $\lambda \neq 0$ must lie in the span of $\Phi$-images of the training data. Thus, we may expand the solution **v** as

$$\mathbf{v} = \sum_{i=1}^{m} \alpha_i \Phi(x_i) \tag{45}$$

thereby reducing the problem to that of finding the $\alpha_i$. It turns out that this leads to a dual eigenvalue problem for the expansion coefficients,

$$m\lambda\boldsymbol{\alpha} = K\boldsymbol{\alpha} \tag{46}$$

where $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_m)^{\top}$ is normalized to satisfy $\|\boldsymbol{\alpha}\|^2 = 1/\lambda$.

To extract nonlinear features from a test point $x$, we compute the dot product between $\Phi(x)$ and the $n$th normalized eigenvector in feature space,

$$\langle \mathbf{v}^n, \Phi(x) \rangle = \sum_{i=1}^{m} \alpha_i^n k(x_i, x) \tag{47}$$

A toy example is given in Figure 7. As in the case of SVMs, the architecture can be visualized by Figure 6.

**Figure 6.** Architecture of SVMs and related kernel methods. The input $x$ and the expansion patterns (SVs) $x_i$ (we assume that we are dealing with handwritten digits) are nonlinearly mapped (by $\Phi$) into a feature space $\mathcal{H}$ where dot products are computed. Through the use of the kernel $k$, these two layers are in practice computed in one step. The results are linearly combined using weights $v_i$, found by solving a quadratic program (in pattern recognition, $v_i = y_i\alpha_i$; in regression estimation, $v_i = \alpha_i^* - \alpha_i$) or an eigenvalue problem (kernel PCA). The linear combination is fed into the function $\sigma$ (in pattern recognition, $\sigma(x) = \text{sgn}\,(x + b)$; in regression estimation, $\sigma(x) = x + b$; in kernel PCA, $\sigma(x) = x$). (From Schölkopf, B., and Smola, A. J., 2002, *Learning with Kernels*, Cambridge, MA: MIT Press. Reprinted with permission.)

## Implementation and Empirical Results

An initial weakness of SVMs was that the size of the quadratic programming problem scaled with the number of SVs. This was due to the fact that in Equation 32, the quadratic part contained at least all SVs—the common practice was to extract the SVs by going through the training data in chunks while regularly testing for the possibility that patterns initially not identified as SVs become SVs at a later stage. This procedure is referred to as *chunking*. Note that without chunking, the size of the matrix in the quadratic part of the objective function would be $m \times m$, where $m$ is the number of all training examples.

What happens if we have a high-noise problem? In this case, many of the slack variables $\xi_i$ become non-zero, and all the corresponding examples become SVs. For this case, decomposition algorithms were proposed, based on the observation that not only can we leave out the non-SV examples (the $x_i$ with $\alpha_i = 0$) from the current chunk, but also some of the SVs, especially those that hit the upper boundary ($\alpha_i = C$). The chunks are usually dealt with using quadratic optimizers. Several public domain SV packages and optimizers are listed on the web page http://www.kernel-machines.org.

Modern SVM implementations made it possible to train on some rather large problems. Success stories include the 60,000 example

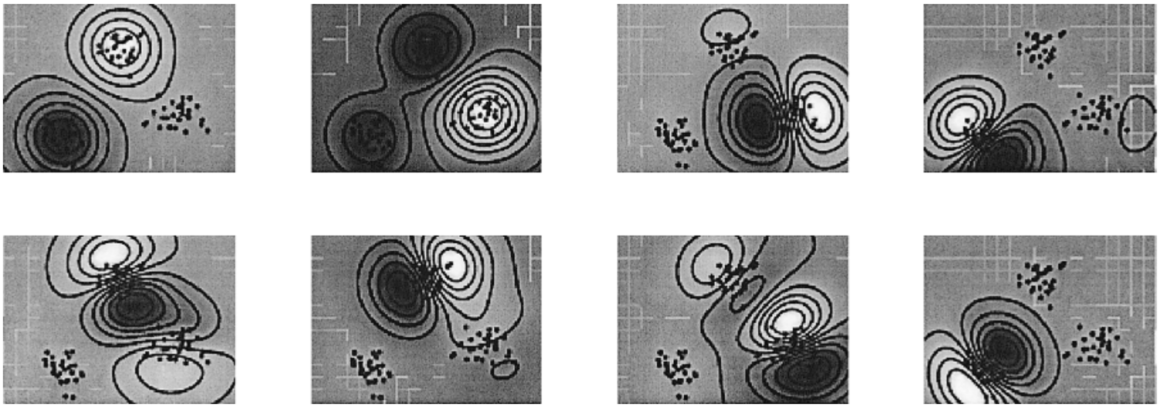

**Figure 7.** Contour plots of the first eight nonlinear features of kernel PCA using a radial basis function kernel on a toy data set consisting of three Gaussian clusters. In the upper left panel, the first and second component's split the data into three clusters. Note that kernel PCA is not deliberately designed to perform clustering; it tries to find a PCA description of the data in feature space by looking for directions of large variance. In input space, this reveals the cluster structure. The following three components depicted split each cluster in halves (components 3–5), while the last three achieve splits to the earlier ones.

MNIST digit recognition benchmark (with record results, see DeCoste and Schölkopf, 2002), as well as problems in text categorization (e.g., Joachims, 1999) and bioinformatics. For overviews of further applications as well as extensions of the approach to problems such as multiclass classification, density estimation, and novelty detection, the interested reader is referred to Burges (1998), Vapnik (1998), Schölkopf, Burges, and Smola (1999), Smola et al. (2000), Cristianini and Shawe-Taylor (2000), and Schölkopf and Smola (2002).

## Discussion

During the last few years, SVMs and other kernel methods have rapidly advanced into the standard toolkit of techniques for machine learning and high-dimensional data analysis. This was probably due to a number of advantages compared to neural networks, such as the absence of spurious local minima in the optimization procedure, the fact that there are only few parameters to tune, enabling fast deployment in applications, the modularity in the design, where various kernels can be combined with a number of different learning algorithms, and the excellent performance on high-dimensional data.

Of particular interest for the cognitive science community are the way in which kernel methods connect similarity measures, nonlinearities, and data representations in linear spaces where simple geometric algorithms are performed. Moreover, it is worthwhile to note that as approaches based on a mathematical analysis of the problem of learning (in the formulation given by Vapnik and Chervonenkis), they are in principle not bound to any particular implementation.

Along with the observation that SV sets contain all the information required to solve a given classification task, this has led to speculation whether they could be related to prototypes believed to be used by the brain for categorization (cf. Poggio, 1990). This question, along with the one of whether SVMs might help explain some aspects of how the brain works, is as yet unanswered.

# Synaptic Interactions

*Alain Destexhe, Zachary F. Mainen, and Terrence J. Sejnowski*

## Introduction

Modeling synaptic interactions in network models poses a particular challenge. Not only should such models capture the important physiological properties of synaptic interactions, but they must do so in a computationally efficient manner in order to facilitate simulations of large networks. This article reviews several types of models that address these goals.

Synaptic currents are mediated by ion channels activated by neurotransmitter released from presynaptic terminals. Kinetic models are expressive enough to describe the behavior of ion channels underlying synaptic currents. Although full representation of the molecular details of the synapse generally requires highly complex kinetic models, we focus here on simpler kinetic models that are more computationally efficient. We show that these models can capture the time course and dynamics of several types of synaptic responses, allowing them to be useful tools for modeling synaptic interactions in large networks.

## Models of Synaptic Currents

For neural models that do not include action potentials, synaptic currents are typically modeled as a direct function of the some presynaptic activity measure. In the simplest case, synaptic interactions are described by a sigmoid function, and presynaptic activity is interpreted as the average firing rate of the afferent neuron. Alternatively, the postsynaptic currents can be described by a first-order differential equation in which one term depends on the presynaptic membrane potential through a sigmoid function. Another possibility is to interpret the activity level as the fraction of neurons active per unit of time, thus representing the interaction between neural populations rather than single neurons (Wilson and Cowan, 1973).

A different approach is needed to model synaptic interactions between spiking neurons. It is usually assumed that a presynaptic spike triggers a conductance waveform postsynaptically. A popular model of postsynaptic conductance increase is the alpha function introduced by Rall (1967):

$$r(t - t_0) = \frac{(t - t_0)}{\tau_1} \exp\left[-(t - t_0)/\tau_1\right] \qquad (1)$$

where $r(t)$ resembles the time course of experimentally recorded postsynaptic potentials (PSPs) with a time constant $\tau_1$. The alpha function and its double-exponential generalization can be used to approximate most synaptic currents with a small number of parameters that require, implemented properly, low computation and memory requirements (Srinivasan and Chiel, 1993). The disadvantages of the alpha function, or related approaches, include the lack of direct biophysical interpretation and the absence of a natural method for handling successive temporally overlapping postsynaptic currents (PSCs) from a train of presynaptic impulses.

A natural way to model synaptic currents is based on the kinetic properties of the underlying synaptic ion channels. The kinetic approach is closely related to the well-known model of Hodgkin and Huxley (1952) for voltage-dependent ion channels (reviewed in Hille, 2001). Kinetic models can describe in great detail the properties of synaptic ion channels and can be integrated coherently with chemical kinetic models for enzymatic cascades underlying signal transduction and neuromodulation (Destexhe, Mainen, and Sejnowski, 1994). In the next section, we show how to model various types of ion channels with the kinetic formalism.

## The Kinetic Description

Ion channels are proteins that have distinct conformational states, some of which are "open" and conduct ionic current, and some of which are "closed," "inactivated," or "desensitized" and do not conduct. Single-channel recording techniques have demonstrated that the transitions between conformational states occurs rapidly and stochastically (reviewed in Sakmann and Neher, 1995). It has furthermore been shown that the behavior of single ion channels is well-described by *Markov models*, in which stochastic transitions between states occur with a time-independent probability.

It is straightforward to move from a microscopic description of single channel behavior to a macroscopic description of a population of similar channels. In the limit of large numbers, the stochastic behavior of individual channels can be described by a set of continuous differential equations analogous to ordinary chemical reaction kinetics. The kinetic analogue of Markov models posits the existence of a group of conformational states $S_1 \ldots S_n$ linked by a set of transitions

$$\begin{tikzcd}
S_1 \arrow[r, shift left] & S_2 \arrow[l, shift left] \arrow[r, shift left] \arrow[d, shift left] & S_4 \arrow[l, shift left] \arrow[r, shift left] \arrow[d, shift left] & \cdots \arrow[l, shift left] \\
& S_3 \arrow[u, shift left] \arrow[r, shift left] & \cdots \arrow[l, shift left] \arrow[u, shift left] &
\end{tikzcd} \qquad (2)$$

Define $s_i$ as the fraction of channels in state $S_i$ and $r_{ij}$ as the rate constant of the transition

$$S_i \underset{r_{ji}}{\overset{r_{ij}}{\rightleftarrows}} S_j \qquad (3)$$

which obeys the kinetic equation

$$\frac{ds_i}{dt} = \sum_{j=1}^{n} s_j r_{ji} - \sum_{j=1}^{n} s_i r_{ij} \qquad (4)$$

The wide range of interesting behavior exhibited by channels arises from the dependence of certain transitions on factors extrinsic to the channel, such as the binding of another molecule to the protein or the electric field across the cell membrane. These influences are referred to as *ligand-gating* and *voltage-gating* respectively.

For voltage-dependent ion channels, the transition between two states $S_i$ and $S_j$ occurs with rate constants that are dependent on voltage, such as

$$S_i \underset{r_{ji}(V)}{\overset{r_{ij}(V)}{\rightleftarrows}} S_j \qquad (5)$$

The functional form of the voltage-dependence can be obtained from single-channel recordings (see Sakmann and Neher, 1995). The kinetics-based description of the voltage-dependence of channels is quite general. In particular, the well-known model of Hodgkin and Huxley (1952) for the fast sodium channel and the delayed-rectifier potassium channel can be written in the form of a Markov model that is equivalent to the original Hodgkin-Huxley equations.

For ligand-gated ion channels, the transition between two states $S_i$ and $S_j$ can depend on the binding of $n$ molecules of a ligand $L$:

$$S_i + nL \underset{r_{ji}}{\overset{r_{ij}}{\rightleftarrows}} S_j \qquad (6)$$

which can be rewritten as

$$S_i + nL \underset{r_{ji}}{\overset{r_{ij}([L])}{\rightleftarrows}} S_j \qquad (7)$$

where $[L]$ is the concentration of ligand and $r_{ij}([L]) = r_{ij}[L]^n$. In this model, there is a simple functional dependence of the rate constants on ligand concentration. For some receptor types, rate constants may also depend on the voltage.

Ligand-gating is typified by *ionotropic synaptic receptors*, which are ion channels that are directly gated by neurotransmitter molecules. By contrast, *metabotropic synaptic receptors* do not have an ion channel and neurotransmitter binding to the receptor induces the formation of an intracellular messenger (calcium or G proteins, for example) that controls the gating of an ion channel independent of the receptor. These two types of synaptic receptors will be considered in the next two sections.

## Kinetic Models of Ionotropic Receptors: AMPA, NMDA, and GABA$_A$

The most common types of ligand-gated synaptic channels are the excitatory AMPA and NMDA types of glutamate receptor and the inhibitory GABA$_A$ receptor. Many kinetic models have been proposed for these receptors (reviewed in Sakmann and Neher, 1995; Destexhe, Mainen, and Sejnowski, 1998). For example, a multistate Markov scheme for AMPA-Kainate receptors (Standley, Ramsey, and Usherwood, 1993) is:

$$D_2 \underset{r_9([L])}{\overset{r_{10}}{\rightleftarrows}} D_1 \underset{r_7([L])}{\overset{r_8}{\rightleftarrows}} C \underset{r_2}{\overset{r_1([L])}{\rightleftarrows}} C_1 \underset{r_4}{\overset{r_3([L])}{\rightleftarrows}} C_2 \underset{r_6}{\overset{r_5}{\rightleftarrows}} O \tag{8}$$

where $C$ is the unbound closed state, $C_1$ and $C_2$ are respectively the singly and doubly bound closed states, $O$ is the open state, and $D_1$ and $D_2$ are respectively the desensitized singly and doubly bound states. $r_1$ through $r_{10}$ are the associated rate constants and $[L]$ is the concentration of neurotransmitter in the synaptic cleft.

The six states of this AMPA model are required to account for the electrophysiological properties of these receptors as determined by single-channel recordings (Standley et al., 1993). However, simplified kinetic schemes with fewer states and transitions can constitute fairly good approximations for the time courses and the dynamic behavior of synaptic currents (Destexhe et al., 1994, 1998). In particular, consider the simplest kinetic schemes involving two states

$$C \underset{r_2}{\overset{r_1([L])}{\rightleftarrows}} O \tag{9}$$

or three states

$$\begin{tikzcd} C \arrow[rr, shift left, "r_1({[L]})"] & & O \arrow[ll, shift left, "r_2"] \arrow[dl, shift left, "r_4"] \\ & D \arrow[ul, shift left, "r_5"] \arrow[ur, shift left, "r_3"] & \end{tikzcd} \tag{10}$$

In these two schemes, $C$ and $O$ represent the closed and open states of the channel, $D$ represents the desensitized state, and $r_1 \ldots r_6$ are the associated rate constants. Not only are these simple schemes easier to compute than more complex schemes, but the time course of the current can be obtained analytically under some approximations (Destexhe et al., 1994).

Another way to simplify the model is suggested by experiments using artificial application of neurotransmitter, where it has been shown that synaptic currents with a time course very similar to that of intact synapses can be produced using very brief pulses of agonist (reviewed in Sakmann and Neher, 1995). These data suggest that the response time course is dominated by the postsynaptic kinetics rather than the time course of the neurotransmitter concentration. Hence, one can assume that the neurotransmitter is delivered as a brief (≈1 ms) pulse triggered at the time of each presynaptic spike.

Simplified kinetic schemes for the AMPA response can be compared to detailed kinetic models to judge the quality of the approximation (Figure 1*A–D*). Both simple and detailed synaptic responses first require a trigger event, corresponding to the release of neurotransmitter in the synaptic cleft. In simulations of the Markov kinetic model, the time course of neurotransmitter was derived using a model that included presynaptic action potentials, calcium-dependent fusion of presynaptic vesicles, and clearance of neurotransmitter. Figure 1*A–C* shows the AMPA response resulting from a high-frequency train of presynaptic spikes. The amplitude of successive PSCs decreased progressively due to an increasing fraction of receptors in desensitized states. A simplified kinetic scheme using transmitter pulses gave a good fit, both to the time course of the AMPA current (shown in Figure 2*A*) and to the response desensitization that occurs during multiple successive events (Figure

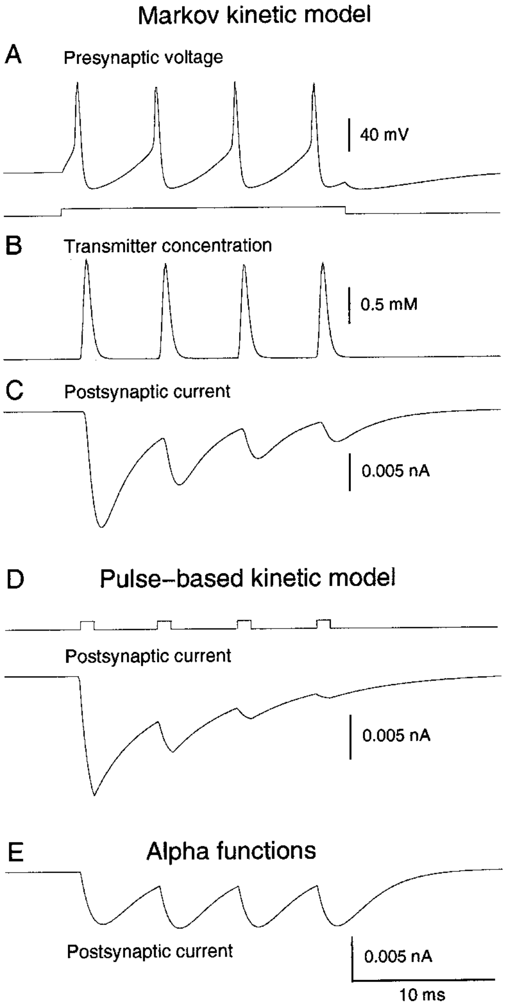

**Figure 1.** Comparison of three models for AMPA receptors. *A–C*, Markov model of AMPA receptors. *A*, Presynaptic train of action potentials elicited by current injection. *B*, Corresponding glutamate release in the synaptic cleft obtained using a kinetic model for transmitter release. *C*, Postsynaptic current from AMPA receptors modeled by a six-state Markov model. *D*, Same simulation with AMPA receptors modeled by a simpler three-state kinetic scheme and transmitter time course approximated by spike-triggered pulses (trace above). *E*, Postsynaptic current modeled by summed alpha functions. (Modified from Destexhe et al., 1994.)

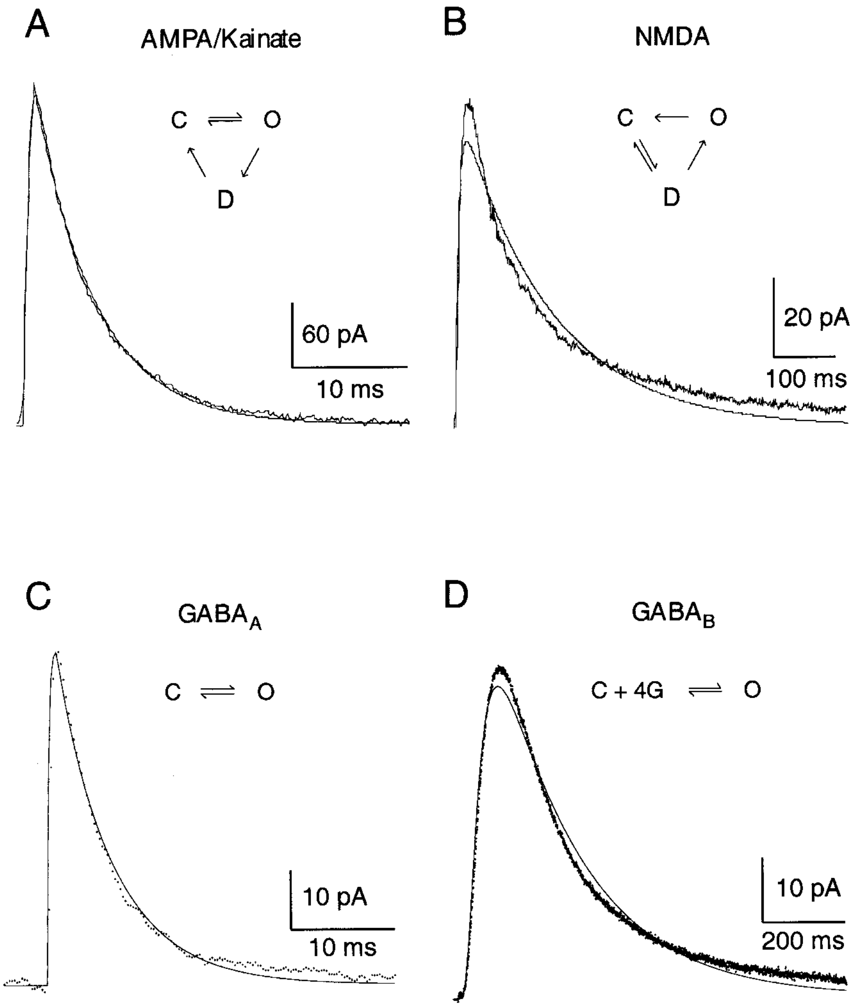

**Figure 2.** Elementary kinetic schemes provide good models of postsynaptic currents. *A*, AMPA-mediated currents (courtesy of Z. Xiang, A. C. Greenwood, and T. Brown). *B*, NMDA-mediated currents (courtesy of N. A. Hessler and R. Malinow). *C*, GABA$_A$-mediated currents (courtesy of T. S. Otis and I. Mody). *D*, GABA$_B$-mediated currents (courtesy of T. S. Otis, Y. Dekoninck, and I. Mody). The averaged recording of the synaptic current (negative currents upwards for *A* and *B*) is shown with the best fit obtained using simple kinetics (continuous trace—1 *ms* pulse of agonist for *A*, *B*, *C*). (*A* modified from Destexhe et al., 1994, *B*–*D*, modified from Destexhe et al., 1998. Values of rate constants and other parameters can be found in Destexhe et al., 1998.)

1*D*). Alpha functions, in contrast, did not match the summation behavior of the synaptic current (Figure 1*E*).

Procedures similar to those applied to the AMPA response can be used to obtain simple kinetic models for other types of ligand-gated synaptic channels, including the NMDA and GABA$_A$ receptors. Two-state and three-state models provide good fits of averaged whole-cell recordings of the corresponding PSCs (Figure 2*B*–*C*; for more details see Destexhe et al., 1994, 1998).

## Kinetic Models of Metabotropic Receptors: GABA$_B$ and Neuromodulation

Some neurotransmitters do not bind directly to the ion channel, but act through an intracellular second messenger, which links the activated receptor to the opening or closing of an ion channel. This type of synaptic interaction, called *neuromodulation*, occurs at a slower time scale than ligand-gated channels. Neuromodulators such as GABA (GABA$_B$), acetylcholine (M2), noradrenaline (alpha-2), serotonin (5HT-1), dopamine (D2), and others gate a K$^+$ channel through the action of G-proteins (reviewed in Brown, 1990). We have developed a kinetic model of the G protein-mediated slow intracellular response mediated by GABA$_B$ receptors (Destexhe and Sejnowski, 1995) that can be applied to any of these transmitters.

Unlike GABA$_A$ receptors which respond to weak stimuli, GABA$_B$ responses require high levels of presynaptic activity (Mody et al., 1994). This property might be due to extrasynaptic localization of GABA$_B$ receptors, but it can also be accounted solely from the kinetics of the G-protein cascade underlying GABA$_B$ responses (Destexhe and Sejnowski, 1995). The high level of activity needed to activate GABA$_B$ responses could be reproduced by the following kinetic scheme:

$$R_0 + T \rightleftarrows R \rightleftarrows D \tag{11}$$

$$R + G_0 \rightleftarrows RG \rightarrow R + G \tag{12}$$

$$G \rightarrow G_0 \tag{13}$$

$$C_1 + nG \rightleftarrows O \tag{14}$$

where the transmitter, *T*, binds to the receptor, $R_0$, leading to its activated form, *R*, and desensitized form, *D*. The G-protein is transformed from an inactive (GDP-bound) form, $G_0$, to an activated form, *G*, catalyzed by *R*. Finally, *G* binds to open the $K^+$ channel, with *n* independent binding sites. A simplified model with very similar behavior can be obtained by assuming quasi-stationarity in Equations 12 and 14, neglecting desensitization, and considering $G_0$ in excess, leading to:

$$\frac{dr}{dt} = K_1[T](1 - r) - K_2 r \tag{15}$$

$$\frac{ds}{dt} = K_3 r - K_4 s \tag{16}$$

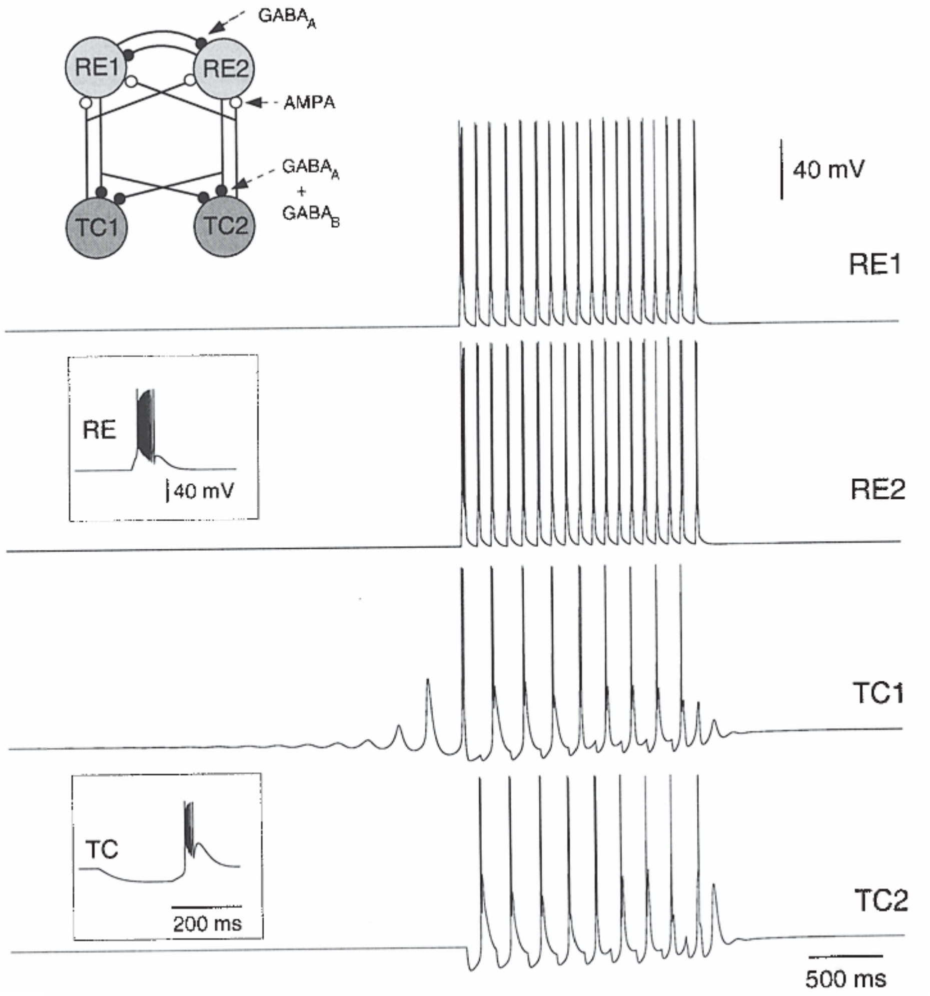

**Figure 3.** Kinetic models of synaptic currents used to simulate a small network of thalamic reticular (RE) and thalamocortical (TC) neurons. These neurones have complex intrinsic firing properties and generate bursts of action potentials following depolarization or hyperpolarization (insets). They are connected with different receptor types (scheme on top: AMPA from TC to RE, GABA$_A$ within RE and a mixture of GABA$_A$ and GABA$_B$ from RE to TC). The simulations exhibit oscillatory behavior in which the exact frequency and cellular phase relationships are dependent on intrinsic calcium- and voltage-dependent currents as well as synaptic currents. Modeling synaptic currents with the correct kinetics was needed to match experimental observations (modified from Destexhe et al., 1996; see also Sleep Oscillations).

where $r$ is the fraction of receptors in the activated form, $g$ is the normalized concentration of activated G-proteins, and $K_1 \ldots K_4$ are rate constants. The fraction of K$^+$ channels in the open form is then given by:

$$[O] = \frac{s^n}{s^n + K_d} \qquad (17)$$

where $K_d$ is the dissociation constant of the binding of $G$ on K$^+$ channels. This computationally efficient model can fit single GABA$_B$ IPSCs (Figure 2$D$) and account for the typical stimulus dependence of GABA$_B$ responses (Destexhe and Sejnowski, 1995; Destexhe et al., 1998). Models have shown that this property has drastic consequences for the genesis of epileptic discharges (reviewed in Destexhe and Sejnowski, 2001).

Other neuromodulators listed previously have a G protein-mediated intracellular response similar to that of GABA$_B$ receptors. Details of the rate constants obtained from fitting different kinetic schemes to GABA$_B$ PSC are given in Destexhe et al. (1998).

## Simulating Networks of Neurons

Simplified kinetic models of synaptic receptors can be used to model complex cellular interactions that depend on the kinetics of synaptic currents. For example, several types of oscillations are generated by thalamic circuits. Thalamic neurons have complex intrinsic firing properties and can generate bursts of action potentials in rebound to inhibition due to low-threshold calcium currents (see insets in Figure 3). Thalamic neurons are also characterized by different types of synaptic receptors, such as AMPA, GABA$_A$ and GABA$_B$ (see scheme in Figure 3). Modeling this system using Hodgkin and Huxley's (1952) type of models for intrinsic currents and simple kinetics models of synaptic currents led to oscillations in the ~10 Hz frequency range (Figure 3). These simulations have been used to explore the cellular mechanisms for the different types of oscillations in these circuits (Destexhe et al., 1996), which depend on the kinetics of intrinsic and synaptic currents. For example, the ~10 Hz frequency depends on the decay of GABA$_A$-mediated currents and the transformation of these oscillations into more synchronized ~3 Hz oscillations depends critically on the activation properties of GABA$_B$ responses (Destexhe et al., 1996).

This example shows that simplified kinetic models consisting of only a few states can capture the essential properties necessary to explain complex cellular interactions. They are useful for investigating network interactions involving multiple types of synaptic receptors. In addition, kinetic models can be used to model both synaptic currents and voltage-dependent currents, providing a single formalism to describe all currents in a neuron (Destexhe et al., 1994). This approach has been used to model different types of oscillations and pathological behavior in networks of the cerebral cortex, the thalamus, and the thalamocortical system (Destexhe and Sejnowski, 2001).

## Summary and Conclusions

Simple and fast mechanisms are needed to model synaptic interactions in biophysically based network simulations involving thousands of synapses. A class of models based directly on the kinetics of the ion channels mediating synaptic responses can be implemented with minimal computational expense. These models capture both the time course of individual synaptic and neuromodulatory events and also the interactions between successive events (summation, saturation, desensitization), which may be critical when investigating the behavior of networks where neurons have complex intrinsic firing properties.

All models shown here were simulated using NEURON (Hines and Carnevale, 1997; see NEURON SIMULATION ENVIRONMENT). Computer generated movies and NEURON programs to simulate these models are available at http://cns.iaf.cnrs-gif.fr and http://www.cnl.salk.edu/~alain/ or on request.

# Synaptic Noise and Chaos in Vertebrate Neurons

*Philippe Faure and Henri Korn*

## Introduction

The membrane potential of central neurons undergoes continuous fluctuations called synaptic noise (SN), which is a mixture of ongoing and overlapping inhibitory and/or excitatory postsynaptic potentials. Synaptic noise depends on both the summed firing of action potentials by neurons presynaptic to the investigated cell and the spontaneous release of transmitter, analogous to that producing miniature end-plate potentials. Classical methods such as interevent interval histograms led to the conclusion that SN is stochastic (see references in Faure and Korn, 2000), and in the absence of further understanding it has generally been modeled as such. However, despite its random appearance, SN may be a true signal associated with neural coding, often believed to involve well-defined firing patterns (Perkel and Bullock, 1968; Fujii et al., 1996) including chaotic ones (Skarda and Freeman, 1990; see also CHAOS IN NEURAL SYSTEMS). Tools derived from nonlinear dynamics can be used to address this issue.

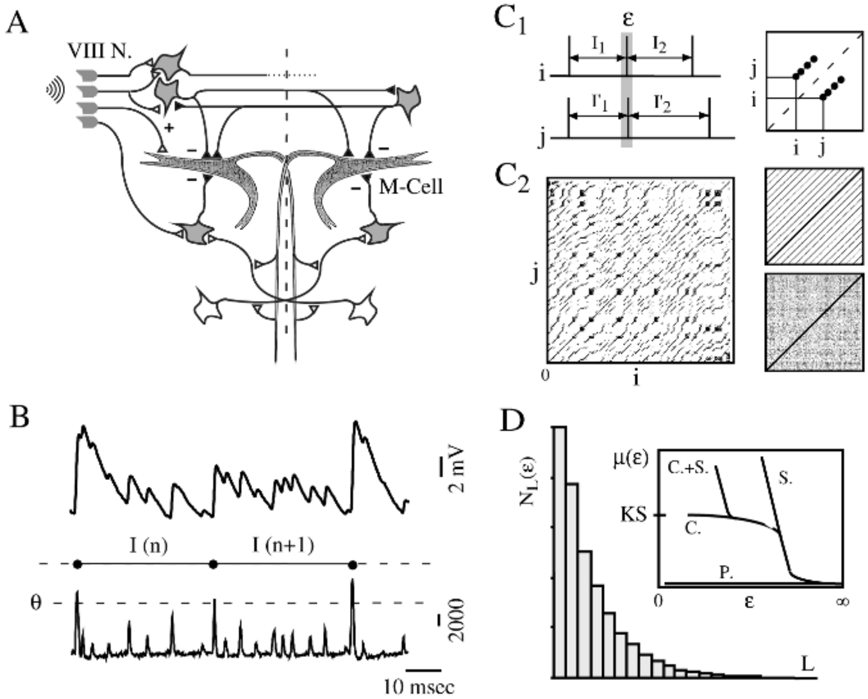
## The Basic Material

Mauthner (M-) cells are a pair of identified neurons in the hindbrain of teleosts. When the animal is subjected to an unexpected stimulus, one of the cells triggers an escape reaction by activating contralateral motor neurons via a complex reticulospinal network (Figure 1*A*). Their excitability is controlled by powerful inhibitory presynaptic interneurons that continuously generate an intense SN consisting of successive inhibitory postsynaptic potentials (IPSPs), which can be recorded with intracellular electrodes (Figure 1*B*, top).

## Analysis of Synaptic Noise with Tools Derived from Nonlinear Dynamics

To eliminate nonlinearities due to the asymmetric waveform of synaptic potentials, reliable time series require SN to be converted into time intervals by differentiating the initial signal (Figure 1*B*, bottom). Thus, the time of occurrence and the peak amplitude of the resulting upstroke "spikes" constitute the raw events train to be used for further analysis. In addition, dynamic parameters can be extracted from these time series with a number of nonlinear methods. Note that the use of these methods requires particular care when dealing with nonstationary and noisy data (see CHAOS IN BIOLOGICAL SYSTEMS).

**Figure 1.** *A*, M-cell inhibitory (−) networks with their excitatory (+) inputs. *B*, In upper tier, inhibitory synaptic noise with inverted IPSPs. In lower tier, time derivative of this sample and illustration of the threshold ($\theta$) method. *C*, RP analysis. $C_1$, At left are trains of three spikes starting at times *i* and *j*, with the difference between their intervals $I_1 - I'_1$ and $I_2 - I'_2$ less than and more than $\varepsilon$, respectively. On the right are recurrence plots (RPs) of two almost identical sequences of five intervals each. $C_2$, RPs of chaotic (left), periodic (right top), and stochastic (right bottom) systems. *D*, Histogram of the number $N_L$ of line segments of length L from a "chaotic" RP. The parameter $\mu(\varepsilon)$ corresponds to the power law of this histogram. Inset: Evolution of $\mu(\varepsilon)$ versus $\varepsilon$ (see text). Abbreviations: C, chaotic; P, periodic; S, stochastic. KS indicates the Kolmogorov-Sinai entropy. ($C_2$ left and *D* adapted from Faure and Korn, 1998.)



## Recurrence Plots

Recurrence plots (RPs) portray the dynamics of a *d*-dimensional signal in the form of dots interspersed in a square matrix (Eckmann, Kamphorst, and Ruelle, 1985). The plot is an $N*N$ array where a dot is placed at $(i, j)$ whenever the embedded vectors $(x_i, x_j)$ are within a predetermined cutoff distance $\varepsilon$. In a two-dimensional space, the embedded vectors are defined by $x_i = (I_i, I_{i+1})$, where $I_1, I_2, \ldots, I_{N+1}$ is the time interval series and, using a maximum norm, $x_i$ and $x_j$ are close if $\max_{n=0,1}\{|I_{i+n} - I_{j+n}| \leq \varepsilon\}$ (Figure 1$C_1$, left). Thus, a diagonal segment of length L indicates the number of recurrent points in the phase space that remain close for L successive time steps. For example, two almost identical trains of six spikes starting at time *i* and *j* appear as two diagonal segments of length L = 4 each (Figure 1$C_1$, right).

This procedure identifies several dynamics, independent of whether the studied signal is discrete or continuous and embedded in a phase space with appropriate techniques (Schreiber, 1999). The RPs take the form of small-scale discontinuous segments, or of parallel lines, or are homogenous, in the cases of chaotic, periodic, or stochastic systems, respectively (Figure 1$C_2$). This approach is useful for detecting periodic and apparently chaotic patterns hidden in SN (Faure and Korn, 1998).

Several sequence-sensitive parameters can be estimated to quantify the degree of determinism using histograms of length L of the upward diagonal segments (Figure 1*D*). Two are particularly convenient for studies of SN. The first, called percent of determinism (%det), is the ratio of the number of dots in diagonal line segments divided by the total number of dots in the RP (Webber and Zbilut, 1994). The second is defined by the slope $\mu(\varepsilon)$ of the power law of the histogram. It is related to a classical invariant of dynamic systems, i.e., the Kolmogorov-Sinai entropy (Faure and Korn, 1998) and its variations as a function of $\varepsilon$ can be used to characterize the dynamics of a time series (Figure 1*D*, inset).

## Return Maps

In the case of time interval series between successive events, one way to look for deterministic relationships between one interval and the next is simply to plot each interval, $I_N$, against the next $I_{N+1}$. The result is a return map (RM), sometimes called a Poincaré map (see Dynamics and Bifurcation in Neural Nets), that allows the dynamics to be visualized as a sequence of pairs of points. These points are grouped in clusters, in the case of periodic motion, or as an extended structure that is not space filling, in the case of chaotic motion. For studies of M-cell SN, RMs were constructed with subsets of events selected, according to their amplitudes, by varying a threshold $\theta$. As $\theta$ was progressively lowered, RMs disclosed three distinct superimposed patterns. The first is periodic and indicates a dominant frequency of the involved IPSPs, denoted fp (Figure 2$A_1$). The second and most striking configuration is a triangular motif with its apex at fp (Figure 2$A_2$). For the lowest $\theta$'s, this pattern is replaced by an undefined partial filling of the map (Figure 2$A_3$).

A more refined analysis can be used to determine if temporal processes other than the dominant frequency are hidden in SN. This involves subtracting events associated with fp from the initial time series. RMs reconstructed in this manner revealed at least three populations of IPSPs occurring with distinct and unexpected periodicities, all in the so-called gamma range (Faure, Kaplan, and Korn, 2000).

## Unstable Periodic Orbits and Determinism in SN

In a phase space, periodic orbits are the equilibrium state of a dynamic system (see Dynamics and Bifurcation in Neural Nets). If these orbits are not stable, any trajectory will wander endlessly in a sequence of close approaches followed by rapid divergences, thereby defining unstable periodic orbits (UPOs), which have recently been used as indicators of chaos. In RMs they can be identified by detecting rare sequences of events that approach and depart from a fixed point on the identity line according to strict geometrical rules (So et al., 1998). UPOs were found in SN at the level of the triangular patterns (Figure 2*B*). In addition, M-cells' SN contains other forms of recurrence defined by repeated sequences of identical intervals.

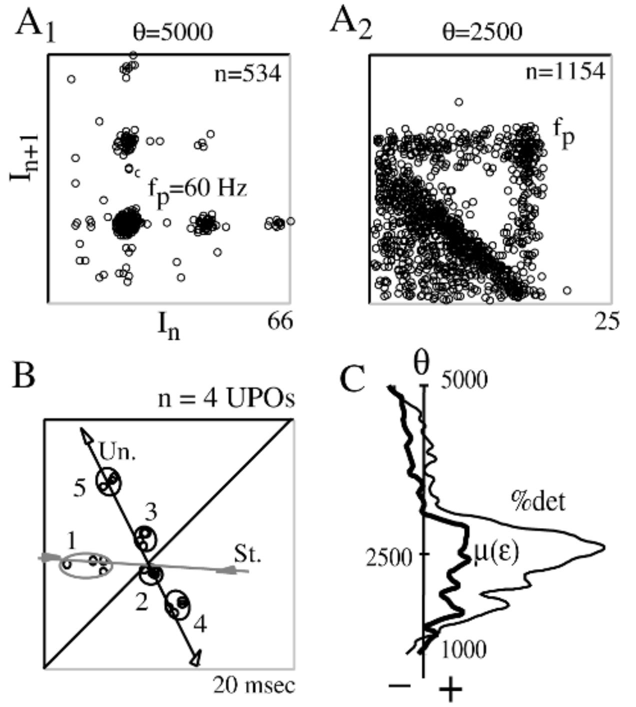


**Figure 2.** PM analysis. $A_1$ and $A_2$, Experimental maps obtained with a 10-s sample of SN for two levels of detection $\theta$. *B*, four UPOs extracted from the map in $A_2$, with their stable (St.) and unstable (Un.) manifolds crossing at a period-1 orbit (labeled 2). *C*, Variation of the significance level of the %det and $\mu(\varepsilon)$ parameters in the same sample, as a function of $\theta$. The vertical line indicates a confidence level at $2e^{-5}$% after comparison with surrogates. (*A* and $B_1$ modified from Faure et al., 2000.)

The degree of recurrence, i.e., of determinism, can be quantified to ascertain the nonrandom distribution of the time intervals between events. Both the %det and $\mu(\varepsilon)$ were significantly increased (Faure and Korn, 1998) when SN was studied at intermediate values of $\theta$, in regions of well-defined triangular patterns (Figure 2*D*). The statistical significance of these results was assessed using surrogate strategies (see Chaos in Biological Systems).

Taken together, results from the M-cell system support the notion that a form of determinism compatible with chaos may be embedded in SN.

## Determinism in Presynaptic Networks

Periodic and chaotic processes can be generated by coupled oscillators (Borisyuck et al., 1995), and studies of SN can reveal the presence of such a mechanism in the nervous system. The triangular structures in experimental RMs are consistent with the periodic events varying at random. However, another explanation is possible, namely, that sets of interneurons in the presynaptic networks behave as coupled "oscillators." Two arguments favor this interpretation (Faure et al., 2000). First, analysis of the phase relationships between the identified frequencies indicates a weak coupling between them. The second argument relies on the confrontation of a formal model with observed data. A model of neurons was built that incorporated the fact that M-cells' presynaptic inhibitory interneurons are coupled by chemical and electrical junctions (Figure 1*A*), with each "neuron" firing action potentials at one of the observed frequency. The coupling between the parent modeled neurons produces fluctuations between action potentials with UPOs and intermittent locking (not shown). Thus, the diversity of temporal patterns contained in SN may already be present in presynaptic networks.

## Transmission of Temporal Patterns; Effects of Learning

If nerve inputs converge from a population of independent channels on an integrating neuron, any information coded temporally in a single one is lost, so that this population can in principle be replaced by a single random channel. But this is only true if these parallel channels induce similar postsynaptic effects (Perkel and Bullock, 1968).

The various, almost periodic components of SN are manifest in the same train if, and only if, some types of events are sometimes above and sometimes below $\theta$. The distribution of the amplitudes of events then allows for gradual transitions between the types of patterns observed (Figures 2$A_1$ to 2$A_3$) as $\theta$ is lowered (Figure 3*A*). Such properties of RMs are consistent with an involvement of synaptic junctions.

Indeed, the principal feature of evoked transmitter release is its probabilistic nature. That is, chemical transmission is governed by two binomial parameters, *n* and *p* (Figure 3*B*, left), where *n* represents the population of basic "quantal units," *q*, capable of responding to a nerve impulse, and *p* represents their average probability of responding. The product *np* is the mean quantal content that is equal to the average number of quanta released by a given junction during successive trials (Figure 3*B*, right). The product *npq*, where *q* is the size of a quantum, determines the synaptic efficacy (Korn and Faber, 1991).

Implementing the model in Figure 3*C* with terminal "synapses" at each oscillator indicates that if *np* is the same at all of them, the postsynaptic events fluctuate in the same range, and therefore no frequency emerges for a given $\theta$ (Figure 3$D_1$). In contrast, if the synapses have different synaptic efficacies, the RMs exhibit the hierarchical features of those observed experimentally (Figure 3$D_2$). Thus, synaptic heterogeneity confers a "separating power" on the terminals and allows SN to contain precise information about the dynamics of the presynaptic networks. This prediction has been verified experimentally by taking advantage of long-term tetanic potentiation, which increases *p* in the M-cell inhibitory system. This paradigm of learning sharpens the shape of triangular patterns in PMs and increases the determinism in SN (Faure et al., 2000).

## Discussion

Nonrandom patterns compatible with chaos can be detected in SN, and more generally in neural networks (Rabinovich and Abarbanel, 1998; see also Chaos in Neural Systems), but it should be stressed that nonlinear dynamics tend now to focus on global modifications of the nervous system rather than on demonstrating chaos per se (see EEG and MEG Analysis). This aproach can provide unexpected information about the functional organization of neural networks (such as the synchronization of presynaptic cells in the form of coupled oscillators that generate SN) and about their state of activity (such as the enhancement of determinism in SN by learning).

Exept for its influence on the input-output function of neurons (see Stochastic Resonance), the role of SN remains uncertain. In the M cells, either one of which triggers a vital escape reaction, the magnitude of inhibitory SN is a critical factor for selecting which of the two cells fires for an appropriate response (Hatta and Korn, 1999). Furthermore, the variability of SN at relay stations of the output pathways introduces uncertainty into the expression of the reflex, and therefore enhances its success in evading predators.

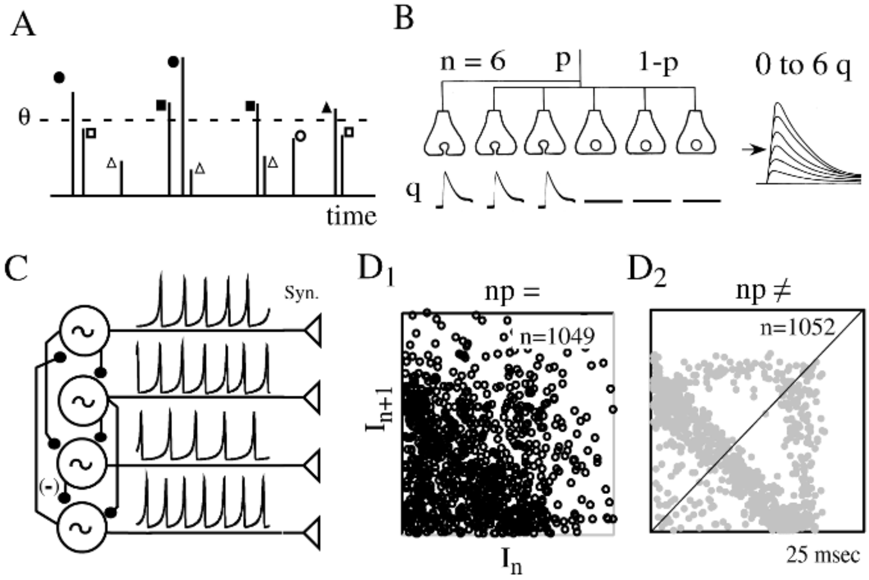

**Figure 3.** *A*, Schematic time series with three classes of periodic IPSPs, labeled ○, □, and △ according to their parent frequency. Events above and below $\theta$ are indicated by filled and empty symbols, respectively. *B*, Transmitter release at a central synapse. At left is an axon with $n = 6$ terminals. Following an action potential, some of them release a quantum, $q$, whereas the others do not, with probabilities $p$ and $1 - p$, respectively. At right, as a result of successive impulses, the amplitude of postsynaptic events fluctuates in discrete steps, from 0 to $n$ and around the mean quantal content, $np$ (arrow). $C'$, Modeled neurons with their terminal synapses (Syn.) and a sample of their respective spike trains. *D*, Contribution of synaptic properties to the transmission of the presynaptic patterns illustrated in *C*. Return maps constructed with the simulated SN when all the synapses have identical ($D_1$) or distinct ($D_2$) quantal contents. (*B* modified from Faure et al., 2000.)

Experimental data are still necessary to assess the possible behavioral advantages of deterministic patterns over truly random ones and to determine how chaotic dynamics affect neural function.

Particularly relevant here are the possible relationships between nonlinear dynamics and higher brain functions. There is growing evidence that the apparent variability of neuronal spike trains, which plays a major role in perception, is mostly the consequence of precise dynamics rather than of a random “noise.” That is, the brain would be continuously browsing through various possible internal states until new information induces transitions to a more specific one (Skarda and Freeman, 1990; Tsodyks et al., 1999). Chaos, and possibly SN, may play a role in such adaptative processes (Tsuda, 2001).

# Synaptic Transmission

*Charles F. Stevens and Yongling Zhu*

## Introduction

Information flows from one neuron to the next at specialized points of contact known as *synapses*. Because brain function depends essentially on such information flow, synapses play a central role in neural computations. This article reviews the structure and function of synapses, and describes the ways that *synaptic strength*—the magnitude of the effects that synapses produce, often termed the *synaptic weight*—is regulated through the probabilistic nature of synapse function.

Each neuron typically makes synaptic contact with about ten thousand other neurons, and receives synapses from approximately the same number. As a microliter of mammalian neocortex contains about $10^5$ neurons, each with about $10^4$ synapses, the density of synapses in cortex is about a billion per microliter; the human neocortex has about $10^{10}$ neurons, so the entire cortex would transmit information between neurons at about $10^{14}$ synapses.

Synapses provide a unidirectional flow of information, from the *sending* (presynaptic) to the *receiving* (postsynaptic) neuron, but not in the reverse direction. Two distinct types of synapses are present in brain, *excitatory* and *inhibitory*; the excitatory synapses—about 80% of all synapses fall in this category—tend to cause the receiving neuron to produce nerve impulses, whereas inhibitory synapses tend to prevent the receiving neuron from generating nerve impulses. The actual output of a neuron depends, of course, on the joint action of the two types of synaptic inputs. All of the synapses made by a particular neuron are of the same type, so one can divide neurons in the brain into those that are excitatory (make excitatory synapses) and those that are inhibitory (make inhibitory synapses).

Modifiability is one of the hallmarks of brain, and the principle way the function of neural circuits is adapted to the computational needs of the organism is through changes in the average size of the signal generated in the receiving neuron by synaptic action. This synaptic efficacy is usually referred to a *synaptic strength* or *weight*, and the modifications of synaptic strength are key both for the study of artificial and actual neural networks. To understand how synapses function, and how their strength is modified, it is necessary to consider synaptic structure.

## Synapse Structure

Three main parts of a synapse can be identified: the *bouton* (the part of the synapse contributed by the sending cell), *postsynaptic structures* (the parts of the synapses contributed by the receiving cell), and the *synaptic cleft* (a 20-nm space that separates the sending and receiving neurons). The bouton contains a cluster of 35-nm diameter spherical structures, the *synaptic vesicles*, a few of which appear to be touching the presynaptic membrane, and the remainder of which fill the regions of the bouton not immediately adjacent to the membrane. The population of vesicles that appear to touch the membrane constitute the *docked vesicle pool*, and the non-docked vesicles are called the *reserve* vesicles (Harris and Sultan, 1995; Schikorski and Stevens, 1997). Vesicles are docked to a specialized region of membrane, called the *active zone*, positioned immediately opposite the postsynaptic structures. Most synapses have only a single active zone, but some large ones have dozens or even hundreds.

The postsynaptic structure of most excitatory synapses is organized around a thorn-like protuberance from the *dendrite* (dendrites constitute another kind of brain "wire" for carrying information) of the receiving neuron, the synaptic *spine* (Harris and Kater, 1994). The spine has a thin neck and a bulb-like head just opposite the bouton. Aligned with the active zone, and having exactly the same size and shape, is a specialized postsynaptic membrane called the *postsynaptic density* (PSD). The synaptic cleft is the extracellular region bounded by the active zone on the sending neuron side and by the PSD on the receiving neuron side.

## Outline of Synaptic Transmission

Information flows from the sending to the receiving neuron by the bizarre process known as *synaptic transmission*. The sequence of steps that constitute synaptic transmission are as follows: when a nerve impulse arrives at a bouton, it causes a brief increase in the calcium ion concentration in the bouton that is sensed by a special protein that initiates a process known as *exocytosis* of a synaptic vesicle. The vesicle then releases the fixed amount of *neurotransmitter* it contains.

The postsynaptic density contains *receptors* that bind the neurotransmitter and produce a current known as the *postsynaptic current* (PSC). This current, in turn, produces a voltage change, the *postsynaptic potential* (PSP), that constitutes the postsynaptic signal. The result, then, of a nerve impulse in the sending neuron is an electrical signal in the receiving cell.

## Probabilistic Nature of Synaptic Transmission

Early studies, from the middle of the twentieth century, revealed that neurotransmitter release is *quantal* (that is, only an integral number of vesicles can undergo exocytosis) and *probabilistic* (that is, the exocytic event occurs in a probabilistic fashion) (Katz, 1969). The probability that an individual docked vesicle will undergo exocytosis when a nerve impulse arrives is about 0.05, and the number of docked vesicles (although very variable from synapse to synapse) is on the order of 10, so the probability that no neurotransmitter release will occur at a synapse is $(0.95)^{10} = 0.6$; this calculation assumes that the vesicles are independent and identical (neither is likely not to be exactly true). Instances for which a presynaptic nerve impulse fails to cause neurotransmitter release are termed *failures*, and occasions on which release does occur are called *successes*, a terminology taken from the coin-flipping theory that is the mathematical model for the release process. The probability of a success (1 minus the probability of a failure) is commonly called the synapse's *release probability*.

Because the study of individual synapses is difficult, the first evidence that individual synapses are unreliable—in the sense that the probability of a failure is high—was indirect, but more direct methods revealed, at about the same time, that the failure rate is around 0.7 for many synapses (Allen and Stevens, 1994; Bolshakov and Siegelbaum, 1995; Raastad, Storm, and Anderson, 1992). More recently, imaging methods have shown that the release probability for synapses made by a single neuron has a broad distribution, well fitted by a gamma function, with a mean near 0.3 (Murthy, Sejnowski, and Stevens, 1997). Furthermore, this release probability distribution is, as might be expected, produced by a range in synapse sizes and numbers of docked vesicles.

## Changes in Synaptic Strength

One of the main insights provided by study of artificial neural networks is that proper adjustment of *synaptic weights* is a key to determining function a neural circuit performs. The physiological analog of the synaptic weight in an artificial network is *synapse strength*, the average size of the postsynaptic response (PSC or PSP) produced by a nerve impulse that occurs on the sending side of the synapse. Synaptic strength is constantly being altered in the functioning brain on many time scales, from a few milliseconds to days or, perhaps, years through many different mechanisms. Some of these mechanisms have been assigned names like *facilitation, augmentation, depression, long-term potentiation*, and *long-term depression*. The very long-term changes are believed to arise from structural modifications in synapse size or number, but the short-term dynamic modification of synaptic strength occurs primarily through alterations in release probability (Dobrunz and Stevens, 1999).

The dynamic regulation of synaptic strength depends on a complicated set of mechanisms that record the history of synaptic use over many time scales, and serve to filter in incoming spike train in a way that reflects the past use of the synapse. Although many of these mechanisms are reasonably well understood at the descriptive level as presented in later sections of this article, the molecular basis and computation significance of the filter is the subject of current study.

The fundamental relation that determines release probability is

$$p = 1 - (1 - \alpha)^n \tag{1}$$

where $p$ is the probability that a vesicle will be released from an active zone, $n$ is the number of docked vesicles, and $\alpha$ is the average release probability for an individual vesicle to be released (Dobrunz and Stevens, 1997). This equation assumes that vesicles are identical and independent—not quite true—and that at most one vesicle can be released by a nerve impulse at an active zone. Although this and the other equations presented here have a long history, only the more recent references, in which experiments were carried out with modern techniques, are provided; see these references for citations of earlier literature. Release probability is modified both by changes in $n$, the size of the docked vesicle pool, and $\alpha$, the probability that an individual vesicle will be released.

The size of the docked vesicle pool (also called the readily releasable pool) varies because of releases (which decrease the size of the pool) and refilling (which tends to restore the pool size to its current capacity $N$). The difference-differential equation that governs the pool size $n$ during intervals between action potentials is

$$\begin{aligned}\frac{dP(n, t)}{dt} = &-(\rho(N - n) + \lambda n)P(n, t)\\ &+ \lambda(n + 1)P(n + 1, t)\\ &+ \rho(N - n + 1)P(n - 1, t)\end{aligned} \tag{2}$$

where $P(n, t)$ is the probability of having $n$ docked vesicles at time $t$, $\rho$ is the rate constant per vesicle for spontaneous release, and $\lambda$ is the rate of refilling empty docking sites. Both $N$ and $\lambda$ in this equation depend on the history of synapse use as described later in this article.

The refilling rate constant $\lambda$ is increased, through a mechanism that involves intrabouton calcium concentration, by activity according to the equation

$$\frac{d\lambda}{dt} = A \frac{r(t)}{1 + \frac{r(t)}{r_0}} - B(\lambda(t) + \lambda_0) \tag{3}$$

where $A$, $r_0$, $B$, and $\lambda_0$ are all constants and $r(t)$ is the rate at which action potentials enter the terminal (Stevens and Wesseling, 1998).

The maximum size of the docked vesicle pool ($N$), known as the *pool capacity*, also depends on the history of use according to the pair of equations

$$N = N_0 - \theta(u - u_0) \tag{4}$$

and

$$\frac{du}{dt} = R(t) - \mu u(t) \tag{5}$$

where $N_0$is the maximum possible capacity, $u$ is the number of vesicles that have been released but not yet recovered by endocytosis, $\mu$ is a rate constant (value about .1/s), $R(t)$ is the rate at which vesicles are undergoing exocytosis, and $\theta$ is a function whose value is its argument if the argument is non-negative and zero otherwise. These equations describe the process through which unrecovered vesicles start to occlude docking sites once a threshold number ($u_0$) is reached (Stevens and Wesseling, 1999b).

The equations above describe how synaptic use determines the number of vesicles available for release, and this quantity in turn is a key factor in setting the release probability according to the fundamental equation set out at the start of this discussion. As the number of vesicles in the readily releasable pool declines with use, the release probability also tends to decrease, and synaptic strength is diminished; this process is generally termed "depression," and it is a prominent mechanism at all synapses.

Several sets of mechanisms also modify synaptic strength through the parameter $\alpha = \alpha_0(1 + \phi(t))$, where $\alpha_0$ is the resting average release probability per vesicle and $\phi(t)$ is a function of time $t$ that depends on the history of synapse use. The best-studied and most familiar of these mechanisms is known as *facilitation*, a process that remembers synaptic use for about half a second and increases release probability during that period. The function $\phi(t)$ reflects concentration of calcium ions in the bouton but the mechanistic basis is still unclear. Whatever the detailed mechanism, $\phi(t)$ is incremented by an approximately constant amount with each nerve impulse arrival, and it decays exponentially between nerve impulses. Facilitation $f$ is usually defined for a pair of stimuli—this is the way it is studied in the laboratory—and is given by the ratio of the release probability on the second impulse to that on the first. As a consequence of the fundamental relation between number of docked vesicles and release probability, facilitation is given by

$$f = \frac{1 - (1 - p)^{\alpha(t)}}{p} \tag{6}$$

where $p$ is the release probability in the resting state (the first stimulus of the pair) and $\alpha(t)$ depends on $\alpha_0$ and $\varphi(t)$ as set out above. A typical value for $f$ at interstimulus intervals of 50 ms would be 2 (Dobrunz and Stevens, 1997).

Another process that increases synaptic strength is called *augmentation*. This phenomenon follows the same equation as facilitation (above), but the increment in $\phi(t)$ per impulse is much smaller than for facilitation, and the decay is much slower (about half a minute). Note that $\phi(t)$ is really the sum of two exponentials, one for facilitation and the other for augmentation. Because augmentation increments a constant amount with each nerve impulse arrival at the synapse and decays exponentially in the time between stimuli, the steady-state augmentation is linearly related to the stimulation frequency. The effect of augmentation can be a large one: with reasonable stimulation rates, augmentation can increase the synaptic strength sixfold or more (Stevens and Wesseling, 1999a).

As noted previously, the processes just described combine to specify synaptic strength in a rather complicated way that defines a type of history dependent filter. Thus, the synapse does not simply relay information from one cell to the next, but rather plays an essential computational role. A major challenge is to define this role and explain how such a filter is related to the other computational mechanisms used by neural circuits.

## Introduction

Neuronal systems have to cope with combinatorial complexity. In the context of cognitive functions, combinatorial problems arise because perceptual objects consist of unique constellations of features. Although nervous systems exploit only a limited set of basic features to classify perceptual objects, the diversity of possible constellations of such elementary features is, for all practical purposes, virtually unlimited. Thus, cognitive systems have to explore a huge combinatorial space when searching for the consistent relations among features that define a perceptual object. Combinatorial problems of similar nature have to be solved for the programming and execution of movements. Although the elementary components of motor acts—the movements of individual muscle fibers—are limited in number, the diversity of movements that can be composed by combining the elementary components is, again, virtually infinite. Thus, mechanisms are required that permit rapid analysis and representation of relations between the responses of neurons whose activity signals the presence of particular features.

A common and well-documented strategy for the binding of distributed responses is the implementation of conjunction specific neurons. In the primary visual cortex of mammals, for example, relations are established between the responses of collinearly aligned retinal ganglion cells by having their output converge onto individual cortical neurons. Because of this convergence, cortical cells come to respond preferentially to elongated contours, thereby extracting and encoding the feature "orientation." This strategy of representing relations by selective combination of feedforward connections is common in all sensory systems and at all levels of processing. Its iteration in hierarchically structured processing architectures leads to conjunction-specific neurons that encode increasingly complex relations among elementary features. Representing features and their relations by conjunction units is rapid because it can be realized by feedforward processing, and it is reliable because the response of a particular cell always signals the same content (labeled line coding). However, this coding strategy, if not complemented by additional binding mechanisms, meets with a number of problems. First, large numbers of conjunction units are required for the exhaustive representation of the manifold intra- and cross-modal feature constellations of real world objects. Second, it is hard to see how novel objects and hence entirely new relations among features can be recognized and represented, as this would require rapid reconfiguration of input connections to previously uncommitted cells. Third, unresolved problems arise with the representation of the nested relations among the components of composite objects, such as visual scenes or sentences (for review of the arguments, see Singer, 1999).

A complementary strategy is needed, therefore—one that permits a more flexible definition of relations than can be achieved with hardwired conjunction units. As proposed by Hebb and subsequently elaborated by numerous authors, assembly coding is such a complementary strategy. The assumption is that individual cells represent only components of objects, which may consist of rather complex conjunctions of elementary features but may be common to different objects. Presumably, then, the presence of the whole object is signaled by the simultaneous responses of the ensemble of cells responding to the respective components. In this way, individual neurons can contribute at different times to the representation of different objects by forming ensembles with varying partners. Thus, a neuron tuned to a particular component can contribute to the representation of all objects containing this particular component, and neurons representing elementary features can be recombined in ever-changing constellations to represent novel objects. The requirements for the generation and read out of assembly codes are as follows: (1) Component coding neurons can become bound in variable constellations into different assemblies when input configurations change; (2) assemblies can be stabilized by learning so that a familiar object always activates its corresponding assembly; (3) the responses of cells constituting an assembly can be distinguished as related by subsequent processing stages and do not become confounded with responses of cells participating in other assemblies; (4) assemblies can be read out by triggering the formation of corresponding assemblies at other processing stages rather than by conjunction-specific units.

## How to Tag Responses as Related

Numerous theoretical studies have addressed the question how assemblies can self-organize on the basis of cooperative interactions within associative neuronal networks. Here, we focus on the problem of how responses of cells that have been grouped into an assembly can be tagged as related. An unambiguous signature of relatedness is critical for assembly codes because, unlike in labeled line codes, the meaning of responses changes with the context in which they are interpreted; hence, false conjunctions are deleterious. Assembly coding requires a mechanism that assures that the responses of the neurons constituting an assembly are processed and evaluated together at subsequent processing stages and are not confounded with other, unrelated responses. In principle, this can be achieved by raising, jointly and selectively, the saliency of the responses belonging to an assembly. There are essentially three options to achieve this goal. First, unrelated responses can be inhibited and excluded from further processing. Second, the discharge frequency of the selected responses can be enhanced. Third, the selected cells can be made to discharge in precise temporal synchrony. All three mechanisms enhance the relative impact of the selected responses and can therefore be used to tag them as related. Single-cell studies have provided robust evidence that the first two mechanisms play a crucial role in the selection and grouping of responses. However, if joint increases in discharge rate are used for response selection and grouping, certain additional requirements must be fulfilled to comply with processing speed. Estimates based on reaction times, evoked potentials, and latencies of single-cell responses suggest that it takes maximally a few tens of milliseconds per processing stage to perform the computations necessary for the analysis and recognition of patterns of average complexity (Thorpe, Fize, and Marlot, 1996). Given the relatively low discharge rates of cortical neurons, with interspike intervals ranging typically from 20 to many hundreds of milliseconds, decisions on response selection and grouping can only be based on a small number of spikes per neuron. This precludes selection and read out mechanisms that analyze rate changes of individual neurons. It has been proposed that this problem can be overcome by population coding. The idea is that a particular feature is signaled in parallel by a large number of neurons (on average about a hundred) and that downstream neurons average across these population responses. Owing to spatial summation, increases in discharge rate become detectable with sufficiently high temporal resolution, provided that spike density increases significantly across channels within the relevant integration interval. Such changes in the spike density of population responses can result from two, in principle independent, mechanisms. They can result from simultaneous increases in discharge rate if these are sufficiently coherent across channels; or they can result from a coordinated redistribution of individual discharges without this leading to major changes in average discharge frequency of individual channels. What is required in this case is temporal regrouping of discharges across channels, advancing some and delaying others, so that more spikes than predicted by average discharge rates co-occur within the integration interval set by downstream neurons. Evidence suggests that both strategies are used by the nervous system to increase the saliency of responses and to permit rapid read out. In bottom-up feedforward processing, covarying increases in discharge frequency across channels are common because of stimulus locking. In top-down selection of responses, rate increases are made coherent by the coordinating action of attentional mechanisms (reviewed in Engel, Fries, and Singer, 2001). Evidence for rate-independent regrouping of spike timing is more difficult to obtain because it requires correlation analysis between the responses of different but simultaneously recorded neurons. However, such data are now available and reveal the existence of synchronizing mechanisms that can transiently augment cross-channel spike densities above the level predicted by average discharge rate. Frequently, this grouping of discharges occurs on the basis of an oscillatory patterning of the discharge sequences so that there are also periodically reoccurring intervals in which the cross-channel spike density drops below the level predicted by average discharge rate (see below).

## Rate Covariation and Synchrony

Because the distinction between rate covariation and synchronization has led to fierce controversies and numerous misinterpretations, a brief comment is warranted here. According to classical conventions, discharge rates of individual neurons are measured over time spans long enough to count at least three or four spikes, i.e., 100 ms to several 100 ms, depending on discharge rate. Over the past few years, however, the duration of the intervals of effective synaptic integration had to be revised toward shorter values. Neurons are now considered capable of discriminating between synchronous and temporally dispersed inputs with a resolution in the millisecond range (Mainen and Sejnowski, 1995). This implies that neurons are sensitive to fluctuations of cross-channel spike densities at time scales at least one order of magnitude shorter than those relevant for the assessment of rate changes of individual neurons. However, once the relevant integration windows become considerably shorter than the average interspike interval of individual responses, it begins to matter whether the spikes in parallel channels are distributed randomly or clustered in time. Thus, with conventional rate definitions, two variables need to be determined to describe a population response: the changes of discharge rate of the individual cells and the amount of synchrony/asynchrony of spikes across channels. As these measures are defined at different time scales, they can obviously vary independently. An alternative description would be time-resolved counts of cross-channel spike densities. If the time slices are sufficiently short ($<10$ ms), this measure captures coincident events of putative functional significance that may be independent of rate fluctuations. These cross-channel measurements of spike density are equivalent to a time-resolved assessment of "instantaneous" firing rates of the population; and if the windows for assessment of coincidences and for estimation of population firing rates are of the same duration, fluctuations in the number of coincidences can also be described in terms of ultrarapid fluctuations of population rate. However, by simply counting events across channels, one loses potentially important information—which cells contributed at which time to the population vector. Conditions can be imagined where the population rate is constant but the entries in each successive time slice are provided by different subsets of neurons. Thus, measures of synchrony and measures of cross-channel spike density may dissociate. Because which subset of neurons undergoes an enhancement of response saliency is relevant for the definition of relations, one should expect that it matters which subset of neurons contributes spikes within time slices of 10 ms or less.

## Response Selection

While jointly increasing tonic firing is a common strategy of response selection and binding in feedforward processing and labeled line coding, it has several disadvantages if applied to encode relations in assemblies. The reason is that tonic increases in firing lead to sustained enhancement of saliency of the activated channels by augmenting both the frequency of EPSPs in individual channels and the number of coincidences across channels. Thus, sustained increases in rate, if used as the only tag of relations, preclude rapid changes in the assignment of relations. However, a rapid and time-resolved definition of relations is important to comply with fast processing. Assemblies sharing common subsets of neurons cannot be organized strictly simultaneously because it would be unclear which of the shared neurons belong to which assembly. Hence, if assemblies overlap, which is frequently the case, they need to be segregated in time by a multiplexing operation. Processing speed is limited by the rate with which different assemblies can follow one another or, in other terms, by the temporal resolution of the mechanism that labels responses as related. Modulating the saliency of responses by synchronization, i.e., by temporal regrouping of spikes rather than by tonic changes in firing rate, permits definition of relations at very short time scales. As synchronization exploits exclusively spatial summation, with no additional temporal summation, this tagging mechanism can operate, in principle, with a temporal resolution at the level of individual spikes. Using synchronization as a complementary mechanism for the definition of relations has the additional advantage that it permits specification of relations independently of firing rate. The discharge rates of neurons depend on numerous variables such as the physical energy of stimuli or the match between stimulus and receptive field properties, and it may not always be obvious how these modulations of response amplitude can be distinguished from those signaling the relatedness of responses. Not all strong responses are necessarily related. Because synchrony can be modulated independently of rates by temporal regrouping of discharges, it can be used as a tag of relatedness that is orthogonal to rate fluctuations. This can contribute to resolving the ambiguities resulting from stimulus-dependent rate fluctuations. Response amplitudes could thus be reserved to signal the presence and saliency of features, and synchronicity could be used in parallel to signal whether these features are related.

Another advantage of selecting responses by synchronization is that the timing of synchronized input events is preserved with high precision in the output activity of cells because synchronized input is transmitted with minimal latency jitter (Abeles, 1991; Diesmann, Gewaltig, and Aertsen, 1999). This, in turn, could be exploited to preserve the signature of relatedness across processing stages, thus further reducing the risk of getting false conjunctions. Finally, synchronization enhances processing speed also by accelerating synaptic transmission per se because synchronized EPSPs trigger action potentials with minimal delay.

In conclusion, response synchronization appears to be an attractive strategy to encode relations with high temporal resolution and within limits independently of rate fluctuations. However, response synchronization can only be used as a mechanism of response selection and grouping if neuronal networks are able to distinguish synchronous from temporally dispersed activity with a precision in the millisecond range.

## Evidence for a Functional Role of Precise Timing

There is increasing evidence that neuronal networks can encode, transmit, and evaluate the temporal structure of stimuli with astounding precision. Temporal resolution is probably highest in the specialized circuits of the auditory system that can exploit latency differences in the submillisecond range for sound localization. Although signal transduction in the retina is slower than that in the ear, the visual system, too, is capable of resolving temporal patterns with a precision in the millisecond range. Thus, timing differences in the millisecond range suffice for the identification of depth cues in rapidly moving patterns, and stimulus onset asynchronies of less than 10 ms seem to support perceptual grouping. The visual system binds simultaneously appearing pattern elements and segregates them from elements presented with temporal offset (for review, see Singer, 1999).

Electrophysiological evidence confirms the ability of neuronal networks to transmit temporally modulated responses with a precision in the millisecond range over several processing stages. Cross-correlations between simultaneously recorded responses of retinal ganglion cells, relay neurons in the lateral geniculate, and cortical cells show that the oscillatory patterning of retinal responses is reliably transmitted to the cortex. Given the high frequency of the retinal oscillations (up to 100 Hz), this implies that the timing of discharges can be transmitted over several synaptic stages with a resolution in the millisecond range, at least when the discharges in parallel channels are precisely synchronized. The well-synchronized cortical responses to flicker stimuli point in the same direction. This temporal fidelity of synaptic transmission is not confined to primary sensory pathways, but holds as well for intracortical transmission. Cortical neurons can engage in oscillatory firing patterns in the $\gamma$-frequency range and synchronize their responses with millisecond precision over surprisingly large distances, indicating that cortical networks can handle temporally structured activity with low temporal dispersion (reviewed in Singer, 1999).

Simulation studies indicate that such precision is readily obtained with neurons that operate with conventional time constants if transmission occurs in reciprocally coupled parallel channels, i.e., if a population coding strategy is used (Diesmann et al., 1999). In this case, neurons at the same processing level synchronize their discharges and these highly coherent pulse packets are then conveyed with minimal dispersion across several synaptic stages as postulated for synfire chains (Abeles, 1991).

Other indications for the high temporal resolution of cortical computations come from recent studies on use-dependent synaptic plasticity. Varying the temporal relations between presynaptic EPSPs and postsynaptic spike responses in simultaneously recorded coupled cortical cells revealed that long-term potentiation (LTP) results when the EPSP precedes the postsynaptic spike within intervals of 10 ms or less while the polarity of the modification reverses to long-term depression (LTD) as soon as the EPSP follows the spike (Markram et al., 1997). Thus, shifts of a few milliseconds in the timing relations between pre- and postsynaptic discharges suffice to invert the polarity of use-dependent synaptic modifications. The mechanism permitting such precise evaluation of the temporal contiguity of pre- and postsynaptic responses is the active dendritic response associated with the backpropagating spike. Recent results from visual cortex slices point in the same direction. In addition, they suggest that the temporal windows for Hebbian coincidence matching are sharpened further if neurons engage in oscillatory responses.

Pyramidal cells of rat visual cortex slices were made to discharge tonically at 20 or 40 Hz by injecting sinusoidally modulated current through a patch pipette. Simultaneously, EPSPs were evoked at 20 Hz by electrical stimulation of excitatory afferents. Changing the phase relations between pre- and postsynaptic activity revealed that the stimulated input tended to undergo LTP when the EPSPs were coincident with the spikes, while afferents consistently underwent LTD when the EPSPs fell in the troughs of the membrane potential oscillations. Thus, although high-frequency pre- and postsynaptic activation overlapped completely on a coarse time scale, phase shifts of about 12 ms between individual EPSPs and spikes reversed the polarity of the synaptic modifications (Wespatat, Tennigkeit, and Singer, in preparation). The temporal windows within which synaptic events or spikes are treated as contingent and related in signal processing must have the same duration as those relevant for Hebbian modifications in order to avoid learning of false conjunctions. Thus, the kinetics of neuronal plasticity imply that precise temporal relations between neuronal discharges matter not only for synaptic modifications but also in signal processing.

In conclusion, the experimental evidence and theoretical arguments indicate that neuronal networks can handle temporal patterns with high precision and that precise timing relations among the discharges of distributed neurons are computationally relevant.

## Synchrony as a Code for the Definition of Relations

Following the discoveries that (1) cortical neurons often engage in synchronous oscillatory activity which is not stimulus locked but caused by internal interactions (Gray and Singer, 1989), (2) neurons distributed both within and across cortical areas can synchronize their discharges with a precision in the millisecond range, and (3) synchronization probability reflects common gestalt criteria of perceptual grouping, it had been proposed that the cerebral cortex imposes a temporal microstructure on otherwise sustained responses and uses this temporal patterning to express, through synchronization, the degree of relatedness of the responses (for a review of pertinent literature see Singer, 1999; Engel et al., 2001).

Synchronization of activity is defined operationally as a transient increase of coincident firing of two or more units that exceeds the level of coincidences predicted from estimations of actual discharge rates. Therefore, synchronization must be assessed by correlation analysis and cannot be deduced from comparisons of rate fluctuations alone. When synchronization is caused by internal interactions—as is the case for context-dependent response selection and binding—the time of occurrence of synchronized discharges is locked only loosely or not at all to external events. This intertrial variability precludes detection of synchronized response segments in histograms averaged over successive trials even in cases where synchronization is caused by a transient increase in discharge rate. In the numerous other cases where synchronization is achieved without any noticeable rate changes (e.g., by coordinated latency shifting of individual spikes or by phase locking of oscillatory response patterns), measurements of rate fluctuation cannot in principle disclose the presence of synchronized events even if responses are recorded simultaneously. Thus, internally generated synchrony is detectable only if responses are subjected to a trial-by-trial correlation analysis.

The results of such analyses indicate that synchronization by internal neuronal interactions is a frequent phenomenon that occurs in many cerebral structures (for recent reviews, see Singer, 1999; Engel et al., 2001). It has also been noticed that responses often exhibit an oscillatory patterning that is best revealed by recording jointly the activity of several adjacent cells. The reason for the better detectability of oscillations in population responses is twofold. First, individual cells tend to skip oscillation cycles in an irregular manner; second, oscillatory epochs are usually short and oscillation frequencies are variable. Therefore, the periodicity of oscillatory population responses is often not apparent in the firing patterns of individual cells, even if their discharges are precisely phase locked to the oscillatory activity of the population. For this reason, the search for synchronized oscillatory activity requires methods that assess population responses, such as recordings of multiunit activity, local field potentials (LFPs), or the electroencephalogram (EEG). These global signals can then be correlated with the activity of individual cells to determine whether the discharges of the recorded cells are correlated with the synchronized activity of surrounding cell populations. Such measurements of spike-field coherence have proved highly efficient in detecting changes in the synchronization of neurons and the frequency of oscillatory patterning (see below).

If internally generated synchronization is to serve as a signature of relatedness, it must meet several criteria. First, its precision should be in the millisecond range to match the temporal windows for effective spatial summation and Hebbian modifications. Second, it must be possible to generate and dissolve episodes of synchronous firing at a rate fast enough to be compatible with known processing speed. Third, synchronized activity must be more effective than nonsynchronized activity in driving cells in target structures because it can serve as a tag of relatedness only if it enhances the saliency of the synchronized responses. Fourth, there should be correlations between the occurrence of synchronization patterns and perceptual or motor processes. Fifth, disruption or artificial enhancement of synchrony should lead to changes in cognitive or motor functions.

The postulate that the precision of internally generated synchronization should match the windows for effective synaptic summation and Hebbian contingency matching is supported by cross-correlation data. The widths of the correlation peaks at half-height are typically in the range of less than 10 ms, particularly when the global EEG is in a desynchronized state. In this case, internally generated synchronization is often associated with an oscillatory patterning of the respective responses in the high $\beta$- or $\gamma$-frequency range (from 20 to 60 Hz). This limits the duration of the episodes of joint firing to the peaks of the oscillations and causes a sharp temporal demarcation of synchronous events because the oscillation troughs tend to be free of spikes.

The second postulate that internally generated synchronization must be established and dissolved very rapidly (within maximally a few tens of milliseconds) has received theoretical and experimental support only recently. Simulations with spiking neurons revealed that networks of appropriately coupled units can indeed undergo very rapid transitions from uncorrelated to synchronized states and vice versa. In physiological recordings, it is not uncommon that neurons engage in synchronous activity, often with additional oscillatory patterning, at the very same time they increase their discharge rate in response to the light stimulus (for review, see Singer, 1999).

Experimental support is also available for the third postulate that synchronized activity should have a stronger impact in target structures than temporally dispersed firing. Simultaneous recordings from coupled neuron triplets along thalamocortical and intracortical pathways in the visual system by Reid and colleagues (Usrey and Reid, 1999) have revealed that EPSPs synchronized within intervals below 2 ms are much more effective than EPSPs dispersed over longer intervals. Simulation studies, *in vitro* experiments, and *in vivo* recordings suggest similar conclusions. Multielectrode recordings from several sites of the cat visual cortex and retinotopically corresponding loci in the superior colliculus indicated that the impact of a particular group of cortical cells on target cells in the colliculus increases substantially whenever the cortical cells synchronize their discharges with other cortical cell groups projecting to the same site in the tectum. Finally, enhanced saliency of synchronized responses can also be inferred from the tight correlation between the strength of neuronal response synchronization and perception observed in experiments on binocular rivalry in cats and human subjects (reviewed in Singer, 1999).

Several mechanisms, some of which have been identified only recently, make synchronously arriving EPSPs more efficient than temporally dispersed EPSPs. First, because of their exponential decay, simultaneous EPSPs summate more effectively than temporally dispersed EPSPs, and there is some evidence for supralinear summation due to voltage-gated dendritic conductances. Second, firing threshold is sensitive to the rising slope of the depolarization and lowers for fast rising depolarizations (C. M. Gray, personal communication). Third, the effect of EPSPs is dramatically enhanced when these coincide with a backpropagating dendritic spike and hence with the input that generated this spike (Larkum, Zhu, and Sakmann, 1999). All three mechanisms are sensitive to dispersions of EPSPs in the range of a few milliseconds.

## Putative Functions of Response Synchronization

### *Attention and Response Selection*

A functional role of spike synchronization and the often concomitant oscillatory patterning of responses in the $\beta$- and $\gamma$-frequency range is suggested by the evidence that both phenomena are particularly well expressed when the brain is in an activated state, i.e., when the EEG is desynchronized and exhibits high power in the $\beta$- and $\gamma$-frequency range. Such EEG patterns are characteristic for the aroused and attentive brain as well as the dreaming brain, and hence for states in which sensory representations can be activated. Numerous observations in animal and human subjects point in the same direction. Synchronous oscillations in the $\gamma$-frequency range and their synchronization become more prominent during states of focused attention or when subjects are engaged in cognitive tasks that put strong demands on feature binding or short-term memory functions (reviewed in Tallon-Baudry and Bertrand, 1999; Engel et al., 2001). Multielectrode recordings from awake cats and monkeys trained to perform discrimination tasks indicate that attentional mechanisms enhance neuronal synchrony in anticipation of the expected task. One observes an increase in oscillatory activity in the $\gamma$-frequency range; this is associated with increased coherence between the spontaneous discharges of cells and the oscillations of the local field potential. These attentional effects appear to be selective and are confined to cortical areas and sites that must be engaged for the execution of the anticipated tasks. This priming has the effect that responses to attended stimuli synchronize faster and with greater precision than do responses to nonattended stimuli. These results support the hypothesis that response synchronization is one of the mechanisms by which responses are made more salient and selected for further processing. Recent evidence suggests in addition that the spontaneous $\gamma$-oscillations exhibit distinct patterns of coherence that reflect the functional architecture of intracortical association fibers. It has been proposed, therefore, that the spatiotemporal patterns of self-generated oscillatory activity are dynamic correlates of the system's inherent processing rules. The hypothesis is that the a priori knowledge of the system that resides in its functional architecture is permanently translated into dynamic states and that signal processing consists of a matching operation in which afferent sensory activity is compared with these "states of expectancy." This anticipatory nature of cortical computations is probably one reason why processing of sensory signals is so fast (for review, see Engel et al., 2001).

A close correlation between response synchronization and stimulus selection has been found in experiments on binocular rivalry that were performed in strabismic animals (Fries et al., 2002). Owing to experience-dependent modifications of processing circuitry, perception in nonamblyopic strabismic subjects always alternates between the two eyes. We have exploited this phenomenon of rivalry to investigate how neuronal responses that are selected and perceived differ from those that are suppressed and excluded from supporting perception (Figure 1). The outcome of these experiments was surprising because the responses of neurons in areas 17 and 18 were not attenuated during epochs in which they were excluded from controlling eye movements and supporting perception. A close and highly significant correlation existed, however, between changes in the strength of response synchronization and the outcome of rivalry. Cells mediating responses of the eye that won in interocular competition increased the synchronicity of their responses on presentation of the rivalrous stimulus to the other, los-

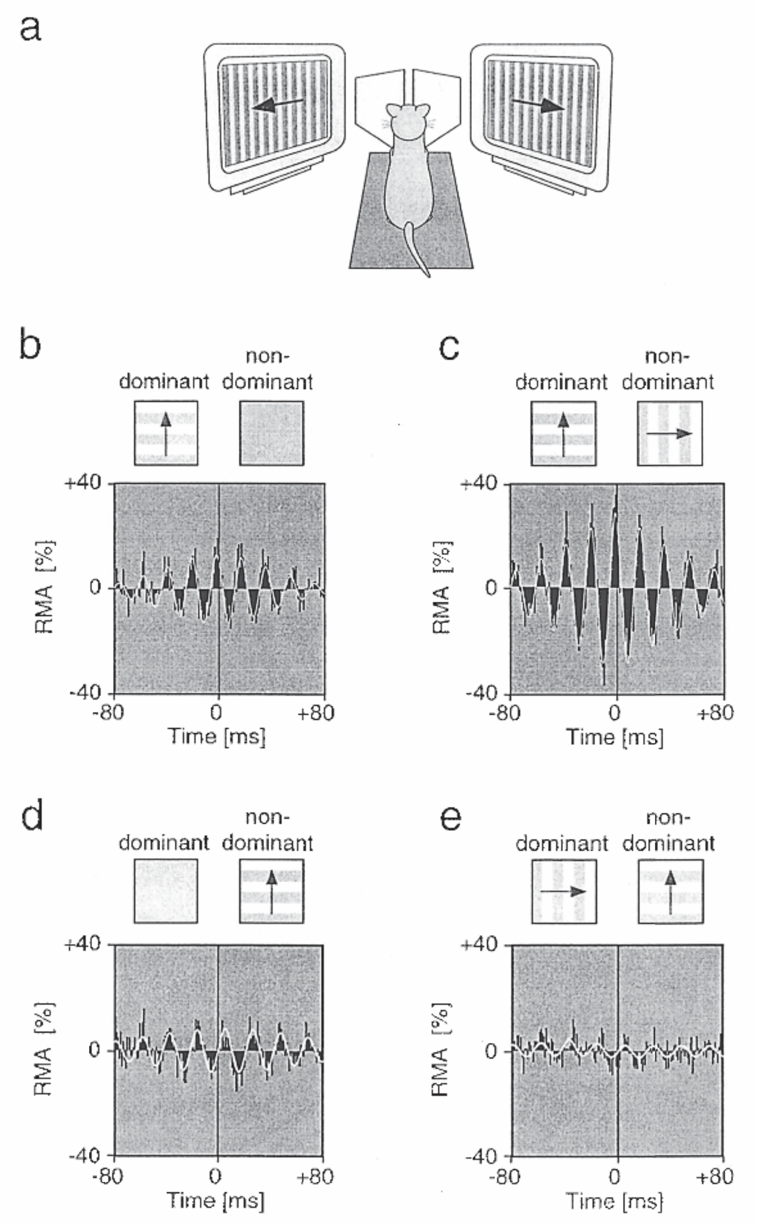

**Figure 1.** Neuronal synchronization under conditions of binocular rivalry. *A*, Using two mirrors, different patterns were presented to the two eyes of strabismic cats. Panels *B–E* show normalized cross-correlograms for two pairs of recording sites activated by the eye that won (*B*, *C*) and lost (*D*, *E*) in interocular competition. Insets above the correlograms indicate stimulation conditions. Under monocular stimulation (*B*), cells driven by the winning eye show a significant correlation, which is enhanced after introduction of the rivalrous stimulus to the other eye (*C*). For cells driven by the losing eye, the reverse is the case (compare conditions *D* and *E*). The white continuous line superimposed on the correlograms represents a damped cosine function fitted to the data. RMA is the relative modulation amplitude of the center peak in the correlogram, computed as the ratio of peak amplitude over offset of correlogram modulation; this measure reflects the strength of synchrony. (Modified from Fries et al., 2002.)

ing eye, while the reverse was true for cells driven by the eye that became suppressed. The synchronized responses exhibited an oscillatory modulation in the $\gamma$-frequency range, and differential changes of synchrony were particularly pronounced in measurements of spike-field coherence. Thus, in early visual areas selection of responses for further processing appeared to be achieved by modulating the degree of synchronization among large populations of neurons rather than by modifying the amplitude of responses. It is only at later processing stages that the poorly synchronized responses to the suppressed stimuli fail to elicit suprathreshold responses and that cells respond only to the selected stimulus (Leopold and Logothetis, 1996).

## *Synchronization and Feature Binding*

The hypothesis that internal synchronization of discharges serves to group responses for joint processing predicts that synchronization probability should reflect some of the basic gestalt criteria according to which the visual system groups related features during scene segmentation. In agreement with this prediction, a series of studies provided evidence that neurons distributed across different columns within the same or different visual areas and even across hemispheres synchronize their responses with close to zero phase lag when activated with a single contour, but fire independently when stimulated simultaneously with two different contours. This suggests that synchronization was the result of a context-dependent selection and grouping process. Indeed, the probability and strength of response synchronization reflect some of the elementary gestalt criteria that underlie perceptual grouping. Stimulus configurations that comply with criteria such as continuity, proximity, similarity in the orientation domain, collinearity, and common fate evoke synchronized responses with higher probability than do configurations devoid of groupable features (for review, see Singer, 1999). Early experiments were performed in anesthetized animals, but more recent multielectrode recordings from awake cats and monkeys indicate that these synchronization phenomena are readily observed and even more pronounced when the animals are awake and attentive.

A particularly close correlation between neuronal synchrony and perceptual grouping has been observed in recent experiments with plaid stimuli. These stimuli are well suited for the study of dynamic binding mechanisms because minor changes of the stimulus cause a binary switch in perceptual grouping. Two superimposed gratings moving in different directions (plaid stimuli) may be perceived either as two surfaces, one being transparent and sliding on top of the other (component motion), or as a single surface, consisting of crossed bars, that moves in a direction intermediate to the component vectors (pattern motion). Which percept dominates depends on the luminance of grating intersections because this variable defines the degree of transparency. Component (pattern) motion is perceived when luminance conditions are compatible (incompatible) with transparency (Figure 2*A*). Here is a case where local changes in stimulus properties cause global changes in perceptual grouping. In the case of component motion, responses evoked by the two gratings must be segregated, and only responses evoked by the contours of the same grating must be grouped to represent the two surfaces. In the case of pattern motion, responses to all contours must be bound together to represent a single surface. If this grouping of responses is initiated by selective synchronization, three predictions must hold (Figure 2*B*). (1) Neurons that prefer the direction of motion of one of the two gratings and have collinearly aligned receptive fields should always synchronize their responses because they always respond to contours that belong to the same surface. (2) Neurons that are tuned to the respective motion directions of the two gratings should synchronize their responses in the case of pattern motion because they then respond to contours of the same surface, but they should not synchronize in the case of component motion because their responses are then evoked by contours belonging to different surfaces. (3) Neurons preferring the direction of pattern motion should also synchronize only in the pattern and not the component motion condition.

Cross-correlation analysis of responses from cell pairs distributed either within or across area 18 and the posterior mediolateral suprasylvian sulcus (PMLS) of the cat visual cortex confirmed all three predictions. Cells synchronized their activity if they responded to contours that are perceived as belonging to the same surface (Castelo-Branco et al., 2000; Figure 2*C*). Interestingly, in contrast to synchrony, variations in response amplitude failed to reflect the transition from component to pattern motion induced by transparency manipulation. Dynamic changes in synchronization could therefore serve to encode, in a context-dependent way, the relations among the simultaneous responses to spatially superimposed contours, biasing their association with distinct surfaces.

Close relations between response synchronization and perception have also been found in animals suffering from developmental disturbances of their visual functions. Strabismic subjects, animals as well as humans, avoid double vision by selecting signals from one eye at a time and suppressing the signals from the other eye. If subjects always select the same eye, the cortical circuits receiving input from the suppressed eye cannot develop normally, and the result is an irreversible perturbation of vision in the suppressed eye—a syndrome known as strabismic amblyopia. Deficits comprise reduced visual acuity, spatial distortions, and problems with perceptual grouping of crowded scenes. Quite unexpectedly, in amblyopic cats, the responses of individual neurons appear normal in the primary visual cortex. Deficits become apparent only in measures that assess the temporal relations among simultaneously recorded responses of distributed neurons. Neurons driven by the amblyopic eye had a drastically reduced ability to synchronize their responses, and this deficit accounts well for some of the perceptual disturbances. Poorly synchronized responses are less salient than well-synchronized discharges; this can explain why the signals from the amblyopic eye always lose the competition with signals from the normal eye and are not perceived when this eye is open. Likewise, if deficiencies in the synchronizing mechanism are equivalent to impaired response selection and grouping, this would account for the reduced visual acuity and the difficulties in scene segmentation that frequently accompany amblyopia.

The interpretation that poorly synchronized activity fails to support perception because of reduced impact on cells at subsequent processing stages agrees with the finding that neurons at higher processing levels fail to respond to the temporally disorganized signals arriving from the primary visual cortex (Schröder et al., 2002).

Further indications for a functional role of precise timing relations between the discharges of distributed neurons have recently been obtained with multielectrode recordings from the motor and prefrontal cortex of monkeys performing a visually cued reaching task (Riehle et al., 1997) and from studies of the insect olfactory system. In insect antennal lobes, as in mammalian olfactory bulbs, odors evoke oscillatory population responses that are synchronized across parallel channels. Interestingly, information about the composition of a particular odor is encoded both in the pattern of rate fluctuations in parallel channels and in the distribution of coincident spikes. When the oscillatory patterning and the resulting synchronization are disrupted by pharmacological manipulations without modification of the spatiotemporal pattern of rate fluctuations, simple, noncomposite odors could still be discriminated while complex, composite odors were confounded (Stopfer et al., 1997).

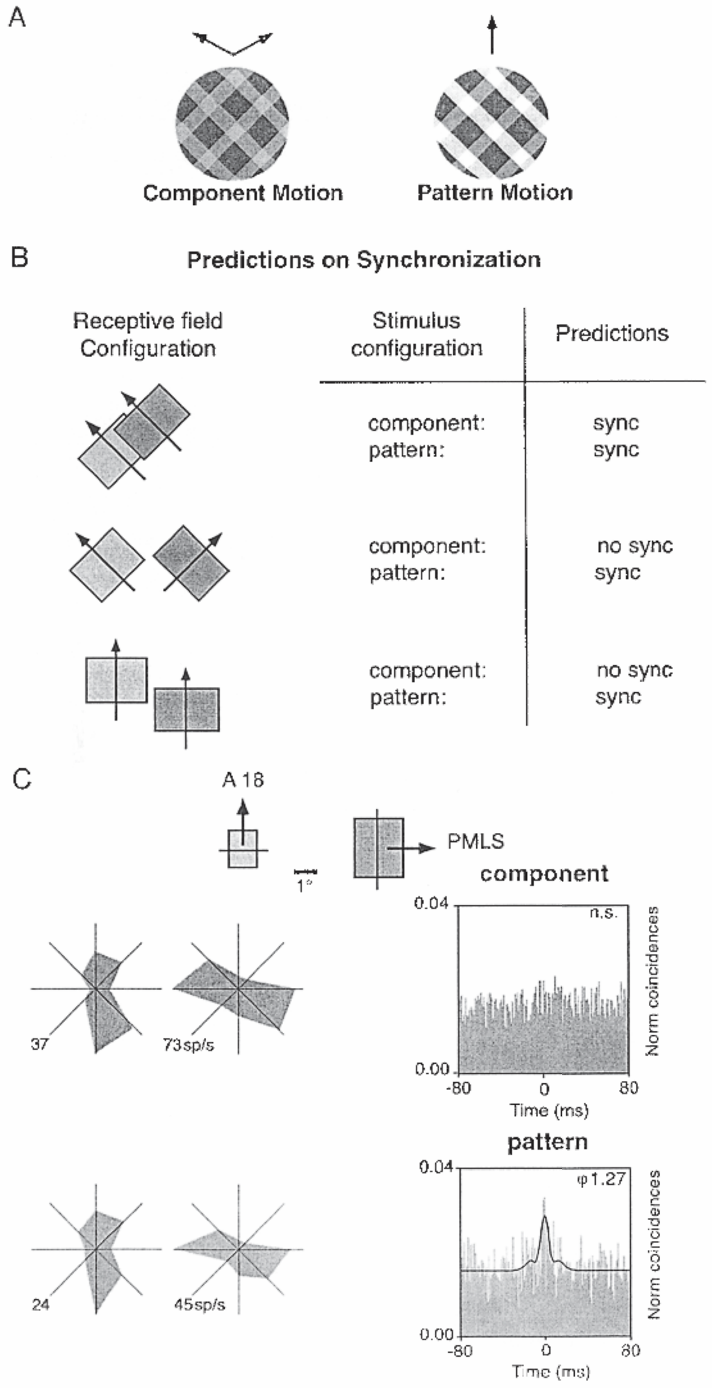

**Figure 2.** *A*, Two superimposed gratings that differ in orientation and directional drift directions are perceived either as two independently moving gratings (component motion) or as a single pattern drifting in the intermediate direction (pattern motion), depending on whether the luminance conditions at the intersections are compatible with transparency. *B*, Predictions on the synchronization behavior of neurons as a function of their receptive field configuration (left) and stimulation conditions (right). *C*, Changes in synchronization behavior of two neurons recorded simultaneously from area 18 and PMLS that were activated with a plaid stimulus under component (upper graph) and pattern motion conditions (lower graph). The two neurons preferred gratings with orthogonal orientation (see receptive field configuration, top, and tuning curves obtained with component and pattern, respectively) and synchronized their responses only when activated with the pattern stimulus (compare cross-correlograms on the right). (Adapted from Castelo-Branco et al., 2000.)

## Conclusions

Taken together, the data and arguments described in this chapter support the notion that neuronal networks are capable of evaluating, with a precision in the millisecond range, the temporal relations among the discharges of neuronal populations and that they exploit this ability for at least three purposes: (1) for the precise signaling of temporal features across processing stages, (2) for the selection of responses, and (3) for the definition of relations among distributed responses with high temporal resolution. It is proposed that this selection and binding mechanism is used in ensemble coding because it meets the requirement for flexible and rapid binding of distributed responses in ever-changing constellations. Assembly coding, in turn, appears necessary in order to cope with the representation of the astronomical number of possible relations among features describing real world objects. It appears, then, that cerebral cortex applies two complementary coding strategies: (1) an explicit representation of features and their conjunctions in the tuned responses of individual, specialized neurons or populations of such neurons; (2) an implicit representation of conjunctions of such explicitly coded contents in dynamically associated assemblies. The first strategy seems to be applied for the representation of a limited set of features and some of their conjunctions and is, in all likelihood, reserved for items that occur very frequently and/or are of particular behavioral importance. The second strategy seems to be reserved for the representation of novel objects and of all those items for which no explicit representation can be realized, either because the explicit representation would require too many neurons or because the contents to be represented are too infrequent to warrant the implementation of specialized neurons.

# Synfire Chains

*Moshe Abeles*

## Introduction

A synfire chain is a feedforward network with many layers. The term *synfire chain* was coined by Abeles (1982) to account for the appearance of precise firing sequences with long interspike delays that resisted explanation in terms of the known properties of cortical physiology. Figure 1 illustrates such a sequence. Subsequently, a number of studies have considered how such chains might be generated, activity propagation along the chain, how synfire chains can be used to compute, and how they might be detected in electrophysiological recordings. Several critical views of these features have also been published. This article discusses the structure and function of synfire chains and differing views on synfire chain properties.

## Structure

A synfire chain is composed of many pools (or layers) of neurons connected in a feedforward fashion. Each neuron in pool $i$ forms about $m$ excitatory connections to neurons in pool $i + 1$, and each neuron in pool $i + 1$ receives about $m$ excitatory connections from neurons in pool $i$. Each pool is assumed to contain $w$ neurons. The number of such pools in a chain is the *length* of the chain, $w$ is the *width* of the chain, and $m$ is the *multiplicity* of the connections. Typically, the width and multiplicity are assumed to be constant

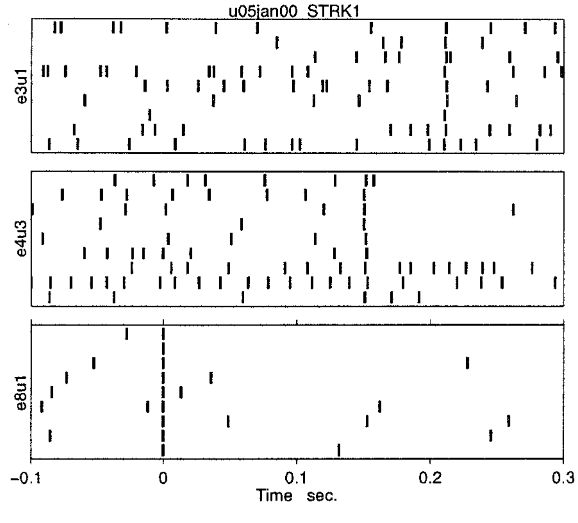

**Figure 1.** A precise firing sequence. Nine repetitions of the structure unit e8u1 (unit 1 from electrode 8) fired, then within 151.5 ± 1.5 ms, unit e4u3 fired, and also within 211.5 ± 1.5 ms, unit e3u1 fired. This sequence repeated 9 times within 519 seconds. Considering the firing rate fluctuations and the rate correlations among these units, the probability of observing this by chance is less then 4 in 10 million.

along the chain, and the connections between two successive pools are random.

This structure, with $m = w$, was first suggested by Griffith in 1963 as a structure that can ensure a fixed level of activity in a network of excitatory neurons. Griffith called this structure a "complete transmission line." He did not study its properties in any detail. Similar structures were presumably used by Grossberg in 1969 to learn and reproduce complicated space-time patterns.

In a random network with moderate connectivity, many synfire chains can be found by chance (Abeles, 1991). For example, let us examine a random network that might mimic a cortical hypercolumn with 20,000 pyramidal neurons and a connectivity of 25%. If one selects a pool of 100 neurons by chance, there will almost always be another pool of 100 neurons in which every neuron is connected to at least 30 neurons from the first pool. Such random synfire chains may not function reproducibly unless the synaptic connections are strengthened by some appropriate learning rule.

A given neuron can participate in more than one synfire chain. The extent to which such repeated membership can occur without compromising reproducibility is known as the *memory capacity* of synfire chains and is addressed in the next section.

## Function

A synfire chain can presumably operate in two modes: asynchronous and synchronous. In the asynchronous mode, each neuron in a pool fires at some elevated firing rate, but the activities are uncorrelated (or only weakly correlated). The activities of one pool are summed by the neurons of the next pool, and each of them fires in an elevated random fashion as well. Shadlen and Newsome (1998) argued that this is the preferential mode of activation.

In the synchronous mode, each pool fires a synchronized volley that induces a large depolarizing wave in the neurons of the next pool, which would then also fire a synchronized volley, and so on. For a synfire chain composed solely of excitatory neurons, this is the preferred mode of activity (Abeles, 1991; Herrmann, Hertz, and Prugel-Bennett, 1995; Diesmann, Gewaltig, and Aertsen, 1999), because each neuron in a pool is subject to approximately the same compound EPSP. Typically, neurons fire during the rising phase of a compound EPSP. The distribution of the times to threshold will be more peaked than the distribution of the firing times of the presynaptic pool.

Diesmann et al. (1999) used EPSP shapes, time constants, thresholds, and so on derived from recordings in cortex and analyzed the transmission between pools numerically. They found that when $m = w = 100$, activity will either propagate as a stable wave with jitter of less than 0.5 ms and saturation of over 90%, or not at all (depending on the initial activation of the chain).

The term *synfire chains* was given to these feedforward structures because of their tendency to transmit activity in this synchronous fashion. The volley of synchronous firing that propagates along a synfire chain is referred to as a *synfire wave*.

Because the effect of a pool resides in the combined synchronous firing of most of its members, the same neuron can participate in a number of pools. This multiple participation is, however, limited. If all neurons participate in every pool, then the network is a fully connected one, and no reproducible synfire waves may be expected.

Bienenstock (1995) and Herrmann et al. (1995) examined how many synfire pools can be embedded in a network of $N$ neurons without interfering with the reproducibility of the activation. Although they used two very different approaches, both came to similar conclusions, namely, the number of pools ($P$) is proportional to the network size ($N$), it decreases when the average firing rate in the network increases, and it depends on the width ($w$) of the pools. A cortical network with an average firing rate of 5 per second and with $w = 100$ may sustain $N$ synfire pools ($P = N$). This means that each neuron can participate in 100 synfire pools.

These pools can be concatenated into one huge synfire chain or into many shorter chains. As pointed out by Maass, any structure that can be wired from individual neurons could just as easily be composed of synfire pools. The advantages would be more reliable operation, shorter input-output delays, and immunity to fallout.

Thus, an average cortical hypercolumn of 20,000 pyramidal neurons may contain 200 synfire chains, each 100 pools long and 100 neurons wide. At 5 spikes per second per neuron, this column will have 300 neurons firing every 3 ms. If the average transmission time between two pools is 3 ms, there could be three synfire waves active concomitantly. These waves may be distributed over three synfire chains or confined to repeated activation of one chain.

## Usage

There have only been a few applications using synfire chains. Arnoldi used them to find invariances in a picture, Jacquemin used them to parse and classify French sentences, and Wrigley used synfire chains to parse an auditory scene. However, the main application seems to lie in Bienenstock's (1996) suggestion to use synfire chains for implementing "compositional" systems. He posits that only a few cross-links between two synfire chains that obey appropriate timing constraints are necessary to assure that both synfire chains will act as a wider and more stable synfire chain. This in turn could lock in to activities of other synfire chains, and so on. Thus a large structure of synfire chains can be dynamically generated to represent binding of many simple components into a meaningful composite mental representation. This type of binding is dynamic, so that a single synfire chain may, under different conditions, lock in to a number of other chains and therefore be part of numerous distinct composite representations. In Bienenstock's view, the most important aspect of such dynamic binding is vertical binding, in which a higher-level concept binds to the lower-level elements that compose it.

Abeles et al. (1993) have shown, by way of simulations, that two synfire chains with random connections may learn to lock in to each other if activated synchronously several times and if the synaptic modifications follow a time-asymmetric rule (i.e., synapses are strengthened if the presynaptic spike precedes the postsynaptic spike and weakened if the time order is reversed). Such learning rules were experimentally reported (e.g., Zhang et al., 1998). Hayon has shown by way of simulation that hierarchical systems of synfire chains could be used to separate figure from ground, to implement a minimal description length (MDL) principle, and to exhibit the property of compositionality. However, these demonstrations were for toy problems. It remains to be shown that synfire chains can efficiently solve such problems in real-world situations.

## Experimental Evidence

Direct experimental support for the existence of synfire chains requires simultaneous recording of several neurons from one pool and several from the next pool under conditions in which the synfire chain is repeatedly activated. Using current techniques, one can simultaneously record from 10 to 30 neurons in the same hypercolumn. This is far too diluted a sampling. Thus, the most one can hope for is to record a few neurons from the same chain simultaneously. In this case, whenever this chain is activated, one expects to see a precise firing sequence of these neurons. With the numbers given above, each neuron may take part in up to 100 chains within a hypercolumn that contains 200 chains. Thus, the chance that a given neuron will participate in a given chain is approximately 0.5. The chance that three neurons will participate in this chain is 0.125. Because there are many different synfire chains and because one can record from more than three neurons simultaneously, there could be numerous different precise firing sequences in any recording site. This was reported to be the case in behaving monkeys

(Prut et al., 1998). Although the method needed for detecting such excessively repeating firing sequences is still under debate (see the next section), there are examples in which the association of such patterns with behavior demonstrates their functional significance. Such a case is illustrated in Figure 2. Clearly, the time of appearance of the sequence ⟨1, 4, 1; 116 ± 1,198 ± 1⟩ is associated with the monkey's expectation and not with the firing rates of the neurons involved.

## Discussion

Synfire chains may be considered a special case of the "cell assembly" suggested by Hebb. A synchronous volley traversing such a chain is equivalent to the concept of "phase sequences." However, Hebb conceived the cell assembly as a network with multiple feedback connections, whereas the synfire chain is a feedforward net. This results in a basic functional difference. Whereas activity in Hebb's cell assembly is characterized by elevated firing rates of all its members for an extended period, a single volley in a prescribed group is enough to characterize the activity in a synfire chain. This allows for much faster computations by synfire chains.

The succession of synchronous volleys generated by a synfire chain can be thought of as a general case of synchrony. Zero-lag synchrony and phase-locked oscillations may be considered special cases. However, the activity wave in a synfire chain is an all-or-none phenomenon. Thus, synfire chains are more suitable for representing categorical mental entities and less suitable for gradual feature representations as required, for instance, by the population vector model.

Several aspects of synfire chain properties have been criticized. These criticisms question the feasibility of their function in cortical environment, self-organization of synfire chains, the existence of precise firing sequences, and their explanatory power.

Shadlen and Newsome (1998) simulated a multilayered feedforward network where in each layer exactly half of the neurons were excitatory and half were inhibitory. They claimed that when two neurons shared fewer than 40% inputs, activity would propagate in the uncorrelated mode through the layers. Their architecture was thoroughly examined by Litvak et al. (submitted), who found that even with 10% of shared inputs, synchrony builds up and renders information transmission by rate codes useless. Furthermore, if the inhibition balances the excitation but is not synchronized with it, synfire waves will develop within two layers.

Bienenstock and Doursat found that in a random network of excitatory neurons, with simple learning rules, if one seeds synchrony by exciting *w* neurons synchronously from time to time, a synfire chain will spontaneously form. Herz and Prugel-Bennett (1996) tried to replicate these results and found that parameters had to be carefully trimmed in order to grow synfire chains; even then, the chains tended to be short and to form closed loops. Similar results were obtained by Levy et al. (2001), who employed time-

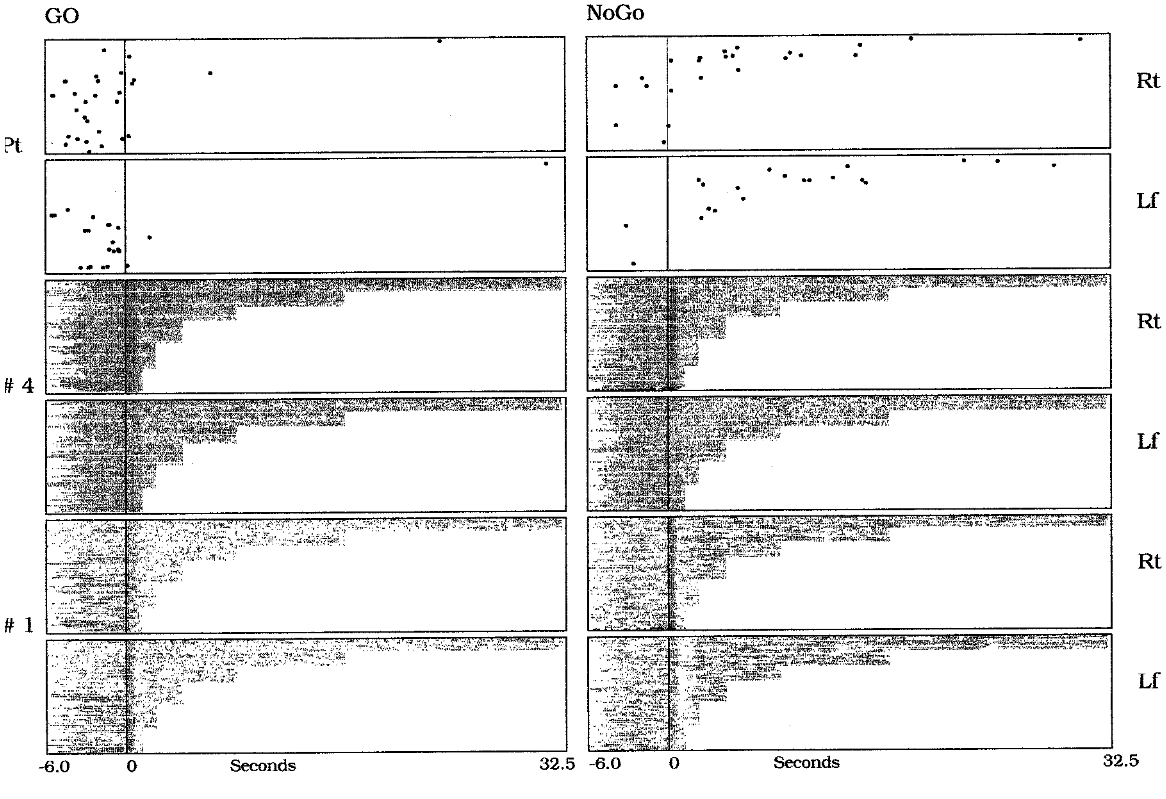

**Figure 2.** Relations between a precise firing sequence and behavior. A monkey was trained to switch between two modes. In one mode it had to memorize a location of a target for 1–32 seconds and touch it when instructed. In the second mode it had to refrain from moving its hand after the instruction to touch the target. Single-unit activity was recorded from frontal cortex through six microelectrodes. See Prut et al. (1998) for more details. GO, trials in which the monkey behaved in the first mode; NoGo, trials in which the monkey behaved according to the second mode. 1, activity of unit number 1. Each line corresponds to one trial, each dot to one spike. Only the activity from the start of a trial until the instruction to move is shown. Throughout this period the monkey did not move its hand. 4, activity of unit 4; same convention as for unit 1. Pt, times of appearance of the sequence unit 1 fired. After 116 ± 1 ms unit 4 fired, and after 198 ± 1 ms unit 1 fired again. Rt, the target was 15° to the right. Lf, the target was 15° to the left. Time 0 is the time at which a short light blink marked the target to be recalled. Trials were presented at random, but they were sorted and displayed here according to category (Go/NoGo and Rt/Lf) and the delay from marking the target until the instruction to go.

asymmetric learning rules. The network would typically become organized into short cyclical synfire chains, which caused the network to generate cyclical activation of groups of neurons. They called this activity mode *distributed synchrony*. The reasons for these differences are not clear and should be studied further.

Recently, Oram et al. argued that for lateral geniculate nucleus and V1, precise firing sequences carry no specific information on the visual stimuli, nor is there any excess of such sequences beyond what would be expected by chance. However, neither their definition of what constitutes a precise firing sequence nor their analysis of information content fits with what one would expect from the synfire chain model. Baker and Lemon (2000) did treat these sequences as coming from synfire chains but found that their actual number was significantly *smaller* than expected by chance. The main differences between these two last works and earlier works on precise sequences seem to lie in the way the chance level is computed from surrogate spike trains. This and other statistical issues were solved by Abeles and Gat (2001) in a study that confirmed once again the existence of a significant excess of precise firing sequences in data from cortex of behaving monkeys.

A synfire chain is a very simplified structure. There might be other structures with less specific connections that can generate precise firing sequences. Indeed, any network that can produce and recognize precise firing sequences would have all the advantages of a synfire chain. However, to the best of my knowledge, nobody has proposed such a network. Earlier in this article we argued that in a random diluted network, if one chooses $w$ and $m$ appropriately, one can find an almost infinite number of synfire chains by chance. However, the activity in such a network is not reproducible. If we start the activity by activating the same $w$ neurons twice, then even a very small amount of noise will cause the activity patterns to diverge very fast. Van Vreeswijk and Sompolinsky (1996) showed that a random network with balanced excitation and inhibition behaves in this “chaotic” manner.

In summary, classical anatomy and physiology of the cortex sustain the idea that activity may be organized in synfire chains. Synfire chains generate and can recognize sequences of coactivated neurons. Therefore, one can create compositional systems from synfire chains. It remains for future work to show if, when, and where cortical activity is organized in synfire-like modes, and whether real-world problems can be solved by synfire chains.

# Synthetic Functional Brain Mapping

*Barry Horwitz and M.-A. Tagamets*

## Introduction

The last decade witnessed a conceptual revolution in our understanding of the neural basis of human cognition, emotion, and sensorimotor behavior. This change was driven mainly by the development of functional brain imaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), and to a lesser degree electric and magnetic encephalography (Horwitz, Tagamets, and McIntosh, 1999). Prior to the use of these methods, the neural correlates of human behavior were inferred primarily by examining the effects of brain lesions on cognitive function, along with extrapolating the results obtained from recordings of neuronal activity in particular brain regions in nonhuman primates while they performed specific sensorimotor and cognitive tasks. Electrical recording and stimulation studies in humans undergoing neurosurgery provided additional important information. These techniques, however, focus on one brain area at a time. PET and fMRI afford a way to see functional activity in most of the brain simultaneously in awake, normal human subjects as they perform specific cognitive, emotional, and sensorimotor tasks. With these techniques, researchers can determine not only which brain areas are active during one task compared to another, but also how different brain areas interact during a task.

Functional neuroimaging data are rich and complex. However, only recently have neural modeling methods been applied to these kinds of data (for overviews, see Horwitz, Tagamets, and McIntosh, 1999; Horwitz, Friston, and Taylor, 2000). These modeling techniques fall into essentially two distinct categories. One, called *systems-level neural modeling*, aims at determining the network of brain regions mediating a specific cognitive task. This means finding the nodes of the network (i.e., the brain regions) and determining the task-dependent functional strengths of their interregional anatomical linkages (McIntosh et al., 1994). This method uses techniques such as covariance structural equation modeling applied to the correlations (functional connectivities) between (PET- or fMRI-determined) regional brain activities. Examples of questions that can be answered using this approach are: (1) As one learns a task, do the functional links between specific brain regions change their values? (2) Despite similar performance, are the same brain networks being used by healthy subjects and those with illnesses? A discussion of covariance structural equation modeling can be found in COVARIANCE STRUCTURAL EQUATION MODELING (q.v.).

The second category of neural modeling, and one that is the focus of this article, has alternatively been referred to as *synthetic functional brain imaging* (Arbib et al., 1995) or as *large-scale neural modeling* (Tagamets and Horwitz, 1998). The goal is to relate neural electrical activity to functional neuroimaging data. This kind of neural modeling is more ambitious and less (PET/fMRI) data-driven than the first category, but it is crucial for furthering our understanding of the neural basis of behavior. Large-scale modeling entails determining both the neural basis for local brain activations and the neurobiological correlates for the PET/fMRI-determined functional connections.

From a practical point of view, the two methods are connected. Systems-level modeling helps identify the nodes of the network corresponding to the cognitive tasks of interest, especially when little or no nonhuman data are available (e.g., most language tasks). Large-scale modeling enables one to hypothesize about the neural underpinnings for how these tasks are implemented in humans, with PET and fMRI data providing constraints on the possible ways by which these neural systems function.

## Functional Brain Imaging Data

PET and fMRI are hemodynamic/metabolic methods that provide indirect measures of neuronal activity (Friston, 1997; Horwitz et al., 2000). Increased blood flow and oxidative metabolism are thought to be needed to restore neuronal ionic concentrations following neural activation, with the largest effects occurring in the vicinity of synapses (for an overview, see Horwitz and Sporns, 1994). In PET, the distribution of brain radioactivity is determined by detecting the coincident gamma rays that are produced by positron-electron pair annihilation. A common method for measuring regional cerebral blood flow (rCBF) involves the bolus injection of $H_2{}^{15}O$. The half-life of $^{15}O$ is 123 s, thus permitting multiple scans (e.g., 6–20, each corresponding to a separate injection of tracer) to be performed in an individual subject during a single scanning session. The time interval needed to obtain a single scan is about 1 minute, and the spatial resolution of PET is about 5–6 mm. The most common method for measuring brain functional activity with fMRI is called blood oxygenation level–dependent contrast, or BOLD. Changes in neural activity lead to changes in blood oxygenation and blood volume, and deoxygenated blood acts as an endogenous paramagnetic contrast agent. The spatial resolution of fMRI images can be about 2 mm within plane. The temporal resolution for fMRI seems limited by the slowness of the hemodynamic response to changes in neural activity (about 5–10 s). In a typical scanning session, a time series of activity (e.g., one scan every few seconds) is obtained in a single subject.

There are two primary data analysis techniques used with PET and fMRI data (Friston, 1997; Horwitz et al., 2000). One, called the *subtraction paradigm*, assumes that different brain regions are engaged in different functions (i.e., computations). This technique is implemented by comparing the functional signals between two (in the simplest case) scans, each representing a different experimental condition. The locations of the large differences in signal between the two scans presumably delineate the brain regions differentially involved in the two conditions. The second method, termed the *covariance paradigm*, assumes that the task represented by an experimental condition is mediated by a network of interacting brain regions, and that different tasks correspond to different, but possibly overlapping, functional networks. By examining the covariances in brain activity between different brain areas, one infers something about which areas are important nodes in the networks under study, and how these nodes are functionally connected. Because functional neuroimaging methods obtain data simultaneously from multiple brain regions, they are ideal for use with the covariance paradigm. The subtraction and covariance paradigms complement one another, and both are necessary to get a clear picture of how the brain works.

## Large-Scale Modeling of Functional Brain Imaging Data

The subtraction and covariance paradigms use statistical tests to discover important features of the data under examination. Inferences about how the results so obtained are related to other functional brain imaging data, and to other kinds of data (e.g., neuroanatomy, neurophysiology) are generally made post hoc and in a qualitative manner. In this sense, these methods are descriptive. In contrast, neural modeling explicitly chooses from the data what is hypothesized to be important, combines neuroimaging data with results obtained by other methods, makes its hypotheses prior to analysis, and does so quantitatively. As stated before, two major modeling methods have been used for analysis of functional imaging data. The first, covariance structural equation modeling (see COVARIANCE STRUCTURAL EQUATION MODELING), is the natural extension of the covariance paradigm's focus on the functional connectivity between brain regions (McIntosh et al., 1994; Horwitz et al., 1999).

However, several problems make it difficult to directly interpret PET or fMRI imaging data in terms of the underlying neuronal activity (Horwitz and Sporns, 1994; Tagamets and Horwitz, 1998; Horwitz et al., 1999). First, the spatial resolution of human brain imaging devices is large compared with the size of neurons or cortical columns, which means that multiple and diverse neuronal populations are lumped together in any resolvable PET or fMRI region of interest (even a single voxel). Second, whereas the temporal resolution of neuronal events is on the order of milliseconds, the appropriate temporal dimension for the hemodynamic methods is on the order of a few seconds, implying that important transient components of activity can be missed by PET and fMRI. Third, electrical recordings of activity measured in nonhuman animal studies generally reflect the firing of action potentials, whereas hemodynamic measurements most likely reflect synaptic activity to a larger extent than neuronal activity (Logothetis et al., 2001). Furthermore, it is likely that inhibitory synaptic activity, which can lead to decreased neuronal spiking, may result in increased PET or fMRI activity (Horwitz and Sporns, 1994).

Because computational neuroscience provides a framework for integrating data from various methods into an explanatory model, it can address a number of issues related to human brain imaging (Arbib et al., 1995; Tagamets and Horwitz, 1998). For example, because of the large difference between the time scale of neuronal events and the temporal resolution of PET and fMRI data, several different cognitive operations usually contribute to the data from a single scan. Modeling can explicitly examine how each component can alter the results, and thus aid interpretation. Another issue is the effect of synaptic inhibition on imaging data (Tagamets and Horwitz, 2001). As mentioned earlier, an inhibition-induced decrease in neural activity in a region will be reflected as a rise in the PET or fMRI measure, as has been found experimentally in some animal studies (see Horwitz and Sporns, 1994, for details). This issue is closely allied to the question of the relative importance of local versus global connectivity in generating the observed imaging data in a specific region. Several neural modeling efforts have been undertaken to address these questions.

Arbib et al. (1995) used a large-scale model of saccade generation (Dominey and Arbib, 1992) and adapted it to generate simulated PET data, a technique they called *synthetic PET.* The model includes a number of brain structures, such as posterior parietal and visual cortex, superior colliculus, the frontal eye field, the mediodorsal and lateral geniculate nuclei of the thalamus, and the caudate and substantia nigra of the basal ganglia (Figure 1*A*). Because some of the pathways involving the basal ganglia are inhibitory, the model is a good testing ground for examining the effects of inhibitory synapses on simulated blood flow. The main hypothesis tested in the synthetic PET simulation was that rCBF, as measured by PET, correlates with local synaptic activity in a region. PET activation in the model was computed by summing the absolute values of both excitatory and inhibitory synaptic weights times firing rates of presynaptic neurons and integrating these values over a time period that corresponded to the time scale of PET while the model performed a specific task. To simulate the subtraction paradigm typically used in PET experiments, computed PET activity was calculated during two different tasks (generating simple saccades and memory-driven saccades) and the differences in PET activity between the two conditions were evaluated in all regions of the model. In the simple saccade condition, disinhibition of the superior colliculus allows a saccade to be generated to a target present in the field of view. Memory-driven saccades, however, are driven by activation of a memory loop between the frontal eye field and mediodorsal nucleus (MD) of the thalamus, which is disinhibited by the substantia nigra, generating a saccade (via the superior colliculus) to a remembered target when there is no stimulus present. When compared to the simple saccade task, spiking activity in the modeled MD region increased as a result of the disinhibition, while simulated PET activation decreased in MD (Figure 1*B*). This result showed how modeling can illuminate a counterintuitive effect: during the simple saccade, synaptic activity from the tonic inhibition of the MD contributes more synaptic activity to the PET measure than the increase in excitation that results from disinhibition.

Tagamets and Horwitz (1998, 2001) developed a large-scale model of working memory that was designed specifically for simulating the quantitative aspects of imaging data. Three types of factors that can influence imaging data were identified and implemented in the model. Emphasis was on using biological constraints for (1) setting local proportions of excitatory and inhibitory connections (Figure 2*A*), (2) determining interregional connection strengths and patterns (Figure 2*B*), and (3) determining activation rule parameters that yield appropriate electrical activity behaviors in the local circuits. Because most corticocortical connections are local and excitatory, a basic local circuit that reflects this connectivity pattern was used to construct the model. Local connections account for about 80%–90% of all corticocortical synapses in the model, with the remaining 10%–20% being interregional (Figure 2*A*). The activation rule (Equation 1) determines the electrical activity of the local circuits:

$$da_{m,i}(t)/dt = \Delta\left[1 + \exp\left(-K_m\left(\sum_{q,j} w_{ji}a_{qj} - \tau_m + N_m(t)\right)\right)\right]^{-1} - \delta a_{m,i}(t)$$

where $m$ and $q$ denote the unit type (either E or I, for excitatory and inhibitory, respectively), $a_{m,i}$ is the activity of the $i$th unit of type $m$, $\tau_{\text{m}}$ is a threshold, and $N_m(t)$ is a noise term for units of type $m$; $w_{ji}$ is the synaptic weight from unit $j$ to $i$. Parameters were chosen so that the behavior of a single circuit has maximal flexibility in response to various types of stimuli. For example, for the parameter $K$ (the steepness of the sigmoid, which determines responsiveness of the unit), it was found that a ratio of approximately 2:1 for inhibitory and excitatory units, respectively, yields maximal reactivity to both excitatory and inhibitory inputs.

Simulations with the model suggest that effects such as the interaction between afferent and local connections, interaction between task type and inhibitory input, and effects of feedback con-

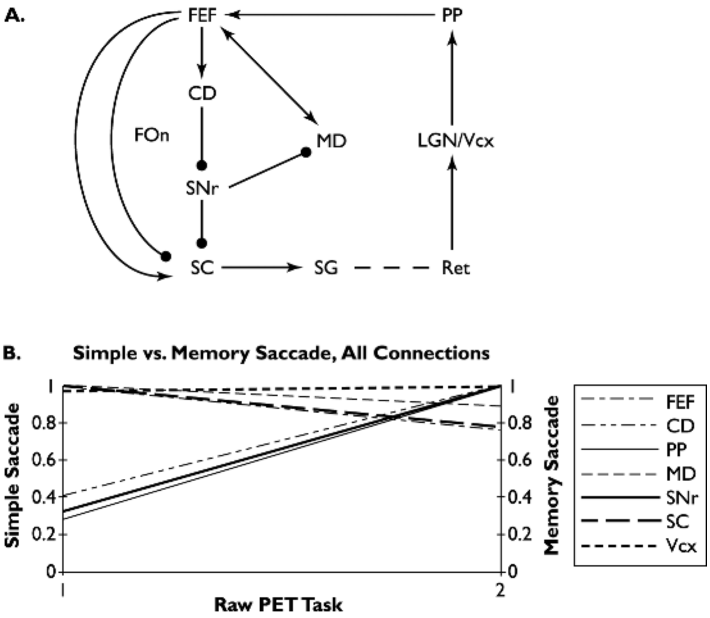

**Figure 1.** *A*, Simplified schematic model for saccade generation (Dominey and Arbib, 1992). Arrows denote excitatory connections; solid circles, inhibitory connections. CD, caudate; FEF, frontal eye fields; FOn, foveal-on cells; LGN, lateral geniculate nucleus; MD, mediodorsal thalamus; PP, posterior parietal cortex; Ret, retina; SC, superior colliculus; SG, brainstem saccade burst generator; SNr, substantia nigra pars reticulata; Vcx, visual cortex. *B*, Simulated PET activity for each brain area in the neural model of *A* for saccade generation. Simple saccades are given by the values on the left, memory saccades by those on the right. (From Arbib et al., 1995. Reprinted with permission.)

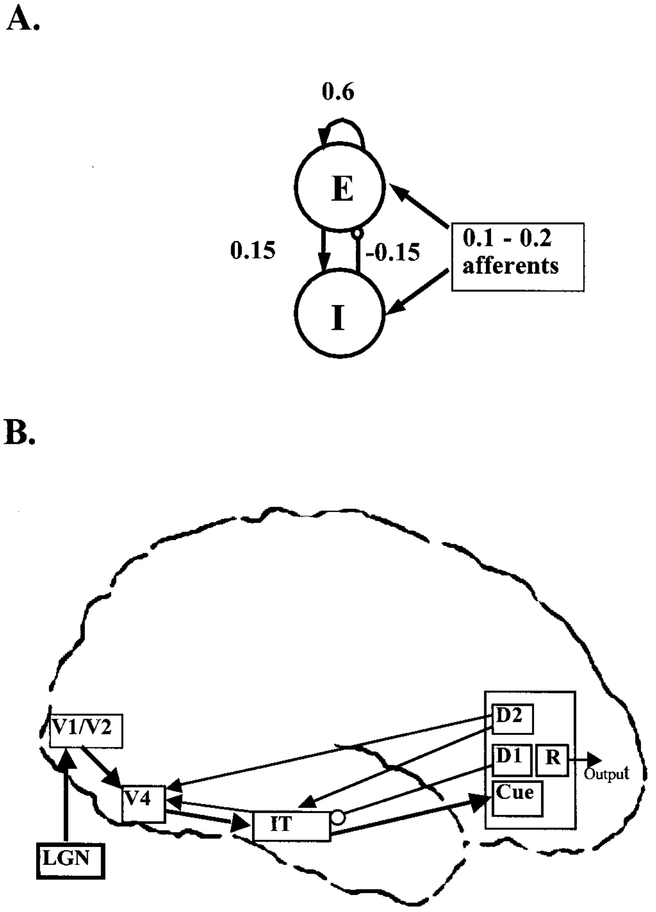

**Figure 2.** *A*, The basic unit of the Tagamets-Horwitz (1998) model. This local assembly, representing a cortical column, consists of an excitatory group (E) and an inhibitory group (I). Local synaptic activity is dominated by local excitation and inhibition, while afferents from other cortical regions account for the smallest proportion, as indicated by the values of the synaptic weights. *B*, The anatomical regions comprising the Tagamets-Horwitz network. Shown are the regions and the anatomical connections between them. Arrows denote excitatory connections, open circles inhibitory connections. (Modified from Tagamets and Horwitz, 1998.)

nections are likely to play major roles in imaging results (Tagamets and Horwitz, 1998, 2001). The full model is composed of a number of regions along the ventral visual pathway, including V1/V2, V4, inferotemporal cortex (IT), and a prefrontal region (Figure 2*B*). A working memory circuit in the frontal region of the model (Figure *3*) implements a delayed match-to-sample task similar to those used in both electrophysiological experiments in monkeys and human neuroimaging studies. The memory is modulated by a continuous-valued parameter that projects diffusely into all members of a subpopulation (D2) of the frontal working memory circuit. When this parameter is set to a low value, the model performs a passive viewing task, stimuli are not kept in memory, and there is little activity in the frontal units during the delay period (Figure 4*A*). At a higher value, this parameter causes two subpopulations of the working memory circuit (D1 and D2) to act as a feedback loop that maintains the memory during the delay interval (Figure 4*B*). Similar to Arbib et al. (1995), simulated PET/fMRI activity is taken to be the absolute value of the local synaptic activity over the time course of the scan. Using this model, it was shown that subtracting a passive viewing task from a match-to-sample task yielded electrical ("spiking") activities that matched those found in monkeys (e.g., Funahashi, Bruce, and Goldman-Rakic, 1990), and simulated PET data that were quantitatively similar to those obtained in human imaging studies of the same tasks, with increases in V4, IT, and frontal regions and little change in early visual cortex (V1/V2) (Haxby et al., 1995). The increases seen in V4 and IT are the result of feedback connections from the frontal working memory circuit.

Although single-cell recordings have been used for years, they have tended to focus on individual neurons that are especially responsive to a particular type of stimulus. Neuroimaging, on the other hand, blends the activity of large ensembles of neurons into a single measure. This leads to the question, to what extent do such "special neurons" contribute to overall activity in a local patch of cortex? Scannell and Young (1999) explored this relationship and discussed the implications for neuroimaging results. They showed that a rise in a population activation can be caused by changes in spontaneous background activity (e.g., via attention) at least as much as by changes in spiking of single stimulus-specific neurons.

The modeling examined in this section focused primarily on relating neural activity to PET signals. Recently, emphasis has shifted toward fMRI studies (Horwitz and Tagamets, 1999; Arbib et al., 2000). For example, the Tagamets-Horwitz model was extended so that fMRI studies could be simulated (Horwitz and Tagamets,

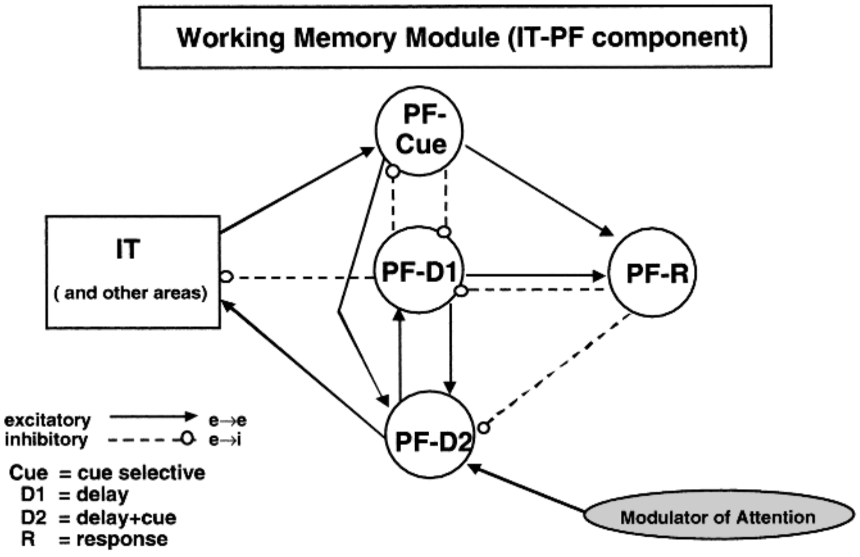

**Figure 3.** The working memory module in prefrontal cortex is composed of four types of units, whose electrical activities are similar to the types identified by Funahashi et al. (1990). Each element of the circuit is a basic unit of the type shown in Figure 2*A*. Inhibitory connections are implemented as excitatory connections onto inhibitory units. The attentional modulation is modeled as a diffuse, weak activity directed at the D2 units. For details concerning the connection weights, see Tagamets and Horwitz (1998).

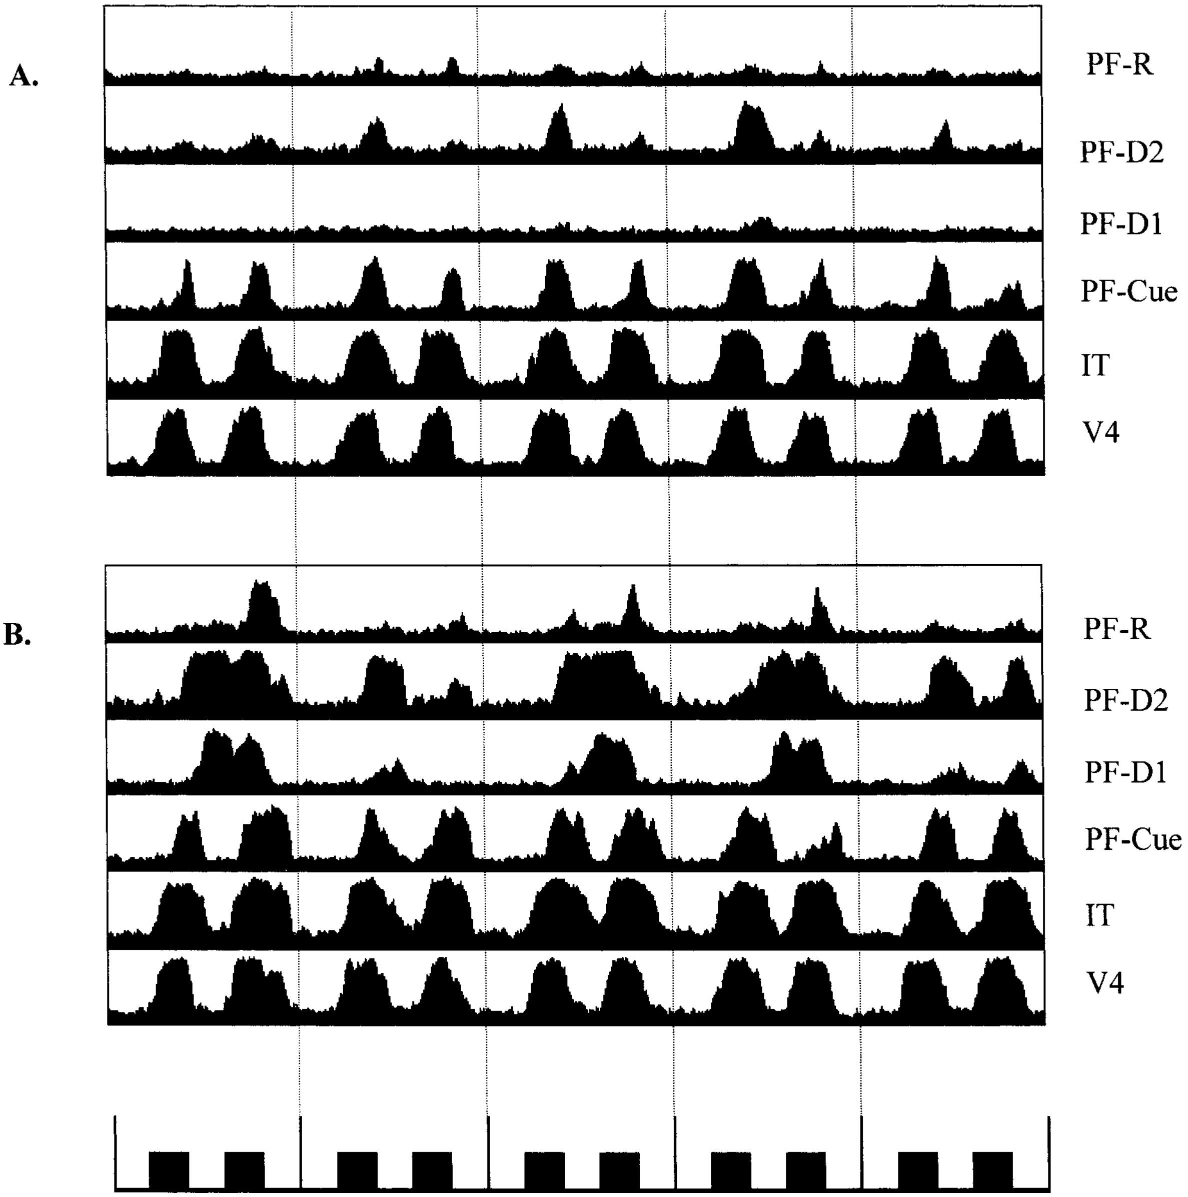

**Figure 4.** Time course of electrical activities of sample units from the different cortical areas of the Tagamets-Horwitz model during five trials of a task, including each type of frontal unit in the memory circuit. *A*, Low-attention level; *B*, high-attention level. Stimuli are represented by filled blocks in the time line at the bottom of the figure, with each block corresponding to 1 s of simulated time. Trials are separated by dotted lines. (Modified from Tagamets and Horwitz, 1998.)

1999). Rather than integrating the absolute value of the summed synaptic activities in each brain region over the entire experiment, as would be done to simulate a PET study, the integration time was reduced to 50 ms, which compares favorably to the slice acquisition time for many fMRI scanners. The problem of hemodynamic delay must also be dealt with: the brain's vascular response to a transient change in neural activity is delayed and dispersed in time (estimated to be about 5–8 s). A Poisson function was used to represent the hemodynamic delay. One simulation then focused on examining event-related fMRI designs, which use the relatively high temporal resolution of fMRI to capture different components of the cognitive tasks under study. The studies that have been employed to validate these designs generally have been simple sensory or motor tasks. The problem is that in higher cognitive tasks, there can be extensive neural activity in multiple brain regions in the absence of external stimuli, or when no overt motor responses are employed. Moreover, much of this neural activity is not directly under experimental control. Simulations examined these issues and found that fMRI signals often can be misleading, owing to the fact that the hemodynamic delay results in the convolving of neural signals associated with the presence of stimuli and those related to internal processing. These results demonstrated the need for care in interpreting the results of event-related fMRI experiments.

In preliminary work from our laboratories, the neural basis for PET-determined measures of functional connectivity has also been addressed using neural modeling. Because in PET, interregional correlations are evaluated across subjects, to generate subject-to-subject variability we added a "left" hemisphere whose regions are randomly connected (different for each subject) to regions in the right hemisphere that implemented the Tagamets-Horwitz model of visual processing (Tagamets and Horwitz, 1998). Random noise patterns were presented to the left hemisphere, whereas shapes were presented to the right during the simulated PET studies. We found that interregional correlations (i.e., functional connectivity) were smaller during the control task using noise patterns than during the delayed-match-to-sample task for shape. Moreover, for the shape task, the functional connectivity was reduced in value if the strength of an interregional anatomical connection was reduced. Thus, our analysis showed that for two anatomically linked brain regions, the strength of the PET functional connectivity between them depends on the strength of their anatomical connectivity (as embodied in the synaptic weights), and also on the extent to which the circuit in which the two regions are nodes is being utilized.

Another area of research is represented by efforts to relate cognitive models to functional brain imaging data. For example, Just, Carpenter, and Varma (1999) used a computational model of sentence comprehension called 4CAPS (which is a production model) to account for how fMRI activation levels varied as a function of sentence complexity in three brain areas (Broca's, Wernicke's, and dorsolateral prefrontal cortex). In their computational model, resource utilization in a given unit of time in each component of the system is assumed to correspond to the amount of activation observed with the neuroimaging measure in the corresponding component during that time interval. They found good agreement between the experimental number of activated voxels in Broca's and Wernicke's areas and the prediction of their model for three sentence types of different complexity.

## Discussion

In this article, we focused primarily on large-scale neural modeling (synthetic brain imaging), which is used to help elucidate the relation between neural activity and functional brain imaging data. Much still needs to be done to effectively utilize neural modeling methods with functional neuroimaging data. Issues to be addressed in the near future include developing a better understanding of the connection between neuronal activity and the concomitant alterations in blood flow and metabolism. Because so many factors regulate blood flow and metabolism, this topic itself will require neurocomputational techniques, perhaps at the level of cortical columns. Researchers will also need to be able to simulate electric and magnetic encephalographic data, because these studies are the best sources of temporal information on high-level cognitive tasks in humans, such as those associated with language processing. Nonetheless, functional brain imaging has become central to cognitive neuroscience and, because the data it generates are so multidimensional and complex, only neurocomputational approaches such as those discussed here can provide a framework for its integration into a cohesive account of the neural basis of behavior.

# Systematicity of Generalizations in Connectionist Networks

*Robert F. Hadley*

## Introduction

The use of the term *systematicity* in relation to connectionist networks originated with Fodor and Pylyshyn's (1988) critique of connectionist architecture. Fodor and Pylyshyn sought to demonstrate that insofar as connectionism offers a novel *architectural* paradigm (as distinct from neurally inspired implementations of symbolic artificial intelligence), it will fail to explain certain fundamental aspects of human cognition. One such aspect, identified by Fodor and Pylyshyn as *systematicity*, consists in the fact that human thought and language comprehension are manifestations of a coherent, underlying system; our ability to entertain certain thoughts (and to understand certain sentences) is *caused* by the very mechanisms that ensure our ability to think (or understand) systematically related variants of the original thoughts and sentences. Thus, humans who can understand sentences of the form *x Relation y* (e.g., *John loves Mary*) can also, as a matter of causal necessity, understand sentences of the form *y Relation x* (*Mary loves John*). Fodor and Pylyshyn provide other, more complex examples of cognitive abilities that "come in clumps" (i.e., the abilities are systematically related). Specifically, they maintain that humans display *systematicity of inference*. Anyone who can perform elementary logical inferences of a given form can perform other elementary inferences of the same logical form.

Even as Fodor and Pylyshyn's 1988 critique went to press, connectionists were preparing rebuttals and counterexamples. Some have argued (see Chalmers, 1990; Smolensky, 1990) that Fodor and Pylyshyn underestimated the manner in which distributed representations can encode compositional structure (see COMPOSITIONALITY IN NEURAL SYSTEMS). Others have argued that Fodor and Pylyshyn's initial conception of systematicity was vague and unworkable (cf. Niklasson and van Gelder, 1994). Nevertheless, the Fodor-Pylyshyn critique spurred a flurry of connectionist research, some of which is described below.

It is important to realize that Fodor and Pylyshyn's conception of systematicity made no reference to learning-based generalization. Rather, they offered indications that causal mechanisms supporting systematicity were innate. At the very least, they viewed systematicity as a *nomologically necessary* feature of human cognition (i.e., it was necessary by virtue of natural law). While acknowledging that connectionist networks might achieve isolated instances of systematicity by means of ad hoc, arbitrary "wiring" configurations, they dismissed such arbitrary devices as scientifically uninteresting.

In 1990, Chalmers offered a refutation of Fodor and Pylyshyn's thesis, based on a simple backpropagation network that transformed distributed representations of active-voice sentences into representations of passive-voice sentences (and vice versa). Significantly, Chalmers demonstrated that *novel* distributed activation patterns can possess structure that bears a systematic relationship to previously encountered, distributed patterns (see CONNECTIONIST AND SYMBOLIC REPRESENTATIONS). This systematic relationship becomes apparent in the presence of trained, weighted link configurations within his three-layer network. Although Fodor and Pylyshyn regard such weighted link configurations as "nomologically arbitrary," it has been argued (Hadley, 1994) that even classical architectures can engender systematicity only when background computational mechanisms are present. The existence of these background mechanisms appears arbitrary from a nomological standpoint.

Independently, Smolensky (1990) described a mathematically sound method, based on tensor products, which ensured that systematically related sentences could all be represented within a single layer of connectionist units. Ignoring for the present the issue of how tensor products can be decomposed, the basic method of representation is straightforward. If a given sentence contains a series of symbols (called fillers), $s_1$, $s_2$, . . . $s_n$, each playing the respective role $r_1$, $r_2$, . . . $r_n$, then the tensor representation is simply the Cartesian product of the numerical activation levels which respectively represent the individual fillers and roles. Viewed mathematically, Smolensky's approach is unproblematic. However, Smolensky did not initially address the issue of whether his tensor product representations could be acquired via training. Thus, their role in generalization was not readily apparent.

Fodor and his colleague McLaughlin soon disputed Smolensky's "solution" to the systematicity challenge (Fodor and McLaughlin, 1990). Among other things, they maintained that Smolensky's tensor product representations constituted "implementations" of classical symbolic structures. Smolensky, however, vigorously stressed the nonclassical aspects of tensor product representations. For example, one may activate the tensor product representation of a compound expression (e.g., the representation of *John loves Mary*) without simultaneously activating the atomic constituents of that expression. Moreover, tensor product representations permit some degree of graceful degradation.

Before we proceed to more complex considerations, a brief explanation of two widely used network architectures may be helpful. Readers already familiar with simple recurrent networks (SRNs) and Recursive Auto-Associative Memory (RAAM) may pass over this digression.

SRNs (Elman, 1990) resemble the familar three-layer backpropagation network except that, in addition to the standard hidden layer, the architecture includes a supplementary *context layer* whose dimensions match the hidden layer's. Links flow from the hidden layer to this context layer, enabling any activation pattern currently present on the hidden layer to be merged with whatever activation pattern happens to be present in the context layer during the current input cycle. Moreover, another set of links flow from the context layer back into the standard hidden layer; hence the adjective *recurrent*. On each input cycle, the hidden layer receives input both from the normal input layer and from the context layer.

RAAM networks (Pollack, 1990) are simple three-layer backpropagation networks whose input and output layers are each divided into regions (*N* regions, let us say). The network is trained to autoassociate, i.e., to reproduce a given pattern of input on the output layer. The purpose of this training is to permit condensed, distributed encodings of those *n*-tuples (or *n*-sequences) of information (which are presented to the *N* regions of the input layer) to be developed on the hidden layer. Once such a distributed encoding has been developed for a given *n*-tuple of information, that encoding may later be presented as input to a single region of the input layer, while the remaining input regions receive similarly derived distributed encodings. The network may then be trained to autoassociate on this more complex set of input information. By following this general iterative pattern, condensed distributed encodings for entire tree structures (such as binary parse trees) can be generated and extracted from the RAAM's hidden layer.

## Learning-Based Definitions of Systematicity

As previously noted, Fodor and Pylyshyn's conception of systematicity does not involve a process of learning. It does, however, require that agents extend their understanding of symbolic structures to novel instances. Many of the "novel instances" cited by Fodor and Pylyshyn involved *re-ordered constituents*. For example, any agent who has understood *mice fear cats* will, by virtue of the same mechanisms of understanding, comprehend *cats fear mice*. On their view, these mechanisms involve processes of *semantic compositionality*. Now, although it had been established by 1990 that both SRNs and RAAMs could successfully process sentences in which novel combinations of words were present, it remained unclear whether networks could be trained to accommodate novel orderings of constituents. Indeed, to all appearances, an important form of systematic generalization remained untested. This fact was noted in Hadley (1992), where a hierarchy of degrees of learning-based systematicity was first introduced.

For purposes of the following discussion, it will be helpful to have in mind a brief paraphrase of a portion of this hierarchy. (A somewhat similar though less hierarchical set of distinctions can be found in Niklasson and van Gelder, 1994.)

A cognitive agent, or a connectionist network, might exhibit any of the following degrees of systematicity (or systematic generalization). In the following, *novel* is measured relative to a known training corpus.

1. *Weak systematicity*. An agent is at most weakly systematic if, after training, it can process "test" sentences (or symbol sequences) containing novel combinations of words (symbols) but cannot process sentences containing familiar words in positions that are novel for those words.
2. *Strong systematicity* requires that an agent *learn* to generalize the use of a *significant fraction* of its vocabulary to novel syntactic positions, in both simple and embedded sentences. In this context, a word or symbol is considered to occupy a novel position (e.g., grammatical subject) only if the agent has not encountered that word in that syntactic position at any level of sentential embedding.

The forms of systematicity just listed do not require that an agent be capable of semantically interpreting the sentences in question. Recall, however, that Fodor and Pylyshyn's examples of systematicity included cases where an agent assigns meaning to the sentences involved (e.g., whoever understands *John loves Mary* can also understand *Mary loves John*). Any learning-based conception of systematicity that approaches the depth of Fodor and Pylyshyn's initial challenge must therefore include the ability to assign correct semantic interpretations. For this reason, a more demanding criterion (given below) of systematicity was employed by Hadley and Hayward (1997).

3. *Strong semantic systematicity* (henceforth Semantic-Sys) is displayed when agents not only manifest strong systematicity (i.e., level 2 above), but they are also able to assign appropriate meanings to all words occurring in novel test sentences that could be used to establish a mastery of level 2.

(It is here intended that when an agent assigns an appropriate meaning to a word, the agent can at least map the word onto an internal conceptual representation.)

It is noteworthy that Semantic-Sys presents connectionist networks with an especially demanding challenge. In order to achieve this level of systematicity, networks must not only generalize to novel positions, but simultaneously *retain precision* in the assignment of meanings to each symbol involved. Symbols belonging to the same category (e.g., nouns) must not be conflated. Very few connectionists working on systematic generalization have taken up this challenge, yet it is clear that humans do display Semantic-Sys (see Hadley, 1994).

We have now seen a reasonable sampling of various levels of systematic generalization that connectionist networks might attain (though finer-grained distinctions can be made). The question naturally arises, how have artificial neural networks fared against the challenges posed by these levels? In what follows, we consider connectionist systems belonging to two broad categories: (1) networks that, via training, develop some degree of combinatorial structure in their distributed representations, and (2) networks that possess, a priori, at least one representational layer whose combinatorial structure is prearranged by virtue of the number of nodes present and the configuration of links entering those nodes.

## Fundamentally Empirical Approaches

Much connectionist research on systematic generalization has employed network architectures that develop strongly distributed, internal representations, whose topological properties derive both from the statistical nature of input sequences and from the fully connected (and largely general-purpose) link configurations. As in most fully connected networks, the resultant generalization capacities derive largely from the tendency of overlapping activation vectors to be assimilated to one another. Indeed, the very factors that account for "graceful degradation" also play a role in the systematic generalizations formed by these networks. However, in each case, the network possesses additional characteristics that contribute to the systematicity effect. Here we shall consider just two general classes, those that employ a recurrent context layer and those that rely strongly on the distributed nature of input patterns.

### Context Layer Effects

By 1990, several connectionist networks had exhibited the capacity to successfully "process," in one sense or another, sentences in which novel combinations of words were present (relative to the training corpus). Six such systems (respectively due to Chalmers, Elman, McClelland and Kawamoto, Pollack, Smolensky, and St. John and McClelland) were examined in Hadley (1994), and of these, five were shown to exhibit at least weak systematicity. Unfortunately, none of the six systems had been subjected to the training and testing regimens necessary to establish strong systematicity. However, Christiansen and Chater (1994) subjected Elman's SRN architecture to appropriate training and testing in an effort to establish its potential for what they dubbed "strong generalization." As in Elman's earlier (1990) work, Christiansen and Chater focused on a syntactic prediction task.

During training, a large corpus of sentences was fed, word by word, through the network's input layer, and backpropagation was employed to train the network to predict (on its output layer) the *next* word to appear in the input stream. As it happened, given the complexity of the training corpus involved, the network eventually learned to predict not just a single word, but a range of possible next words. Throughout the training process, the network's recurrent *context layer* retained a composite (or blended) memory of the main hidden layer's contents during the previous *N* iterations.

Crucially, during the testing phase, Christiansen and Chater ensured that some sentences presented specific nouns in two grammatical positions they had not occupied during training. The results obtained for these chosen sentences were encouraging in one respect and disappointing in another. Christiansen and Chater emphasized that within one of the selected grammatical positions, their network's predictive capacity was not derailed by the unexpected appearance of hitherto contextually restricted nouns. Importantly, the pervasive effect of the network's context layer explained this ability to "carry on." (Note that the context layer's activation patterns blended with any contextually novel noun's activation. In consequence, the resultant blended activations were only partially novel. Thus, graceful degradation played an essential role in this success.) On the other hand, the network displayed almost no capacity to predict the occurrence of the previously restricted nouns within the critical contexts. (The assigned activation levels were minimal.)

In contrast, Elman (1998) conducted experiments basically similar to Christiansen and Chater's, though with a much smaller grammar and training corpus. Elman examined the behavior of a particular noun (*boy*) that had not appeared as the direct object of any verb during training. However, the noun had appeared as grammatical subject, as had other human nouns. The effects of the SRN's context layer were such that, after 10,000 passes through training corpora of various sizes, the network was able to predict the possible occurrence of *boy* in the position of direct object with nearly the same probability as predicted for the unrestricted human nouns.

Whether Elman has produced a convincing example of positional generalization as opposed to a chance result is not straightforward. In light of the Christiansen-Chater network's failure to make predictions comparable to Elman's successful but solitary example, the robustness of Elman's result is in doubt. Moreover, rigorously extensive experiments, conducted by Hadley with J. Hsiao, failed to reproduce Elman's success when the vocabulary of Elman's simple (noun-verb-noun) grammar was expanded to include roughly twice the initial number of nouns and verbs, and a total of four nouns were positionally restricted during training (as opposed to Elman's single noun).

In any case, it should be borne in mind that the experiments of neither Christiansen and Chater nor Elman addressed the problem of generalizing *while retaining specificity* in assigning semantic interpretations to complete sentences, as would be required to satisfy either the spirit of Fodor and Pylyshyn's initial challenge or the criteria of Semantic-Sys.

### Distributed Input Patterns

Working in a different domain, Niklasson and van Gelder (1994) described a backpropagation-trained network that successfully transformed simple logic formulas (in which a single level of embedding is permitted) into expressions of related form. Niklasson and van Gelder explicitly addressed both strong systematicity and the related issue of permitting entirely novel atomic symbols to appear within test sentences. They forthrightly claimed that their network attained 100% accuracy in both kinds of systematic generalization.

The architecture employed by Niklasson and van Gelder involves a hybrid of two standard methods. They train a three-layer RAAM network to develop distributed encodings of the structured logic formulas that comprise the input and output of the transformation task. While this training occurs, the central (hidden) layer of the RAAM is used as the input layer of a separate, three-layer formula-transformation network. The latter network is trained, via backpropagation, concurrently with the RAAM.

Now, although the Niklasson and van Gelder model unquestionably yields intriguing results, some concerns have been voiced (see Phillips, 1994). Among other issues, distributed encodings are assigned a priori to all atomic symbols (including the sole symbol presented, during testing, in a novel context). Crucially, these encodings already include substantial information about the syntactic category of each atomic symbol. Moreover, the featural encoding of these atomic propositional symbols ensures that at least half the features assigned to the lone novel symbol have already been presented, within the crucial context, during the training phase. Thus, the *transformation network* may, in the main, be exhibiting a form of graceful degradation. This agrees with the fact that Niklasson and van Gelder employ a lenient criterion of correctness. Other reservations concern the fact that just one symbol is ever presented in a novel context. Recall that strong systematicity requires that a significant fraction of terms be tested in novel contexts.

In more recent work, Bodén and Niklasson (2000) present a RAAM-based connectionist model that, in their view, displays a form of Semanitic-Sys. Fundamental to Bodén and Niklasson's approach is their construal of semantic content. On their construal, any network that develops distributed, *contextually influenced*, internal representations for words in its training corpus will thereby have assigned semantic content to those words. In essence, Bodén and Niklasson equate a word's semantic content with activation patterns that reflect statistical information concerning the word's typical syntactic context.

A problematic aspect of Bodén and Niklasson's construal of semantic content is that this precise kind of statistical information can be extracted when the training and test corpora consist entirely of artificial sentences containing only words that have *no* prior associations with any concept or meaning representation. Thus, their approach would entail that each sentence in such a case has semantic content, although the sentences possess no descriptive (or expressive) relationship to any world situation, state of affairs, or proposition. (It is well known among mathematical logicians that purely syntactic constraints cannot, in general, suffice to uniquely determine the standard semantic interpretation of a set of sentences, including axiom sets.) For these reasons, measured in terms of the definition of semantic systematicity given earlier in this article, the connectionist model of Bodén and Niklasson does not satisfy the Semantic-Sys challenge that has concerned us here.

Apart from the above difficulties, Bodén and Niklasson's case for Semantic-Sys rests on the similarity of an internal activation pattern (which was assigned to a purportedly novel word—call it *W*—by their network) to activation patterns assigned to certain known words. Yet the activation pattern assigned to *W* was developed by *training* the network to perform the *same* association task, on a sentence containing *W*, as the network had (earlier) been trained to perform on sentences containing the aforementioned "known" words. The latter appear in exactly the same syntactic position as *W*. Given this, it is doubtful whether *W* should be viewed as novel in the relevant sense.

## Combinatorially Endowed Networks

We turn now to network models that, in part, incorporate *preconfigured* node and link structures that intrinsically possess combinatorial properties.

Phillips (1994) employs an intricate architecture that devotes special layers to the calculation and addition of tensor product representations. (See the foregoing discussion of Smolensky, 1990.) The network is trained, via backpropagation, both to autoassociate on simple (noun-verb-noun) sentences and to answer simple queries about roles that words play in those sentences. Five nouns and three verbs were employed in the initial studies. Phillips reported an impressive degree of positional generalization (92% accuracy) even when all five nouns were restricted to a single syntactic position (either agent or patient) during training. However, since embedded sentences were not employed in training or testing, the criteria for *strong systematicity* were not strictly satisfied. It remains to be determined whether the underlying strategy will eventually yield either strong (syntactic) systematicity or Semantic-Sys.

A detailed examination of Phillip's model is not possible here. However, of special significance for the challenge initially posed by Fodor and Pylyshyn (1988) is the structure of layers Phillips employs for creating and storing tensor product representations. The dimensions of these layers are carefully chosen, and wiring leading into each of their units is carefully handcrafted. For example, each unit in the tensor product layer receives just one link from a carefully chosen unit in a special "role vector" layer, and similarly, one link from the network's first hidden layer. Activation functions are also designed to ensure, in the case of the tensor product layer, that addition of tensor products will occur. As a result, the overall appearance and behavior of these crucial layers is strongly reminiscent of conventional hardware networks. Moreover, the layers arguably perform classical structure-sensitive processing, as defined by Fodor and Pylyshyn. Links feeding into these crucial layers are crafted in a manner that is highly sensitive to the structure of the other vectors involved. A plausible case could be made, therefore, that Fodor and Pylyshyn would regard Phillip's model as a connectionist implementation of a classical architecture.

Thus far, the authors we have considered either have addressed only syntactic generalization or have employed a contentious sense of "novel." We now consider a model, due to Hadley and Hayward

(1997), that is designed to achieve the most stringent criterion of systematicity defined above, Semantic-Sys. In contrast to the previous models, training of the Hadley-Hayward network employs no error feedback; all learning arises from Hebbian-inspired processes (Figure 1). During the training regime, two-thirds of all nouns are restricted to a single syntactic position. Nevertheless, the network successfully generalizes and assigns entirely accurate semantic interpretations even when novel levels of clausal embedding are present.

Arguably, the model employs, within its output layer, semantic representations that possess a fundamental classical property, viz., the activation (tokening) of complex representations requires the activation (tokening) of its semantic constituents. Also, Hadley and Hayward employ explicit binding nodes (as in Smolensky, 1990) to ensure that concept and role nodes have the *potential* to bind in novel combinations. This potential is only realized, however, once the model learns to activate role nodes in an appropriate fashion. Such learning arises as a *by-product* of (1) unsupervised spreading activation within the semantic layer and (2) Hebbian learning of associations between words (locally represented in the input layer) and concepts (represented in the semantic layer).

Training involves the presentation of a corpus of sentences, word by word, to the input layer. As each sentence is presented, a target (presumably "guessed") meaning representation for the entire sentence is active within the semantic layer. Hebbian-based incrementing of weights, between simultaneously active nodes, both between layers and within the semantic layer, accounts for all learning. Once learning is complete, the various role nodes become active in an appropriate sequence and bind with appropriate concept nodes. Activation decay plays a crucial role in the binding process, and supports correct attachment of embedded sentence meanings.

## Discussion

In light of the preceding, it would appear that the most robust forms of systematicity attained by connectionist networks thus far are found in systems that incorporate at least some classical features, whether in link preconfigurations or in modes of representation. However, we have also seen that, in the cases of Christiansen and Chater (1994) and Niklasson and van Gelder (1994), interesting forms of syntactic generalization have emerged even when little or no classical dispositions are present. These researchers and others continue to explore the potential of radically distributed representations to display stronger forms of systematicity. In this regard, at least two principle challenges now engender further research. First, can networks employing radically nonclassical architectures meet the simultaneous requirements of generalization and specificity imposed by Semantic-Sys? Second, will any of the architectures con-

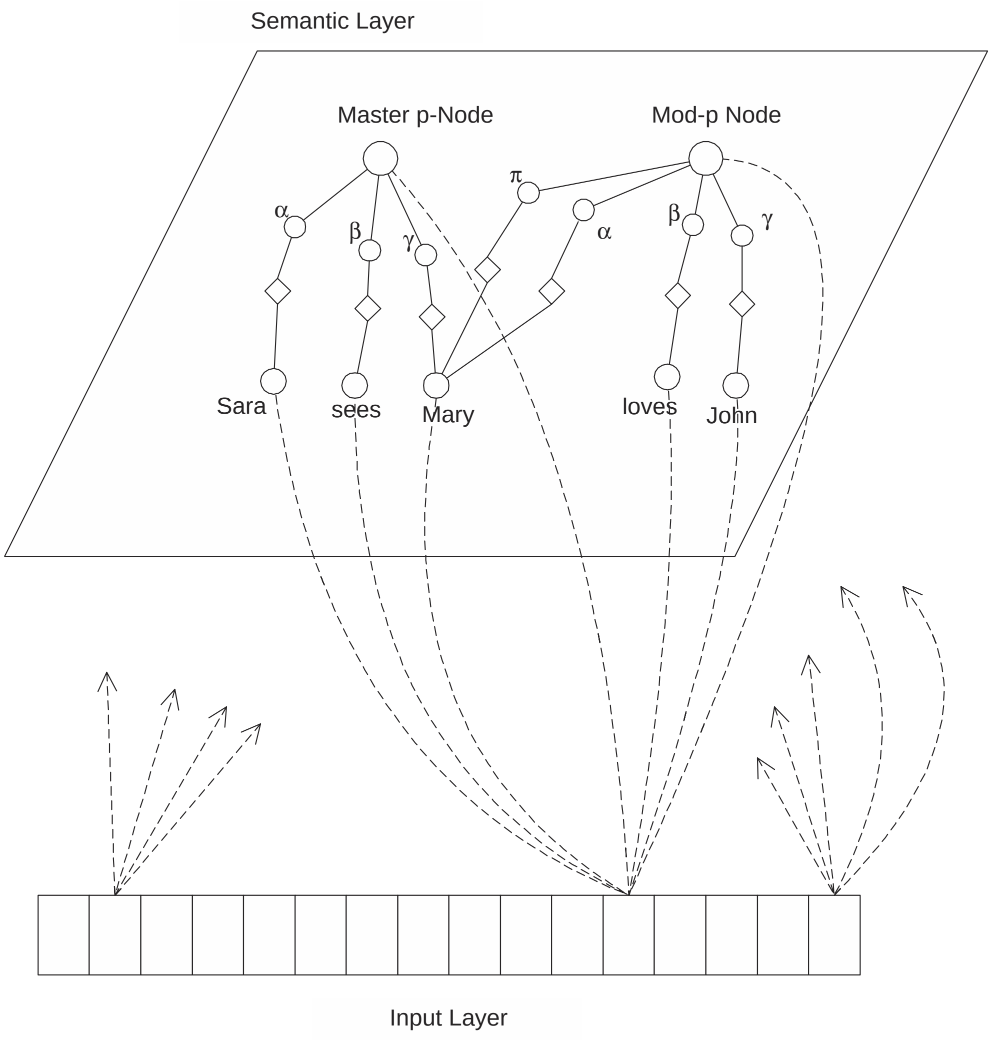

**Figure 1.** In this illustration, $\alpha$, $\beta$, and $\gamma$ denote role nodes. Other labeled nodes represent concepts. Diamonds represent binding nodes.

sidered here lead to neurologically plausible solutions to the challenges of systematicity? Arguments offered by Marcus (2001) suggest that the first of these challenges may be theoretically insuperable.

# Temporal Dynamics of Biological Synapses

*Larry F. Abbott and Sacha B. Nelson*

## Introduction

Most experimental and theoretical work on synaptic plasticity in the brain has focused on long-term changes in synaptic strength. However, synaptic function is also profoundly influenced by activity over time scales of milliseconds to seconds. Synapses that exhibit such short-term plasticity are powerful computational elements that can have a profound impact on cortical circuits (Grossberg, 1984; Abbott et al., 1997; Tsodyks and Markram, 1997).

Short-term plasticity was first characterized in studies of the neuromuscular junction that revealed the richness of synaptic dynamics (Magleby, 1987; Zucker, 1989). Both synaptic depression and a number of components of short-term enhancement (facilitation, augmentation, and post-tetanic potentiation) acting over increasingly longer periods of time were observed. Synaptic facilitation appears to result from enhanced transmitter release due to elevated presynaptic calcium levels. Like facilitation, depression can occur with multiple time constants of onset and recovery, and depression and facilitation can coexist at the same synapse. Depression is believed to result, at least in part, from depletion of a readily releasable pool of vesicles. The terminology used to characterize different types of short-term synaptic plasticity is somewhat variable. The following table provides definitions:

| *Type of Short-Term Plasticity* | *Onset* | *Decay* |
|---|---|---|
| Fast facilitation | 1–5 spikes | 10–100 ms |
| Fast depression | 1–10 spikes | 100 ms–1 s |
| Slow depression | >10 spikes | >1 s |
| Augmentation | 1–10 spikes | 1–5 s |
| Post-tetanic potentiation | >10 spikes | >5 s |

Cortical synapses exhibit short-term plasticity in a variety of forms. Studies of cat visual cortex (Stratford et al., 1996) and rodent somatosensory and motor cortices (Thomson and Deuchars, 1994; Castro-Alamancos and Connors, 1996) indicate that different classes of synapses may exhibit different forms of short-term plasticity. Depression appears to be a particularly prominent feature of transmission at excitatory synapses onto pyramidal cells (Deisz and Prince, 1989; Thomson and Deuchars, 1994; Markram and Tsodyks, 1996; Tsodyks and Markram, 1997; Abbott et al., 1997; Varela et al., 1997).

In addition to having complex short-term dynamics, synapses are stochastic. Indeed, synaptic transmission in the cortex and hippocampus appears to be quite unreliable (Stevens and Wang, 1995). If synaptic transmission occurs with a fixed probability, it is hard to imagine a functional role for this degree of unreliability, since it would act as a significant source of noise. Constructive roles for unreliable transmission become apparent when short-term plasticity is considered in connection with stochastic transmission. The probability that a given presynaptic action potential induces transmitter release at a synapse displaying short-term plasticity is not constant; it depends on the temporal pattern of action potentials that preceded it. Such synapses can act as selective filters, preferentially transmitting particular presynaptic spikes that appear within certain sequences. If the probability of synaptic transmission at cortical synapses is low, synapses are highly selective.

## Models

Mathematical models of short-term synaptic transmission were originally developed to describe the neuromuscular junction and other synapses (Krausz and Friesen, 1977; Magleby, 1987) and then extended to deal with cortical synapses (Abbott et al., 1997; Tsodyks and Markram, 1997; Varela et al., 1997). Let $A$ denote the amplitude of the postsynaptic response to a presynaptic action potential. We will discuss a model with one form of facilitation and one form of depression. The same basic model can be extended to more complex cases. We write the postsynaptic amplitude as the product of three factors, $A = A_0FD$. $A_0$ is a constant equal to the amplitude of the response to a single isolated presynaptic stimulation. $F$ and $D$ are dynamic factors that reflect the effects of facilitation and depression, respectively. In the absence of presynaptic action potentials, $F$ and $D$ both tend toward the value one exponentially,

$$\tau_F \frac{dF}{dt} = 1 - F \quad \text{and} \quad \tau_D \frac{dD}{dt} = 1 - D$$

The time constants $\tau_F$ and $\tau_D$ reflect the recovery rates of the facilitation and depression processes. When a presynaptic spike occurs, $A$ increases in the case of facilitation and decreases for depression. This is done by making an additive change in $F$ and by modifying $D$ in a multiplicative manner. In other words, whenever a presynaptic spike occurs, we make the replacements

$$F \rightarrow F + (f - 1) \quad \text{and} \quad D \rightarrow dD$$

The parameters $f$ and $d$, which satisfy $f > 1$ and $d < 1$, determine the onset rate for facilitation and depression, respectively. Facilitation is modeled additively, not multiplicatively, to prevent it from growing without bound. Conversely, depression is modeled multiplicatively to prevent the depression factor from becoming negative. This formalism successfully describes data on cortical short-term plasticity (Varela et al., 1997) and, at the same time, is compact enough to be incorporated easily into network models.

## Results

One of the most striking features of the data on cortical short-term plasticity is the dependence of the steady-state amplitude on stimulation frequency. There are strong indications that the synaptic depression seen in cortical slices is the result of a frequency-dependent decrease in the probability of vesicle release. Interpreted in this way, the amplitude of the postsynaptic response is proportional to the probability that a synapse transmits a given presynaptic spike. Experimental results indicate that the synaptic transmission probability for a presynaptic spike train of frequency $r$ is approximately proportional to $1/r$ for $r > 10$–20 Hz (Abbott et al., 1997; Tsodyks and Markram, 1997; Varela et al., 1997). The number of transmitted spikes per unit time is equal to the rate $r$ that presynaptic spikes arrive at the synapse times the probability of transmission, which is proportional to $1/r$. The net result is that the rate at which presynaptic spikes are transmitted is proportional to $r(1/r)$, which is independent of $r$. Figure 1 illustrates this cancellation of rate dependence. In this example, Poisson spike trains were used as the presynaptic input to a model stochastic synapse with depression. The probability of transmitter release was computed, and the presynaptic spike was transmitted with this probability. Figure 1 shows presynaptic spike trains at two different frequencies, along with the subset of presynaptic spikes actually transmitted by the synapse. Doubling the presynaptic firing rate has only a small effect on the number of successful transmissions. Synaptic depression thus appears to challenge some of our most basic ideas about neuronal coding and signaling.

Synapses that depress transmit action potentials that follow a silent period with a higher probability than action potentials within high-frequency trains. This results in a dramatic enhancement in the response to transient as opposed to static stimuli. Analysis of the response to transients reveals an interesting feature of the $1/r$ dependence of the steady-state depression for these synapses. Suppose that a presynaptic neuron has fired steadily at a rate $r$ long enough to allow the level of depression to reach its steady-state value proportional to $1/r$. Now imagine that the presynaptic firing rate suddenly changes by an amount $\Delta r$. Initially, before the level of depression has had time to adjust to its new steady-state level, the first few spikes at the new rate will be transmitted with an amplitude proportional to the previous level of depression. The transient change in the synaptic input to the postsynaptic neuron will be proportional to the change in the presynaptic firing rate, $\Delta r$, times the level of synaptic depression, $1/r$. This means that the magnitude of the postsynaptic transient is not proportional to the absolute magnitude of the presynaptic change, $\Delta r$, but rather to the fractional or percentage change, $\Delta r/r$.

In psychophysics, the Weber-Fechner law states that the subjective measure of a change $\Delta I$ in the magnitude $I$ of a stimulus is proportional to the fraction $\Delta I/I$. Synaptic depression realizes a similar Weber-Fechner relation at the level of individual synapses (Grossberg, 1984; Abbott et al., 1997). The fact that the steady-state postsynaptic response is independent of $r$, and that the transient response is proportional to $\Delta r/r$, means that a type of firing-rate scale invariance applies to these synapses. This is illustrated in Figure 2. The two spike trains shown are the postsynaptic responses of the same model neuron to 100 synaptic inputs firing asynchronous Poisson spike trains at the rates indicated. The two postsynaptic spike trains are virtually identical despite the fact that the presynaptic firing rates for the two cases are completely different. In one case the firing rate changed by 75 Hz (from 25 Hz to 100 Hz) and in the other by 150 Hz (from 50 Hz to 200 Hz), but the two postsynaptic responses are similar because these change both have $\Delta r/r = 75/25 = 150/50 = 3$.

There are a number of indications that the short-term plasticity of cortical synapses has a significant effect on the dynamics of neural responses. The time course of synaptic depression in slices

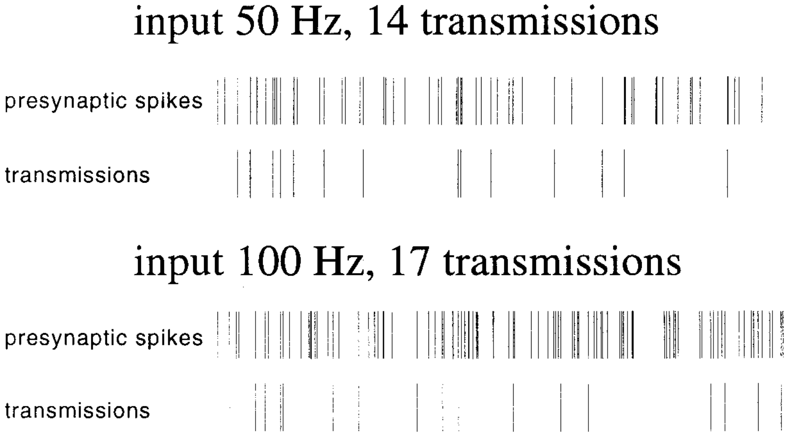

**Figure 1.** Relative independence of the rate of successful synaptic transmission on the presynaptic firing rate. Poisson spike trains with two different average frequencies were fed into a stochastic synapse model with synaptic depression. Doubling the presynaptic rate increased the number of successful transmissions by only 20%. Note that the spikes shown in the lower rows in this figure represent transmission events, not postsynaptic action potentials.

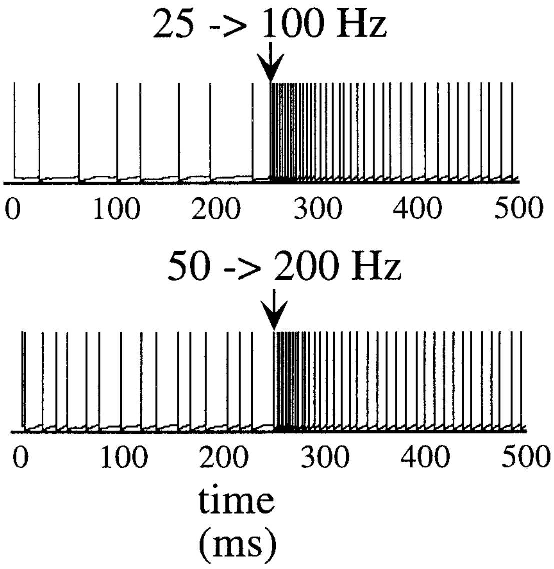

**Figure 2.** Response of a model neuron to a transient increase in the presynaptic firing rate. The spiking pattern shown is that of an integrate-and-fire model neuron driven by 100 presynaptic afferents firing Poisson spike trains through synapses modeled after those measure in cortical slices. In the top panel, the 100 presynaptic afferents all fired at 25 Hz initially, and then this was increased (at the time denoted by the arrow) to 100 Hz. In the bottom panel, the same procedure was followed, but an initial presynaptic rate of 50 Hz was raised to 200 Hz. Despite the difference in presynaptic firing rate, the spike trains are virtually identical, a result of the scale-invariant property of synapses with the type of depression we observed.

of visual cortex (Abbott et al., 1997; Varela et al., 1997) closely parallels the temporal characteristics of cortical responses to visual stimuli (Chance, Nelson, and Abbott, 1998). Neurons in primary visual cortex have relatively low temporal frequency cutoffs, but, paradoxically, they respond briskly to transients containing high-frequency components. The depression measured in cortical slices, when studied in model simulations, reproduces these apparently contradictory effects, enhancing transient and suppressing steady-state responses to high-frequency stimulation. This can account for a number response properties of simple cells, including directional selectivity, response phase, contrast saturation, nonlinear temporal summation, and contrast adaptation (Chance et al., 1998).

## Discussion

Because of their probabilistic nature and their dynamics, synapses act as stochastic temporal filters of their presynaptic spike trains. Both facilitation and depression can have important filtering effects. Synapses that exhibit a high degree of facilitation are selective for spikes that appear in groups or bursts (Lisman, 1997). Synapses that depress are selective for transients; they transmit action potentials that follow a period of silence more reliably than those appearing within high-frequency trains.

Synaptic reliability and short-term plasticity are related. At many synapses, changes in release probability are accompanied by changes in short-term plasticity. Synapses with a high probability of transmitter release are more likely to depress, while those with low release probability tend to facilitate (Zucker, 1989). Modulations that affect release probability consequently modify short-term plasticity. Markram and Tsodyks (1996) have found that a form of cortical long-term potentiation can modify the short-term plasticity of synapses between layer 5 pyramidal neurons. This is consistent with the idea that this form of long-term potentiation is acting presynaptically to increase the probability of transmitter release.

Short-term depression has a profound impact on the nature of information transmission between cortical neurons. Synapses showing the degree of synaptic depression seen in cortical slice experiments are relatively ineffective at transmitting information about the rate of presynaptic firing if it is greater than about 10–20 Hz (Abbott et al., 1997; Tsodyks and Markram, 1997). This result challenges a basic assumption, used in virtually all network modeling studies, that synapses transmit signals proportional to their presynaptic firing rates. On the other hand, these synapses transmit information about transient changes in presynaptic firing rates in an extremely efficient, logarithmically compressed, scale-invariant manner.

# Temporal Integration in Recurrent Microcircuits

*Wolfgang Maass and Henry Markram*

## Introduction

An essential feature of neural computation in behaving organisms is the capability to produce at any time $t$ a response $y(t)$ that depends on sensory and internal inputs $u(s)$ that the system received at various times $s < t$ back in the past. Such anytime intelligent response to temporally integrated input, which does not have to wait until some algorithm has completed its computation, is also desirable for artificial computing machinery. It would therefore be helpful to understand how neural systems solve this task. Because of the stereotypical features of cortical microcircuits (see Shepherd, 1988; De Felipe, 1997; Douglas and Martin, 1998; von Melchner, Pallas, and Sur, 2000; Thomson et al., 2002), one may hypothesize that there exists a common principle by which neural microcircuits in different cortical areas and species solve the task of adaptive real-time response to temporally integrated information. We survey in this article the primary models that have been proposed for temporal integration in neural microcircuits of the cortex.

## Tapped Delay Lines

The most straightforward approach to make past inputs $u(s)$ available for the current output response $y(t)$ is to maintain a finite sliding memory window for inputs $u(t - \Delta)$, $u(t - 2\Delta)$, . . . , $u(t - k\Delta)$ that arrived at a fixed number $k$ of discrete-time points in the past. This memory window has to be updated after every time interval $\Delta$. In a digital computer, such tapped delay line can easily be implemented by a shift operation applied to $k$ registers. An obvious disadvantage of this strategy is the rigid prescribed sampling of inputs $u$ at a discrete set of time points and the rigid prescribed length $k\Delta$ of the memory window, since they may be adequate for some computational tasks but not for others. Neural systems use delay lines for special tasks such as auditory processing or echolocation, but there is no evidence that they use tapped delay lines as the primary tool for temporal integration tasks that require temporal integration over a few hundred milliseconds (ms) and longer. Even for long-range projections such as those across hemispheres or posterior anterior projections, transmission delays between neurons rarely exceed 10–20 ms. Implementing tapped delay lines in the nervous system as a universal solution for temporal integration would also imply a rigid temporal relationship between spatially segregated and specialized brain areas. Furthermore, the largest fraction of synapses in the nervous system (as much as 80%) are those forming local microcircuits, which are characterized by diverse components with highly recurrent connectivity "loops within loops," as shown, for example, in White (1989) and Gupta, Wang, and Markram (2000), rather than uniform units arranged in regular feedforward architectures. The spectrum of delays in information transmission between different neurons of such recurrent microcircuits is in the sub-millisecond to millisecond range, indicating that even the membrane time constant of neurons can perform more temporal integration than delay lines could in recurrent neural microcircuits.

## Finite-State Machines and Attractor Neural Networks

Another strategy for making information from past inputs $u(s)$ available for a subsequent response $y(t)$ is to condense all information from earlier inputs that might be needed for a decision at some future time $t$ into the current internal state $x(t)$ of the system. (Such states that contain all information on which future actions of the systems depend are commonly referred to as Markovian states because this property is characteristic for the states in a Markov chain, a well-known model for stochastic systems.) This strategy has the advantage that temporal integration is not restricted to a fixed sampling interval $\Delta$ for past inputs nor a fixed memory time window $k\Delta$. The problem of task-specific temporal integration of past inputs is moved here to the definition and implementation of a suitable set $X$ of states $x(t)$ that the system is allowed to assume and a transition function $\delta$ that updates the internal state in regular time intervals $\Delta'$ in light of new input $u(t)$ arriving at time $t$:

$$x(t + \Delta') = \delta(x(t), u(t))$$

The transition function $\delta$ can be deterministic or stochastic (similar to the stochastic transition function in a Markov chain). This framework for temporal integration is commonly used in formal models for Reinforcement Learning (q.v.). In the case in which the state set $X$ is a finite set, one refers to such system as a finite automaton or finite-state machine. To facilitate learning of a transition function $\delta$, the underlying state set $X$ should be fairly small. Popular soft versions of this model that do not require a fixed time interval $\Delta'$ for state updates are the attractor neural networks (see Computing with Attractors). The state set X is replaced here by a finite or infinite set of attractors in combination with an infinite set of transient intermediate states. Because of the iterative character of the state update function $\delta$, all these models are in principle compatible with the recurrent connectivity pattern of generic neural microcircuits.

A somewhat problematic aspect of this approach, which constrains its applicability to artificial behaving systems and also its appeal as a model for temporal integration in behaving organisms, is its need for an a priori definition of a suitable set $X$ of internal states or attractors (whereas the transition function $\delta$ can in principle be learned through reinforcement learning once the set $X$ has been defined). Attractor neural networks have to cope with the additional difficulty that for the dynamical system defined by a recurrent analog circuit, no general and stable mechanisms are known for controlling the landscape of its attractors and fast online transition between its attractors (except for simulating a discrete finite-state machine). An attractor neural network is in general also not able to produce at any time $t$ a meaningful response $y(t)$ to an ongoing input stream because it is likely to spend most of its time in transient states between attractors. The mathematical theory that underlies attractor neural networks and dynamical systems theory has focused on the case of autonomous dynamical systems (i.e., systems whose input can be encoded in the initial state of the system), usually of a very low dimension. Consequently, there exists a lack of analytical tools for understanding temporal integration of a continuous input stream in the high-dimensional dynamic systems formed by neural circuits.

## Using Perturbations of Recurrent Circuits for Temporal Integration

Since the transient dynamics of a recurrent circuit is in general even harder to control than its attractor structure, it might seem hopeless to use it for purposeful computations. However, it turns out that it is not necessary to take control of or manipulate the transient dynamics of a recurrent circuit in order to use it for complex computations requiring temporal integration. If the recurrent circuit is sufficiently complex, its inherent dynamics automatically absorbs and stores information from the incoming input stream (Buonomano and Merzenich, 1995). More precisely, the current state $x(t)$ of a recurrent circuit automatically contains information about preceding inputs $u(s)$. It only remains to read out this information, but this is a standard spatial pattern recognition task requiring no temporal integration. Readout neurons can easily be trained by supervised (Maass, Natschlaeger, and Markram, 2001) or unsupervised (Legenstein, Maass, and Markram, 2002) learning to perform this task, provided that the recurrent circuit—and hence the dimension of its transient states $x(t)$—is sufficiently large. An important class of methods in machine learning (see SUPPORT VECTOR MACHINES) relies on a closely related principle. In fact, one might compare the computational role of a neural microcircuit with a kernel for support vector machines that implements a nonlinear projection of time series (the input stream that has reached the neural microcircuit up to time $t$) onto points $x(t)$ in a very high dimensional space. If the dimension of this space is sufficiently high, then most complex nonlinear classification problems for time series $u(\cdot)$ are transformed through this nonlinear projection into linearly separable classification tasks for the subsequent state $x(t)$. Hence, in principle, even a single (memoryless) readout neuron can be trained to perform such a task, thereby classifying at time $t$ the input stream $u(\cdot)$ that had reached the recurrent neural circuit up to time $t$.

From this point of view, a recurrent neural circuit accomplishes more than a tapped delay line, since it not only stores information about the past, but also preprocesses it (in a general-purpose manner, like a kernel, without specialization for a specific task) by projecting it nonlinearly into a very high dimensional space to boost the power of diverse linear readouts for specific tasks.

The abstract computational model on which this view of computation in neural microcircuits is based is the liquid-state machine (see Figure 1; see also Maass et al., 2001, Markram et al., 2002) that is quite different from a Turing machine, the traditional paradigm for universal neural computation. In this new model, a recurrent neural circuit is represented by a generic nonlinear filter $L$ that transforms time-varying input $u(\cdot)$ into a trajectory of internal states $x(t)$ and a task-specific readout of information from $x(t)$ by memoryless readout functions $f$ (see Figure 1). Since in contrast to a finite-state machine the internal state $x(t)$ may change in this new computational model in a "liquid" manner, continuously in time and space, the model is called a *liquid-state machine*. Like Turing machines, the liquid-state machine provides theoretically unlimited computational power if the recurrent microcircuit is sufficiently large but for real-time computing (with fading memory) on continuous input streams, instead of off-line computation on discrete batch inputs, for which Turing machines are universal. The recurrent microcircuit serves in this model as a general-purpose analog fading memory (represented mathematically by a nonlinear filter $L$). Its current state, $x(t)$, contains, for example, information about the temporal pattern of spike trains that had previously entered the circuit but with lower reliability for spike trains that had arrived farther back in the past (fading memory) (see Figure 2).

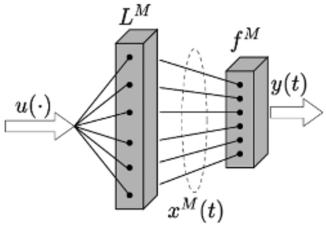

**Figure 1.** Schema of a liquid-state machine $M$, consisting of a (in general nonlinear) filter $L^M$ and a memoryless readout map $f^M$ (the latter is applied to the liquid state $x(t)$ defined as the output of the filter at time $t$ for input function $u(\cdot)$). Provided that the available pools of filters $L$ and readout functions $f$ satisfy some rather basic necessary properties (pointwise separation property for filters $L$—which is approximately met by recurrent neural circuits—and approximation property for readout functions $f$; see Maass et al., 2001, for details), the resulting liquid-state machines $M$ can in principle approximate any time-invariant fading memory filter. Hence, it can arguably perform any real-time computational task involving temporal integration that a behaving organism might need.

So far, we have discussed only the situation in which the readout neuron has to extract information from the current state $x(t)$ of a circuit at one specific time $t$. But the same mechanisms and principles also apply to the more realistic case in which a target output $y(t)$, requiring integration of information from inputs $u(s)$ at various numbers and combinations of preceding time points $s < t$, has to be provided in real time *at any time t*. From the point of view of a readout neuron, this means that it has to be able to classify states $x(t)$ that occur at different time points $t$. Hence it has to solve a more complex spatial classification task. But the same principle as before applies: This task can still be solved by simple time-invariant linear readouts if the dimension of the current circuit states $x(t)$ is sufficiently high.

In the context of time-varying outputs $y(t)$, it is biologically more realistic to consider functions $y(t)$ that assume analog values in some interval [0, 1] rather than just discrete values {0, 1}. The target values for such time-varying analog readouts $y(t)$ from recurrent microcircuits could, for example, be predictions of future values of specific inputs, which can be learned in an unsupervised manner (Legenstein et al., 2002). Such time-varying analog readouts could be implemented in a neural system, for example, by a pool $P$ of integrate-and-fire neurons that all receive the same circuit state $x(t)$ as input (but may apply different synaptic efficacies to this common input $x(t)$), where the fraction of neurons in this pool $P$ that fire around time $t$ may be viewed as the time-varying analog readout $y(t)$. It has been shown that any continuous readout map $f$ (see Figure 1) can be approximated by such pool $P$ and that a simple local learning rule suffices for training such pool $P$ of integrate-and-fire neurons to approximate a given function $f$ (Maass et al., 2001). Consider, for example, the case in which a readout neuron has to give the same constant target response $y(t) = y_0$ for all $t$ from some interval $[T, T']$ even if the internal state $x(t)$ (and possibly also the circuit input) keeps changing during this time period. Some of the readouts shown in Figure 3 face exactly this task during those intervals in which their target output, plotted as a dashed line, is constant or almost constant, whereas the circuit input (four spike trains in parallel shown at the top) varies during these time intervals and the internal circuit activity $x(t)$ also varies (this is in fact necessary because other readouts have at the same time quickly varying target outputs $y(t)$, but their weights are assumed to remain fixed after learning). Such diverse readouts are possible because each readout (implemented in this case by a pool $P$ of neurons whose current firing activity represents its current analog output $y(t)$, plotted as a solid line in Figure 3) is trained by the task to define its own notion of equivalence on circuit states $x(t)$ (and thereby implicitly its own neural code). In particular, a readout neuron can give a stable output even if the underlying circuit never reaches a fixpoint attractor, showing that attractors are not necessary for producing stable system outputs. Hence, stable perception is possible even if the internal state of the nervous system may never repeat.

The fact that the previously sketched model for temporal integration of information in a neural circuit does not require to force the internal dynamics $x(t)$ of the circuit to respond to specific time-varying inputs $u(\cdot)$ with specific trajectories $x(\cdot)$ (which is in general very difficult, if not impossible, to achieve for a noisy recurrent circuit) has an additional side benefit. Since the circuit responses $x(t)$ have not been modified to optimally support a particular readout task, different readout neurons can simultaneously extract from

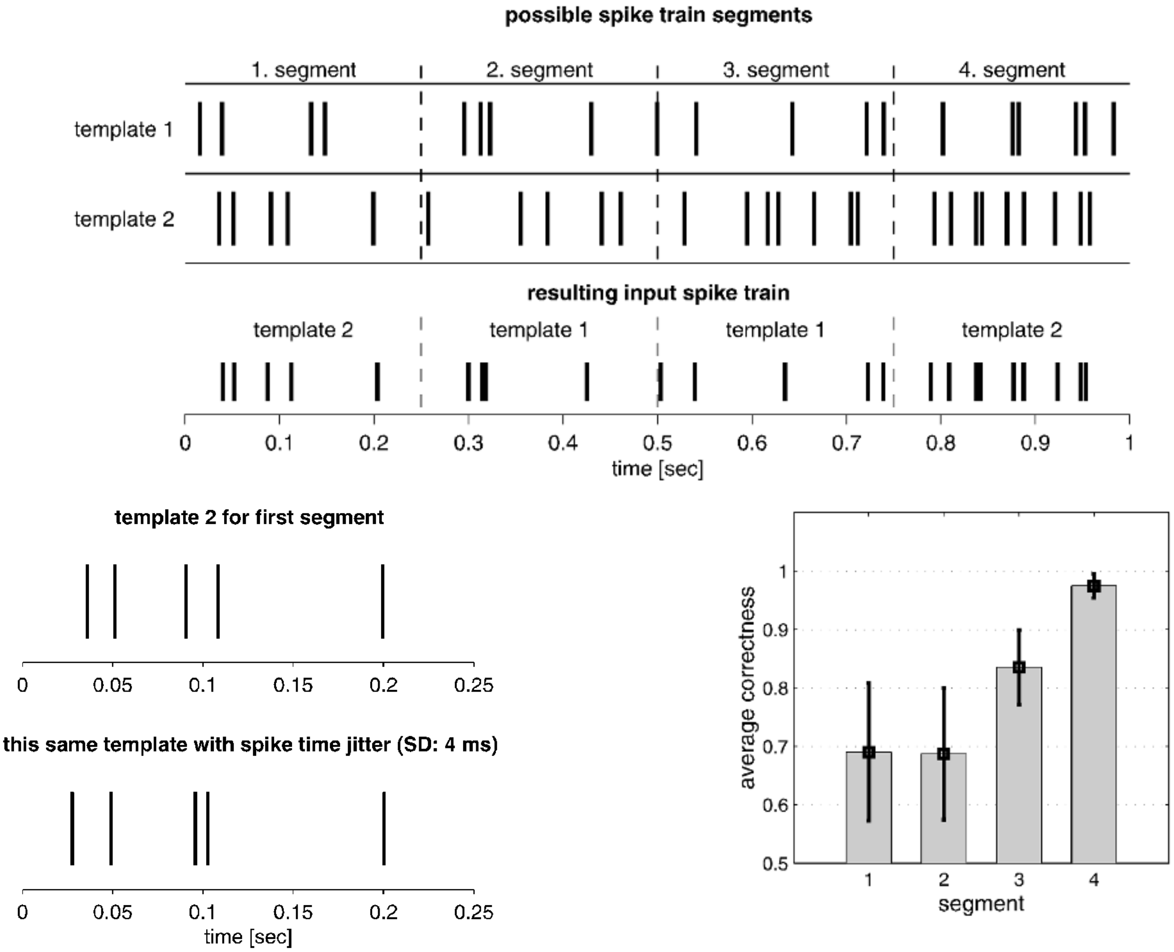

**Figure 2.** Performance of a recurrent neural microcircuit as analog fading memory. Results shown are from computer simulations of a recurrent (randomly connected) generic circuit of 135 integrate-and-fire neurons. Circuit inputs were spike trains over 1 s. Sixteen temporal patterns of such spike trains had been fixed, each a concatenation of four shorter templates (which were randomly chosen fixed Poisson spike trains over 250 ms, shown at the top of Figure 2*A*), Two templates were available for each of the 250 ms segments of the spike train, yielding $2^4 = 16$ temporal patterns for spike trains over 1 s. Inputs $u(\cdot)$ to the circuit were noisy variations of these 16 temporal patterns, in which each spike was independently moved by an amount chosen from a Gaussian distribution with SD 4 ms (see Figure 2*B* for an example). Figure 2*C* shows the average correctness (for novel test examples of jittered spike trains) of four readout neurons that had been trained to extract from the spatial pattern $x(t)$ of the circuit activity at time $t = 1$ s (i.e., after the spike train $u(\cdot)$ had been sent to the circuit) the information that templates had been chosen for each of the four segments of this input spike train. Error bars shown represent the standard deviation over nine trials with different randomly drawn recurrent circuits and different randomly drawn Poisson spike trains as templates. The *i*th readout neuron had been trained to fire at time $t = 1$ s if and only if the first one of the two templates had been chosen as template for the *i*th segment of the preceding spike train. Obviously, this task requires substantial temporal integration of information, since one has to recover information about input segments that had arrived several hundred milliseconds ago. This task is in addition a rather difficult computational task, since the desired information is not contained in any specific interspike interval of the preceding input spike train (owing to the randomly chosen dislocation of spikes). Obviously, the readout neuron that has to recover the identity of the template for the last 250 ms could solve its task with the highest accuracy. However, substantial amounts of information about earlier segments were also recovered, in spite of the fact that all this information had been overwritten in an uncontrollable nonlinear manner by later spikes entering the recurrent circuit. The circuit had not been optimized for this task, and performance can easily be improved by using a larger recurrent circuit or readout units consisting of several neurons. Results shown are from a computer simulation by Maass et al. (2001).

the same trajectory $x(\cdot)$ different temporally integrated information needed for diverse tasks (see Figure 3). The trajectory of internal states of the dynamical system may therefore be viewed as a universal source of information about past inputs, from which different readout neurons can extract different components. Hence this approach not only provides a framework in which purposeful anytime responses to temporally integrated information can be explained, but it also provides a model for parallel real-time computing on temporally integrated information.

We have made two conceptual simplifications in the preceding account. The first one is that synaptic plasticity was assumed to be restricted to readout neurons, while synapses within the recurrent microcircuit itself could remain unmodified. Although this may in principle suffice, the performance of the system could be optimized by adjusting also synapses within the recurrent microcircuit. For example, the dynamic responses $x(t)$ could be optimized by unsupervised learning (for example, nonlinear ICA) for the statistics of actually occurring external stimuli $u(\cdot)$ to provide optimal support

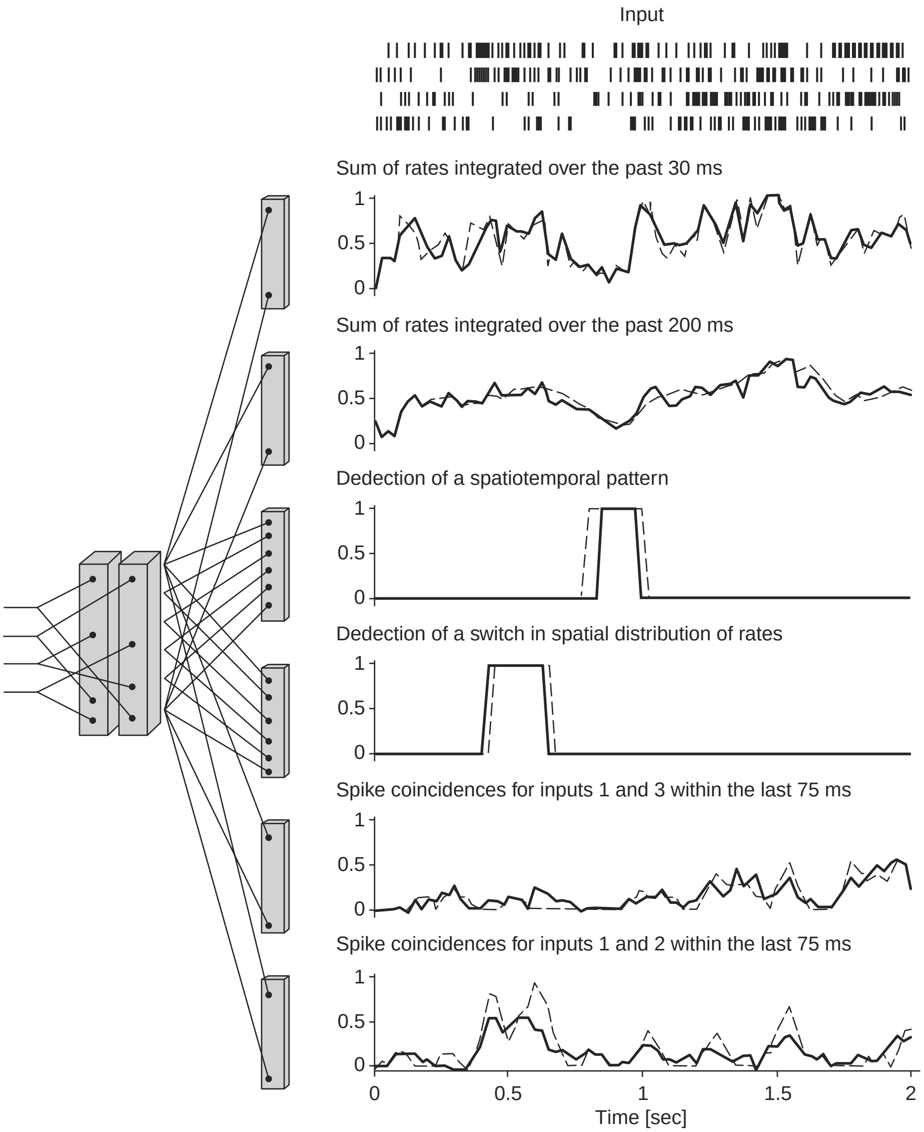

**Figure 3.** Six readout units were trained to extract completely different temporally integrated information from the current firing activity of two recurrent circuits (columns) consisting of 135 integrate-and-fire neurons each and both receiving the same four input spike trains over 2,000 ms, shown at the top. The tasks for the readout units were to represent the sum of firing rates of the four input spike trains integrated over the last 30 ms, to represent the sum of firing rates of the four input spike trains integrated over 200 ms, to output a high value only if a specific spatiotemporal pattern occurs, to output a high value only if the firing rates go up in spike train 1 and 2 and simultaneously go down in spike trains 3 and 4, to report the number of spike coincidence (i.e., spikes within a 5 ms window) of spike trains 1 and 3 during the last 75 ms, and to report the corresponding number of spike coincidence for spike trains 1 and 2. Results shown are for novel input spike trains, generated from the same distribution as the spike trains used for training.

for a variety of different readouts (rather than for just one specific readout or task). This may be seen as analogy to a common procedure for support vector machines in machine learning, in which specific kernels are chosen to optimally support a specific family of classification and regression tasks. The other simplification we made was the assumed partition of neurons into neurons that belong to a recurrent microcircuit (“liquid”) and neurons that read out information from such recurrent circuit. Of course, in a more sophisticated model of cortical circuitry, one would arrive at a network of many liquid-state machines, in which a neuron that reads out information from one recurrent circuit is embedded into the “liquid” recurrent circuit of another liquid-state machine and also sends backprojections into the recurrent circuit from which it reads out information. In fact, benefits of backprojections from the readout into the recurrent circuit have already been demonstrated by Jaeger (2001), who had independently discovered a closely related computational model (echo-state networks) in the context of artificial neural networks with sigmoidal neurons. Wyss, König, and Verschure (2002) exhibit a complementary mechanism: Static batch inputs are transformed by recurrent circuits into a trajectory of transient states, from which the identity of the batch input can be recovered.

## Summary

We have surveyed the main approaches toward modeling temporal integration in neural microcircuits. Approaches based on tapped delay lines, finite-state machines, and attractor neural networks are suitable for modeling specific tasks. But as models for universal real-time computations in neural microcircuits, they appear to be incompatible with results from neuroanatomy (such as highly recurrent diverse circuitry) and neurophysiology (fast transient dynamics of firing activity with few attractor states). A more recent approach views the transient dynamics of neural microcircuits as the main carrier of information about past inputs, from which specific information, needed for a variety of different tasks, can be read out in parallel and at any time by different readout neurons. This model promises to solve four fundamental problems neural systems face in a real-world situation: (1) how to process continuously changing input, (2) how to respond in real time, (3) how to combine information across a large number and combination of time points (universal temporal integration), and (4) unrestricted parallel processing that allows neuronal activity to partake simultaneously in the perception of multiple features and objects. In other words, this approach supports the solution of binding problems (see Singer and Gray, 1995) by avoiding to scatter information into isolated features at the first level of processing.

This approach has provided so far the only method for using computer models of generic recurrent circuits of integrate-and-fire neurons for complex information processing tasks, in particular for tasks that require temporal integration of inputs. This yields a novel tool for exploring through computer simulations of more and more realistic models for neural microcircuits the specific computational role of the experimentally observed diversity of neurons and synapses with regard to their dynamic behavior and connection preferences (see NEOCORTEX: BASIC NEURON TYPES and Gupta et al., 2000). As a first step in this program, Maass et al. (2001) showed that a recurrent neural circuit serves best as analog fading memory if its statistics of connection lengths is biologically realistic, with primary local connections but also a few long-range connections (whereas preceding theoretical approaches had focused either on recurrent circuits with full connectivity, such as Hopfield nets, or on circuits with strictly local connectivity, such as cellular automata). Furthermore, in contrast to virtually all other theory-based modeling approaches, the liquid-state machine model is enhanced, rather than hampered, by the given biological diversity of circuit components. It also provides a new conceptual framework for the experimental investigation of neural microcircuits and larger neural systems, especially for a possible understanding of the ubiquitous trial-to-trial variations that are traditionally washed out through averaging of data over many trials. It also suggests that beyond neural codes that are clearly understandable for a human observer, there may exist substantially more complex internal neural codes represented through high-dimensional activation states of neural circuits, which are easy to classify for a readout neuron but cannot be adequately characterized in terms of commonly considered special cases of neural codes.

# Temporal Pattern Processing

*DeLiang Wang*

## Introduction

Temporal pattern processing is important for various intelligent behaviors, including hearing, vision, speech, music, and motor control. Because we live in an ever-changing environment, an intelligent system—human or robot—must encode patterns over time, recognizing and generating temporal patterns. Time is embodied in a temporal pattern in two ways.

- *Temporal order*. This refers to the ordering among the components of a sequence. For example, the sequence *N-E-T* is different from *T-E-N*. Temporal order may also refer to a syntactic structure, such as subject-verb-object, where each component may be any of a category of possible symbols.
- *Time duration*. Duration can play a critical role for temporal processing. In speech recognition, for example, we want rate invariance while distinguishing relative durations of the vowel /i:/ (as in b*ee*t) and /i/ (as in b*i*t).

Following Wang and Arbib (1990), a sequence is defined as *complex* if it contains repetitions of the same subsequence, as in *C-O-N-F-R-O-N-T*; otherwise, it is defined as *simple*. For generation of complex sequences, the correct successor can be determined only by knowing components prior to the current one. We refer to the prior subsequence required to determine the current component as the *context* of the component, and the length of this context as the *degree* of the component. The *degree of a sequence* is defined as the maximum degree of its components. Thus, a simple sequence is a degree 1 sequence.

Temporal pattern processing is a challenging topic because the information is embedded in time (thus inherently dynamic), not simultaneously available. Nevertheless, this topic has been studied by a number of investigators; see Sun and Giles (2001) for a recent collection of articles on this topic.

Fundamentally different from static pattern processing, temporal processing requires that a neural network have a capacity for short-term memory (STM) in order to maintain a component for some time. This is because a temporal pattern extends over a time period. How to encode STM thus becomes one of the criteria for classifying neural networks for temporal processing. In this article, I provide an outline of temporal pattern processing, discussing the topics of recognition and generation separately. In the end, I point out several outstanding issues, including time warping and chunking, that require future investigation.

## STM Models

### *Delay Lines*

The simplest form of STM uses a fixed-length buffer of $N$ units to maintain the $N$ most recent input items. This can be implemented either by a shift register with a fixed delay between consecutive units or by an array of systematic delay lines. The delay line STM transforms a temporal pattern into a spatial one where time forms another dimension. This idea forms the basis of many recognition models (Waibel et al., 1989).

### *Decay Traces*

Here, an item in STM decays in time, corresponding to the decay theory of forgetting in human STM. The decay usually takes an exponential form. Theoretically, time information can be precisely recovered from the current value. But owing to rapid decay and noise, only a limited number of the most recent items can be reliably discerned from STM. This form has been used by Jordan (1986) and Wang and Arbib (1990), among others. Figure 1*A* shows a typical decay trace.

### *Exponential Kernels*

Tank and Hopfield (1987) proposed a set of normalized exponential kernels to sample the history, described as

$$f_k(t) = \left(\frac{t}{k}\right)^{\alpha} e^{\alpha(1-t/k)} \quad \text{for } k = 1, \ldots, K \qquad (1)$$

where $\alpha$ regulates the width of each kernel. Notice that $f_k(t) = 1$ if $t = k$. Figure 1*B* shows a set of four kernels. There are $K$ units to represent each symbol. Unlike delay line STM, each unit here samples a symbol within a certain period peaked at a specific time step ($t = k$).

Along similar lines, de Vries and Principe (1992) proposed the *gamma model*, which uses a set of gamma kernels (integrands of $\Gamma$-functions, hence the name)

$$g_k(t) = \frac{\mu^k}{(k-1)!} t^{k-1} e^{-\mu t} \quad \text{for } k = 1, \ldots, K \qquad (2)$$

where $\mu$ is a parameter between 0 and 1. $K$ is called the order of the memory, and there are $K$ units for storing a symbol $S$ in STM. Figure 1*C* shows a set of four kernels. Since $g_k$ has a maximum value at $t = (k - 1)/\mu$, $\mu$ determines the depth of the peak of each kernel in STM. Thus, unlike normalized exponential kernels, an $N$-step history may be sampled by less than $N$ gamma kernels. Note that gamma kernels can be computed recursively.

### *STORE Model*

The STM models examined so far are autonomous, for the trace of each item is fully independent of other items in STM. A basic property of human STM is that it has a limited capacity (7 ± 2), so that whether and how long an item is held in STM depends on other inputs entering STM. In addition, the study of human retention of sequences shows a recency factor, where more recent items tend to be better retained, and a primacy factor, whereby the beginning items of a sequence are less prone to forgetting. These two factors together give rise to the bowing effect, which motivated the STORE model (Bradski, Carpenter, and Grossberg, 1992) using a pair of units

$$x_i(t + 1) = x_i(t) + [\beta I_i(t) + y_i(t) - x_i(t)x(t)]I(t) \qquad (3a)$$

$$y_i(t + 1) = y_i(t) + [x_i(t) - y_i(t)][1 - I(t)] \qquad (3b)$$

where $x(t) = \Sigma_j x_j(t)$ is the sum of STM item values, and $I(t) = \Sigma_j I_j(t)$ is the sum of external inputs. The behavior of STORE has two aspects. The first is the global inhibition term in Equation 3a, which reduces the value of $x_i$ in favor of new items. The second is the excitatory loop between $x_i$ and $y_i$, which favors old items in STM. Combined, they are able to produce the bowing shape for a

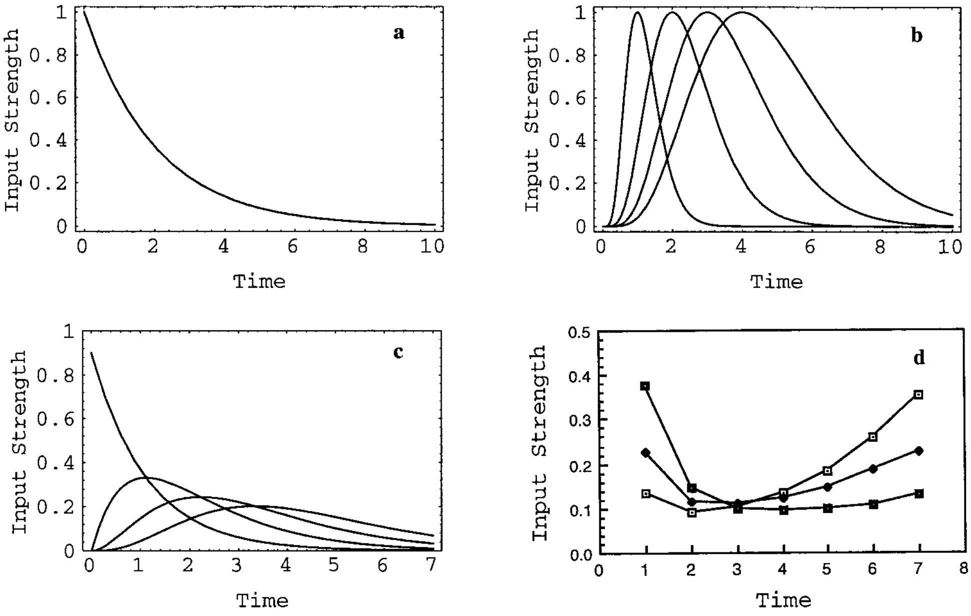

**Figure 1.** STM traces. *a*, Exponential decay. *b*, Normalized exponential kernels. $\alpha = 5.0$, and $k = 1, \ldots, 4$ for the curves from left to right, respectively. *c*, Gamma kernels. $\mu = 0.9$, and $k = 1, \ldots, 4$ for the curves from left to right, respectively. *d*, The STORE model. $\beta = 0.5$ for the empty square bow, 0.3 for the diamond bow, and 0.15 for the filled square bow. Seven items are kept in STM.

sequence of items. Figure 1*D* shows three bows generated with different values of $\beta$.

## Temporal Pattern Recognition

The shared goal of all STM models is to make input history available simultaneously when recognition takes place. With an STM model in place, recognition is not much different from the recognition of static patterns.

### *Template Matching Using Hebbian Learning*

The architecture for this type of recognition is simply a two-layer network: the input layer that incorporates STM, and the sequence recognition layer where each unit encodes an individual sequence. The recognition scheme is essentially template matching, where templates are formed by following Hebbian learning

$$W_{ij}(t) = W_{ij}(t-1) + Cs_i(t)[x_j(t) - W_{ij}(t-1)] \quad (4)$$

where $W_{ij}$ is the connection weight from unit $x_j$ in the input layer to sequence recognizer $s_i$ in the recognition layer. Parameter $C$ controls learning rate. Hebbian learning is applied after the presentation of the entire sequence is completed. The templates thus formed can be used to recognize specific input sequences. The recognition layer typically includes recurrent connections for selecting a winner by self-organization (e.g., winner-take-all) during training or recognition.

Kohonen (1990) proposed an architecture, called the *phonetic typewriter* for phoneme recognition. The phonetic typewriter extracts a vector of frequency components using FFT (fast Fourier transform). After this step, his algorithm of feature mapping is applied for recognition, where winner-take-all is applied in both training and recognition. The phonetic typewriter has been applied to recognize Finnish and Japanese phonemes (Kohonen, 1990). Wang and colleagues (Wang and Arbib, 1990; Wang and Yuwono, 1995) adopted a learning method similar to Equation 4, and showed that a recognition algorithm plus either decay trace or shift register can recognize complex sequences.

### *Associative Memory Approach*

The dynamics of the Hopfield associative memory model can be characterized as evolving toward the memory state most similar to the current input pattern. If one views each memory state as a category, the Hopfield net performs pattern recognition: The recalled category is the recognized pattern. This process of dynamic evolution can also be viewed as an optimization process, which minimizes a cost function until equilibrium is reached.

With normalized exponential kernel STM, Tank and Hopfield (1987) described a recognition network based on associative memory dynamics. A layer of sequence recognizers receives inputs from the STM model. Each recognizer encodes a different template sequence by its unique weight vector acting on the inputs in STM. In addition, recognizers form a competitive network. The recognition process uses the current input sequence (evidence) to bias a minimization process so that the most similar template wins the competition, thus activating its corresponding recognizer. Due to the exponential kernels, they demonstrated that recognition is fairly robust to *time warping*, distortions in duration. A similar architecture is later applied to speaker-independent spoken digit recognition.

### *Multilayer Perceptrons*

Multilayer perceptrons (MLP) offer a popular approach to temporal pattern learning. MLPs have been demonstrated to be effective for static pattern recognition. It is natural to combine MLP with an STM model to do temporal pattern recognition. For example, using delay line STM, Waibel et al. (1989) reported an architecture called Time Delay Neural Networks (TDNN) for spoken phoneme recognition. Besides the input layer, TDNN uses two hidden layers and an output layer where each unit encodes one phoneme. The feedforward connections converge from the input layer to each successive layer so that each unit in a specific layer receives inputs within a limited time window from the previous layer. They demonstrated good recognition performance: For the three stop consonants /b/, /d/, and /g/, the accuracy of speaker-dependent recognition reached 98.5%.

## Temporal Pattern Generation

In 1969, S. Grossberg introduced an early model of sequence generation, the *outstar avalanche*, which is composed of *n* sequential outstars. Each outstar $\mathbf{M}_i$ stores a static pattern and is activated by a signal in the vertex $v_i$. These vertices are connected as: $v_1 \rightarrow v_2 \rightarrow \cdots \rightarrow v_n$. So an initial signal at $v_1$ can generate sequentially the spatial patterns stored in $\mathbf{M}_1, \mathbf{M}_2, \ldots, \mathbf{M}_n$. See Grossberg (1982) for a more detailed description as well as some of the later extensions. In recent years, a number of more sophisticated solutions have been proposed for temporal pattern generation.

### *Associative Memory Approach*

Since associative memory studies how to associate one pattern with another, its mechanism can be extended to generating a sequence. A sequence is treated as a set of pairs between consecutive components, and these pairs are stored into an associative memory. Hence, after the first component of the sequence is presented, the next component will be activated after some delay, which further activates the third one, and so on. This basic idea, however, leads to ambiguity when generating a complex sequence, where one pattern may be followed by different ones. Several investigators have proposed to use high-order networks to deal with the problem. In a *k*th-order network, the input to each unit is the weighted sum of *k*-tuples, instead of individual units, and each *k*-tuple is a product of *k* units. In such a network, one component in a sequence is associated by a prior subsequence of length *k*. Thus, a sequence of degree *k* can be generated without ambiguity by a *k*th-order associative memory (Guyon et al., 1988). A major problem with high-order networks is the required number of connections, which grows exponentially with the order of the network.

### *Multilayer Perceptron Approach*

Jordan (1986) described the first MLP architecture with recurrent connections for sequence generation. The input layer has two parts: plan units representing external input and the identity of the sequence and state units that receive one-to-one projections from the output layer, forming decay trace STM. After a sequence is stored into the network by backpropagation training, it can be generated by an external input representing the identity of the sequence. This input activates the first component of the sequence in the output layer. This component feeds back to the input layer and, together with the external input, activates the second component, and so on. A particular component of a sequence is generated by the part of the sequence prior to the component, earlier components having lesser roles due to exponential decay. Elman (1990) later modified Jordan's architecture by having the hidden layer connect to a part of the input layer, called the context layer. The context layer simply duplicates the activation of the hidden layer in the previous time step. Elman used this architecture to learn a set of individual sequences satisfying a syntactic description, and found that the network exhibits a kind of syntax recognition. This result suggests a way of learning high-level structures, such as natural language grammar.

### *Anticipation Model and Multi-Associative Networks*

Generation of complex sequences has been a major issue. The approaches described so far rely either on fixed degree contexts or on a composite vector recording the history. The latter is prone to ambiguity. The former entails high system overhead, because, in order to avoid ambiguity, such a method must use a degree no smaller than the degree of the sequence, which is usually much greater than the degrees of most components. This analysis calls for a mechanism of self-organization, where each component in a sequence can learn the degree of its own context.

By extending basic ideas for complex sequence processing reported in Wang and Arbib (1990), Wang and Yuwono (1995) introduced such a mechanism of self-organization for generating complex patterns. This so-called *anticipation model* is based on the following two ideas. First, the system actively anticipates the next component in sequence learning, and a mismatch between the anticipated component and the actual component triggers context adjustment through competitive learning. Second, generation of a sequence component hinges on recognition of the component's context. Figure 2*A* shows the architecture of the anticipation model, using a shift-register STM model. Each unit in the detector layer recognizes a specific context, and a winner-take-all mechanism is implemented within the detector layer. There is a modulator layer that corresponds to the detector layer, and each modulator receives a downward connection from its respective detector as well as upward connections from every input terminal. The modulators perform a comparison between anticipation from a winning detector and the next input component. Wang and Yuwono (1995) showed that the anticipation model can learn to generate an arbitrary temporal sequence.

Wang and Yuwono (1996) later applied the anticipation model to learn multiple complex sequences sequentially; i.e., new training does not take place until existing sequences are acquired. Using a set of 97 highly correlated complex sequences, they demonstrated that learning a new sequence can interfere with already acquired ones. However, the number of intact sequences increases linearly with the size of the existing memory, while the amount of retraining needed to eliminate interference is independent of the size of the memory, as illustrated in Figure 2*B*. Such characteristics are largely

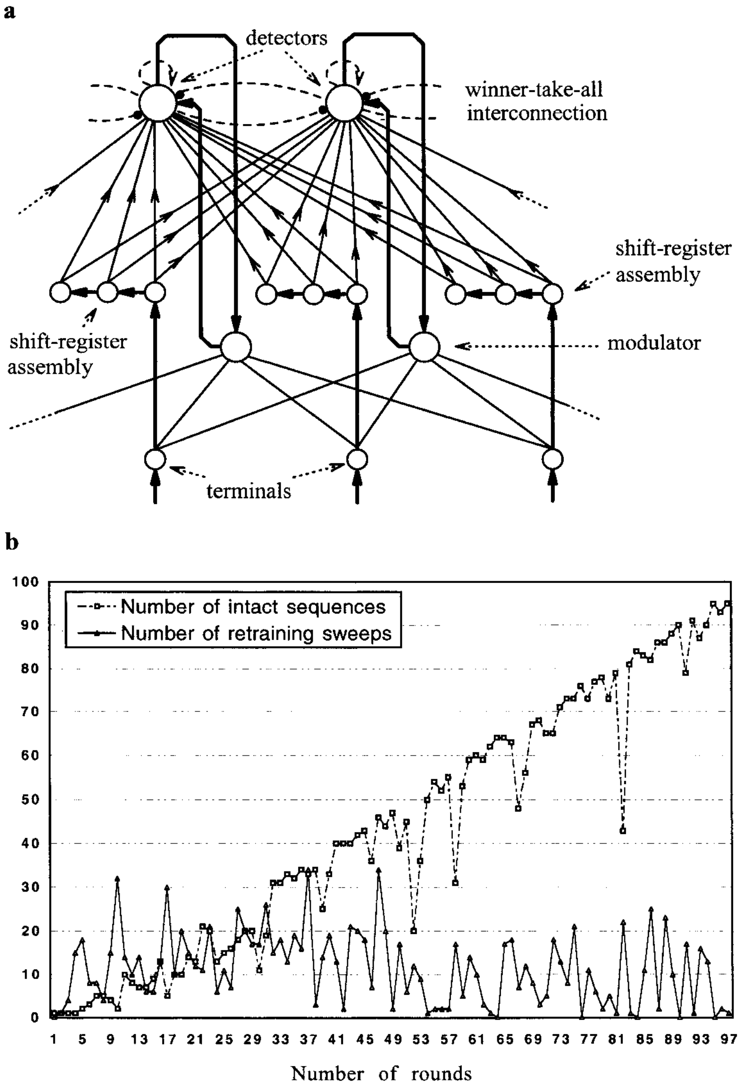

**Figure 2.** Anticipation model. *a*, Architecture (adapted from Wang and Yuwono, 1995). Thin solid lines denote modifiable connections, thick dashed lines denote fixed connections, and undirected lines denote bidirectional connections. *b*, The number of intact sequences and the number of retraining sweeps with respect to the number of training rounds for individual sequences (adapted from Wang and Yuwono, 1996). The 97 sequences denote all the session titles of the 1994 IEEE International Conference on Neural Networks.

derived from the fact that each sequence is represented in a distributed manner, and different sequences and subsequences within a sequence may share context detectors. The interference properties of the anticipation model are consistent with human retroactive interference, which is well documented in psychology, while contrasting with MLP that shows catastrophic interference in sequential learning.

A limitation of the anticipation model is that it deals with symbol sequences rather than sequences of spatial patterns. Recently, Wang (1999) proposed using multi-associative neural networks for learning and retrieving spatiotemporal patterns. STM is coded as systematic delay lines. The basic idea is that, when dealing with complex sequences, one pattern is allowed to be associated with a set of multiple subsequent patterns, and ambiguity can be eliminated by intersecting multiple sets associated by the previous pattern, the pattern prior to the previous pattern, and so on. A complex sequence of degree $k$ can thus be unambiguously generated with $k$ systematic delay lines. Associations between spatial patterns are established through individual units in a competitive layer. A drawback of this model is that many network operations are algorithmically described, rather than arising from a network autonomously.

## Discussion

This brief tour of neural network processing of temporal patterns shows that effective models and techniques exist for both recognition and generation (see Sequence Learning for a more biologically oriented review). There are, however, many questions yet to be answered. In my view, the following two problems are particularly interesting and challenging for future research:

1. *Rate invariance and time warp*. Humans show rate invariance to a certain extent in recognizing a temporal pattern. *Rate invariance* is different from what I call *interval invariance*; the former is invariance only to global scaling of durations and the latter is invariance to all changes of durations. Interval invariance is exhibited in several models, but not rate invariance (see Wang, Liu, and Ahalt, 1996, for a comprehensive discussion). One must be careful about time warping. We would like to have invariance over limited warping, but dramatic change in relative duration must be recognized differently.
2. *Chunking*. A fundamental ability of human information processing is chunking, which, in the context of temporal processing, means that frequently encountered and meaningful subsequences organize into chunks that form basic units for further chunking at a higher level. Chunking and STM are closely related. A chunk often corresponds to a meaningful subsequence (such as a melody), but it may be just a convenient way of breaking a long sequence into shorter parts to cope with limited capacity of STM. One aspect of chunking is studied by Wang and Yuwono (1996), but the general problem of unsupervised chunking has been little addressed and will be increasingly important for future research into temporal pattern processing.

# Temporal Sequences: Learning and Global Analysis

*Andreas V. M. Herz*

## Introduction

The capability to process spatiotemporal information is a prerequisite for any action in or reaction to a natural, that is, time-varying, environment. This simple fact explains why biological organisms have developed highly sophisticated mechanisms to recognize, generate, and learn pattern sequences (see Sequence learning; Temporal Pattern Processing).

A comprehensive theory of the neural processes underlying temporal associations is far beyond the present knowledge (see Herz, 2002, for a review). However, even complicated pattern sequences consist in general of simpler building blocks with a duration of up to a few hundred milliseconds. Hard-wired or learned in a reliable manner, those building blocks are stored in dedicated brain regions such as the cerebellum (see Cerebellum and Motor Control) or the hippocampus (see Hippocampus: Spatial Models) and facilitate a faithful replay or recognition of the entire spatiotemporal object.

How could elementary pattern sequences be represented in neural structures at a low architectural and computational cost? What are possible mechanisms to memorize spatiotemporal associations in a robust fashion within model neural networks? Is it possible to understand their global computation on a theoretical level? What is the relevance of these models for biological systems?

This article presents some qualitative and quantitative answers to these questions. It focuses on formal neural networks whose dynamics can be analyzed using methods from nonlinear dynamics and statistical mechanics. Such simplified systems are necessarily caricatures of biological structures. Still, they may capture aspects that are important for more elaborate approaches and real neural systems.

## Signal Delays

Signal delays are omnipresent in the brain. Time lags of a few milliseconds are characteristic for axonal propagation of action potentials, synaptic transmission, and dendritic transport processes. The delay times are of the same order of magnitude or slightly smaller than the typical time scale of various important neurobiological phenomena, for example, mean interspike intervals or periods of neural oscillations. The incorporation of signal delays into theoretical models of neural dynamics is thus mandatory, especially if one allows for a distribution of time lags.

Kleinfeld (1986) and Sompolinsky and Kanter (1986) proposed models for temporal associations, using a single delay line between each pair of neurons. Tank and Hopfield (1987) presented a feed-forward architecture for sequence recognition based on multiple delays, encoding information relative to the very end of a given sequence. Elements of both approaches have been combined to construct a class of feedback networks with a *broad* distribution of transmission lines (Coolen and Gielen, 1988; Herz et al., 1989). For concreteness, the present contribution focuses on networks with discrete-time dynamics and synchronous updating. Systems with (random) sequential dynamics and other extensions are discussed in Amit (1989); Hertz, Krogh, and Palmer (1991); and Kühn and van Hemmen (1991).

## Neural Dynamics

Throughout what follows, a neural network will be described as a collection of $N$ two-state neurons with activities $S_i = 1$ for a firing cell and $S_i = -1$ for a quiescent one. The neurons are connected by synapses with modifiable efficacies $J_{ij}(\tau)$ where $\tau$ denotes the delay for the information transport from $j$ to $i$. For simplicity, a model will be considered in which each pair of neurons is linked by *several* delay lines with time lags $0 \le \tau \le \tau_{\max}$, which are integer multiples of a small unit time step $\Delta t = 1$ (see Herz et al., 1989, for other network architectures). External stimuli are fed into the system through receptor neurons $\sigma_i = \pm 1$ with normalized input sensitivity $\gamma$, $0 \le \gamma \le 1$. The postsynaptic potentials $h_i$ are then given by

$$h_i(t) = (1 - \gamma) \sum_{j=1}^{N} \sum_{\tau=0}^{\tau_{\max}} J_{ij}(\tau) S_j(t - \tau) + \gamma \sigma_i(t) \qquad (1)$$

The network dynamics are assumed to be synchronous, that is, all neurons are updated in parallel. A spike is generated if the postsynaptic potential exceeds the firing threshold. In what follows, this threshold is set to zero for simplicity so that

$$S_i(t + 1) = \operatorname{sign}[h_i(t)] \qquad (2)$$

If one takes synaptic noise into account, the postsynaptic potential becomes a fluctuating quantity $h_i + \nu_i$ where $\nu_i$ denotes stochastic contributions due to the probabilistic nature of neurotransmitter release. A careful analysis of synaptic transmission reveals that under the assumption of linear dendritic processing, the variable $\nu_i$ is distributed according to a Gaussian probability distribution (Amit, 1989). The probability for spike generation may then be approximated by the stochastic dynamics

$$\text{Prob}[S_i(t + 1) = \pm 1] = \tfrac{1}{2} \{1 \pm \tanh[T^{-1} h_i(t)]\} \qquad (3)$$

where Prob denotes probability and $T$ represents the noise level. Within the physics literature, the update rule (Equation 3) is known as Glauber dynamics. In the limit $T \to 0$, one recovers the deterministic description (Equation 2). See also DYNAMICS OF ASSOCIATION AND RECALL.

## Hebbian Learning

According to Hebb's neurophysiological postulate for learning, information presented to a neural network is physically embedded through an alteration of the network structure: "When an axon of cell $A$ is near enough to excite cell $B$ and *repeatedly* or *persistently* takes part in firing it, some growth process or metabolic change takes place in one or both cells such that $A$'s efficiency, as one of the cells firing $B$ is increased." (Hebb, 1949; see also HEBBIAN SYNAPTIC PLASTICITY). How should this postulate be implemented in a formal neural network with transmission delays?

Let us focus on a connection with delay $\tau$ between neurons $j$ and $i$. According to Hebb's postulate, the corresponding synaptic strength $J_{ij}(\tau)$ should be increased if cell $j$ takes part in *firing* cell $i$. (In its physiological context, the postulate was formulated for excitatory synapses only, but for simplicity, it will be applied to all model synapses.) Due to the delay $\tau$ and the parallel dynamics, it takes $\tau + 1$ time steps until neuron $j$ actually influences the *state* $S_i$ of neuron $i$: $\tau$ time steps for the signal propagation (Equation 1) and one further time step to determine the cell's new firing state given the postsynaptic potential (Equation 2). Following Hebb's rule, $J_{ij}(\tau)$ should therefore be altered at time $t + 1$ by some function of $S_j(t - \tau)$ and $S_i(t + 1)$—most simply by their product. Note that for more general neural dynamics, the term $S_i(t + 1)$ has to be replaced by a properly time-shifted short-term average of the postsynaptic activity. It is worthwile to compare this theoretical result with recent experimental findings concerning the temporal requirements for synaptic plasticity (Bi and Poo, 1998).

Starting with a *tabula rasa*, $J_{ij}(\tau) = 0$, one obtains after $P$ learning sessions, labeled by $\mu$ and each of duration $D_\mu$,

$$J_{ij}(\tau) = \varepsilon(\tau) N^{-1} \sum_{\mu=1}^{P} \sum_{t_\mu=1}^{D_\mu} S_i(t_\mu + 1) S_j(t_\mu - \tau) \equiv \varepsilon(\tau) \tilde{J}_{ij}(\tau) \qquad (4)$$

The parameters $\varepsilon(\tau)$ model morphological characteristics of the delay lines; $N^{-1}$ is a scaling factor useful for the theoretical analysis. By Equation 4, synapses act as microscopic feature detectors during the learning sessions: they measure and store correlations of the taught sequences in both space $(i, j)$ and time $(\tau)$. This leads to a resonance phenomenon: connections with delays that approximately match the time course of the external input receive maximum strength. Note that these connections are also the ones that would support a stable sequence of the same duration. Thus, due to a subtle interplay between external stimulus and internal architecture (distribution of $\tau$s), the Hebb rule (Equation 4), which *prima facie* appears to be instructive in character, exhibits in fact also pronounced selective aspects.

Encoded in a network with a *broad* distribution of transmission delays, an external stimulus enjoys a rather multifaceted representation. According to Equation 4, synaptic couplings with delays that are short compared to the typical time scale of single patterns within the taught sequence are almost symmetric in the sense that $J_{ij}(\tau) \approx J_{ji}(\tau)$. They encode the individual patterns of the sequence as *unrelated static objects*. On the other hand, synapses with transmission delays that approximately match the duration of single patterns of the sequence are able to detect the transitions between patterns. The corresponding synaptic efficacies are asymmetric and establish various temporal relations between the patterns, thereby representing the complete sequence as *one dynamic object*.

Once the learning sessions are over the $J_{ij}(\tau)$ are kept fixed. The retrieval process (Equations 1–3), operating with the very same delays as the synaptic dynamics (Equation 4), is then able to extract the spatiotemporal information encoded in the $J_{ij}(\tau)$. Retrieval is therefore extremely robust as shown in numerous simulations (Herz et al., 1989).

It should be noted that the above mechanism requires delay times that are of the same order as the duration of *single* quasi-static elements of a temporal sequence. The length of the *entire* sequence, however, remains unconstrained. A number of authors have discussed the interplay between neural and synaptic dynamics and, in particular, the role of transmission delays (e.g. Hebb, 1949, and Caianiello, 1961). However, the full consequences, discussed in the present article, have only been explored recently.

## Global Analysis

Equations 1–4 describe a "double dynamics" where both neurons and synapses change in time. In general, such a scenario cannot be analyzed mathematically. The situation simplifies if teaching is performed in a "clamped" fashion where the system evolves according to the external stimuli, $S_i(t_\mu) = \sigma_i(t_\mu - 1)$, so that the synapses measure the true correlations of external stimuli without any interference by the internal dynamics. Clamped learning is achieved by setting $T = 0$ in (3) and $\gamma = 1$ in Equation 1 during learning sessions. Numerical experiments demonstrate that this condition can be relaxed without significant changes in the emergent network behavior.

One may derive approximate equations of motion for the macroscopic network dynamics (for a detailed discussion see Kühn and van Hemmen, 1991). These equations are nonlinear due to the nonlinear signal processing of single neurons (Equations 2 and 3) and contain previous activities due to the memory effects modeled by Equation 1. The solutions agree well with numerical simulations, but an exact analysis is in general not possible.

The mathematics become tractable in the special case where all input sequences $\sigma_i(t_\mu)$ are cyclic with equal periods $D_\mu = D$. If one defines patterns $\xi^{\mu 0}_{ia}$ by $\xi^{\mu 0}_{ia} \equiv \sigma_i(t_\mu = a)$ for $0 \le a < D$, one obtains

$$\tilde{J}_{ij}(\tau) = N^{-1} \sum_{\mu=1}^{P} \sum_{a=0}^{D-1} \xi^{\mu 0}_{i,a+1} \xi^{\mu 0}_{j,a-\tau} \tag{5}$$

Note that the synaptic strengths are in general still asymmetric in the sense that $\tilde{J}_{ij}(\tau) \neq \tilde{J}_{ji}(\tau)$. They do, however, obey the symmetry $\tilde{J}_{ij}(\tau) = \tilde{J}_{ji}(D - (2 + \tau))$ for $\tau < D - 1$ and $\tilde{J}_{ij}(D - 1) = \tilde{J}_{ji}(D - 1)$. For all networks whose *a priori* weights $\varepsilon(\tau)$ satisfy $\varepsilon(\tau) = \varepsilon(D - (2 + \tau))$ for $\tau < D - 1$ one has thus found an "extended synaptic symmetry,"

$$J_{ij}(\tau) = J_{ji}((D - (2 + \tau))(\text{modulo } D)) \tag{6}$$

generalizing the symmetry assumption $J_{ij} = J_{ji}$ of Hopfield Networks in a natural way to the temporal domain. The symmetry (Equation 6) suggests that one may be able to find a Lyapunov (or "energy") function for the noiseless retrieval dynamics (Equation 2) (see Energy Functionals for Neural Networks). This is indeed the case if $\varepsilon(D - 1) = 0$ (Herz, Li, and van Hemmen, 1991). One takes $\gamma = 0$ in Equation 1 and defines

$$H(t) \equiv -\frac{1}{2} \sum_{i,j=1}^{N} \sum_{a,\tau=0}^{D-1} J_{ij}(\tau) S_i(t - a) \times S_j(t - (a + \tau + 1)(\text{modulo } D)) \tag{7}$$

By Equation 1, Equation 2, and Equation 6 the difference $\Delta H(t) \equiv H(t) - H(t - 1)$ is

$$\Delta H(t) = -\sum_{i=1}^{N} [S_i(t) - S_i(t - D)] h_i(t - 1) \tag{8}$$

As a finite sum of finite terms, $H$ is bounded. $H(t)$ is nonincreasing because the right-hand side of Equation 8 is nonpositive: the term $S_i(t)h_i(t - 1)$ equals $|h_i(t - 1)|$ due to the dynamics (Equation 2) and is therefore larger than or at least equal to the product $S_i(t - D)h_i(t - 1)$, which is $\pm h_i(t - 1)$. Consequently, $\Delta H(t)$ has to vanish as $t \to \infty$. This is only possible if the system settles into a state with $S_i(t) = S_i(t - D)$ for all $i$.

The analysis has exposed two important facts: (1) the retrieval process of certain delay networks is governed by a Lyapunov function. The time evolution during retrieval sessions can thus be understood as a downhill march in an abstract energy landscape. (2) The networks relax to a static state or a limit cycle with $S_i(t) = S_i(t - D)$—oscillatory solutions with the *same* period as that of the taught cycles or a period which is equal to an integer fraction of $D$.

Stepping back for an overview, one notices that $H$ is a Lyapunov function for all networks that exhibit an "extended synaptic symmetry" (Equation 6) and for which the matrix $\mathbf{J}(D - 1)$ vanishes. The Hebbian synapses (Equation 4) are one important special case and will be the main subject of the further discussion.

## Statistical Mechanics

The last section shows that certain delay networks relax to fixed points or oscillatory solutions with well-determined periods. Are there limit cycles that resemble the taught sequences? How many sequences can be stored in a given network?

The answers are obtained in a two-step process. First, it is demonstrated that networks with cyclic temporal associations and deterministic dynamics can be mapped onto symmetric Hopfield-like systems without delays. In a second step, one shows that this correspondence holds for the stochastic Glauber dynamics (Equation 3) as well. One may then apply equilibrium statistical mechanics to derive quantitative results. A detailed discussion of the technical issues involved can be found in (Herz et al., 1991). Let me briefly sketch the main ideas.

$D$-periodic oscillatory solutions of the retrieval dynamics can be interpreted as static states in a fictitious "$D$-plicated" system with $N$ rows and $D$ columns of cells with activities $S_{ia}$ where $1 \le i \le N$ and $0 \le a < D$. The parallel dynamics of the original system are reproduced by the update rule

$$S_{ia}(t + 1) = \begin{cases} \operatorname{sign}\left[\sum_{j=1}^{N} \sum_{b=0}^{D-1} J_{ij}^{ab} S_{jb}(t)\right] & \text{if } a = t \,(\text{modulo } D) \\ S_{ia}(t) & \text{otherwise} \end{cases} \tag{9}$$

In terms of the original synaptic efficacies $J_{ij}(\tau)$, the couplings $J_{ij}^{ab}$ are given by $J_{ij}^{ab} = J_{ij}((b - a - 1)\,(\text{modulo } D))$. Due to Equation 6, they are symmetric, that is, $J_{ij}^{ab} = J_{ji}^{ba}$.

The time evolution of the new network has a pseudo-sequential characteristic: synchronous within single columns and sequentially ordered with respect to these columns. The interpretation of the retrieval process is changed significantly: a *limit cycle* of period $D$ in the original network corresponds to a *fixed-point* of the new system of size $ND$. Storing one cycle $\sigma_i(t_\mu) = \xi^{\mu 0}_{ia}$ in the delay network thus corresponds to memorizing $D$ shifted duplicates $\xi^{\mu\nu}_{ia}$, $0 \le \nu < D$, in the equivalent system. This reflects the fact that a cycle with period $D$ can be retrieved in $D$ different time-shifted versions in the original network.

Let me now turn to quantitative results. They were obtained within a replica-symmetric theory (see Statistical Mechanics of Neural Networks) for the case where each of the $P$ learning sessions corresponds to teaching a (different) cycle of $D$ unbiased random patterns $\xi_{ia}^{\mu 0}$, each lasting for one time step.

The retrieval quality for a given cycle $\mu$ is best described in terms of the generalized "overlap" $m^{\mu} = \max_{\nu}\{N^{-1}D^{-1}\Sigma_{i,a}\xi_{ia}^{\mu\nu}S_{ia}\}$: this order parameter equals one for perfect recall and zero if the network state is uncorrelated with the $\mu$th cycle. Retrieval is possible as long as the network dynamics admit solutions with one large $m^{\mu}$. Due to interference between different memories, this is only possible if the number $P$ of stored sequences remains below a critical number $P_c$. The analysis shows that $P_c$ scales linearly with $N$ for large $N$, $P_c = \alpha_c N$. The factor $\alpha_c$ is called the storage capacity of the network. As in the Hopfield model, the retrieval quality $m^{\mu}$ drops suddenly as $P$ is increased beyond $\alpha_c N$—a first-order phase transition (see Cooperative Phenomena and Statistical Mechanics of Neural Networks).

It should be noted that each cycle consists of $D$ patterns so that the storage capacity for *single* patterns is $\bar{\alpha}_c = D\alpha_c$. During the recognition process, however, each of them will trigger the cycle it belongs to and cannot be retrieved as a static pattern. For systems with a delay distribution that vanishes for $\tau = D - 1$ and is uniform for $\tau < D - 1$, that is, $\varepsilon(\tau) = (D - 1)^{-1}(1 - \delta_{\tau,D-1})$, one obtains

$$\begin{array}{cccccc} D & 2 & 3 & 4 & 5 & \infty \\ \alpha_c & 0.100 & 0.110 & 0.116 & 0.120 & 0.138 \end{array} \tag{10}$$

The findings agree well with estimates from numerical simulations. The results demonstrate that the storage capacity for temporal associations is comparable to that for static memories. As an example, take $D = 2$. In the limit of large $N$, $0.100 \cdot N$ two-cycles of the form $\xi_{i0}^{\mu 0} \rightleftarrows \xi_{i1}^{\mu 0}$ may be recalled as compared to $0.138 \cdot N$ static patterns (Amit, 1989); since $2 \times 1.00/1.38 \approx 1.45$, this amounts to a 1.45-fold increase of the information content per synapse.

The influence of the weight distribution on the network behavior is demonstrated by some choices of $\varepsilon(\tau)$ for $D = 4$:

$$\begin{array}{rcccccccc} \tau & = & 0 & 1 & 2 & 3 & \alpha_c & m_c \\ \varepsilon(\tau) & = & 1/3 & 1/3 & 1/3 & 0 & 0.116 & 0.96 \\ \varepsilon(\tau) & = & 1/2 & 0 & 1/2 & 0 & 0.100 & 0.93 \\ \varepsilon(\tau) & = & 0 & 1 & 0 & 0 & 0.050 & 0.93 \end{array} \tag{11}$$

The storage capacity decreases with decreasing number of delay lines, but measured *per synapse*, it does increase. However, networks with only a few number of delays are less fault-tolerant as shown by numerical simulations.

## Discussion

Learning schemes can only be successful if the structure of the learning task is compatible with both the network architecture and the learning algorithm. In the present context, the task is to store simple temporal associations. It can be accomplished in neural networks with a broad distribution of signal delays and Hebbian synapses which, during learning periods, operate as microscopic feature detectors for spatiotemporal correlations within the external stimuli. The retrieval process utilizes the very same delays and synapses, and is therefore rather robust.

Let me emphasize that the Hebbian mechanism discussed here does *not* limit the overall length of a pattern sequence stored in a neural network with transmission delays. It is the duration of a single pattern within a temporal association that is constrained and cannot exceed the time lags provided by transmission delays.

Quantitative results for the storage capacity and retrieval quality can be obtained for a certain class of delay networks using a global Lyapunov function and techniques from statistical mechanics. Unlike in the general case, the total length of a pattern sequence has to approximately match the maximum time lag to allow for the extended synaptic symmetry (Equation 6). The analytical findings prove that an extensive number of temporal associations can be stored as spatiotemporal attractors for the retrieval dynamics. Numerical simulations with pattern sequences that are long with respect to the available signal delays show a qualitatively similar picture. Both results indicate that dynamic systems with delayed interactions can be programmed in an efficient manner to perform associative computations in the space-time domain.

The approach sketched in this article has also been extended to neural networks with continuous units that store cycles of correlated real-valued pattern sequences (Herz, 1995). Numerical studies have been performed for low-dimensional trajectories (small $N$) with high numbers of data points (large $D$). For many examples, good retrieval could be obtained without any need for highly time-consuming supervised learning schemes. However, algorithms of the latter kind are eventually necessary to solve more sophisticated real-world associations. Here, once again, the existence of Lyapunov functions is of great help since it allows for the application of powerful techniques from Statistical Mechanics of On-Line Learning and Generalization (q.v.) to a wide class of supervised learning strategies such as spatiotemporal extensions of the Boltzmann Machine (see Simulated Annealing and Boltzmann Machines).

Delays add a new dimension—time—to *any* learning mechanism based on correlation measurements of pre- and postsynaptic events. This extra dimension naturally extends the structure of objects representable in the synaptic code generated by such a learning mechanism, thereby considerably increasing its potential power. Transmission delays do therefore not induce a loss of the associative capabilities of neural networks as one might have feared. On the contrary, if properly included in the learning process, they provide a physical structure to perform spatiotemporal computations at low architectural cost. Nature may have opted to make constructive use of them, as is also indicated by the success of more elaborate models with delayed interactions (see, for example, Gerstner et al., 1996).

## Introduction

In computer vision, we often face the problem of identifying salient and structured information in a noisy data set. In three-dimensional (3D) data sets, constructed from binocular images, surfaces are inferred by obtaining depth hypotheses for points and/or edges using local correlation measures, and then selecting and interpolating appropriate values for all points in the images. In image sequence analysis, the estimation of motion and shape starts with local measurements of feature correspondences, which yields noisy data for the subsequence computation of scene information. Hence, any salient structure estimator must be able to handle the presence of multiple structures and their interaction in the presence of noisy data.

In this article, we analyze representative approaches to early to midlevel vision problems and present our *tensor voting* method for the robust inference of multiple salient structures such as junctions, curves, regions, and surfaces from any combination of point, curve element, and surface patch element inputs in 2D and 3D.

The problem formulation dominates the design of any algorithms, and computer vision is no exception. We can roughly classify major approaches found in computer vision literature into the following five categories, which may not be mutually exclusive:

- *Artificial neural network*—Inspired by biological visual systems, the artificial neural network (ANN) approach devises solutions that mimic operations found in biological neural systems.
- *Regularization*—Because early vision problems are ill-posed inverse problems, extra constraints are introduced to limit the search space of the solution.
- *Consistent labeling*—Computer vision problems are cast as a problem of finding the set of consistent labels for all the image pixels.
- *Statistical methods*—Vision problems are formulated as clustering or parametric model fitting in order to infer relevant visual information.
- *Perceptual saliency approach*—Salient properties emerge from the input data and are detected by a non-maximal-suppression process.

## Artificial Neural Network

In the ANN approach, it is suggested that vision problems might be solved computationally if biological vision structures discovered by neurologists can be simulated. An ANN is characterized by a large number of weighted connections among a large number of very simple processing elements. One emphasis is to learn the weighting and internal structure, in either a supervised or an unsupervised way. The absence of explicit models, however, makes the assessment somewhat difficult.

The work by Grossberg and Mingolla (1987) describes a theory and a implementation of surface perception based on the neural network approach. It consists of two interacting systems, the boundary contour system and the feature contour system. Excellent results are obtained on some examples. The use of scalar values can be a limitation.

## Regularization

Because of the projective nature of imaging, a single image can correspond to different scene configurations. Because of this ambiguity in image formation, the inverse problem, namely, the inference of structures from images, is ill posed. Below we describe two regularization formalisms. *Regularization theories* entail imposing certain physical constraints, so that the search space can be constrained and algorithmically tractable. *Stochastic regularization* uses a Bayesian formalism to transform the ill-posed problem into one of functional optimization.

### Regularization Theory

The underlying spirit of regularization theory is to restrict the solution space by choosing the function that minimizes an appropriate function. For solving the ill-posed problem of finding $x$ from data $y$, where $y = F(x)$, regularization theories provide the mathematical foundation for choosing the norms and a stabilizing function that characterizes the global constraints of the problem.

In the case of early vision, the problem is transformed into the nonlinear, scalar functional optimization framework, which can then be solved using standard numerical techniques, namely the calculus of variations (Terzopoulos, 1986).

### Stochastic Regularization

A Bayesian formalism can also be used to transform ill-posed inverse problem into the functional optimization framework. In Bayesian terms, the task can be described as the maximization problem of a posterior probability density function.

Other modeling approaches, such as minimum description language (Leclerc, 1989), are allowed in describing the model constraints. Various stochastic or probabilistic optimization methods such as simulated annealing (Kirkpatrick, Gelatt, and Vecchi, 1983), genetic algorithm, or evolutionary strategy (Koza, 1992), or the Expectation-Maximization (EM) algorithm are also employed in the search for a solution.

### Level Set Approach

Recently, a new implicit representation has been proposed under the name of level set method (Zhao et al., 1988). The main idea is to describe a curve (or a surface) as the zero-level set of a higher-dimension function Φ. Then, instead of evolving the curve, we consider the evolution of the function Φ, and extract the zero levels. This method permits topological changes to be made easily and has proved to be a powerful tool for many applications in physics, geometry, and computer vision (see Sethian, 1996, for a review).

Some interesting results have been reported that also reveal some limitations to this approach. First, the method is based on the computation of a distance function, which may be inaccurate if a large amount of noise is present. It may be difficult to distinguish whether points are relevant or not for the reconstruction.

More generally, concerning the level set formulation itself, even if we do not have any parameters, we are still restricted to consider special shapes. In the 3D case, the formulation can only recover surfaces, not curves. As for the geometrical properties, curves or surfaces can only be enclosed sets, and we cannot represent multiple junctions. Note that in this last problem, solutions have been derived for multiphase problems (Zhao et al., 1988) involving several Φ functions, but the knowledge that such a junction exists must be available beforehand.

In conclusion, level sets (or other implicit representations) rely on shape hypotheses and have a number of inherent limitations. Also, they are representations, and not descriptions, as they do not make explicit edges, crossings, or singularities. This information has to be inferred at a postprocessing stage.

## Clustering and Robust Methods

Another major formulation approach is to cast vision problems as a problem in data analysis or classification. *Clustering* methods employ the statistical approach to infer compact groups of points in multidimensional space. *Robust techniques* employ data analysis formalism to perform parametric model fitting.

### Consistent Labeling

As pointed out in Medioni, Lee, and Tang (2000), the major issues in computer vision are to infer salient smooth features, detect discontinuities, and identify outliers. Since these roles are mutually exclusive, it seems reasonable to pose early vision problems as problems in *consistent labeling*. A labeling problem is defined by a set of objects, a set of possible labels for each object, a neighbor relation over the objects, and a compatibility relation over labels as *n*-tuples of neighboring objects.

The goal is to assign labels to each object that respect the compatibility relationship. A labeling problem can be formulated as a *relaxation* operation because its formulation is similar to that of a system of linear equations. Three main types of relaxation methods exist: *discrete relaxation labeling, continuous relaxation labeling*, and *stochastic relaxation labeling*.

*Discrete relaxation labeling.* The labeling problem can be described as one of assigning labels to nodes in the graph defined above. *Discrete relaxation labeling* is an algorithmic approach to tackling this graph-labeling problem. The constraints are required to be expressed by logical assertions. The relaxation is governed by the label-discarding rule: discard a label at a node if there exists a neighbor such that every label currently assigned to the neighbor is incompatible with the label. The discrete relaxation labeling process is defined by the iterative application of the label-discarding rule, applied in parallel at each node, until limiting label sets are obtained.

*Continuous relaxation labeling.* Continuous relaxation labeling attempts to allow greater flexibility in the constraints by replacing the logical assertions about compatibilities with weighted values representing relative preferences. In addition, by allowing weights to be used for label assignment, the labeling problem is transformed into the functional optimization framework, which can then be solved by numerical relaxation techniques. Because of the mathematical context in which continuous relaxation labeling has come to exist, a number of attempts have been made to develop an underlying theory for the process. We refer readers to articles by Faugeras and Berthod discussed in Faugeras (1993) and Hummel and Zucker (1983) for two different formulations of the continuous relaxation labeling process.

*Stochastic relaxation labeling.* Stochastic relaxation labeling is similar to continuous relaxation labeling except that the labeling weights and the constraint preferences weights are replaced by probability distributions. Stochastic relaxation labeling makes use a model of physical phenomena known as Markov random field (MRF) modeling (see Geman and Geman, 1984, for a definition of MRF in the context of computer vision). The MRF model is often combined with the Bayesian estimation technique known as maximum a posteriori (MAP) estimation, forming an MRF-MAP framework for solving computer vision problems. The MRF-MAP approach also requires solving an energy minimization problem. Typically, one uses a global minimum–seeking algorithm such as simulated annealing (Kirkpatrick et al., 1983), evolutionary algorithms (Koza, 1992), or the EM algorithm to minimize the energy functions, which are often nonconvex.

### Properties of Consistent Labeling

Regardless of the formulation of the problem, all solutions for consistent labeling entail the intrinsically iterative process of relaxation. As for all iterative processes, the main issues in defining a relaxation process are initialization, updating, and stopping condition. The different formulations just provide different justifications for setting the functions and parameters. Nevertheless, the labeling framework makes it relatively easy to incorporate terms to account for discontinuities.

### Clustering

The common use of clustering in solving early vision problems is to create a partition of points such that points in each cluster share similar properties. Partitional clustering methods can be divided into error-square clustering, density estimation clustering, and clustering by graph theory.

Error-square clustering minimizes the squared error for a fixed number of clusters. Density estimation clustering make use of histograms to find clusters. Clustering by graph theory uses geometric structures such as the minimum spanning tree, relative neighborhood graph, and mutual nearest neighborhood to obtain the desired partitions. Methods that use these geometric structures construct the graph first, then remove inconsistent edges of the graph. Inconsistent edges and their elimination are specified for each method. Recently, Shi and Malik (1998) devised a clustering by graph technique called normalized cuts and applied it to image segmentation, motion segmentation, and tracking.

Most of the clustering techniques are iterative and sensitive to the a priori choice of the number of clusters in the feature space. If this choice is poor, the final partition of the space may be incorrect as well. This sensitivity is an important limitation in computer vision, where the number of significant feature properties is rarely known a priori.

### Robust Techniques

Another aspect of data analysis is to robustly recover the parameters of a given model from noisy observations.

There are essentially two major issues that needed to be addressed: parameter estimation and inlier/outlier identification (data error correction). Robust estimators often make use of the algebraic properties of the carrier functions and the constraint equation to handle parameter estimation, and apply statistical tools to tackle data error correction. Although techniques such as the Hough transform can be very robust to noise, the parametric formalism of these techniques make it hard to deliver the same robustness in solving early vision problems. In computer vision, usually the models employed are only approximations, and that real data can only be represented by multiple models. Worst, the outliers are often structured, and they obey the same model with a different parameter.

## Perceptual Saliency Approach

In 1988, Sha'ashua and Ullman suggested use of a *saliency map* to guide the perceptual grouping process. A saliency map, derived from the input 2D image, is a dense map in which the value of each pixel corresponds to the degree of "perceptual importance," such as smoothness, length, and constancy of curvature. Their method uses an incremental optimization scheme to avoid the exponential complexity involved in picking subsets from a large set of data. A local operator chooses the *optimal continuation* from a given segment. However, this method cannot handle large gaps, and can be fooled by erroneous segments along a correct curve. Moreover, the method is iterative, running on a locally connected network.

Recently, Medioni et al. (2000) combined the representational power of a tensor (introduced by Knutsson, 1989, in the context of signal processing for computer vision) and the computational efficiency of linear voting for salient structure inference. The result is a unified framework for dealing with various input types that retains all the desirable properties of vector voting. The novelty of this approach is that tensor voting avoids searching through the solution space, by formulating the computation as a voting process. Although deriving the best scene description is an optimization problem, the *optimal solution* emerges from the data set.

Unlike regularization and labeling approaches, this formulation avoids all the inherent problems in iterative optimization: no initialization is needed. Thus the choice of size and search direction for each iteration is no longer an issue. The method is noniterative, parameter-free, depends on no critical thresholds, and allows any number of objects in the scene, each of any genus. The only free parameter is the scale of analysis. Also, tensor voting does not need to estimate a large number of parameters, which is common in other statistical approaches. Tensor voting uses dense voting fields, whose designs are based on the good continuity constraint (one of the *Gestalt* principles). When compared with the absence of explicit models in the ANN approach, the analysis of tensor voting is more approachable.

## Tensor Voting

We use *tensor* for data representation and *voting* for data communication. A point in the 3D space can assume one of the following configurations: a surface patch, a discontinuity, or an outlier. A point on a smooth surface is very certain about its surface normal orientation (or stick tensor), whereas a point at a junction where surfaces intersect has absolute orientation uncertainty (indicated by a ball tensor). A second-order symmetric tensor in 3D is used to represent this continuum. This tensor representation can be visualized as an ellipsoid.

### *Overview of the Salient Structure Inference Engine*

Figure 1 shows the overall approach in this methodology. Each input token is first encoded as a second-order symmetric tensor. For instance, if the input token has only position information, it is transformed into an isotropic tensor (a ball) of unit radius.

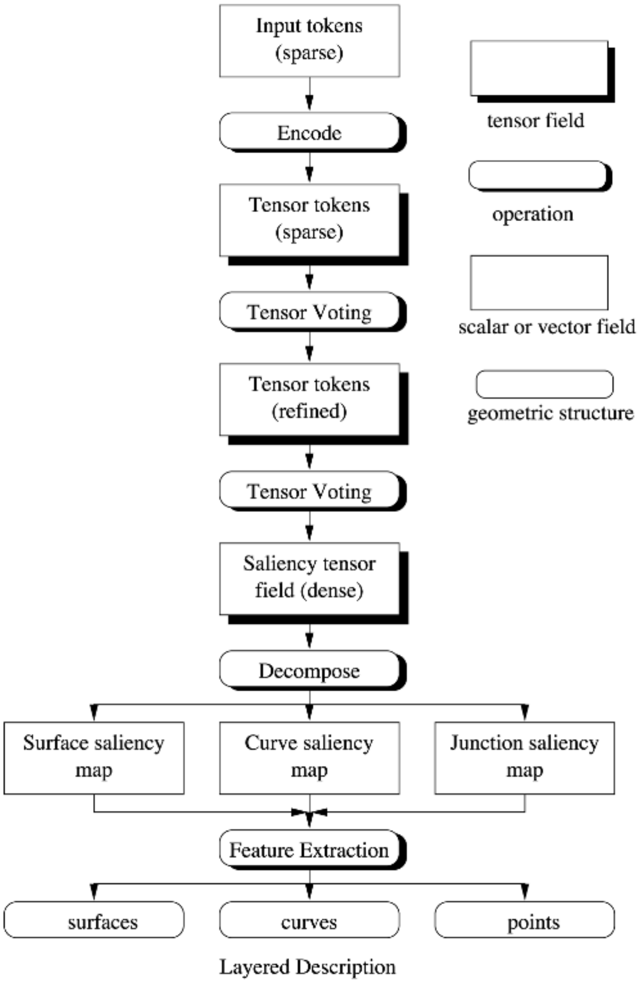

**Figure 1.** Overview of the essential components of tensor voting.

In the first voting stage, tokens communicate their information to each other in a neighborhood, and refine the information they carry. After this process, each token is now a generic second-order symmetric tensor that encodes confidence of this knowledge (given by the tensor size) and curve and surface orientation information (given by the tensor orientations).

In the second stage, these generic tensor tokens propagate their information in their neighborhood, leading to a dense tensor map that encodes feature saliency at every point in the domain. In practice, the domain space is digitized into a uniform array of cells. In each cell the tensor can be decomposed into elementary components that express different aspects of the information captured.

The resulting dense tensor map is then decomposed. Surface, curve, and junction features are then obtained by extracting, with subvoxel precision, local extrema of the corresponding saliency values along a direction. The final output is the aggregate of the outputs for each of the components.

### *Tensor Representation*

The goal is to extract geometrical features such as regions, curves, surfaces, and the intersections between them. We will first summarize the various differential properties of these entities and their behavior at singularities. Then we discuss using tensors as a representation scheme.

Points can be represented by their coordinates. For curve inference, a first-order local description of a curve is given by the point coordinates and its associated tangent. A second-order description would also include the associated curvature.

For surface inference, a first-order local description of a surface patch is given by the point coordinates and its associated normal information. A second-order description would also include the principal curvatures and their directions.

However, we do not know in advance what type of entity—point, curve, or surface—a token may belong to. Furthermore, singularities occur when these entities intersect each other. For example, when two smooth surfaces intersect, there is no associated normal information at the point of intersection. However, if we consider a small finite neighborhood around a curve junction, it has an associated tangent corresponding to the intersection curves.

*Second order symmetric tensor.* To capture first-order differential geometry information and its singularities, a second-order symmetric tensor is proposed that captures both the information and its confidence, or *saliency*. Such a tensor can be visualized as an ellipse in 2D or as an ellipsoid in 3D.

Intuitively, the shape of the tensor defines the type of information captured (point, curve, or surface element), and the associated size represents the saliency. For instance, in 2D, a very salient curve element is represented by a thin ellipse whose major axis represents the estimated tangent direction and whose length reflects the saliency of the estimation. Therefore, it encapsulates both orientation and certainty information at the same time.

In 3D, the second-order symmetric tensor is an ellipsoid that is fully described by its associated eigensystem, with three eigenvectors $\hat{e}_1$, $\hat{e}_2$, and $\hat{e}_3$ and the three corresponding eigenvalues $\lambda_1 \geq \lambda_2 \geq \lambda_3 \geq 0$.

Rearranging the eigensystem, the 3D ellipsoid is given by $(\lambda_1 - \lambda_2)\mathbf{S} + (\lambda_2 - \lambda_3)\mathbf{P} + \lambda_3\mathbf{B}$, $\mathbf{S} = \hat{e}_1\hat{e}_1^T$, $\mathbf{P} = \hat{e}_1\hat{e}_1^T + \hat{e}_2\hat{e}_2^T$, and $\mathbf{B} = \hat{e}_1\hat{e}_1^T + \hat{e}_2\hat{e}_2^T + \hat{e}_3\hat{e}_3^T$, where **S** defines a *stick tensor*, **P** defines a *plate tensor*, and **B** defines a *ball tensor*.

These tensors define the three basis tensors for any general 3D ellipsoid. A linear combination of these basis tensors defines any second-order symmetric tensor.

### Tensor Decomposition

The *eigenvectors* encode *orientation (un)certainties*. Surface orientation (normal) is described by the stick tensor, which indicates certainty along a single direction. *Orientation uncertainty* is abstracted by two other tensors. *Curve* junction results from two intersecting surfaces, where the uncertainty in orientation only spans a single plane perpendicular to the tangent of the junction curve, and thus is described by a plate tensor. At *point* junctions, where more than two intersecting surfaces are present, a ball tensor is used, since all orientations are equally probable.

The *eigenvalues*, on the other hand, effectively encode the *magnitude* of orientation (un)certainties, since they indicate the size of the corresponding 3D ellipsoid.

Therefore, we can decompose a tensor token into the following 2-tuples $(s, \hat{v})$, where $s$ is a scalar indicating feature saliency and $\hat{v}$ is a unit vector indicating direction:

- *Surfaceness*: $s = \lambda_1 - \lambda_2$, and $\hat{v} = \hat{e}_1$ indicates the normal direction.
- *Curveness*: $s = \lambda_2 - \lambda_3$, and $\hat{v} = \hat{e}_3$ indicates the tangent direction.
- *Junctionness*: $s = \lambda_3$, $\hat{v}$ is arbitrary.

### Token Refinement and Dense Extrapolation

We now turn to our communication and computation scheme, which allows a site to exchange information with its neighbors and infer new information. The input tokens are first encoded as tensors. These initial tensors communicate with each other in order to (1) derive the most preferred orientation information, or refine the initial orientation if given, for each of the input tokens (token refinement); and (2) extrapolate the inferred information at every location in the domain for the purpose of subsequent coherent feature extraction (dense extrapolation).

These two tasks can be implemented by a *voting* process, which involves having each input token aligned with predefined, dense *voting kernels* (or voting fields). This alignment is simply a translation followed by rotation. The dense voting kernels encode the basis tensors (i.e., stick, plate, and ball tensors in the 3D case). This voting process is similar to a convolution, except that the output of this process is a tensor (instead of a scalar).

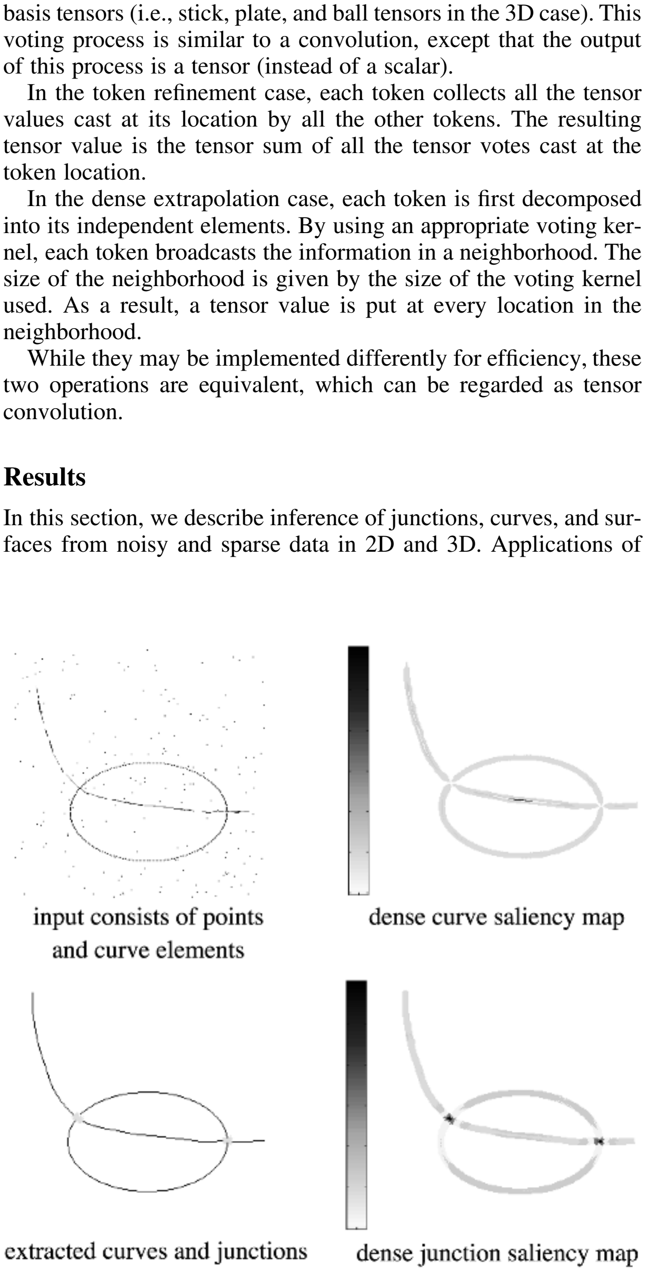
In the token refinement case, each token collects all the tensor values cast at its location by all the other tokens. The resulting tensor value is the tensor sum of all the tensor votes cast at the token location.

In the dense extrapolation case, each token is first decomposed into its independent elements. By using an appropriate voting kernel, each token broadcasts the information in a neighborhood. The size of the neighborhood is given by the size of the voting kernel used. As a result, a tensor value is put at every location in the neighborhood.

While they may be implemented differently for efficiency, these two operations are equivalent, which can be regarded as tensor convolution.

## Results

In this section, we describe inference of junctions, curves, and surfaces from noisy and sparse data in 2D and 3D. Applications of



input consists of points and curve elements

dense curve saliency map

extracted curves and junctions

dense junction saliency map

**Figure 2.** Curve and junction inference from mixed input. The gray levels indicate *curveness* (top) and *junctionness* (bottom). Dark gray indicates a higher value.

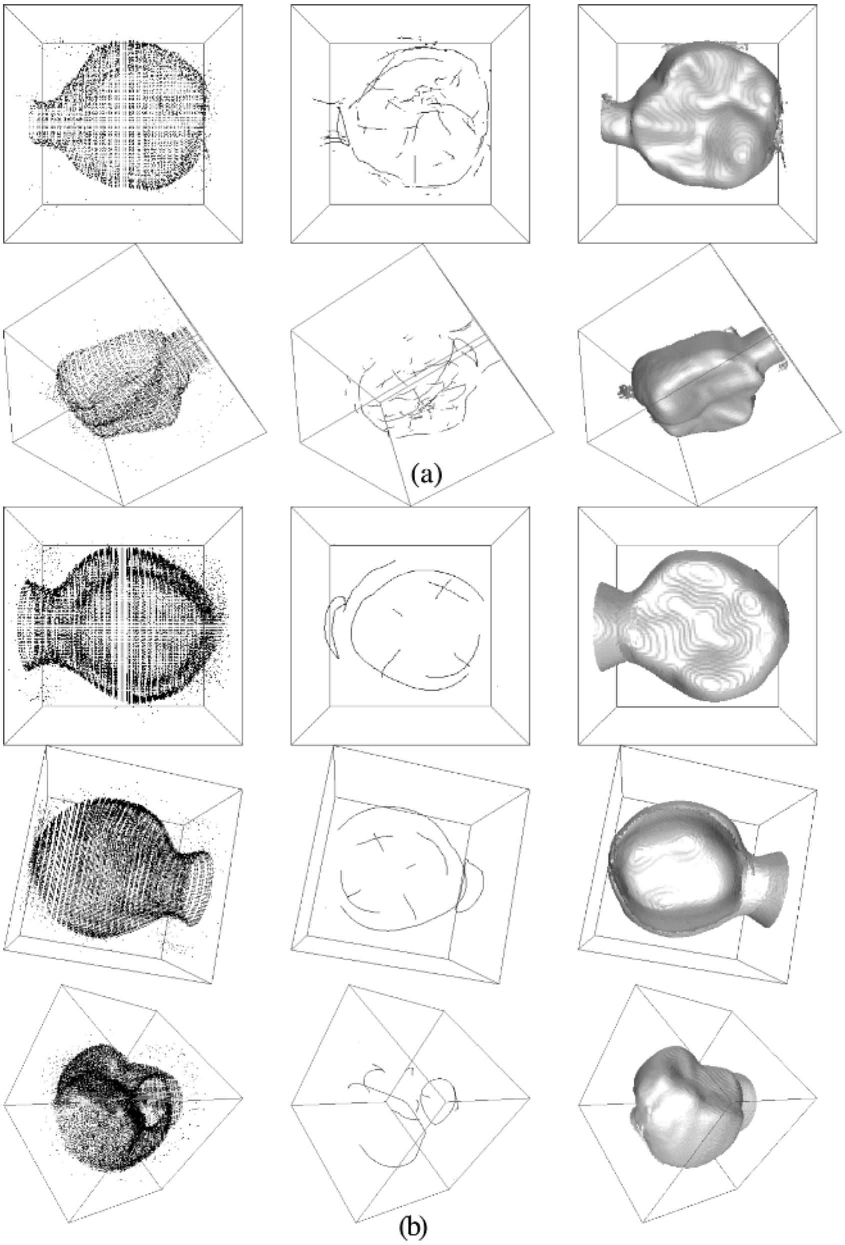


**Figure 3.** Surface and junctions inferred from noisy data sets. *A* and *B* are results on two noisy data sets, the curves and surfaces extracted automatically by tensor voting. (Data courtesy of USC dental school.)

tensor voting to midlevel computer vision problems, such as stereo and motion, can be found in Medioni et al. (2000).

### *2D*

In 2D, the second-order symmetric tensor is an ellipse, described by the eigensystem $\lambda_1 \geq \lambda_2$ with corresponding eigenvectors $\hat{e}_1$, $\hat{e}_2$. We have only curveness and junctionness. Also, the number of voting fields is reduced to two: the stick and ball voting fields.

We consider that the input consists of both oriented and nonoriented data as the general case. We first apply tensor voting. Oriented tokens vote with the stick voting field, and nonoriented tokens vote with a ball voting field. Only locations where tokens are present receive votes. A second round of voting is then performed in which we discard the ball component of the tensor. A dense tensor map is produced, which is then decomposed into a junction map and a curve map. Figure 2 shows an example of curve and junction inference from a mixed input consisting of an ellipse made up of curve elements and a curve made up of dots.

Even more generically, we can process input in which the tokens are already in tensor form, simply by decomposing the tokens into ball and stick components and having them vote initially with the corresponding ball and stick fields, only at token locations. The second voting pass is identical.

### *3D*

Figure 3 shows the data (courtesy of USC dental school) and inferred features. The input points are first encoded into perfect balls. The ball voting field is placed at each point, propagating ball votes in each neighborhood. After the preliminary step of ball field voting, a tensor is produced at each point. The stick components (or $\hat{e}_1$) of these tensors denote the normal direction. These inferred sticks then vote again, with the stick voting field for surface inference, exactly as in the basic case for surface inference from surface elements.

## Discussion

In this article, we compared representative approaches to visual segmentation. These approaches can be classified as artificial neural network, regularization, consistent labeling, statistical methods, and perceptual grouping. Tensor voting can be placed in the last category. Tensor voting makes use of tensors for data representation and a voting procedure for data communication. Unlike other approaches, it is noniterative, does not have genus limitation, and has only one scale as parameter.

# Thalamus

*Sean Hill and Giulio Tononi*

## Introduction

The thalamus is the gateway through which all sensory inputs, except olfaction, are relayed to the cortex. The thalamus can effectively control the flow of information to the cortex: during waking, it may subserve attention, selectively enhancing certain inputs to the cortex and attenuating others; during slow-wave sleep, the firing mode of thalamic cells changes, effectively closing the gateway and diminishing the influence of external stimuli on the cortex. Massive feedback from the cortex to the thalamus suggests that the entire thalamo-cortico-thalamic loop plays a role in sustaining and synchronizing cortical activity. Furthermore, certain thalamic nuclei appear to constitute an integral part of the signal flow between different cortical areas. The organization of the projections to and from the thalamus, and the anatomy and physiology of its nuclei are essential to understanding thalamic function from a neurocomputational perspective.

## Thalamic Organization and Connectivity

### *The Thalamus is Organized into Well-Defined Nuclei*

The dorsal portion of the thalamus can be subdivided into nuclei based on the source of subcortical afferents (visual, auditory, and somatosensory pathways, the cerebellum, the basal ganglia, etc.). Each thalamic nucleus is anatomically segregated from all the others but tightly linked to a specific cortical area. For example, visual input arrives from the retina, via the optic tract, at the lateral geniculate nucleus (LGN) of the thalamus, before being relayed to the primary visual cortex. Auditory input is transmitted to the medial geniculate nucleus, which projects to the primary auditory cortex. The ventral posterior nucleus receives somatosensory inputs such as tactile and kinesthetic information, and projects to the somatosensory cortex. The basal ganglia have direct projections to the ventral anterior nucleus of the thalamus, which projects to motor cortex. The ventral lateral nucleus relays input from cerebellar nuclei to motor cortex. The anterior nuclei receive ascending projections from the subiculum and mammillary body and project densely to olfactory cortex. The intralaminar nuclei, central medial nucleus, and midline nuclei have projections to and from the basal ganglia as well as to the cerebral cortex. Circuits linking other thalamic nuclei with specific cortical areas are less well understood. In some cases, the type of information relayed by these nuclei is not known at all. However, the general principle seems to be that no cortical area is devoid of thalamic afferents.

The dorsal thalamus is surrounded for much of its extent by a thin sheet of cells constituting the ventral thalamus, which includes the thalamic reticular nucleus (TRN) and the perigeniculate nucleus—the visual region of the TRN. These nuclei are pierced by millions of fibers projecting both from thalamus to cortex and from cortex to thalamus, from which they receive collaterals. Unlike nuclei in the dorsal thalamus, the TRN and the perigeniculate nucleus do not send any connections to the cerebral cortex and will be discussed separately.

### *Sensory Afferents Drive Thalamic Cells and Determine Their Response Properties*

The circuit involving the LGN and primary visual cortex is the best understood and will serve as the model for thalamic organization (Figure 1). It is likely that other thalamic nuclei, though subserving other sensory modalities, perform similar operations as the LGN. In the LGN, approximately 75% of the cells are glutamatergic relay cells that receive from the retina and project to primary visual cortex. The remaining 25% of LGN cells are interneurons that form local inhibitory GABAergic contacts. In some mammals, such as rats, interneurons are present in the LGN but are few or missing in other nuclei.

Retinal inputs to the LGN are retinotopically mapped, maintaining the spatial arrangement of the sensory input. The response properties of thalamic neurons are also remarkably similar to those of their retinal afferents. Such afferents make synaptic contacts with both relay neurons and interneurons and provide approximately 10% of the synaptic terminals in the thalamus (Van Horn, Erisir, and Sherman, 2000). They can have strong postsynaptic effects, due to large terminal endings that synapse close to the cell body of target cells (Sherman and Guillery, 2001). They use glutamate as a neurotransmitter by which they activate fast ionotropic receptors. Because they determine the firing properties of thalamic relay cells, these projections are considered the "driving" input to their target cells. In thalamic nuclei containing interneurons, one often finds a complex synaptic structure called a glomerulus, in which afferent terminals interact with the dendritic spines of relay cells and interneurons in synaptic triads. Glomeruli and synaptic triads are believed to implement a form of activity-dependent feedforward inhibition.

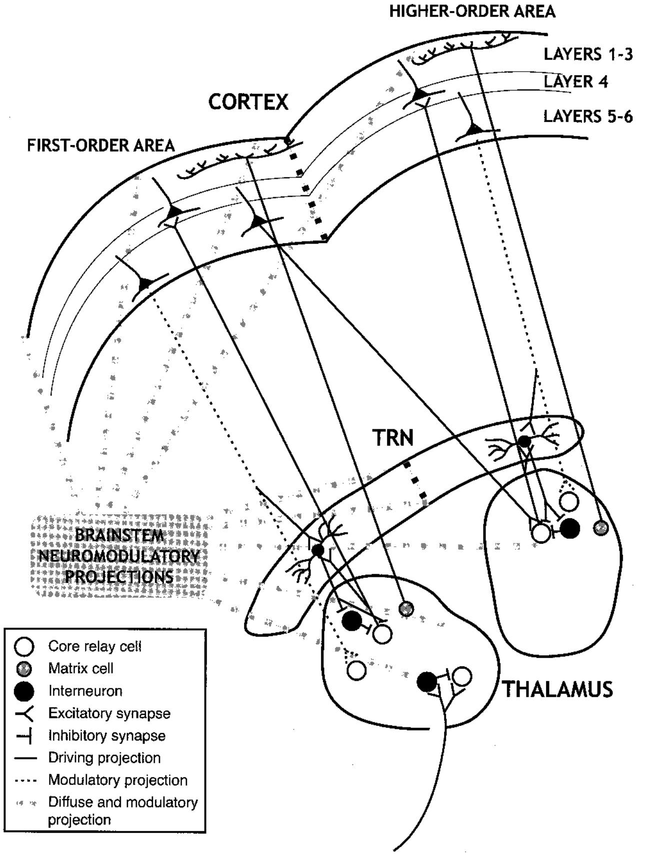

**Figure 1.** Schematic of the primary projections involved in thalamocortical circuitry.

There is substantial evidence for functional segregation within the LGN that reflects features of the input. Inputs from the left and right retina terminate in different LGN layers. These layers are further segregated into parvocellular and magnocellular cell populations. Parvocellular neurons are more sensitive to color contrast and to stimuli of high spatial frequency; magnocellular neurons are sensitive to luminance contrast and to high temporal frequencies. Such segregation is established in part through activity-dependent processes that take place during early development. It remains to be seen whether functional segregation is at work elsewhere in the thalamus.

### *Thalamic Cells Relay Sensory Input to Specific Cortical Areas*

Relay cells in the thalamus project dense topographic connections to the middle layers of the cerebral cortex—typically layer IV. These cells also form less dense projections to cortical layer VI. The majority of thalamocortical relay projections send collaterals to the TRN and provide excitatory input to the inhibitory population of cells in that nucleus (see discussion later in this article).

Thalamic input represents less than 10% of the synapses in cortical layer IV. Thalamocortical input is fast, strong, and excitatory and is mediated by glutamatergic synapses acting primarily through AMPA receptors. Single spikes in the thalamus can elicit spikes in layer IV cells. These projections are divergent and may synapse with patches of cortex up to 1.5 mm apart. The extent of these axonal arborizations in primary visual cortex corresponds to the size of a visual hypercolumn—representing a small region in the visual field. Projections from a given thalamic cell overlap as much as 600 $\mu$m with projections from a neighboring thalamic cell, producing a continuous mapping from thalamus to cortex (Steriade, Jones, and McCormick, 1997). The thalamus also relays afferent input from the basal ganglia and cerebellum to the cortex. However, the degree of organization and precision of these relay projections is not as well understood.

### *There Are Also Diffuse "Matrix" Projections from the Thalamus to the Cortex*

The traditional view of thalamocortical connections is that the focused, highly organized projections to the cortex arise from specific relay nuclei, while broad, diffusely organized projections originate in nonspecific thalamic nuclei, largely identified with the intralaminar nuclei (Jones, 1985). However, recent work has revealed that the key distinction is not between anatomically defined nuclei, but between kinds of cells—core and matrix cells—that can be identified using molecular markers (Steriade et al., 1997). Core cells, which provide the specific, topographically ordered inputs to the cortex, are identified by immunoreactivity to parvalbumin, a calcium-binding protein. Core cells are embedded in a matrix of cells that send diffuse cortical projections and that are immunoreactive for a different calcium-binding protein—D28K calbindin. Matrix cells have been found throughout the thalamus, although they are present in higher numbers in the intralaminar nuclei. The projections of these cells appear to cross the boundaries of cortical areas and to target predominantly the most superficial layers of the cerebral cortex. These connections may play a role in dynamically modulated short-term plasticity such as the augmenting response, in which repetitive stimulation of the thalamus gives rise to an enhancement of thalamic and cortical responses to stimuli (Castro-Alamancos and Connors, 1996).

### *The Cortex Sends Massive Modulatory Projections Back to the Thalamus*

It is customary to describe the flow of signals as going from the thalamus to the cortex. However, there are several times more descending corticothalamic fibers than ascending thalamocortical fibers (Van Horn et al., 2000). It is perhaps to be expected, then, that many corticothalamic projections—those originating from layer VI—modulate, rather than drive, the activity of their thalamic targets. Unlike driving inputs from the sensory periphery, modulatory inputs from layer VI cortical neurons have more subtle postsynaptic effects. Indeed, such inputs are preferentially localized on distal dendrites of thalamocortical cells, have smaller terminal sizes, and may act on both fast ionotropic and slow metabotropic receptors (Sherman and Guillery, 2001).

Connections between the thalamus and cortex are highly reciprocal. Axons originating in layer VI of a specific cortical area project to the same thalamic area that innervates that region of cortex. The arborizations of these axons diverge considerably, extending over an area as wide as 1.5 mm. These arborizations appear to be tightly linked to the hypercolumnar organization of the cortex (Sherman and Koch, 1998). Corticothalamic projections from the cortex form approximately 30% of the synaptic terminals on thalamic cells (Van Horn et al., 2000).

Corticothalamic projections from layer VI also send en passant fibers to the TRN, thus exciting the GABAergic population of thalamic cells in the TRN with the same input that modulates thalamic activity. Corticothalamic and corticoreticular projections have different effective strengths. Recent work has shown that, because of the increased number of glutamate receptor subunits GluR4 at corticothalamic synapses, the effective amplitude of excitatory postsynaptic potentials from synapses in the TRN is more than twice that of corticothalamic synapses in the thalamus (Golshani, Liu, and Jones, 2001). Thus, the influence of the cortex appears to be much greater on the TRN than on the dorsal thalamus.

Cortical deactivation and stimulation experiments have revealed a considerable range of influences of corticothalamic projections on thalamic activity. Initial experiments aimed at determining whether corticothalamic inputs provide excitation or inhibition to thalamic cells produced contradictory results, partly because they necessarily hinged on the combined effect of the corticothalamic projections (excitatory) and cortico-reticulo-thalamic projections (inhibitory). In line with the modulatory nature of these projections, the effect of layer VI cortical inputs appears to be more subtle. Although LGN cells are not orientation-selective, descending input from the cortex renders thalamic cells more sensitive to objects aligned with similar orientation in the visual field. Furthermore, corticothalamic feedback enhances the synchronization of cells responding to a single stimulus (Murphy, Duckett, and Sillito, 1999). Corticothalamic feedback is also essential to maintain the coherence of sleep spindles across the thalamocortical system. After decortication these oscillations continue to be generated by thalamic circuits at their normal frequency of about 7–14 Hz, but they become desynchronized (Contreras et al., 1996). Finally, lesioning the corticothalamic projections can prevent the development of binocular organization in the visual system (Weliky and Katz, 1999).

### *There Are First and Higher-Order Thalamic Nuclei*

The notion that the thalamus merely relays peripheral signals to the cortex is further challenged by another anatomical observation. Several large thalamic nuclei, such as the pulvinar, the mediodorsal nucleus, and the dorsal division of the medial geniculate nucleus do not seem to receive any subcortical afferents capable of providing driving inputs. Instead, these nuclei receive driving input from the cortex itself, specifically from pyramidal cells in layer V. Thus, thalamic nuclei can be placed in two categories: first-order—those that receive driving input from subcortical afferents; and higher-order—those that receive driving input from cortex (Sherman and Guillery, 2001).

Although both classes of nuclei receive modulatory feedback projections from layer VI cortical cells, only higher-order nuclei receive corticothalamic inputs from layer V cells, which share many of the morphological traits of primary afferent inputs. Like retinal inputs, and unlike corticothalamic inputs from layer VI, inputs from layer V terminate in richly branched axons, end with large synapses, mostly on proximal dendrites, and often in triadic arrangements within glomeruli. Moreover, they do not send off collaterals to the TRN, but send branches to various brainstem nuclei. Axons from layer V thus appear to provide strong, driving inputs to higher-order thalamic nuclei. Indeed, the effect of cortical deactivation on the activity of higher-order thalamic nuclei is dramatic. For example, although lesions in the striate cortex alter the response of neurons in the LGN, they eliminate all activity in the pulvinar. Thus, higher-order thalamic nuclei receive driving inputs from one cortical area and relay it further to another cortical area to which they project. From this perspective, the thalamus can be considered an integral part of cortical circuitry, virtually serving as another layer of cerebral cortex that is essential for corticocortical communication (Sherman and Guillery, 2001). It remains to be seen whether any thalamic nucleus receives driving input from more than one cortical area, opening the possibility that the thalamus may be a site for the integration of information from multiple cortical sources.

### *The Reticular Nucleus Is Interposed Between the Dorsal Thalamus and the Cortex*

As mentioned previously, the dorsal thalamus is surrounded by a thin sheet of cells—the thalamic reticular nucleus (TRN) and the associated perigeniculate nucleus. The TRN and associated nuclei receive collaterals from both thalamocortical fibers and corticothalamic fibers originating in layer VI cells, but do not send any projections to the cortex. Since thalamocortical and corticothalamic collaterals are topographically mapped, and they appear to largely overlap, the TRN is organized into functional sectors responsive to different modalities and submodalities (e.g., visual, auditory, somatosensory, and motor).

The TRN contains exclusively GABAergic cells, which project to the dorsal thalamus in a topographically organized manner. GABA released by reticulothalamic cells affects its targets via $\mathrm{GABA}_A$ and $\mathrm{GABA}_B$ receptors. $\mathrm{GABA}_A$ receptors have fast ionotropic responses (tens of milliseconds) acting on the conductance of Cl channels. The kinetics of $\mathrm{GABA}_B$ receptors are much slower (hundreds of milliseconds) and influence the conductance of $K^+$ channels. Since the reversal potential of $K^+$ is more negative than that of $Cl^-$ ($-100$ mV vs. $-70$ mV), the hyperpolarizing effect of the activation of $\mathrm{GABA}_B$ receptors is substantially larger than that of $\mathrm{GABA}_A$ receptors.

Lesioning the TRN reveals the impact of its inhibitory projections on the thalamus. When the TRN is inactivated, thalamic cells tend to respond more readily to inputs and their receptive field generally becomes broader (Lee, Friedberg, and Ebner, 1994). However, these effects can be complicated by the fact that the TRN also projects to inhibitory interneurons in the thalamus and can thus have an excitatory effect on some thalamic neurons. During sleep, reticulothalamic projections are essential for the generation of spindle oscillations (Steriade et al., 1997)

The different nuclei in the dorsal thalamus are not linked by any direct connections. By contrast, throughout the TRN cells are highly interconnected in a dense meshwork of dendrodendritic connections and axonal arborizations. It is possible that the intrareticular connectivity serves to indirectly link the activities of thalamic nuclei that would otherwise be functionally segregated. As a rule, these reticuloreticular interactions, which are mediated largely by $\mathrm{GABA_A}$ receptors, have an inhibitory action. However, due to the relatively high reversal potential of the $\mathrm{Cl}^-$ current, if reticular cells become hyperpolarized below $-70$ mV, as can occur during slow wave sleep, the influence of $\mathrm{GABA_A}$ receptors may become excitatory. Recent work suggests that recurrent inhibition in the TRN plays a significant role in desynchronizing thalamic activity. Knockout mice lacking $\mathrm{GABA_A}$-mediated inhibition exhibit highly synchronized intrathalamic oscillations that are not normally observed, suggesting that the TRN has a role in reducing synchrony in thalamic circuitry and preventing epileptic seizures (Huntsman et al., 1999).

### *Brainstem Afferents Modulate the Firing Mode of Thalamic Neurons by Acting on Intrinsic Conductances*

A large proportion of the synaptic terminals in the thalamus—estimated to be around 30%—originates from neuromodulatory systems in the brainstem (Van Horn et al., 2000). These include the cholinergic neurons of the pedunculopontine tegmental nucleus, noradrenergic neurons of the locus coerulus, serotonergic neurons of the dorsal raphé, histaminergic neurons of the tuberomammilary nucleus, and glutamatergic cells acting through metabotropic receptors that are distributed throughout the reticular formation. These neuromodulatory projections can have differential effects on thalamic and reticular cells. For example, cholinergic projections excite thalamocortical relay cells but inhibit thalamic interneurons and TRN cells, while noradrenergic projections tend to be excitatory and depolarize TRN cells. Unlike other thalamic inputs, these brainstem inputs are not mapped and have a very broad pattern of termination. Most significantly, the neuromodulators released by these diffuse projections can activate or inactivate intrinsic conductances in thalamic cells and contribute to changes in behavioral state. At the beginning of sleep, for example, decreased activity in these neuromodulatory systems contributes to the hyperpolarization of thalamic neurons and triggers a set of intrinsic conductances leading to a change from tonic firing to burst firing. Bursts of action potentials followed by sustained periods of hyperpolarization effectively interrupt the normal relay functions of the thalamus, thereby closing the gateway and helping to entrain the thalamocortical circuit in repetitive, rhythmic firing.

The switch from tonic to burst firing mode results from the interactions of several conductances and is discussed in detail in Sleep Oscillations (q.v.). Key players in burst generation are the conductance responsible for the low-threshold calcium current $I_t$ and the hyperpolarization-activated cation conductance responsible for the depolarizing current $I_h$. In a minority of thalamic cells, burst firing may also occur during waking. Strong inhibition from the TRN may serve to prime some thalamic relay cells for bursts, which may then be triggered by any small depolarizing input. Such bursting, which occurs with greater frequency during visual stimulation, may serve as a "wake-up call" to the cortex. It has been hypothesized that corticothalamic feedback may then depolarize the bursting cells and lead to a more efficient processing of the stimuli (Sherman and Guillery, 2001).

## Discussion

For many years, neurophysiologists have studied the receptive field properties of thalamic cells in the visual thalamus and, to a lesser extent, in the auditory thalamus. Undeniably, the principal finding emerging from these investigations is that the receptive fields of thalamic cells are remarkably similar to those of the primary afferents, retinal or otherwise. From these results, it would appear that the primary function of the thalamus is that of reliably relaying afferent inputs to the cortex.

As mentioned previously, several recent experiments have demonstrated the subtle role played by corticothalamic inputs in shaping the response of thalamic neurons in ways that are not captured by traditional receptive field analysis, such as by facilitating synchronization and contributing contextual influences to orientation selective processing in the LGN. Moreover, the role of the thalamus in gating inputs to the cortex as a function of behavioral state has become clearly established. Corticothalamic feedback is necessary for the synchronization of spindle oscillations throughout the thalamocortical circuit during sleep. The thalamic mode of firing may also influence the way inputs are relayed to the cortex during waking. Most significantly, higher-order thalamic nuclei may play an integral role in the flow of signals between different cortical areas. Finally, it is possible that, under certain circumstances, the thalamus may not only gate but also integrate its inputs.

However, many questions remain about the role of corticothalamic pathways and the function of the thalamus in general. This uncertainty is reflected in the wide array of models designed to address various proposed functions of the thalamus. A number of proposals have suggested that the reticulothalamic circuit is involved in selective attention based on mechanisms for dynamic filtering. It has been suggested that the thalamocortical loop works to complete noisy input patterns based on feedback from the cortex (Harth, Unnikriohnan, and Pandya, 1987). Adaptive Resonance Theory (ART) (q.v.) is an artificial neural network model of these ideas. Active blackboard models combine these ideas with an attention-like mechanism in which a variety of patterns may be selectively enhanced or suppressed (Mumford, 1991). Finally, detailed models of the thalamocortical system have suggested that its dynamic behavior changes considerably when thalamocortical and corticothalamic connections become a functionally closed loop (Lumer, Edelman, and Tononi, 1997). Perhaps the entire thalamocortical loop is the appropriate unit at which to consider the functional role of the thalamus. As with neurocomputational approaches to other brain regions, the principle that function follows form—that is, neuroanatomy—may be most useful in understanding what the thalamus does.

# Universal Approximators

*Vêra Kůrková*

## Universality Versus Complexity

Many classification or pattern recognition tasks can be formulated as mappings between subsets of multidimensional vector spaces by using a suitable coding of inputs and outputs. The goal of a computer scientist in modeling such tasks is to find a computationally feasible procedure capable of recognizing a great variety of patterns by merely changing procedural parameters.

Such versatility in a computational model is often called *universality* with respect to computations to be performed. A classical example of a universal computational model is the Turing machine, which is capable of realizing any algorithm. Within the last decade, it has been shown that many types of feedforward networks, including all standard types that are popular in applications as well as many others that may not have been considered by experimentalists, form a universal computational model with respect to *approximation of mappings between subsets of Euclidean spaces*.

But universality has a price: it cannot be proven within reasonable bounds on *complexity*. Currently, feedforward networks are mostly simulated on classical computers and for such implementations, the limiting factors are number of network units, size, and resolution of their parameters. For most tasks, implementation of theoretically optimal approximation procedures becomes infeasible because of the unmanageably large number of parameters. In particular, high-dimensional tasks are limited by the "curse of dimensionality," i.e., an exponentially fast scaling of the number of parameters with the number of variables.

However, some mappings between high-dimensional representations have been successfully implemented using neural networks of moderate complexity (e.g., NETtalk; see Sejnowski and Rosenberg, 1987). Approximation theory offers some explanation for the feasibility of such implementations by deriving various upper bounds on the complexity, which depend on the number of variables of functions to be approximated together with their other characteristics. Inspection of such bounds shows that we can cope with the "curse of dimensionality" by suitable constraints on characteristics such as smoothness.

This article surveys recent developments in the mathematical theory of feedforward networks and includes proofs of the universal approximation capabilities of perceptron and RBF networks with general activation and radial fnctions, estimates of rates of approximation and description of sets of multivariable functions that can be approximated without the "curse of dimensionality."

## Perceptron and RBF Networks

Tasks representable as mappings can be performed by devices computing functions depending on two vector variables: an input vector (corresponding to a coded pattern to be recognized or transformed) and a parameter vector (to be adjusted during learning mode). Due to error-correcting afterprocessing (such as best guess) it is sufficient when such devices compute mappings that perform the tasks only approximately.

Feedforward neural networks compute parametrized sets of functions depending both on the type of computational units and the type of their interconnections. A *computational unit* can be formally described as a function $\phi : \mathcal{R}^q \times \mathcal{R}^d \rightarrow \mathcal{R}$, where $\mathcal{R}$ denotes the set of real numbers, and $p$ and $d$, respectively, are the dimensions of a *parameter* and an *input space*. Since in practical applications all inputs are bounded, it is sufficient to study networks with inputs in some compact (closed and bounded) subset of $\mathcal{R}$; usually, results are formulated for inputs in the interval [0, 1]. By $G_\phi = \{\phi(a, .) : [0, 1]^d \rightarrow \mathcal{R} : a \in \mathcal{R}^q\}$ is denoted the set of functions on $[0, 1]^d$ computable by a computational unit $\phi$ with all possible choices of parameters $a \in \mathcal{R}^q$.

The simplest model of a feedforward network has a single linear output and one hidden layer with $n$ units computing $\phi$. Such network can compute all functions from the set $span_n G_\phi$ of all linear combinations of at most $n$ elements of $G_\phi$. If an arbitrarily large number of hidden units is allowed, such networks can compute functions from $span\ G_\phi = \cup_{n \in \mathcal{N}_+} span_n G_\phi$, where $\mathcal{N}_+$ denotes the set of all positive integers.

As approximation by sets of the form $span_n G_\phi$ exploits flexible choice of $n$-tuples of inner parameters of computational units, it belongs to *variable-basis approximation* class. Besides neural networks, this class contains free-node splines, rational functions with free poles, and trigonometric sums with free frequencies. In contrast, classical linear approximation can be called *fixed basis approximation*, as it only allows linear combinations of first $n$ elements of a basis with a fixed ordering.

Standard types of hidden units are perceptrons and radial-basis-function units. A *perceptron* with an activation function $\psi : \mathcal{R} \rightarrow \mathcal{R}$ computes functions of the form $\phi((v, b), x) = \psi(v \cdot x + b) : \mathcal{R}^{d+1} \times \mathcal{R}^d \rightarrow \mathcal{R}$, where $v \in \mathcal{R}^d$ is an *input weight* vector and $b \in \mathcal{R}$ is a *bias*. By $P_d(\psi) = \{\psi(v \cdot x + b) : v \in \mathcal{R}^d, b \in \mathcal{R}\}$ is denoted the set of functions on $[0, 1]^d$ computable by $\psi$-perceptrons. The most common activation functions are *sigmo-*

*idals*, i.e., functions $\sigma : \Re \rightarrow [0, 1]$ such that $\lim_{t \rightarrow -\infty}\sigma(t) = 0$ and $\lim_{t \rightarrow \infty}\sigma(t) = 1$. Both continuous sigmoidals (like the logistic sigmoid $1/(1 + e^{-1})$ or the hyperbolic tangent) and the discontinuous Heaviside function $\vartheta$ defined by $\vartheta(t) = 0$ for $t < 0$ and $\vartheta(t) = 1$ for $t \geq 0$ are used.

A *radial-basis-function* (RBF) unit with a radial (even) function $\psi : \Re \rightarrow \Re_+$ ($\Re_+$ denotes the set of positive real numbers) computes $\phi((v, b), x) = \psi(b\|x - v\|)$, where $v \in \Re^d$ is a *centroid*, $b \in \Re_+$ is a *width* and $\|.\|$ is a norm on $\Re^d$. By $F_d(\psi) = \{\psi(b\|x - v\|) : v \in \Re^d, b \in \Re\}$ is denoted the set of functions on $[0, 1]^d$ computable by $\psi$-RBF units networks with distance from centroids measured by the $l_2$-norm $\|.\|$. Standard choice of a radial function is the Gaussian function $\gamma(t) = e^{-t2}$.

Note that sigmoidal perceptrons and RBF units are geometrically opposite: perceptrons apply a sigmoidal function to a weighted sum of inputs plus a bias, and so they respond to *nonlocalized* regions of the input space by partitioning it with fuzzy hyperplanes (or sharp ones if the sigmoid is Heaviside's step function. The functions computed by perceptrons belong to the class of *plane waves*. In contrast, RBF units calculate the distance to a centroid, multiply it by a width factor, and finally apply a radial function—hence they respond to *localized* regions. The functions computed by radial units belong to the class of *spherical waves*. Although perceptrons were inspired biologically, plane waves (sometimes also called ridge functions) have been studied for a long time by mathematiciens motivated by various problems from physics. In contrast to integration theory, where functions are approximated by linear combinations of characteristic functions of boxes (called simple functions), the theory of perceptron networks studies approximation by linear combinations of characteristic functions of half-spaces. Expressions in terms of such functions exhibit the strength and weakeness of plane waves methods described by Courant and Hilbert (1962): "But always the use of plane waves fails to exhibit clearly the domains of dependence and the role of characteristics. This shortcoming, however, is compensated by the elegance of explicit results."

## The Universal Approximation Property

The first theoretical question concerning a given type of a feedforward network architecture is whether a sufficiently elaborate network of this type can approximate all reasonable functions encountered in applications. This capability of a class of neural networks is called the *universal approximation property*. Mathematically, it can be formalized as density in some of standard normed linear spaces. Recall that a subset $F$ of a normed linear space $(X, \|.\|)$ is *dense* in $X$ if $cl\ F = X$, where $cl\ F = \{f \in X : (\forall_\epsilon > 0)(\exists_g \in F)(\|f - g\| < \epsilon\}$. Depending on whether the same quality of performance is required for all input vectors or whether a likelihood or importance of various inputs can be specified, density is studied either in the space $(\mathcal{C}([0, 1]^d), \|.\|_\mathcal{C})$ of all continuous functions on $[0, 1]^d$ with the supremum norm, or in $(\mathcal{L}_p([0, 1]^d, \|.\|_p)$ with the $\mathcal{L}_p$-norm for some $p \in [1, \infty]$. As spaces of continuous functions are dense in $\mathcal{L}_p$-spaces, it is sufficient to investigate the universal approximation property for $\mathcal{C}([0, 1]^d)$.

For RBF networks, the universal approximation capability is intuitively quite clear—one can imagine an approximation of a surface by a combination of Gaussian hills of various widths and heights. The classical method of approximation by convolutions with a suitable sequence of kernels enables one to prove this property for many types of radial functions. The following theorem by Park and Sandberg (1993) is based on the classical method of approximation of continuous functions by convolutions with a sequence of kernels.

*Theorem 1.* For every positive integer $d$ and for every function $\psi : \Re \rightarrow \Re_+$ with finite non-zero integral and for every norm $\|.\|$ on $\Re^d$, span $F_d(\psi, \|.\|)$ is dense in $(\mathcal{C}(\Re^d), \|.\|_\mathcal{C})$.

When $\int_\Re \psi(t)dt = c \neq 0$, then by properly scaling the function $\psi_0 = (\psi/c)$ we can construct a sequence of kernels $\{\psi_n(t) : n \in \mathcal{N}_+\}$, defined as $\psi_n(t) = n^d\psi_0(nt)$, converging to the Dirac delta function $\delta$. Convolutions $f * \psi_n$ of such kernels with any continuous function on $[0, 1]^d$ converge to $f$ uniformly. Approximating the integrals $\int f(x)(n^d/c)\psi(n(x - v))dv$ by Riemann sums we get a sequence of functions of the form of RBF networks with $\psi$ as a radial function.

In contrast to localized Gaussian radial units, for nonlocalized perceptrons the universal approximation property is far from being intuitively clear. Mathematics extends the range of our visualization and offers tools that enable us to prove this capability for perceptrons with almost any type of activations (it is sufficient that the perceptron is locally integrable and bounded.)

Many ingenious proof techniques have been used to derive the universal approximation property for perceptron networks. They include integral representations of the form of a "neural network with a continuum of hidden units" based either on Fourier or Radon transform, Kolmogorov's representation of continuous functions of several variables by means of superpositions of continuous one-variable functions, arguments by contradiction based on the Hahn-Banach theorem, and several others utilizing Stone-Weiersreass' theorem (for a survey see Pinkus, 1998, and Kůrková, 2002a). Here we illustrate methods of verification of universality of perceptron networks by two theorems with quite elegant proofs.

The following input dimension reduction theorem by Stinchcombe and White (1990) shows that for perceptron networks, it is sufficient to check the universal approximation property only for networks with a single input.

*Theorem 2.* Let $\psi : \Re \rightarrow \Re$ be any function. Then span $P_1(\psi)$ is dense in $(\mathcal{C}([0, 1]), \|.\|_\mathcal{C})$. if and only if for every positive integer $d$, span $P_d(\psi)$ is dense in $(\mathcal{C}([0, 1]^d), \|.\|_\mathcal{C})$.

The proof is based on the Stone-Weierstrass theorem, which is Stone's extension of the classical Weierstrass theorem about density of polynomials. It states two conditions on a set of functions $\mathcal{A}$ on a compact (closed and bounded) subset $K$ of $\Re^d$ that imply density in $(\mathcal{C}(K), \|.\|_\mathcal{C})$: (1) $\mathcal{A}$ is an algebra (i.e., it is closed under both addition and multiplication of functions), (2) $\mathcal{A}$ separates points (i.e., for each pair of distinct points $x, y \in K$, there exists $f \in \mathcal{A}$ such that $f(x) \neq f(y)$).

The argument takes advantage of existence of an activation function with special properties that allow us to apply the Stone-Weierstrass theorem. This function is $\exp(t) = e^t$. Sets *span* $P_d(\psi)$ are always closed under addition and for reasonable $\psi$, they also separate points, but they usually fail to be closed under multiplication. Due to special properties of exp, *span* $P_d(\exp)$ is closed under multiplication for all $d$ and hence by the Stone-Weierstrass theorem, it is dense in $(\mathcal{C}([0, 1]^d), \|.\|_\mathcal{C})$. When *span* $P_1(\psi$ is dense in $(\mathcal{C}([0, 1]), \|.\|_\mathcal{C})$, then it can approximate with any accuracy all continuous functions on $[0, 1]$; in particular the function exp. Using composition of two approximations, the first one approximating $f \in \mathcal{C}([0, 1]^d)$ by an element of *span* $P_d(\exp)$, and the second one approximating exp by an element of *span* $P_1(\psi)$, one gets density of *span* $P_d(\psi)$ in $(\mathcal{C}([0, 1]^d), \|.\|_\mathcal{C})$.

Leshno et al. (1993) have shown that the universal approximation property is not restricted to biologically motivated sigmoidals but, with the exception of polynomials, it is satisfied by any reasonable activation function.

*Theorem 3.* Let $\psi : \mathcal{R} \rightarrow \mathcal{R}$ be a locally bounded piecewise continuous function and d be any positive integer. Then span $P_d(\psi)$ is dense in $(\mathcal{C}([0, 1]^d), \|.\|_{\mathcal{C}})$ if and only if $\psi$ is not an algebraic polynomial.

The trick of Leshno et al.'s proof is in expressing all powers as limits of higher-order partial derivatives with respect to the weight parameter $v$ of the function $\psi(vx + b)$ ($\psi$ being analytic guarantees that all the derivatives exist). It follows directly from the definition of iterated partial derivative that $(\delta^k(vx + b))/(\delta v^k)$ can be expressed as a limit of functions computable by perceptron networks with activation $\psi$. More precisely, $(\delta\psi(vx + b))/(\delta v) = \lim_{\eta\rightarrow 0}(\psi((v + \eta)x + b) - \psi(vx + b))/(\eta)$, and similarly for $k > 1$. As $(\delta^k\psi(vx + b))/(\delta v^k) = x^k\psi^{(k)}(vx + b)$ and for $\psi$ nonpolynomial, $\psi^{(k)}$ is not identically equal to zero for all $k$, by setting $v = 0$ and choosing some $b_k$, for which $\psi^{(k)}(b_k) = c_k \neq 0$, we get a sequence of functions from *span* $P_d(\psi)$ converging to $c_kx^k$. As polynomials are linear combinations of powers, they can be obtained as limits of sequences of functions from *span* $P_d(\psi)$. So by Weierstrass's theorem and by the previously mentioned input dimension reduction theorem, *span* $P_d(\psi)$ is dense in $(\mathcal{C}([0, 1]^d), \|.\|_{\mathcal{C}})$ for any $\psi$ that is analytic and nonpolynomial. For nonanalytic functions satisfying the assumptions of the theorem, the result can be obtained using suitable convolutions with analytic functions.

Inspection of Leshno et al.'s (1993) proof shows that the theorem is valid even when all network parameters are bounded by an arbitrarily small upper bound. However, to achieve density, the set of hidden unit parameters must have either a finite or an infinite accumulation point.

In practical applications, neural networks are trained to fit to a given set of input/output pairs of data. Hence the domain of the function to be computed by a network is finite, and we can apply results from interpolation theory. They show that for finite domain functions, we can replace *arbitrary close approximation* by *exact representation*. One of the main results of interpolation theory, Micchelli's (1986) theorem, shows that any function on a finite subset of $\mathcal{R}^d$ can be exactly represented as a network with Gaussian RBF units. An analogous result for sigmoidal perceptron networks has been proven by Ito (1992). However, development of interpolation theory has been motivated by needs to construct surfaces with certain characteristics fitted to a small number of points. Although its results are valid for any number of pairs of data, its application to neurocomputing leads to networks with the same number of hidden units as the number of input/output pairs. For large sets of data, this requirement may prevent implementation. In such cases, estimates of accuracy achievable using networks with fewer hidden units are needed. They can be derived from estimates of rates of approximation that apply to both finite and infinite domains.

## Rates of Approximation

Although density guarantees arbitrarily close approximation of all functions from $\mathcal{C}([0, 1]^d)$, $\mathcal{L}_p([0, 1]^d)$, respectively, for practical purposes, its implications are limited to functions for which a sufficient accuracy can be achieved by networks with $n$ hidden units where $n$ is small enough to allow implementation.

Approximation theory investigates the trade-off between accuracy of approximation and complexity of approximating functions. It has derived various upper bounds on complexity of approximating systems depending on the number of variables of functions to be approximated together with their other characteristics. Inspection of such bounds offers some explanation of feasibility of implementations of high-dimensional tasks, as it shows that we can cope with the "curse of dimensionality" by constraining the characteristics involved.

For example, upper bounds on worst-case errors in linear approximation are of the form $\mathcal{O}(n^{-s/d})$, where $d$ is the number of variables, $s$ degree of smoothness of the functions to be approximated, and $n$ is the number of parameters of the linear approximating family. Thus, in linear approximation, the "curse of dimensionality" can be avoided by increasing smoothness together with the number of variables.

For neural networks, the role of such characteristics is played by norms tailored to computational units. Their definition is fitted to the following Maurey-Jones-Barron's upper bound (see Jones, 1992; Barron, 1993) on rates of approximation by $span_nG$, the set of all convex combinations of at most $n$ elements of $G$. For a subset $M$ of a normed linear space $(X, \|.\|)$ and $f \in X$, the distance of $f$ from $M$ is denoted by $\|f - M\|$. For simplicity, we present here only the version for Hilbert spaces; however, similar upper bounds hold also for $\mathcal{L}_p$-spaces with $p \in [1, \infty]$ (for a survey see Kůrková 2002b).

*Theorem 4.* Let $G$ be a bounded subset of a Hilbert space $(X, \|.\|)$ and $s_G = \sup_{g\in G}\|g\|$. Then for every $f \in$ cl conv $G$ and for every positive integer $n$, $\|f - conv_n\ G\| \leq \sqrt{(s_G^2 - \|f\|^2)/(n)}$.

As $conv_nG \subseteq span_nG$, the upper bound from Theorem 4 also applies to rates of approximation by $span_nG$. Replacing the set $G$ by $G(c) = \{wg : g \in G, |w| \leq c\}$, we can apply Theorem 4 to all elements of $\cup_{c\in\mathcal{N}_+}$ *cl conv* $G(c)$ (as $conv_nG(c) \subset \mathrm{span}_nG(c) = span_nG$ for any $c \in \mathcal{R}$). This approach can be mathematically formulated in terms of a norm tailored to a set $G$. Let $(X, \|.\|)$ be a normed linear space and $G$ be its subset, then *G-variation* (variation with respect to $G$) is defined as the Minkowski functional of the set *cl conv*$(G \cup -G)$, i.e.,

$$\|f\|_G = \inf\{c > 0 : f/c \in cl\ conv(G \cup \ -G)\}$$

When a set of functions has to be approximated, it is useful to estimate worst-case error, which is mathematically formalized by the concept of *deviation* $\delta(B, Y) = \sup_{f\in B}\|f - Y\|$. The following is a corollary of Theorem 4 formulated in terms of $G$-variation. If $(X, \|.\|)$ is a normed linear space and $b > 0$, then $B_b(\|.\|)$ and $S_b(\|.\|)$ denote the ball and sphere, respectively, of radius $b$ centered at zero, i.e., $B_b(\|.\|) = \{f \in X : \|f\| \leq b\}$ and $S_b(\|.\|) = \{f \in X : \|f\| = b\}$.

*Corollary 5.* Let $G$ be a bounded subset of a Hilbert space $(X, \|.\|)$, $s_G = \sup_{g\in G}\|g\|$, $b > 0$, $0 \leq r \leq s_Gb$ and $n$ be a positive integer. Then

(i) for every $f \in X$, $\|f - span_nG\| \leq \sqrt{((s_G\|f\|_G)^2 - \|f\|^2)/(n)}$;
(ii) $\delta(\{f \in B_b(\|.\|_G) : \|f\| \geq r\}, span_nG \leq \sqrt{((s_Gb)^2 - r^2)/(n)}$;
(iii) $\delta(B_b(\|.\|_G), span_nG) \leq (s_Gb)/(\sqrt{n})$.

Corollary 5 shows how to cope with the curse of dimensionality in neural network approximation We can keep rate of approximation by $span_nP_d(\psi)$ or $span_nF_d(\psi)$ within $1/\sqrt{n}$ for all $d$ by restricting approximation to functions from balls in $P_d(\psi)$ variation and $F_d(\psi)$ variation, respectively.

Thus $P_d(\psi)$ and $F_d(\psi)$ variations play a similar role in neural network approximation as the Sobolev norm of the order $d$ does in linear approximation. However in contrast to linear approximation, in neural network approximation sets with worst-case errors bounded by $\mathcal{O}(n^{-1/2})$ are not shrinking with $d$ increasing, as the balls in $P_d(\psi)$, $F_d(\psi)$-variation can be embedded into balls in $P_{d+1}(\psi)$, $F_d(\psi)$-variation, respectively (see Kůrková, 2002b). It was shown by Barron (1993) that balls in Sobolev norms of the order $s > d/2 + 1$ can be embedded into balls in $P_d(\sigma)$-variation. Barron (1993) also described sets of multivariable functions for which neural networks outperform linear approximation methods (see also Kůrková and Sanguineti, 2002.

As Heaviside perceptrons compute characteristic functions of half-spaces restricted to $[0, 1]^d$, $P_d(\vartheta)$-variation is called *variation with respect to half-spaces*. For functions of one variable, variation with respect to half-spaces coincides, up to a constant, with the notion of total variation studied in the integration theory. In $\mathcal{L}_p$-spaces, $P_d(\vartheta)$-variation is equal to $P_d(\sigma)$-variation for any sigmoidal activation function $\sigma$ (see Kůrková, Kainen, and Kreinovich, 1997). Thus to describe the set of functions that do not exhibit the "curse of dimensionality" in approximation by sigmoidal perceptron networks, it is sufficient to study balls in variation with respect to half-spaces.

Upper bounds on variation with respect to half-spaces can be derived from integral representations of the form of a neural network with a continuum of Heavidise perceptrons (see Kůrková et al., 1997). Lower bounds can be obtained from geometrical considerations (angular relationships to hidden unit functions).

For discussion of the strength and weakness of the method of estimation of rates of approximation by neural networks using Maurey-Jones-Barron's bound see Kůrková, Savicky, and Hlaváĉková, 1998. They have described functions with variations depending on the number of variables exponentially. It is an open question, related to difficult problems of complexity of Boolean functions, whether such functions can be approximated within a small error by one-hidden-layer Heaviside perceptron networks with the number of hidden units depending on the number of variables only polynomially.

## Discussion

Within the last decade, it has been shown that many types of feedforward networks are universal approximators. Provided that they contain sufficiently many computational units, their parameters can be adjusted to obtain as an input/output function a good approximation to almost any mapping between subsets of multidimensional spaces.

Each universal computational model determines a hierarchy of complexity on computational tasks with respect to a given type of implementation. Complexity measured by the number of hidden units can be estimated using upper bounds on rates of approximation. Inspection of such bounds shows that it is possible to cope with the "curse of dimensionality" when approximation is restricted to functions with certain norms bounded by a fixed constant independent of the number of variables. For linear approximation, such norms are Sobolev norms of order increasing with the dimension, while for neural networks, such norms are variations with respect to computational units. For sigmoidal perceptrons, they are all equal to variation with respect to half-spaces and for RBF units, they are variations with respect to spherical waves of the shape corresponding to radial functions.

However, examples of functions with variations depending exponentially on the number of variables show that interpretations of upper bounds on rates of neural network approximation of the order of $\mathcal{O}(n^{-1/2})$ as proofs of "dimension-independent" approximation capabilities of neural networks are misleading. It is not possible to approximate all $d$-variable functions by neural networks with rates of the order $\mathcal{O}(n^{-1/2})$. To achieve such rates, approximation has to be restricted to functions from balls in variation with respect to the type of computational units.

# Unsupervised Learning with Global Objective Functions

*Suzanna Becker and Richard S. Zemel*

## Introduction

Unsupervised learning algorithms can be distinguished by the absence of any supervisory feedback from the external environment. Often, however, there is an implicit *internally derived* training signal. This training signal is based on some measure of the quality of the network's internal representation. The main problem in unsupervised learning research is to formulate a performance measure or cost function for the learning, to generate this internal supervisory signal. The cost function is also known as an objective function, since it sets the objective for the learning process. In this article, we review the most promising algorithms for unsupervised learning. We particularly focus on two types of learning procedures: those based on information-theoretic performance measures, and those employing maximum-likelihood density estimation. Another important class of biologically motivated learning algorithms, based on the idea of reinforcement—whether externally provided or internally generated—is covered elsewhere in this *Handbook* (see Reinforcement Learning and Reinforcement Learning in Motor Control).

### Global Objective Functions or Synaptic Learning Rules?

Since our concern is with unsupervised learning in *networks* and their global behavior, we will focus on algorithms based on globally defined objective functions, rather than synaptic learning rules. By viewing the learning process as the optimization of a global objective function, we can reduce a global algorithm to synaptic-level steps (weight changes), but the converse is not necessarily true: a given synaptic learning rule may not correspond to the derivative of any global objective function. Further, a well-defined objective function for the learning allows us to make global predictions about its behavior, which is typically not possible in a bottom-up approach. Finally, the global objective function provides a quantitative measure of the success, or at least convergence, of the learning procedure.

In contrast to this top-down approach, many computational models of learning have been based on synaptic or cellular constraints, such as Hebb's postulate, and more recently, conditions for LTP induction. Hebb postulated that a synapse's efficacy should increase whenever the pre- and postsynaptic neurons are co-active. Hebb's postulate has gained popularity among neurobiologists as a plausible candidate for a cortical synaptic learning mechanism. A typical instantiation of Hebb's rule relates the evolution of the synaptic weight, $w_{ij}$, to the product of the pre- and postsynaptic activities, $y_i$, and $y_j$, as follows:

$$\Delta w_{ij} = \varepsilon y_i \, y_j$$

where $\varepsilon$ is a learning rate constant. Although this rule and its variants (see Post-Hebbian Learning Algorithms) provide a useful way to model cellular- and synaptic-level phenomena, they do not give us much insight into systems-level phenomena arising from neural plasticity. A large multilayered network of neurons all of which follow the same Hebbian rule does not generate particularly useful pattern-processing abilities. Each neuron would tend to behave in a greedy fashion. If we hope to understand large-scale networks of the brain, such as the visual system, we must find more global or network-level constraints on the learning, such as predicting the sensory input over time, that would cause the entire network of neurons to evolve cooperatively toward this common goal. By the same token, once a systems-level goal for the learning has been identified and synaptic-level weight updates have been derived, it is of interest to computational modelers to try to translate their global learning procedures into local, biologically plausible learning rules such as Hebbian learning.

### Self-Organization in Perceptual Systems

One of the major motivations for studying unsupervised learning is to discover the general computational principles underlying brain self-organization. Evidence of experience-dependent plasticity has been reported in a wide variety of brain areas. Perhaps the most startling evidence comes from a series of studies by Sur and colleagues (reviewed in Sur, 1989) in which artificially rerouting of the primary visual cortical input pathways to the auditory cortex in ferrets was followed by the "auditory" cortical cells developing responses to visual stimuli and exhibiting characteristics of typical visual cortical receptive fields. These and other experiments have led to the characterization of a plastic brain capable of dynamical restructuring. Thus, the goal of biologically motivated learning research may be stated as the search for the objective function(s) employed by the brain.

## Information-Preserving Algorithms

Since there is no external teaching signal for unsupervised learning, the goal of the learning must be stated solely in terms of some transformation on the input that will preserve the interesting structure. The first task, then, is to define what constitutes interesting structure. Perhaps the simplest possible goal is to try to preserve *all* of the information, by, for example, simply memorizing the input patterns. Pattern-associators (see Associative Networks) operating in auto-associative mode can be used as such by storing each input pattern associated with itself. However, models that perform exact memorization tend to have very poor capacity and are unable to generalize their knowledge to new inputs.

### Minimizing Reconstruction Error

Given the limited ability of networks to store a set of patterns exactly, a better strategy might be to try to find a *compressed* representation of the patterns. This may be helpful for preprocessing noisy data, and for modeling early stages of perceptual processing. Later stages of processing may impose additional constraints on the data reduction process, such as the need to map inputs to actions and their consequences. A standard data compression technique is Principal Component Analysis (PCA) (q.v.). Several learning procedures (reviewed in Becker and Plumbley, 1996) have been developed that converge to the first $N$ principal directions of the input distribution. These methods are optimal with respect to minimizing the mean squared reconstruction error for linear networks. However, PCA will often fail to capture interesting structure such as clustering in the data.

A more general method for finding a compressed representation that minimizes reconstruction error is to use a nonlinear backpropagation network as an auto-encoder (Hinton, 1989), by making the desired states of the $N$ output units identical to the states of the $N$ input units in each case. Data compression can be achieved by making the number of hidden units $M < N$. Further, the features discovered by the hidden units may be useful for subsequent stages of processing such as classification. However, with complicated input patterns containing multiple features, it may not be possible to relate the activities of individual hidden units to specific features. One way to constrain the hidden unit representation is to add extra penalty terms to the objective function (see Backpropagation: General Principles). For example, Zemel (1994) imposed a penalty term on hidden unit activations that caused these units to represent high-dimensional data as localized bumps of activity in a lower-dimensional constraint surface. This encouraged the hidden units to form a map-like representation that best characterized the input. Other penalty terms led to other forms of hidden representations, such as sparse, or combinatorial, representations (see Minimum Description Length Analysis).

### Direct Minimization of Information Loss

Another approach to ensuring that the important information in the input is preserved in the output is to use concepts from information theory. This use of the term information is in a purely statistical sense, rather than the perhaps more intuitive notion that a sentence is more or less informative based on its semantic content. Viewing a neuron or neural network as a communication channel, one can calculate the rate of information loss through the channel. Atick (1992) provides an excellent review of this and related approaches, as well as a good introduction to information theory. Several learning procedures have been proposed that minimize the information loss in a network, subject to processing constraints (reviewed in Becker and Plumbley, 1996). The common feature of these methods is the preservation of mutual information between input vector $\mathbf{x}$ and output vector $\mathbf{y}$:

$$I_{x;y} = H(\mathbf{x}) + H(\mathbf{y}) - H(\mathbf{x}, \mathbf{y}) \tag{1}$$

where $H(\mathbf{x}) = -\int_{\mathbf{x}} p(\mathbf{x}) \log p(\mathbf{x}) d\mathbf{x}$ is the entropy of random variable $\mathbf{x}$ with probability distribution $p(\mathbf{x})$, and $H(\mathbf{x}, \mathbf{y}) = -\int_{\mathbf{x},\mathbf{y}} p(\mathbf{x}, \mathbf{y}) \log p(\mathbf{x}, \mathbf{y}) d\mathbf{x} d\mathbf{y}$ is the entropy of the joint distribution of $\mathbf{x}$ and $\mathbf{y}$. The mutual information between two variables is highest when the variables have high entropies individually, but their joint distribution has low entropy. For example, a variable $x$ with a highly peaked probability distribution $p(x)$ has very low entropy, $H(x)$; it is highly predictable a priori, and therefore a given observation of the value of $x$ provides very little information. In contrast, a variable with a uniform distribution has maximum entropy; it is completely unpredictable a priori, and therefore one gains maximal information by having observed its value. Thus, $I_{x;y}$ is high when $\mathbf{x}$ and $\mathbf{y}$ are difficult to predict a priori, but $\mathbf{x}$ becomes predictable after the value of $\mathbf{y}$ is known (and vice versa).

If the network is free of processing noise and has enough units, its output layer can convey all the information contained in the input simply by copying the input. In 1988, Linsker first proposed applying the *Infomax principle* in the presence of Gaussian processing noise at the output layer for linear networks (Linsker, 1997). When the input distribution is Gaussian, the entropy greatly simplifies from the expected value of a log of a Gaussian to a function of the log of the variance (or the log determinant of the covariance matrix, for a multivariate Gaussian) (see, e.g., Atick, 1992). Hence, the information is:

$$I = 0.5 \log \left(\frac{|\mathbf{Q}^{\mathbf{y}}|}{V(n)}\right)$$

where $|\mathbf{Q}^{\mathbf{y}}|$ is the determinant of the covariance matrix of the output vector $\mathbf{y}$ (the signal plus noise) and $V(n)$ is the noise variance. Maximizing this quantity results in a trade-off between maximizing the variances of the outputs and decorrelating them, depending on the noise level. For a single output unit, this is equivalent to maximizing the output variance of a unit, and leads to a simple Hebb-like learning rule. In Linsker's more recent work, he has extended this idea to networks with multiple units, nonlinearities, and sparse coding (cited in Linsker, 1997).

A related optimality criterion proposed by Barlow (1989) is to find a minimally *redundant* encoding of the sensory input vector into an $n$-element feature vector, which should facilitate subsequent learning. If the $n$ features are statistically independent, then the formation of new associations with some event $V$ (assuming the features are also approximately independent conditioned on $V$) only requires knowledge of the conditional probabilities of $V$ given each feature $y_i$, rather than complete knowledge of the probabilities of events given each of the $2^m$ possible sensory inputs. Barlow proposes that one could achieve featural independence by finding a *minimum entropy encoding*: an invertible code that minimizes the sum of the feature entropies (see FEATURE ANALYSIS).

A number of algorithms for Independent Component Analysis (ICA) (for a review, see Lee et al., 2000) instantiate Barlow's principle by direct maximization of entropy. For example, in Bell and Sejnowski's algorithm (reviewed in Lee et al., 2000), a one-layer network of units with sigmoidal activation functions is able to solve the blind source separation problem: given a linear combination of $N$ independent sources such as a mixture of acoustic signals, find a transformation to a set of $N$ statistically independent outputs. Although this algorithm is limited in its applicability to dimensionality-preserving mappings of linear mixtures, it has been applied successfully in a number of domains, including EEG analysis, and thus has gained widespread interest in the signal processing community. More recently, Linsker (1997) has proposed a more biologically plausible version of ICA, also based on entropy maximization. It permits fewer than $N$ output components and employs information locally available to each neural unit.

Our brains may engage in something like blind source separation, for example, when performing auditory streaming. However, unlike many ICA algorithms, which are limited in finding at most $N$ features in an $N$-dimensional input, the brain has many more neurons than sensory inputs, and employs a sparse, overcomplete representation. Olshausen and Field (1996) proposed an alternative instantiation of Barlow's principle of redundancy reduction that results in such representations. Rather than directly manipulating the entropy of the coding, they minimized the following energy function:

$$E = -\sum_{x,y} \left[ I(x, y) - \sum_i a_i \phi_i(x, y) \right]^2 - \lambda \sum_i S\left(\frac{a_i}{\sigma}\right) \tag{2}$$

where the leftmost term is the squared reconstruction error as a function of the image $I(x, y)$ and the weighted unit activations $\phi_i a_i$, and the rightmost term is a nonlinear function (e.g., a zero-mean Gaussian) of the unit activations chosen to enforce sparseness. The sparseness constraint favors a small number of feature detectors being active at a given moment while permitting some redundancy in the representation. The reconstruction term ensures the preservation of as much information in the input as possible. Thus, when exposed to visual images, the model tends to form local, partially overlapping receptive fields at a variety of spatial scales closely resembling those seen in early stages of the mammalian visual system (see FEATURE ANALYSIS).

### *Preserving Information Within Extracted Features*

The methods discussed so far try to extract useful structure from data while assuming minimal prior knowledge, and are good for modeling early sensory processing. But can unsupervised learning be applied beyond these preprocessing stages, to extract higher-order features and build more abstract representations? One approach is to make constraining assumptions about the structure of interest, and build these constraints into the network's architecture or objective function.

Spatiotemporal coherence is a ubiquitous feature of sensory signals. Becker and Hinton's Imax learning procedure (reviewed in Becker, 1996) discovers coherent properties of the input by maximizing the mutual information between the *outputs*, $y_a$ and $y_b$, of network modules that receive input from different parts of the sensory input (e.g., different modalities, or different spatial or temporal samples). Note how this objective function differs from the Infomax principle: the latter tries to retain *all* of the information in the input by maximizing the mutual information between inputs and outputs, whereas Imax tries to extract only those features common to two or more distinct parts of the input.

Under Gaussian assumptions about the signal and noise, Becker and Hinton simplified the mutual information $I$ down to a log ratio of two variances, that of the signal plus noise and the noise, to derive the following objective function for the learning:

$$I = 0.5 \log \frac{V(y_a + y_b)}{V(y_a - y_b)}$$

This measure tells how much information the average of $y_a$ and $y_b$ conveys about the common underlying signal, i.e., the feature that is coherent across the two input samples. When applied to networks composed of multilayer modules that receive input from adjacent, nonoverlapping regions of the input, Imax discovered higher-order image features (i.e., features not learnable by single-layer or linear networks), such as stereo disparity in random dot stereograms. This illustrates how one part of the brain might self-organize within the visual modality to learn spatially predictive features. The idea could also be applied to the outputs of two different modalities to learn about their common causes (for a review of related work, see Becker, 1996). For example, when we see an object and hear a sound, the two are often correlated and probably help us to learn object categories.

## Density Estimation Techniques

So far we have focused on algorithms that try to manipulate the information preserved by the network by imposing various processing constraints or representational assumptions. An alternative approach is to model directly the probability distribution over the input patterns. Many unsupervised learning procedures can be viewed in this way. The general approach is to assume a priori a class of models that constrains the general form of the probability density function, then search for the particular model parameters defining the density function most likely to have generated the observed data. This approach of developing *generative models* of data can be cast as an unsupervised learning problem by treating the network weights as the model parameters $\theta$, and the overall function computed by the network as being directly related to the density function. The goal is to find model parameters that maximize the log likelihood that the model generated the data, $x$:

$$\log(L) = \sum_x \log\ (p(\mathbf{x}|\theta)) \tag{3}$$

Many of the information-maximization algorithms described earlier can also be derived from this generative approach. For example, the reconstruction error in auto-encoder learning can be derived as a data-likelihood term, and the additional penalty terms in the different algorithms can be derived as particular priors over the hidden states (Zemel, 1994). And the Bell-Sejnowski ICA algorithm can be obtained by a particular choice of prior over the sources and a noise model over the input (Pearlmutter and Parra, 1997).

### *Mixture Models and Competitive Learning*

One convenient and popular choice of prior model is a mixture of Gaussians. This model performs a type of cluster analysis, and is the basis for deriving two more biologically plausible models that we will consider afterwards. The prior assumption in this case is that each data point was actually generated by one of $n$ Gaussians having different means $\mu_i$, variances $\sigma_i^2$, and prior probabilities $\pi_i$. Fixing the model parameters $\mu_i$, $\sigma_i$, and $\pi_i$, we can compute the probability of a given data point $\mathbf{x}$ under a mixture-of-Gaussians model as follows:

$$p(\mathbf{x}|\{\mu_i\}, \{\sigma_i\}, \{\pi_i\}) = \sum_{i=1}^{n} \pi_i P_i(\mathbf{x}, \mu_i, \sigma_i) \tag{4}$$

where $P_i(\mathbf{x}, \mu_i, \sigma_i)$ is the probability of $\mathbf{x}$ under the $i$th Gaussian. Applying Bayes's rule, we can also compute the probability that any one of the Gaussians generated the data point $\mathbf{x}$:

$$p(i|\mathbf{x}, \{\mu_j\}, \{\sigma_j\}, \{\pi_j\}) = \frac{\pi_i P_i(\mathbf{x}, \mu_i, \sigma_i)}{\sum_{j=1}^{n} \pi_j P_j(\mathbf{x}, \mu_j, \sigma_j)} \tag{5}$$

Given these probabilities, we can now use as a cost function the log likelihood of the data given the model:

$$\log(L) = \sum_x \log\ (p(\mathbf{x}|\{\mu_i\}, \{\sigma_i\}, \{\pi_i\}))$$

By maximizing this function, we can approximate the true probability distribution of the data, given our prior model assumptions. Note that by taking the log of $L$, we obtain a cost function that is a sum of log probabilities, rather than a product of probabilities, for each input pattern. The model parameters can then be adapted by performing gradient ascent in $\log(L)$. The Expectation-Maximization (EM) algorithm alternatingly applies Equation 4 (the expectation step) and adapts the model parameters (the maximization step) to converge on the maximum likelihood mixture model of the data.

Competitive learning procedures (see Competitive Learning) can be viewed as performing a discrete approximation to the density estimation algorithm just described, but it can be implemented in a more biologically realistic neural circuit. The general idea is that units compete to respond (e.g., by a winner-take-all activation function or lateral inhibition), so that only the winning unit in each competitive cluster is active. The winning unit learns by moving its weight vector closer to the current input pattern. Hence, each unit minimizes the squared distance between its weight vector and the patterns nearest to it, as in standard $k$-means clustering. This version of competitive learning is closely related to fitting a mixture-of-Gaussians model with equal priors $\pi_i$ and equal fixed variances $\sigma_i^2$. Using the EM algorithm, every unit (not just the winner) moves its mean closer to the current input vector, in proportion to the probability that its Gaussian model accounts for the current input (Equation 5). Competitive learning approximates this step by making a binary decision as to which unit accounts for the input. Thus, the same learning rule applies, except that the proportional weighting is replaced by an all-or-none decision.

Nowlan (1990) proposed a maximum likelihood competitive learning (MLCL) model for neural networks. Rather than allowing only the winner to adapt, each unit adapts its weights for every input case, in proportion to how strongly it responds on a given case. This is an on-line version of the EM algorithm for Gaussian densities with equal priors, and adaptive means and variances. Nowlan found this method to be superior to traditional competitive learning models on several classification tasks. Becker (1999) extended MLCL to a network that computes the priors using spatiotemporal contextual cues, allowing hierarchical clustering of features based on common contexts. The architecture of Becker's model was motivated by the laminar and columnar organization seen throughout the neocortex. It was shown to learn local views of an object in the first layer, and to group nearby views together into more view-tolerant representations in the second layer.

### *Combinatorial Representations*

A major limitation of mixture models and competitive learning is that they employ a 1-of-$n$ encoding, in which a single unit or feature is assumed to explain each datum. A *multiple causes* model is more appropriate when the most compact data description consists of several independent parameters (e.g., color, shape, size). Some pioneering connectionist work in this area was done by Neal (1992). Neal's multilayer "sigmoid belief networks" (SBNs) resemble stochastic Boltzmann machines (see Simulated Anneling and Boltzmann Machines), but they are strictly feedforward. Output states are held fixed on training patterns selected from the environment, while the hidden unit states are freely but noisily updated. The weights are adjusted so as to increase the probability of the hidden units generating the training patterns. The network thereby learns to represent features in the hidden layer that explain correlations in the pattern set. Unfortunately, Monte Carlo sampling is a prohibitively time-consuming way to search for good hidden layer features. Saul, Jaakkola, and Jordan (1996) proposed a way around this employing a mean field approximation for SBNs.

A major challenge in this area of research is to develop multiple-cause models for multilayered networks with top-down feedback. Perhaps the most noteworthy attempts in this direction are the Helmholtz machine, developed by Hinton et al. (see HELMHOLTZ MACHINES AND SLEEP-WAKE LEARNING), and Rao and Ballard's (1997) model. In the Helmholtz machine, the bottom-up weights embody a "recognition model"; that is, they are used to produce the most probable set of hidden states given the data. At the same time, the top-down weights constitute a "generative model"; that is, they produce a set of hidden states most likely to have generated the data. The "wake-sleep algorithm" maximizes the log likelihood of this model and results in a simple and elegant delta rule for updating either set of weights:

$$\Delta w_{kj} = \varepsilon s_k^{\alpha}(s_j^{\alpha} - p_j^{\alpha}) \qquad (6)$$

where $p_j^{\alpha}$ is the target state for unit $j$ on pattern $\alpha$, and $s_j^{\alpha}$ is the corresponding network state, a stochastic sample based on the logistic function of the unit's net input. Target states for the generative weight updates are derived from top-down expectations based on samples using the recognition model, whereas for the recognition weights, the targets are derived by making bottom-up predictions based on samples from the generative model. The Helmholtz machine is restricted in training either the generative or the recognition connections at a given time. In contrast, Rao and Ballard's (1997) model interleaves the training of these connections. This model is based on the extended Kalman filter. At each level, representational nodes combine top-down predictions with bottom-up information to produce two sources of prediction error: (1) a predicted internal state at the next time instant that is sent to the preceding layer for predicting the bottom-up input, and (2) a prediction of the top-down input that is sent to the subsequent layer. Training is cast within a maximum likelihood framework: the model fit depends on the two sources of error mentioned above, as well as model cost terms for each of the model parameters. The model is presented as an account of learning and real-time processing in the visual cortex, and is shown to develop realistic local receptive fields as well as object-level representations when trained on natural image sequences.

## Discussion

We have argued in favor of the global objective function approach to modeling unsupervised learning processes and have explored several powerful learning procedures based on this approach. These methods have had success in modeling early perceptual processing. With the incorporation of highly constraining prior models, unsupervised learning procedures can form even more abstract representations of data, and extract higher-order features. A major direction of ongoing research is aimed at finding tractable instantiations of these learning procedures and applying them in multiple learning stages to form a diversity of representational levels. Recent work by Hinton and colleagues on tractable versions of the Boltzmann machine is a promising example of such efforts.

# Vapnik-Chervonenkis Dimension of Neural Nets

*Peter L. Bartlett and Wolfgang Maass*

## Introduction

For any assignment of values to its internal parameters $\theta$ (weights, thresholds, etc.) a neural network $\mathcal{N}$ with binary outputs computes a function $x \mapsto \mathcal{N}(\theta, x)$ from $D$ into $\{0, 1\}$, where $D$ is the domain of the network inputs $x$ (e.g., $D = \mathbb{R}^n$). The Vapnik-Chervonenkis dimension (VC-dimension) of $\mathcal{N}$ is a number that may be viewed as a measure of the richness (or diversity) of the collection of all functions $x \mapsto \mathcal{N}(\theta, x)$ that can be computed by $\mathcal{N}$ for different values of its internal parameters $\theta$. Not surprisingly, the VC-dimension of a neural network is related to the number of training examples that are needed in order to train $\mathcal{N}$ to compute—or approximate—a specific target function $h : D \rightarrow \{0, 1\}$. We shall discuss a number of different types of neural networks, but typically the VC-dimension grows polynomially (in many cases, between linearly and quadratically) with the number of adjustable parameters of the neural network. In particular, if the number of training examples is large compared to the VC-dimension, the network's performance on training data is a reliable indication of its future performance on subsequent data.

The concept of the VC-dimension, which was introduced by Vapnik and Chervonenkis in 1971, is not specific to neural networks. It applies to any parameterized class $F$ of functions $x \mapsto f(\theta, x)$ from some domain $D$ into $\{0, 1\}$, where $\theta$ ranges over some given parameter space, for example, $\mathbb{R}^w$. Related notions for the case of real-valued outputs will be discussed later. The largest possible richness of this class $F$ of functions from $D$ into $\{0, 1\}$ is achieved if *every* function $h : D \rightarrow \{0, 1\}$ can be computed by a function $x \mapsto f(\theta, x)$ in $F$. In this case one says that $D$ is *shattered* by $F$, and the VC-dimension of $F$ is equal to $|D|$, the number of elements of the domain $D$. In the general case one defines the VC-dimension of $F$ (VCdim ($F$)) as the size of the largest subset $D'$ of its domain $D$ so that $D'$ is shattered by $F$ (or, more precisely, by the restrictions of the functions $x \mapsto f(\theta, x)$ in $F$ to inputs $x \in D'$). In other words, the VC-dimension of $F$ is the size of the largest subset $D'$ of its domain $D$ for which every dichotomy $h$ over $D'$ (i.e., each of the $2^{|D'|}$ many functions $h : D' \mapsto \{0, 1\}$) can be computed by some function in $F$, or in mathematical notation:

$$\forall h : D' \rightarrow \{0, 1\} \ \exists\ \theta \forall x \in D' (f(\theta, x) = h(x))$$

Although the definition of the VC-dimension focuses on the shattering effect, it yields a remarkable bound that holds for *all* finite subsets $X$ of the domain $D$: If $d$ is the VC-dimension of $F$, then at most $\sum_{i=0}^{d} \binom{|X|}{i} \leq |X|^d + 1$ functions from $X$ into $\{0, 1\}$ can be computed by (restrictions of) functions in $F$. This estimate, which is commonly referred to as Sauer's lemma, was independently discovered by several authors, including Vapnik and Chervonenkis in 1971 (see Anthony and Bartlett, 1999, chap. 3, for a review). Results of this form provide the mathematical basis for bounding the number of training examples that are needed for learning functions in $F$ in terms of the VC-dimension of $F$, as in the following theorem. (This theorem is a consequence of a slightly improved version, due to Talagrand, of a result from Vapnik and Chervonenkis, 1971; see Anthony and Bartlett, 1999, chap. 4, for related references.)

*Theorem 1.* Suppose that $F$ is a class of functions mapping from a domain $X$ into $\{0, 1\}$, and suppose also that $F$ has VC-dimension $d < \infty$. Let $((x_1, y_1), \ldots, (x_m, y_m))$ be a sequence of $m$ randomly chosen labeled training examples from $X \times \{0, 1\}$. Then, with probability at least $1 - \delta$ over this sequence, any function $f \in F$ has

$$\Pr(f(x) \neq y) \leq \frac{1}{m} |\{1 \leq i \leq m : f(x_i) \neq y_i\}| + \varepsilon$$

provided that $m \geq c(d + \log(1/\delta))/\varepsilon^2$, where $c$ is a universal constant.

In particular, if the sample size is large compared to the VC-dimension of the function class, the function from the class that minimizes the number of errors on a training sample will have near-minimal probability of misclassifying subsequent patterns (see PAC Learning and Neural Networks).

The definition of the VC-dimension of a function class $F$ immediately implies that $\mathrm{VCdim}(F) \leq \log_2|F|$ if $F$ is finite. Thus, in particular if $F$ is parameterized by $w$ $k$-bit parameters, $\mathrm{VCdim}(F) \leq kw$. However, many infinite classes $F$ also have a finite VC-dimension. Consider, for example, the class $F_{T2}$ of functions from $\mathbb{R}^2$ into $\{0, 1\}$ that can be computed by linear threshold gates (McCulloch-Pitts neurons) with two inputs:

$$F_{T2} = \{\langle x_1, x_2 \rangle \mapsto \mathcal{H}(\theta_1 x_1 + \theta_2 x_2 - \theta_3) : \theta = \langle \theta_1, \theta_2, \theta_3 \rangle \in \mathbb{R}^3\}$$

where $\mathcal{H}(x) = 1$ if $x \geq 0$, otherwise $\mathcal{H}(x) = 0$. (See Figure 1; the shaded region in each box corresponds to $h(x) = 1$.) Obviously, the set $D' := \{\langle 0, 0 \rangle, \langle 0, 1 \rangle, \langle 1, 0 \rangle\}$ can be shattered by $F_{T2}$ (as illustrated by the eight dichotomies shown in Figure 1). On the other hand it is easy to see that the set $D' \cup \{\langle 1, 1 \rangle\}$ *cannot* be shattered by $F$ (since the dichotomy $h$ that assumes the value 1 on the points $\langle 0, 0 \rangle$ and $\langle 1, 1 \rangle$ and the value 0 on the points $\langle 0, 1 \rangle$ and $\langle 1, 0 \rangle$ cannot be computed by any linear threshold gate). Somewhat less obvious to see is that there exists *no* set $D' \subseteq \mathbb{R}^2$ consisting of four or more points that is shattered by $F_{T2}$, i.e., that 3 is in fact the VC-dimension of $F_{T2}$. This follows immediately from the following theorem.

*Theorem 2.* (Wenocur and Dudley) Let $F_{Tn}$ be the class of functions from $\mathbb{R}^n$ into $\{0, 1\}$ that can be computed by a linear threshold gate, for any $n \in \mathbb{N}$. Then $F_{Tn}$ has VC-dimension $n + 1$.

*Sketch of the proof.* One can easily verify that the set $S := \{\underline{0}\} \cup \{\underline{e}_i : i \in \{1, \ldots, n\}\}$ is shattered by $\mathcal{N}$ (where $\underline{e}_i \in \{0, 1\}^n$ denotes the $i$th unit vector). Hence $\mathrm{VCdim}(\mathcal{N}) \geq n + 1$. The upper bound follows from Radon's theorem, which states that any set $S$ of $\geq n + 2$ points in $\mathbb{R}^n$ can be partitioned into sets $S_0$ and $S_1$ such that the convex hulls of $S_0$ and $S_1$ intersect. Obviously, such sets $S_0$ and $S_1$ cannot be separated by any hyperplane, and hence not by any linear threshold gate. □

## Feedforward Neural Nets with Binary Output

*Theorem 3.* (Cover, 1968; Baum and Haussler, 1989) Let $\mathcal{N}$ be an arbitrary feedforward neural net with $w$ weights that consists of linear threshold gates. Then $\mathrm{VCdim}(\mathcal{N}) = O(w \cdot \log w)$.

*Sketch of the proof.* Let $S$ be some arbitrary set of $m$ input vectors for $\mathcal{N}$. By Theorem 2 and Sauer's lemma, a gate $g$ in $\mathcal{N}$ can compute at most $|X|^{\text{fan-in}(g)+1} + 1$ different functions from any finite set $X \subseteq \mathbb{R}^{\text{fan-in}(g)}$ into $\{0, 1\}$, where fan-in($g$) denotes the number of inputs of gate $g$. Hence $\mathcal{N}$ can compute at most $\Pi_{g \text{ gate in } \mathcal{N}} (m^{\text{fan-in}(g)+1} + 1) \leq m^{2w}$ different functions from $S$ into $\{0, 1\}$. If $S$ is shattered by $\mathcal{N}$, then $\mathcal{N}$ can compute all $2^m$ functions from $S$ into $\{0, 1\}$, which implies that $2^m \leq m^{2w}$, and hence

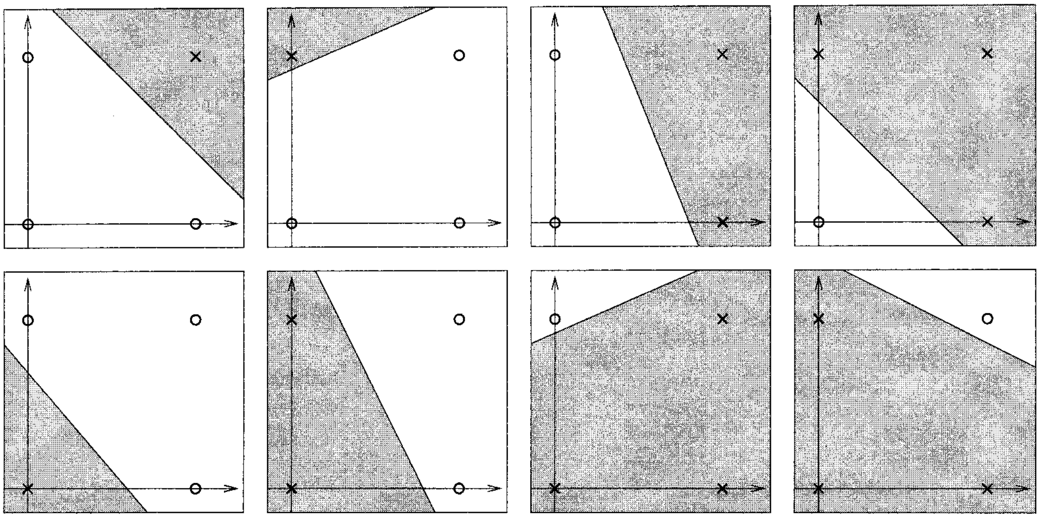

**Figure 1.** Eight dichotomies of four points in $\mathbb{R}^2$ computed by the class $F_{T2}$ of linear threshold functions. For each of the eight functions $h \in F_{T2}$ illustrated, the shaded region represents the half-space where $h(x) = 1$. When a point $x$ satisfies $h(x) = 1$, it is marked as a cross; when it satisfies $h(x) = 0$, it is marked as a circle. The functions illustrated show that the set $\{\langle 0, 0\rangle, \langle 0, 1\rangle, \langle 1, 0\rangle\}$ is shattered by $F_{T2}$.

$m \leq 2w \cdot \log m$. It follows that $\log m = O(\log w)$; thus $m = O(w \cdot \log w)$. □

It is tempting to conjecture that the VC-dimension of a neural net $\mathcal{N}$ cannot be larger than the total number of parameters in $\mathcal{N}$, which, in view of Theorem 2, is equal to the sum of the VC-dimensions of the individual gates in $\mathcal{N}$. This conjecture would imply that the $O(w \log w)$ upper bound of Theorem 3 can be improved to $O(w)$. However, the following result (whose proof uses techniques from circuit complexity theory) shows that the superlinear upper bound of Theorem 3 is in fact asymptotically optimal. Hence, with regard to the VC-dimension it is fair to say that a neural net can be "more than the sum of its parts."

*Theorem 4.* (Maass, 1993) There exist neural networks $\mathcal{N}$ consisting of linear threshold gates whose VC-dimension scales proportional to $w \cdot \log w$, where $w$ is the number of parameters of $\mathcal{N}$.

This superlinear growth of the VC-dimension occurs already for feedforward neural nets with two hidden layers in the case of discrete network inputs. Sakurai (1993) showed that for the case of continuous network inputs it may even occur with a single hidden layer.

Proving upper bounds for sigmoidal neural nets, whose computational units employ some smooth activation function instead of the Heaviside function $\mathcal{H}$, turns out to be quite challenging. For instance, there exists a feedforward neural net consisting of a linear threshold gate as output unit and two hidden units that employ as activation function a very smooth (real analytic) strictly increasing squashing function, which has an infinite VC-dimension. (See, for example, Anthony and Bartlett, 1999; the first result of this form was due to Sontag, 1998.) This shows that it is necessary to exploit more specific properties of a particular activation function, for example, of the logistic sigmoid, in order to achieve a finite upper bound for the VC-dimension of a sigmoidal neural net. The following theorem (Goldberg and Jerrum, 1995) provides the key step in this direction.

*Theorem 5.* (Goldberg and Jerrum, 1995) Consider the parameterized class

$$F = \{x \mapsto f(\theta, x) : \theta \in \mathbb{R}^d\}$$

for some $\{\pm 1\}$-valued function $f$. Suppose that, for each input $x \in \mathbb{R}^n$, there is an algorithm that computes $f(\theta, x)$, and this computation takes no more than $t$ operations of the following types:

- the arithmetic operations $+$, $-$, $\times$, and / on real numbers,
- jumps conditioned on $>$, $\geq$, $<$, $\leq$, $=$, and $\neq$ comparisons of real numbers, and
- output 0 or 1.

Then $\text{VCdim}(H) \leq 4d(t + 2)$.

The proof involves counting cells in parameter space. Consider a single thresholded real-valued function, such as a neural network with a single real output that is thresholded at 0. Fix a set of $n$ input patterns. To estimate the VC-dimension, we can estimate the number of distinct dichotomies of those patterns. Suppose two parameter values give distinct output labels for one of these patterns. Then, in moving between these distinct values in parameter space, we must pass through a parameter value where the real output is zero in response to the pattern. Such values form the boundaries of cells in parameter space, and within a cell all classifications are identical. Under appropriate conditions, counting the number of dichotomies reduces to counting the number of these cells. For well-behaved parameterizations, the number of cells defined by these zero sets is closely related to the number of distinct solutions of generic systems of equations. If the output of the network is polynomial in the parameters, classical results give bounds on the number of such solutions, and hence on the number of dichotomies. (Ben-David and Lindenbaum independently obtained this proof and result in a paper that appeared at the same conference as Goldberg and Jerrum's paper.) The argument is essentially unchanged if the parameterized function class is a fixed Boolean function of a number of thresholded functions that are each polynomial in the parameters. If the computation of $f(\theta, x)$ involves few operations, this implies that $f$ can be represented as a fixed Boolean function of a small number of thresholded, low-degree polynomials.

### *Piecewise Polynomial Activation Functions*

As an example of the application of Theorem 5, the output of a linear threshold net can be computed using $O(w)$ of the operations listed in the theorem, where $w$ is the number of parameters, so the VC-dimension is $O(w^2)$. Theorem 3 shows that this bound can be improved to $O(w \cdot \log w)$. Similarly, if the nonlinearity is a piecewise polynomial function with a fixed number of pieces of fixed degree, the number of operations is again $O(w)$, so the VC-dimension bound of $O(w^2)$ again applies. In some cases, this bound also can be improved, by applying Theorem 5 more carefully. This leads to the following bound (Bartlett, Maiorov, and Meir, 1998) on the VC-dimension of a feedforward neural net of piecewise polynomial gates arranged in $L$ layers (so that each gate has connections only from gates in earlier layers).

*Theorem 6.* (Bartlett, Maiorov, and Meir, 1998) Suppose $\mathcal{N}$ is a feedforward network with $w$ weights, $l$ layers, and all nonoutput gates having a fixed piecewise-polynomial activation function with a fixed number of pieces. Then $\text{VCdim}(\mathcal{N}) = O(wl \log w + wl^2)$.

Linear threshold gates have a piecewise polynomial activation function. Thus, Theorem 6, together with the lower bound for linear threshold nets (Theorem 4), shows that the VC-dimension of piecewise polynomial networks with a fixed number of layers is also $\Theta(w \log w)$. Perhaps surprisingly, the transition from linear threshold gates to piecewise polynomial gates does not increase the rate of growth of the VC-dimension for networks with a fixed number of layers.

In contrast, if the number of layers is unbounded, the rate of growth of the VC-dimension can be faster for piecewise polynomial networks than for linear threshold networks. The following lower bound applies to networks of gates with an activation function satisfying two conditions: it has distinct left and right limits, and it has non-zero slope somewhere. This result is due to Koiran and Sontag (1997) the refinement to give the dependence on the depth was shown by Bartlett, Maiorov, and Meir, and also by Sakurai.

*Theorem 7.* Suppose the activation function $s : \mathbb{R} \to \mathbb{R}$ has the following properties:

1. $\lim_{\alpha \to \infty} s(\alpha) \neq \lim_{\alpha \to -\infty} s(\alpha)$, and
2. $s$ is differentiable at some point $\alpha_0 \in \mathbb{R}$, with $s'(\alpha_0) \neq 0$.

Then for any $l$ and $w \leq 10l$, there is a neural network $\mathcal{N}$ with $l$ layers and $w$ parameters, where every gate but the output gate has activation function $s$, the output gate being a linear threshold gate, and for which the VC-dimension scales as $lw$. In particular, for $l = \Theta(w)$, there are such networks with $\text{VCdim}(\mathcal{N}) = \Omega(w^2)$.

### *Sigmoidal Activation Functions*

While the VC-dimension of networks with piecewise polynomial activation functions is well understood, most applications of neural networks use the logistic sigmoid function, or gaussian radial basis function. Unfortunately, it is not possible to compute such functions using a finite number of the arithmetic operations listed in Theorem 5. However, Karpinski and Macintyre (1997) extended Theorem 5 to allow the computation of exponentials. The proof uses the same ideas, but the bound on the number of solutions of a system of equations is substantially more difficult.

*Theorem 8.* Consider the parameterized class

$$F = \{x \mapsto f(\theta, x) : \theta \in \mathbb{R}^d\}$$

for some $\{\pm 1\}$-valued function $f$. Suppose that, for each input $x \in \mathbb{R}^n$, there is an algorithm that computes $f(\theta, x)$, and this computation takes no more than $t$ operations of the following types:

- the exponential function $\alpha \mapsto e^\alpha$ on real numbers, and
- all of the operations listed in Theorem 5.

Then $\text{VCdim}(F) = O(t^2 d^2)$.

We immediately obtain bounds for the VC-dimension of sigmoid networks and radial basis networks of the form $O(w^4)$, where $w$ is the number of parameters. This upper bound is considerably larger than the $\Theta(w \log w)$ bound achieved for linear threshold networks or fixed-depth piecewise polynomial networks. It remains open whether it is optimal. For fixed-depth sigmoid networks, the best lower bounds are those implied by Theorems 4 and 7: $\Omega(w \log w)$ for networks of fixed depth, and $\Omega(w^2)$ for arbitrary depth.

If the inputs are restricted to a finite set of integers, a simple parameter transformation allows the machinery of the piecewise polynomial case to be applied to two-layer sigmoid networks, giving the following result. (See Anthony and Bartlett, 1999, for a proof.) A related result applies to Gaussian radial basis networks.

*Theorem 9.* Consider a two-layer feedforward network $\mathcal{N}$ with input domain $X = \{-k, \ldots, k\}^n$ (for $k \in \mathbb{N}$) and first-layer computation gates with the standard sigmoid activation function (the output gate being a linear threshold gate). Let $w$ be the total number of parameters in the network. Then $\text{VCdim}(\mathcal{N}) = O(w \log(wk))$.

## Feedforward Neural Nets with Real Outputs

All of the results presented so far apply to nets with binary-valued outputs. Neural networks with real outputs are also commonly used, for instance in regression problems. In such cases, the appropriate measure of complexity of the network is a scale-sensitive version of the VC-dimension called the *fat-shattering dimension*.

Suppose that $F$ is a set of functions mapping from a domain $X$ to $\mathbb{R}$, $D = \{x_1, x_2, \ldots, x_m\}$ is a subset of the domain $X$, and $\gamma$ is a positive real number. Then we say that $D$ is *$\gamma$-shattered* by $F$ if there are real numbers $r_1, r_2, \ldots, r_m$ such that for all $b \in \{0, 1\}^m$ there is a function $f_b$ in $F$ with

$$\begin{aligned} f_b(x_i) &\geq r_i + \gamma \quad \text{if } b_i = 1 \\ f_b(x_i) &\leq r_i - \gamma \quad \text{if } b_i = 0 \end{aligned}$$

for $1 \leq i \leq m$. The *fat-shattering dimension* of $F$ at scale $\gamma$, denoted $\text{fat}_F(\gamma)$, is the size of the largest subset $D$ of the domain $X$ that is $\gamma$-shattered by $F$.

It is significant that this notion of complexity depends on a scale parameter $\gamma$. In a sense, the fat-shattering dimension ignores complex behavior of the function class below a certain scale. If we are concerned with predicting a real value to some accuracy $\varepsilon$ then it seems that the behavior of the function class on a scale much smaller than $\varepsilon$ should not be relevant. The following result formalizes this intuition by showing that the fat-shattering dimension is related to the number of training examples that are needed to solve a regression problem. Although the result is stated in terms of the squared prediction error, similar results apply to a broad class of loss functions. (The result relies on a generalization of Sauer's lemma to the fat-shattering dimension, from Alon et al., 1997.) See, for example, Anthony and Bartlett, 1999, for a proof.)

*Theorem 10.* Suppose that $F$ is a class of functions mapping from a domain $X$ into the real interval $[0, 1]$, and suppose also that $F$ has finite fat-shattering dimension. Let $((x_1, y_1), \ldots, (x_m, y_m))$ be a sequence of $m$ randomly chosen labeled training examples from $X \times [0, 1]$. Then there are constants $c_1, c_2$ such that, with probability at least $1 - \delta$, any function $f^*$ that has the average over the sample of $(f^*(x) - y)^2$ within $1/\sqrt{m}$ of the infimum over $F$ satisfies

$$\mathbf{E}(f^*(x) - y)^2 \leq \inf_{g \in F} \mathbf{E}(g(x) - y)^2 + \varepsilon \qquad (1)$$

provided that $m \geq c_1(\mathrm{fat}_F(c_2\varepsilon) \log^2(1/\varepsilon) + \log(1/\delta))/\varepsilon^2$.

It is also known that for any learning algorithm to return a function $f^*$ that satisfies Equation 1 requires the amount of training data to grow at least as $\mathrm{fat}_F(\varepsilon)$. This shows that the fat-shattering dimension is the right measure of complexity of a function class that is used for regression.

The fat-shattering dimension is also useful for pattern classification using thresholded real-valued functions, like neural networks. Many practical algorithms for such functions typically lead to solutions that have large *margins* on the training data, where the margin of a thresholded real-valued function is the amount by which the function is to the correct side of the threshold. The following result, from Bartlett (1998), shows that in these cases the fat-shattering dimension gives an upper bound on the error.

*Theorem 11.* Consider a class $F$ of real-valued functions. With probability at least $1 - \delta$ over $m$ independently generated examples $(x_1, y_1), \ldots, (x_m, y_m)$, for every function $f$ in $F$, the classifier $\mathcal{H}(f)$ has misclassification probability no more than

$$\frac{b}{m} + O\left(\sqrt{\frac{1}{m}\,(\mathrm{fat}_F(\gamma/16)\,\log^2 m + \log(1/\delta))}\right)$$

where $b$ is the number of labeled training examples with margin no more than $\gamma$.

The easiest way to obtain bounds on the fat-shattering dimension for neural networks is via VC-dimension bounds. The following theorem shows that the fat-shattering dimension of a network is no bigger than the VC-dimension of a slightly larger network with one additional input variable. The theorem is a trivial observation involving another combinatorial dimension, called the *pseudo-dimension*; see Chapters 11 and 14 of Anthony and Bartlett (1999) for details.

*Theorem 12.* Let $\mathcal{N}$ be any neural network with a single real-valued output unit, and form a neural network $\mathcal{N}'$ as follows. The network $\mathcal{N}'$ has one extra real input and one extra computation unit. This additional computation unit is the output unit of $\mathcal{N}'$, and is a linear threshold unit receiving input only from the output unit of $\mathcal{N}$ and from the new input. For any $\gamma > 0$, $\mathrm{fat}_{\mathcal{N}}(\gamma) \leq \mathrm{VCdim}(\mathcal{N}')$.

This result and the upper bounds of the previous section immediately imply upper bounds on the fat-shattering dimension of networks with linear threshold gates, with piecewise polynomial activation functions, and with logistic sigmoidal activation functions. These bounds are in terms of the number of parameters in the network, and, significantly, do not depend on the scale parameter $\gamma$. In some cases, bounds like this are very loose.

For example, the following theorem (Bartlett, 1998) gives an upper bound on the fat-shattering dimension of a two-layer network with an arbitrary number of computation units (and hence parameters).

*Theorem 13.* Suppose that $s : R \to [-b, b]$ is a nondecreasing bounded function. For $v \geq 1$, suppose that $F$ is the class of functions from $R^n$ to $R$ computed by two layer neural networks with an arbitrary number of first layer units, each with activation function $s$, and a linear output unit for which the sum of the magnitudes of the weights is bounded by $v$. Then

$$\mathrm{fat}_F(\varepsilon) = O\left(\frac{nv^2}{\varepsilon^2} \ln\left(\frac{v}{\varepsilon}\right)\right)$$

It follows that for regression and pattern classification (when the learning algorithm finds a network with large margins on the training data), it is not necessary to restrict the number of parameters in the network, provided the parameters are kept small. Bounds of this kind are also known for deeper networks; see Anthony and Bartlett (1999) for details.

## Other Applications to Neural Networks

The VC-dimension of recurrent neural networks was analyzed by DasGupta, Koiran, and Sontag (see Sontag, 1998, for a survey of results for feedforward and recurrent neural nets). In this case it is of interest to consider the case of a time series as the network input. The length $k$ of the time series enters the bounds for the VC-dimension of the neural network as an additional parameter (in most bounds the number $w$ of network parameters is multiplied by a factor of the form $\log k$ or $k$).

In models for biological neural circuits the transmission delays between neurons enter as additional parameters, which influence the VC-dimension of such circuits even more than the synaptic weights: the VC-dimension of a very simple mathematical model for a single spiking neuron grows superlinearly in the number $d$ of adjustable delays, and the VC-dimension of a feedforward network of such neurons grows quadratically in $d$ (Maass and Schmitt, 1999).

In Koiran (1996), a technique was introduced for using *upper* bounds on the VC-dimension of neural networks for proving *lower* bounds on the size of any sigmoidal neural net (with thresholded output) that is able to compute some concrete function. No other method for proving lower bounds on the size of sigmoidal neural nets is known at present. This technique can, for example, be used to show that there exist functions that can be computed with few spiking neurons, but if they are computed by a sigmoidal neural net, the number of neurons must grow linearly in the number of inputs (see SPIKING NEURONS, COMPUTING WITH).

## Discussion

The VC-dimension of a neural net with a binary output measures its "expressiveness." The related notion of the fat-shattering dimension provides a similar tool for the analysis of a neural net with a real-valued output. The derivation of bounds for the VC-dimension and the fat-shattering dimension of neural nets has turned out to be a rather challenging but quite interesting chapter in the mathematical investigation of neural nets. This work has brought a number of sophisticated mathematical tools into this research area, which have subsequently turned out to be also useful for the solution of a variety of other problems regarding the complexity of computing and learning on neural nets. More detailed information about the results presented in this article can be found in Anthony and Bartlett (1999).

Bounds for the VC-dimension (respectively fat-shattering dimension) of a neural net $\mathcal{N}$ provide estimates for the number of random examples that are needed to train $\mathcal{N}$ so that it has good generalization properties (i.e., so that the error of $\mathcal{N}$ on new examples from the same distribution is at most $\varepsilon$, with probability $\geq 1 - \delta$). From the point of view of a single application, these bounds tend to be too large, since they provide such a generalization guarantee for *any* probability distribution on the examples and for *any* training algorithm that minimizes disagreement on the training examples. For some special distributions and specific training algorithms, tighter bounds can be obtained, for instance with the help of heuristic arguments (replica techniques) from statistical physics.

# Vestibulo-Ocular Reflex

*Thomas J. Anastasio*

## Introduction

The function of the vestibulo-ocular reflex (VOR) is to stabilize the retinal image by producing eye rotations that compensate for head rotations (Wilson and Melvill Jones, 1979). The VOR forms an integral part of the oculomotor system, which includes the saccadic and pursuit systems (Robinson, 1989). Although it is considered a simple reflex, the neural circuits that mediate the VOR perform diverse computations that include oculomotor command integration, temporal signal processing, temporal pattern generation, and experience-dependent plasticity. Theory and neural network modeling have played an important role in understanding all of these processes.

## Classical Analysis and Linear Systems Modeling of the VOR

The VOR works in three dimensions. While modelers have recently turned their attention to the three-dimensional VOR (e.g., Schnabolk and Raphan, 1994), most analysis and modeling has focused on the horizontal VOR. A simplified schematic of the horizontal VOR is shown in Figure 1. The bilateral structure of the real VOR is suppressed in the schematic for clarity.

Eye movements elicited by the VOR describe a temporal pattern called nystagmus, in which compensatory slow-phase eye rotations are interrupted by fast-phase eye rotations that reset the orbital position of the eye. The VOR slow phase is produced in large part by the basic three-neuron arc, which consists of semicircular canal afferent neurons (CAs), vestibular nucleus interneurons (VNs), and eye muscle motoneurons (MNs). The slow-phase signal is transformed by two processes, velocity storage (VS) and neural integration (NI), both of which are essentially leaky temporal integrators (VS is much leakier than NI). The fast phase occurs after reticular burst neurons (BNs) are brought to threshold by VNs.

The cerebellum mediates experience-dependent adaptation of the VOR, and is represented in the schematic by a Purknje cell (PC). The VOR interfaces with other oculomotor subsystems at the VN level. For example, pursuit signals modulate VNs through the cerebellum (Pursuit Eye Movements).

### *Semicircular Canals and Canal Afferents*

The semicircular canals (SCs) are fluid-filled tori, imbedded in the skull, with a membrane spanning the lumen at one end. Head rotation causes deflection of the membrane against the fluid. Classical analysis of SC dynamics considers the balance of forces associated with head rotational acceleration, fluid inertia and viscosity, and membrane elasticity (Wilson and Melvill Jones, 1979). Due to the dynamic lag introduced by fluid viscosity, membrane deflection is mostly proportional to head rotational velocity. The SC response to an impulse head rotational acceleration would be a deflection of the membrane, followed by an exponential decay back to baseline with a time constant of about five seconds.

Hair cells (HCs) that are sensitive to canal membrane deflection make synaptic contact with CAs, which transmit head rotation in-

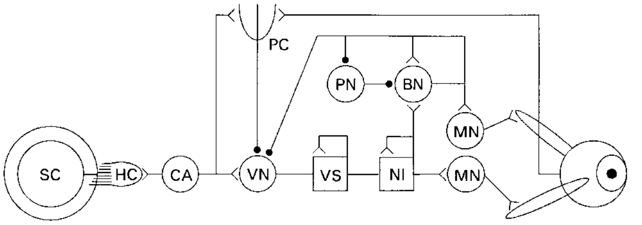

**Figure 1.** Highly simplified schematic diagram of the neural circuitry that mediates the slow- and fast-phases of the vestibulo-ocular reflex, and adaptive modification of the slow-phase by the cerebellum. formation to VNs. The CAs have a baseline firing rate that is modulated up and down for on- and off-direction head rotations, respectively. As expected from SC dynamic analysis, the CA response to an impulse head rotational acceleration decays exponentially with a time constant of about 5 s.

### *Vestibular Nucleus Neurons and Motor neurons*

MNs combine the commands they receive from premotor neurons (such as VNs and BNs) and relay them to the eye muscles (Robinson, 1989). Except for differences in baseline rate and sensitivity, MNs form a homogeneous group. In contrast, VNs receive various oculomotor signals, such as vestibular and pursuit, and combine them in a diverse, seemingly random way (Scudder and Fuchs, 1992). The VNs also form part of the circuits that mediate VS and NI.

The function of VS is to lengthen the CA time constant from about five to about twenty seconds. This prolongs the period during which the VOR can produce compensatory eye movements. Production of the VOR command essentially involves adding the VS and CA signals. Two mechanisms have been proposed whereby this may occur. Raphan, Matsuo, and Cohen (1979) proposed two parallel pathways from VNs to MNs, one carrying the CA and the other the VS signal. Robinson (1981) proposed that VNs feed the CA signal back to themselves through the VS element. Raphan's model predicted that VNs should carry either the CA or the VS signal, while Robinson's model predicted that VNs should carry the VOR signal fully formed. Neither model accounted for the response diversity actually observed for VNs, or for the high sensitivity and low baseline of VNs in comparison to CAs (Baker, Evinger, and McCrea, 1981).

The function of NI is to transform eye velocity commands, such as the VOR signal, into eye position commands. Both velocity and position components are needed to control eye movements (Robinson, 1981). The mechanisms that underlie NI and VS probably involve positive feedback, which is indicated only schematically in Figure 1 using excitatory self-connections. The probable substrate for VS and NI in the nervous system is mutual inhibition between VNs on opposite sides of the VOR pathway, mediated by the inhibitory commissural fibers that interconnect the VNs bilaterally (Wilson and Melvill Jones, 1979). Mutual inhibition allows VNs to integrate push-pull signals in the bilateral pathway without integrating the VN baseline rate. Control systems modeling has demonstrated how commissural connections could produce temporal signal processing in the bilateral VOR and also account for the dynamic properties of VN neurons (Galiana and Outerbridge, 1984).

### *Burst Neurons and Pause Neurons*

Fast-phase eye movements are driven by BNs located in the reticular formation (Shimazu, 1983). BNs are spontaneously silent, due to inhibition from pause neurons (PNs) and perhaps also to intrinsic inhibitory bias. PNs have a constant baseline rate but pause just before and during fast phases. BNs are brought to threshold by VNs and, as a group, inhibit both VNs and PNs. It was widely assumed that the role of PNs is to keep BNs from bursting (Leigh and Zee, 1983). Models of bursting needed a special "trigger" to shut off the PNs before the BNs could burst. No direct evidence for the hypothetical trigger has been provided.

### *VOR Plasticity and the Cerebellum*

The VOR is well known for its ability to undergo experience-dependent adaptation. It can be adapted by altering the normal relationship between head rotation and apparent visual surround rotation. The VOR can also be habituated by prolonged rotation at a low frequency (<0.1 Hz). Analysis of bilateral VOR circuits reveals that commissural connections, in addition to their likely role in temporal signal processing, could provide a powerful site for effecting plastic modification of the VOR (Galiana, 1985). VOR plasticity involves cerebellar processing (Wilson and Melvill Jones, 1979; Robinson, 1989). Models of VOR modification by the cerebellum are based on adaptive linear filters and other concepts from control theory (CEREBELLUM AND MOTOR CONTROL). These models illustrate how VOR adaptation might be guided by error signals. Because they are continuous, they fail to capture the discontinuous phenomena that can be observed during VOR modification.

## Neural Network Models of VOR

Previous models of the VOR were based largely on linear control theory (Robinson, 1981; Galiana and Outerbridge, 1984). The introduction of neural networks that allow nonlinear, distributed, and discontinuous processing have contributed new insights and have expanded the range of explicable phenomena. A generic architecture for VOR neural network models is shown in Figure 2. The bilateral model networks have three layers in which the input, hidden, and output units represent CAs, VNs, and MNs, respectively. Inputs can also represent commands from other oculomotor subsystems such as pursuit (not shown). The recurrent connections between hidden units are used to simulate VOR dynamics. Although this generic architecture is a greatly simplified version of the actual VOR pathway, it can be used to understand general principles that should pertain to the real system.

### *Static Neural Network Models of VOR*

Static neural networks have been used to study how vestibular and other oculomotor commands could be distributed over relatively large numbers of VNs (Anastasio and Robinson, 1989). The networks have several pairs of input units, one pair of output units, and forty hidden units. All units compute the weighted sum of their inputs and bound the result sigmoidally between zero and one. The network is trained using backpropagation (BACKPROPAGATION:

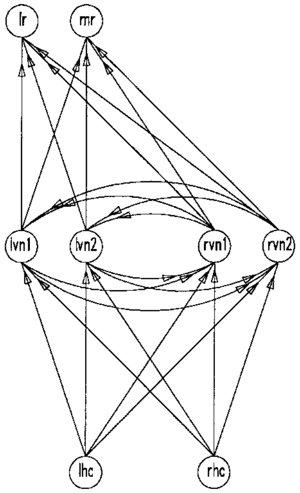

**Figure 2.** Architecture of adaptive, nonlinear neural network models of the VOR. lhc, rhc, left and right horizontal canal afferents; lvn, rvn, left and right vestibular nucleus neurons; lr, mr, lateral and medial rectus motoneurons on the left side. Figure redrawn from Anastasio (1991).

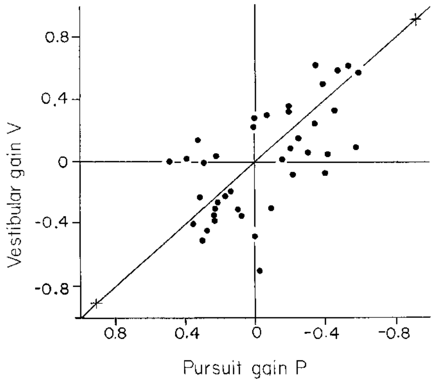

**Figure 3.** Variability in vestibular and pursuit related activity of forty model vestibular nucleus neurons from an adaptive, static neural network model of the VOR. Figure redrawn from Anastasio and Robinson (1989).

General Principles and Perceptrons, Adalines, and Backpropagation) to produce push-pull output activations appropriate to the input patterns. The gains of the hidden and output units after training on vestibular (V) and pursuit (P) commands are shown in Figure 3. The MNs (plus signs in Figure 3) have V and P gains that are equal and opposite, as demanded by training. In contrast, the VNs (dots) vary greatly in their relative proportions of V and P gain. They encode the oculomotor commands in a nonuniform, distributed manner. This accords well with the variability in vestibulo-oculomotor behaviors actually observed for VNs.

### *Dynamic Neural Network Models of VOR*

The NI has been modeled as a dynamic neural network (Recurrent Networks: Neurophysiological Modeling). Dynamic neural networks have also been used to study how a distributed, nonlinear set of model VNs would compute the transformation required for VS (Anastasio, 1991). The dynamic VOR neural network models have recurrent connections and sigmoidal units. They are trained using recurrent backpropagation (Recurrent Networks: Learning Algorithms) to simulate the VOR with VS. The time-varying inputs (Figure 4*A* and 4*B*) (dotted line) and outputs (not shown) are exponential decays. Output amplitude is equal and opposite to input amplitude, but the time constant is four times longer for the output than for the input.

The responses of model VNs in a four-hidden-unit dynamic network after training are shown in Figure 4*A* and 4*B* (right side, solid; left side, dashed). The bilateral pair in Figure 4*A* has developed strong, mutually inhibitory connections. It produces the VS integration in the network. In contrast, the bilateral pair in Figure 4*B* has almost zero mutual inhibition and produces no VS. It appears that the network has developed parallel pathways to the MNs, one that carries the VS and the other the CA signal. However, the weakly coupled pair projects to and receives from the strongly coupled pair over moderately strong connections. This endows the weakly coupled pair with slowly decaying response tails (Figure 4*B*). It appears that the weakly coupled pair feeds the CA signal back to itself through the VS element formed by the strongly coupled pair. Thus, the dynamic neural network effectively combines the parallel pathway and feedback mechanisms suggested by Raphan et al. (1979) and Robinson (1981), respectively.

The dynamic network also learns to make use of neural nonlinearly. Hidden units in the trained network have high sensitivity but low baseline. This causes their off-responses to approach zero at the peak of the CA signal. This reduction in the response of one member of the strongly coupled pair leads to a reduction in the amount of lateral interaction and a reduction in VS at the peak of the CA response. Thus, even the strongly coupled pair of model VNs tends to pass the CA signal at its peak. The dynamic neural network model has adaptively found a solution to the VS problem that reproduces the high sensitivity, low baseline, and dynamic diversity of real VNs.

### *Dynamic and Nonlinear Models of Burst Production*

A dynamic, nonlinear model of fast-phase burst generation was studied to gain insight into how an intense, temporally circumscribed burst could be produced by known brainstem circuitry (Anastasio, 1997). BNs excite themselves directly through excitatory collaterals (Shimazu, 1983). BN self-excitation could cause a burst, once inhibition from PNs and other sources is overcome and BNs start firing. But a burst produced by direct self-excitation, once initiated, could not easily be terminated. A transient burst could be produced through a mechanism involving the PNs. The BNs disinhibit themselves by inhibiting the PNs. Thus, the BN-PN loop constitutes another positive feedback pathway onto BNs in addition

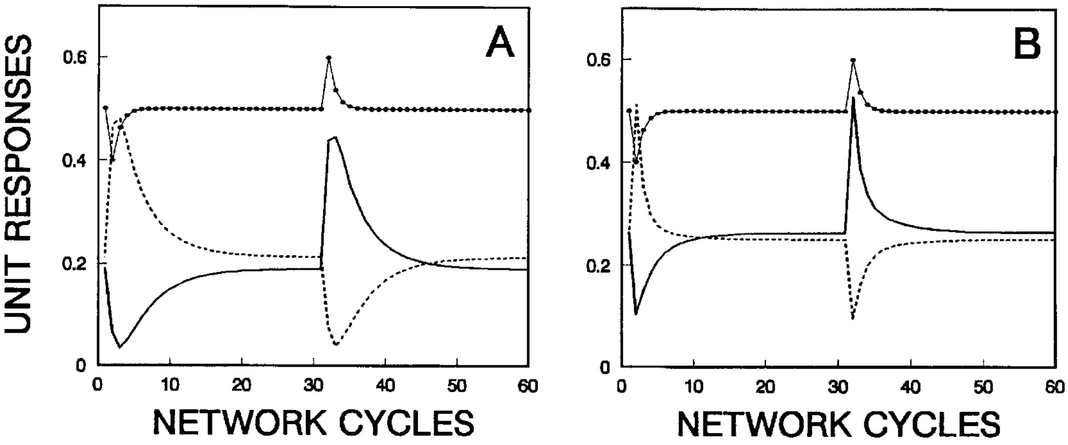

**Figure 4.** Responses of four model vestibular nucleus neurons in an adaptive, dynamic neural network model of velocity storage in the VOR. Solid and dashed curves, vestibular nucleus neuron responses; dotted curves, canal afferent response. Figure redrawn from Anastasio (1991).

to BN self-excitation. The advantage of the BN-PN loop is that it contributes to BN positive feedback at burst onset, but disengages when the PN pauses and breaks open the BN-PN loop. The BN response could then decay back to zero under the influence of its weaker self-excitation and inhibitory bias.

This idea was explored using a distributed network having ten each of units representing BNs, PNs, and VNs. Each unit computes the weighted sum of its inputs and bounds the result between zero and fifty. Connection polarity is as indicated in Figure 1 but the weights are randomly perturbed about previously defined values. The model produces an intense, temporally circumscribed burst that is synchronized over the population of BNs (not shown). It reproduces the diversity in response characteristics observed for real neurons, particularly the variability in BN response lead (Shimazu, 1983). Thus, PNs in the model function to enhance BN positive feedback at burst onset, and then to reduce BN positive feedback when they pause, allowing the burst to terminate. The hypothetical trigger required for previous models is not needed.

### *Pattern Correlation Model of VOR Habituation*

Discontinuous and nonlinear behavior associated with VOR plasticity was studied using a model based on pattern correlation (Anastasio, 2001). It simulates the performance of the VOR as it undergoes habituation, which is a reduction in VOR gain brought about by prolonged exposure to low-frequency input. The patterns, stored by model PCs, are temporal fragments of the input. The PC whose pattern is most highly correlated with the input at any time reduces the VOR response by the amount of that correlation, multiplied by a preassigned weight. This simple model reproduces the discontinuous and nonlinear behavior of the habituating VOR, including superposition violation (Figure 5). The pattern correlation model suggests that the cerebellum works discontinuously in producing VOR adaptive plasticity.

## Discussion

Although many open questions remain concerning VOR performance, the study of the neural mechanisms mediating the VOR has reached maturity and is moving from the laboratory to the clinic (Leigh and Zee, 1983). In contrast, the study of VOR plasticity is still a vibrant area that should continue to provide new results.

**Road Map:** Mammalian Motor Control
**Related Reading:** Action Monitoring and Forward Control of Movements; Collicular Visuomotor Transformations for Gaze Control; Pursuit Eye Movements

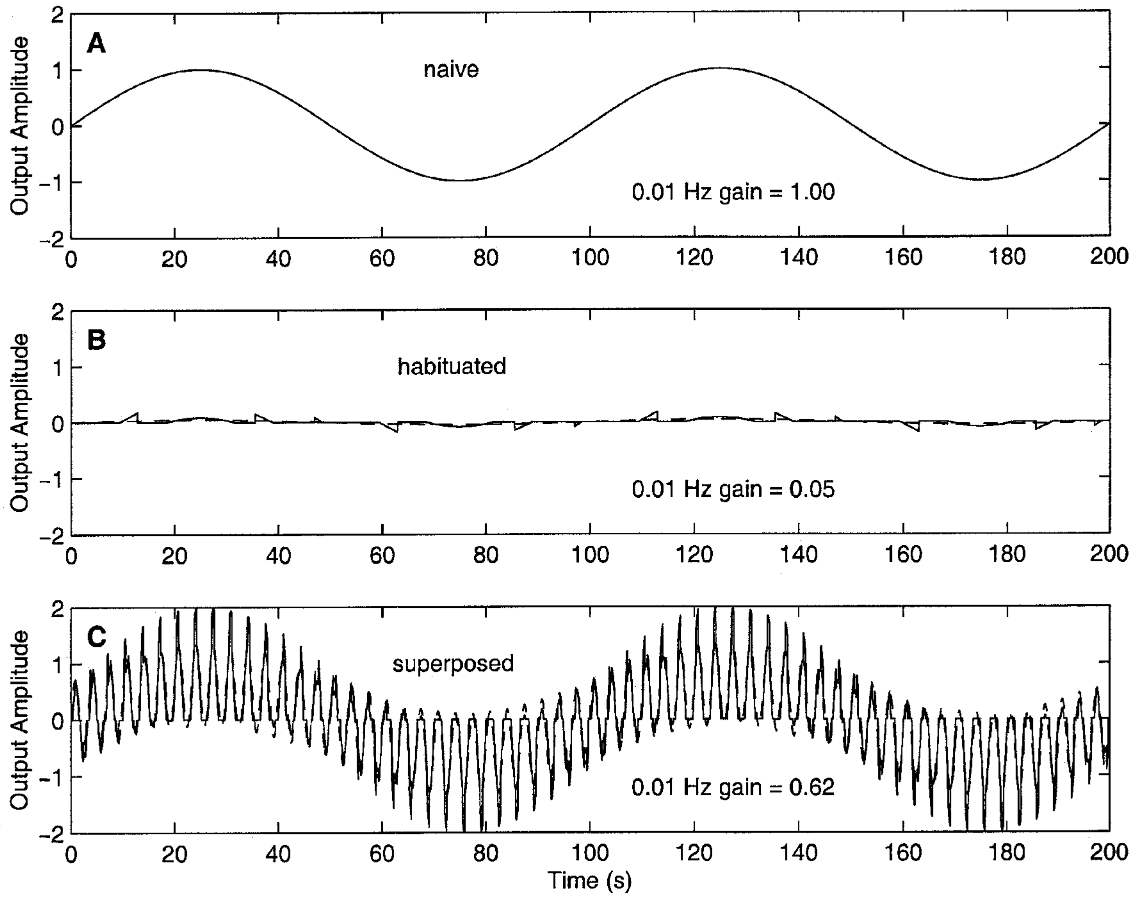

**Figure 5.** Using the pattern correlation model to simulate superposition violation following VOR habituation. Patterns are taken from an input sinusoid at 0.01 Hz to produce habituation at that frequency. Habituated VOR gain at 0.01 Hz (*B*) increases to more than half the naive level (*A*) when the 0.01 Hz input is combined with a second input component at 0.3 Hz (*C*). Combining the input at the habituating frequency with a second component at a different frequency degrades correlations with patterns taken from the habituating sinusoid, and reduces the amount of habituation. For a system that obeys the superposition principle, gain at a particular frequency should not be affected by the superposition of input components at other frequencies. The pattern correlation model, like the habituated VOR, violates superposition. Figure redrawn from Anastasio (2001).

# Visual Attention

*Laurent Itti*

## Introduction

Selective visual attention is the mechanism by which we can rapidly direct our gaze toward objects of interest in our visual environment. It can be bottom-up (image based) or top-down (task dependent). Attention allows only a small part of the incoming sensory information to reach short-term memory and visual awareness, allowing us to break down the problem of scene understanding into rapid series of computationally less demanding, localized visual analysis problems. Moreover, attention mechanisms can provide feedback modulation of neural activity at the location and for the visual attributes of the desired or selected targets. This feedback may be essential for binding the different visual attributes of an object, such as color and form, into a unitary percept. As such, focal visual attention is often compared to a rapidly shiftable *spotlight* that scans our visual environment overtly (with accompanying eye movements) or covertly (with the eyes fixed). Of course, not all of vision is attentional, as we can derive a coarse understanding from presentations of visual scenes that are so brief they do not leave time for attention to explore the scene. Vision thus appears to rely on sophisticated interactions between coarse, massively parallel, full-field preattentive analysis systems and the more detailed, circumscribed, and sequential attentional analysis system.

In what follows, we focus first on the brain areas involved in the control and deployment of attention; second, on the mechanisms by which attention is attracted in a bottom-up or image-based manner toward salient locations in our visual environment; third, on the mechanisms by which attention modulates the early sensory representation of attended stimuli; fourth, on the mechanisms for top-down or voluntary deployment of attention; and fifth, on the interaction between attention, object recognition, and scene understanding.

## Brain Areas

To a first approximation, selecting *where* to attend next is carried out by distinct brain structures from those that recognize *what* is being attended to. This suggests that a cooperation between "two visual systems" is used by normal vision (Didday and Arbib, 1975): selecting where to attend next is primarily controlled by the *dorsal visual processing stream* (or the "where/how" stream), which comprises cortical areas in posterior parietal cortex, whereas the *ventral visual processing stream* (or the "what" stream), comprising cortical areas in inferotemporal cortex, is primarily concerned with localized object recognition (Ungerleider and Mishkin, 1982). It is important to note, however, that object recognition in the ventral stream can bias the next attentional shift by suggesting where the next interesting object may be located. Similarly, attention strongly modulates activity in the object recognition system.

Brain regions participating in the deployment of visual attention (Figure 1) include the lateral geniculate nucleus (LGN) of the thalamus and cortical areas V1 (primary visual cortex) through the parietal cortex along the dorsal stream, as well as subcortical structures instrumental in producing directed eye movements. These include the deeper parts of the superior colliculus, parts of the pulvinar, the frontal eye fields, the precentral gyrus, and areas in the intraparietal sulcus in the macaque and around the intraparietal and postcentral sulci and adjacent gyri in humans.

## Bottom-Up Control

One important mode of operation of attention is largely unconscious and driven by the specific attributes of the stimuli present in our visual environment. This so-called *bottom-up control of visual attention* may be studied using simple *visual search* tasks. Based on these experiments, computational models have been developed for how attention is attracted toward salient scene locations.

### *Visual Search and Pop-Out*

One of the most effective demonstrations of bottom-up attentional guidance uses simple visual search experiments in which an odd

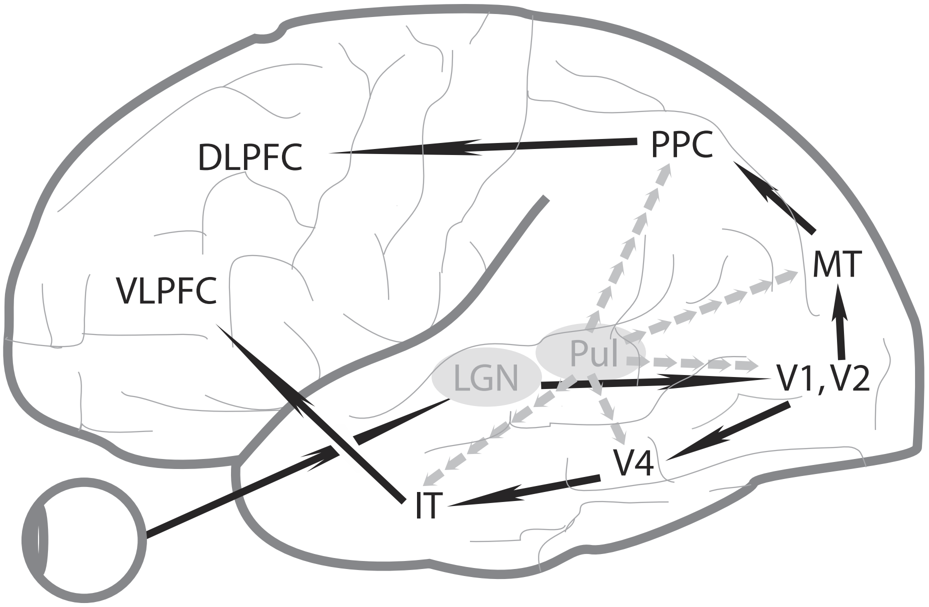

**Figure 1.** Major brain areas involved in the deployment of selective visual attention. Although single-ended arrows are shown to suggest global information flow (from the eyes to prefrontal cortex), anatomical studies suggest reciprocal connections, with the number of feedback fibers often exceeding the number of feedforward fibers (except between retina and LGN). Cortical areas may be grouped into two main visual pathways: the dorsal "where/how" pathway (from V1 to DLPFC via PPC) is mostly concerned with spatial deployment of attention and localization of attended stimuli, while the ventral "what" pathway (from V1 to VLPFC via IT) is mostly concerned with pattern recognition and identification of the attended stimuli. In addition to these cortical areas, several subcortical areas, including LGN and Pul, play important roles in controlling where attention is to be deployed. LGN, lateral geniculate nucleus; Pul, pulvinar nucleus; V1, V2, V4, early cortical visual areas; MT, medial temporal area; PPC, posterior parietal cortex; DLPFC, dorsolateral prefrontal cortex; IT, inferotemporal cortex; VLPFC, ventrolateral prefrontal cortex.

target stimulus to be located by the observer is embedded within an array of distracting visual stimuli (Treisman and Gelade, 1980). Originally, these experiments suggested a dichotomy between situations in which the target stimulus would visually pop out from the array and be found immediately and situations in which locating the target would require extensive scanning of the array (Figure 2). The pop-out cases suggest that the target can be effortlessly located by relying on preattentive visual processing over the entire visual scene. In contrast, the conjunctive search cases suggest that attending to the target is a necessary precondition to being able to identify it as the unique target, thus requiring that the search array be scanned until the target becomes the object of attentional selection.

Further experimentation has revealed that the fast, parallel pop-out search and the slower, serial search, originally conceived as a dichotomy, represent two extremes on a continuum of search difficulty (Wolfe, 1996). Nevertheless, these experiments clearly demonstrate that if a target differs significantly from its surround (in ways that can be characterized in terms of visual attributes of the target and distractors), it will immediately draw attention to itself. Thus, these experiments are evidence of how the composition of the visual scene alone is a strong component of attentional control.

## *Computational Models and the Saliency Map*

The *feature integration theory* of Treisman and colleagues (Treisman and Gelade, 1980), which was derived from visual search experiments, has served as a basis for many computational models of bottom-up attentional deployment. This theory proposed that only fairly simple visual features are computed in a massively parallel manner over the entire visual scene, in early visual processing areas, including primary visual cortex. Attention is then necessary to bind those early features into more sophisticated object representations, and the selected bound representations are (to a first approximation) the only part of the visual world that passes through the *attentional bottleneck* for further processing.

The first explicit neurally plausible bottom-up computational architecture was proposed by Koch and Ullman (1985) and is closely related to the feature integration theory. The model is centered on a *saliency map*, that is, an explicit two-dimensional topographic map that encodes for stimulus conspicuity, or *salience*, at every location in the visual scene. The saliency map receives inputs from early visual processing and provides an efficient control strategy by which the focus of attention simply scans the saliency map in order of decreasing saliency.

This general architecture has been further developed and implemented, yielding the computational model depicted in Figure 3 (Itti and Koch, 2001). In this model, the early stages of visual processing decompose the incoming visual input through an ensemble of feature-selective filtering processes endowed with contextual modulatory effects. To control a single attentional focus based on this multiplicity of features, all feature maps provide input to the saliency map, which encodes visual salience irrespective of feature dimensions. Biasing attention to focus on the most salient location is then reduced to drawing attention toward the locus of highest activity in the saliency map. This is achieved using a *winner-take-all* neural network, which implements a neurally distributed maximum detector. To allow attention to shift to the next most salient location, each attended location is transiently inhibited in the saliency map by an *inhibition-of-return* mechanism, such that the winner-take-all network naturally converges on the next most salient location (Koch and Ullman, 1985; Itti and Koch, 2001; see also WINNER-TAKE-ALL NETWORKS).

Many successful models for the bottom-up control of attention are architectured around a saliency map. What differentiates the

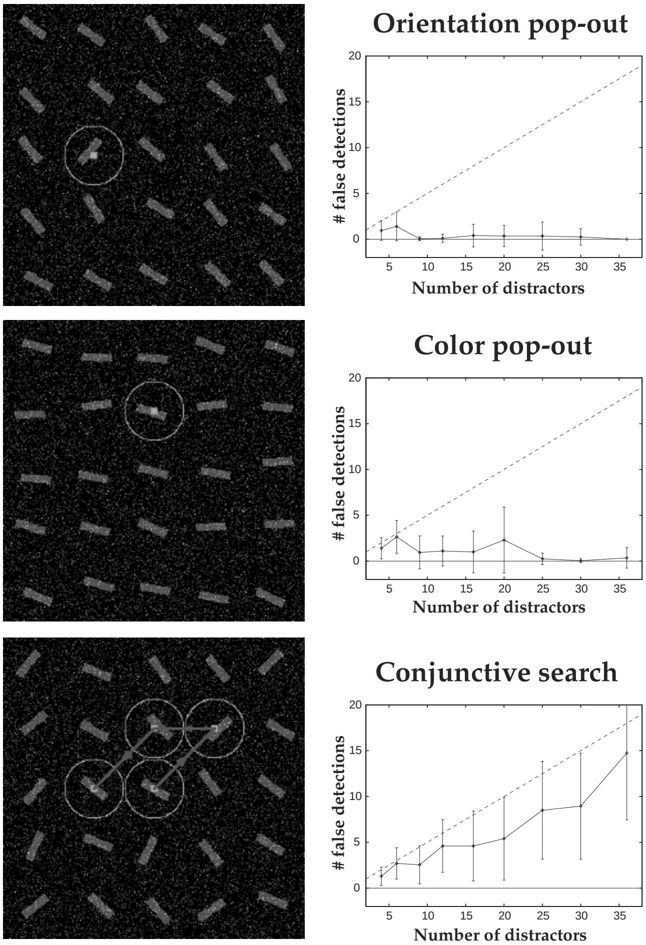

**Figure 2.** Search array experiments of the type pioneered by Treisman and colleagues. The top two panels are examples of pop-out cases where search time (here shown as the number of locations fixated before the target is found) is small and independent of the number of elements in the display. The bottom panel demonstrates a conjunctive search (the target is the only element that is bright *and* oriented like the darker elements); in this case, a serial search is initiated, which will require more time as the number of elements in the display is increased.

models, then, is the strategy employed to prune the incoming sensory input and extract salience. In an influential model mostly aimed at explaining visual search experiments, Wolfe (1996) hypothesized that the selection of relevant features for a given search task could be performed top down, through spatially defined and feature-dependent weighting of the various feature maps. Although limited to cases where attributes of the target are known in advance, this view has recently received experimental support from studies of top-down attentional modulation (see below).

Tsotsos and colleagues (1995) implemented attentional selection using a combination of a feedforward bottom-up feature extraction hierarchy and a feedback selective tuning of these feature extraction mechanisms. The target of attention is selected at the top level of the processing hierarchy (the equivalent of a saliency map), based on feedforward activation and on possible additional top-down biasing for certain locations or features. That location is then propagated back through the feature extraction hierarchy, through the activation of a cascade of winner-take-all networks embedded within the bottom-up processing pyramid. Spatial competition for salience is thus refined at each level of processing, as the feedforward paths not contributing to the winning location are pruned (resulting in the fed-back propagation of an "inhibitory beam" around the selected target).

Itti and Koch (2001) recently proposed a purely bottom-up model in which spatial competition for salience is directly modeled after nonclassical surround modulation effects. The model employs an iterative scheme with early termination. At each iteration, a feature map receives additional inputs from the convolution of itself by a large difference-of-Gaussians filter. The result is half-wave rectified, with a net effect similar to a winner-take-all network with limited inhibitory spread, which allows only a sparse population of locations to remain active. After competition, all feature maps are simply summed to yield the scalar saliency map. Because it includes a complete biological front end, this model has been widely applied to the analysis of natural color scenes (Itti and Koch, 2001). The nonlinear interactions implemented in this model strongly illustrate how, perceptually, whether a given stimulus is salient or not cannot be decided without knowledge of the context within which the stimulus is presented.

Many other models have been proposed, which typically share some of the components of the three models just described. It is thus important to note that postulating centralized control based on such a map is not the only computational alternative. In particular, Desimone and Duncan (1995) argued that salience is not explicitly represented by specific neurons but instead is implicitly coded in a distributed modulatory manner across the various feature maps. Attentional selection is then performed based on top-down weighting of the bottom-up feature maps that are relevant to a target of interest. This top-down biasing (also used in Wolfe's (1996) guided search model) requires that a specific search task be performed for the model to yield useful predictions.

## Top-Down Modulation of Early Vision

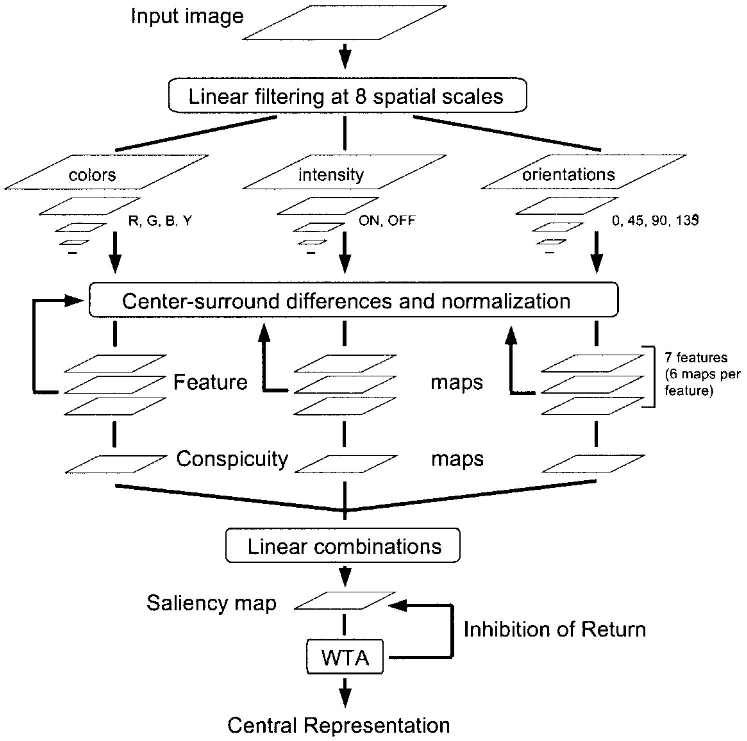
The general architecture for the bottom-up control of attention presented in the previous section opens two important questions about the nature of the attentional bottleneck. First, is it the only means through which incoming visual information can reach higher levels of processing? Second, does it involve only one-way processing of information, from the bottom up, or is attention a two-way process, also feeding back from higher centers to early processing stages?

### *Are We Blind Outside of the Focus of Attention?*

Recent experiments have shown how fairly dramatic changes applied to a visual scene being inspected may go unnoticed by human observers unless those changes occur at the location currently being attended to. These *change blindness* experiments (O'Regan, Rensink, and Clark, 1999) can take several forms, yielding essentially the same conclusions. One implementation consists of alternatively flashing two versions of a same scene separated by a blank screen, with the two versions differing very obviously at one location (for example, a scene containing a jet airplane, with one of its reactors erased from one of the photographs). Although the alteration is obvious when directly attended to, naive observers typically require several tens of seconds to locate it. Not unexpectedly, the most difficult instances of this experiment involve a change at a location of little interest in terms of scene understanding (for example, the aforementioned scene with an airplane also contains many people, who tend to be inspected in priority).

These experiments demonstrate the crucial role of attention in conscious vision: unless we attend to an object, we are unlikely to consciously perceive it in any detail and detect when it is altered. However, as we will see, this does necessarily mean that there is no vision other than through the attention bottleneck.

**Figure 3.** Typical architecture for a model of bottom-up visual attention based on a saliency map. The input image is analyzed by a number of early visual filters sensitive to stimulus properties such as color, intensity, and orientation, at several spatial scales. After spatial competition for salience within each of the resulting feature maps, input is provided to a single saliency map from all of the feature maps. The maximum activity in the saliency map (detected by a winner-take-all network) is the next attended location. Transient inhibition of return at this location in the saliency map allows the system to shift toward the next most salient location.



### Attentional Modulation of Early Vision

A number of psychophysical and electrophysiological studies indicate that we are not entirely blind outside the focus of attention. At the early stages of processing, responses are still observed even if the animal is attending away from the receptive field at the site of recording or is anesthetized. Behaviorally, we can also make fairly specific spatial judgments about objects not being attended to, though those judgments are less accurate than in the presence of attention. This is particularly demonstrated by *dual-task psychophysical experiments* in which observers are able to simultaneously discriminate two visual stimuli presented at two distant locations in the visual field (Lee, Koch, and Braun, 1999).

Thus, although attention appears not to be mandatory for early vision, it has recently become clear that it can vigorously modulate, top down, early visual processing, both in a spatially defined and in a nonspatial but feature-specific manner (Treue and Martinez Trujillo, 1999). This modulatory effect of attention has been described as enhanced gain, biased or intensified competition, enhanced spatial resolution, modulated background activity, effective stimulus strength, or noise (Itti and Koch, 2001).

Of particular interest from a computational perspective, a recent study by Lee et al. (1999) measured psychophysical thresholds for five pattern discrimination tasks (contrast, orientation, and spatial frequency discriminations, and two spatial masking tasks). They employed a dual-task paradigm to measure thresholds either with attention fully available to the task of interest or with attention poorly available because engaged elsewhere by a concurrent attention-demanding task. The mixed pattern of attentional modulation observed in the thresholds (up to a threefold improvement with attention in orientation discrimination, but only a 20% improvement in contrast discrimination) was quantitatively accounted for by a computational model. It predicted that attention strengthens winner-take-all competition among neurons tuned to different orientations and spatial frequencies within one cortical hypercolumn (Lee et al., 1999), a proposition that has recently received additional experimental support.

These results indicate that attention does not implement a feedforward, bottom-up information processing bottleneck. Rather, attention also enhances, through feedback, early visual processing for both the location and visual features being attended to.

## Top-Down Deployment

The precise mechanisms by which voluntary shifts of attention are elicited remain elusive, although several studies have narrowed down the brain areas primarily involved (see Itti and Koch, 2001, for a review). Here we focus on two types of experiments that clearly demonstrate how, first, attention may be deployed on a purely voluntary basis one of several identical stimuli, and second, how eye movements over a scene may dramatically differ, depending on task demands.

### Attentional Facilitation and Cueing

Introspection easily reveals that we are able to voluntarily shift attention toward any location in our visual field, no matter how inconspicuous that location may be. More formally, psychophysical experiments may be used to demonstrate top-down shifts of attention. A typical experiment involves cueing an observer toward one of several possible identical stimuli, but only at a high cognitive level (e.g., with a verbal cue), so that nothing in the visual display distinguishes the target from distractors. Detection or discrimination of the stimulus at the cued (and presumably attended) location are significantly better (e.g., faster reaction time or lower psychophysical thresholds) than at uncued locations. These experiments suggest that voluntarily shifting attention toward a stimulus improves the perception of that stimulus.

Similarly, experiments involving decision uncertainty demonstrate that if a stimulus is to be discriminated by a specific attribute known in advance (e.g., discriminate the spatial frequency of a grating), performance is significantly improved compared to situations where one randomly chosen of several possible stimulus attributes is to be discriminated (e.g., discriminate the spatial frequency, contrast, or orientation of a grating). Thus, we also appear able to voluntarily select the specific features of a stimulus. These results are closely related to and consistent with the spatial and featural nature of attentional modulation mentioned in the previous section.

### *Influence of Task*

Recording eye movements from human observers while they inspect a visual scene has revealed a profound influence of task demands on eye movements (Yarbus, 1967). In a typical experiment, different observers examine the same photograph while their eye movements are being tracked, but they are asked to answer different questions about the scene (for example, estimate the age of the people in the scene, or determine the country in which the photograph was taken). Although all observers are presented with the same visual stimulus, the patterns of eye movements recorded differ dramatically, depending on the question being addressed by each observer.

Building in part on eye-tracking experiments, Stark and colleagues (e.g., Noton and Stark, 1971) have proposed the *scanpath theory* of attention, according to which eye movements are generated almost exclusively under top-down control. The theory proposes that what we see is only remotely related to the patterns of activation of our retinas; rather, a cognitive model of what we expect to see is at the basis of our percepts. The sequence of eye movements that we make to analyze a scene, then, is mostly controlled top down by our cognitive model, and serves the goal of obtaining specific details about the particular scene instance being observed, to embellish the more generic internal model. This theory has had a number of successful applications to robotics control, in which an internal model of a robot's working environment was used to restrict the analysis of incoming video to a small number of task-dependent circumscribed regions.

## Attention and Scene Understanding

We have seen how attention is deployed onto our visual environment through a cooperation between bottom-up and top-down driving influences. One difficulty that arises is the generation of proper top-down biasing signals when exploring a novel scene; indeed, if the scene has not yet been analyzed and understood by means of thorough attentional scanning, how can it be used to direct attention top down? Below we explore two dimensions of this problem. First we describe how merely from a very brief presentation of a scene we are able to extract its gist, basic layout, and other characteristics. This suggests that another part of our visual system, operating much faster than attention, might be responsible for this coarse analysis. The results of this analysis may then be used to guide attention top down. Second, we explore how several computer vision models have used a collaboration between the where and what subsystems to yield sophisticated scene recognition algorithms. Finally, we cast these results into a more global view of our visual system and the function of attention in vision.

### *Is Scene Understanding Purely Attentional?*

Psychophysical experiments pioneered by Biederman and colleagues (Biederman, 1972) have demonstrated how we can derive coarse understanding of a visual scene from a single presentation that is so brief (80 ms or less) that it precludes any attentional scanning or eye movement. A particularly striking example of such experiments consists of presenting to an observer a rapid succession of unrelated photographs of natural scenes at a high frame rate (over 10 scenes/s). After stimuli have been presented for several tens of seconds, observers are asked whether a particular scene, for example an outdoors market scene, was present among the several hundred photographs shown. Although the observers are not made aware in advance of the question, they are able to provide a correct answer, with an overall performance well above chance (I. Biederman, personal communication). Furthermore, observers are able to recall a number of coarse details about the scene of interest, such as whether it contained humans, or whether it was highly colorful or rather dull.

These and many related experiments demonstrate that scene understanding does not exclusively rely on attentional analysis. Rather, a very fast visual subsystem that operates in parallel with attention allows us to rapidly derive the gist and coarse layout of a novel visual scene. This rapid subsystem certainly is one of the key components by which attention may be guided top down toward specific visual locations.

### *Cooperation Between Where and What*

Several computer vision models have been proposed for extended object and scene analysis that rely on cooperation between an attentional (where) and localized recognition (what) subsystems.

A very interesting instance was recently provided by Schill et al. (2001). Their model aims at performing object recognition, using eye movements to focus on those parts of the scene that are most informative in disambiguating its identity. A hierarchical knowledge tree is trained into the model in which leaves represent identified objects, intermediary nodes represent more general object classes, and links between nodes contain sensorimotor information used for discriminating between possible objects (i.e., bottom-up feature responses to be expected for particular points in the object, and eye movement vectors targeted at those points). During the iterative recognition of an object, the system programs its next fixation toward the location that will maximally increase information gain about the object being recognized, and thus will best allow the model to discriminate between the various candidate object classes.

Several related models have been proposed (see Itti and Koch, 2001) in which scanpaths (containing motor control directives stored in a "where" memory and locally expected bottom-up features stored in a "what" memory) are learned for each scene or object to be recognized. The difference between the various models comes from the algorithm used to match the sequences of where/what information to the visual scene. These include using a deterministic matching algorithm (i.e., focus next on the next location stored in the sequence being tested against the new scene), hidden Markov models (in which sequences are stored as transition probabilities between locations, augmented by the visual features expected at those locations), or evidential reasoning (similar to the model of Schill and colleagues). These models typically demonstrate strong ability to recognize complex gray-scale scenes and faces, in a translation-, rotation-, and scale-independent manner, but cannot account for nonlinear image transformations (e.g., 3D viewpoint change).

### *Attention as a Component of Vision*

Thus, vision relies not only on the attentional subsystem but also, and more broadly, on cooperation between crude preattentive subsystems for the computation of gist and layout and for bottom-up attentional control, and the attentive subsystem coupled with the localized object recognition subsystem to obtain fine details at various locations in the scene.

This perspective on the visual system raises a number of questions that remain fairly controversial. These are issues of the internal representation of scenes and objects (e.g., view-based versus 3D models, or a cooperation between both) and of the level of detail with which scenes are stored in memory for later recall and comparison with new scenes (e.g., snapshots versus crude structural models). Such issues are beyond the scope of the present discussion. Nevertheless, it is important to think of attention within the broader framework of vision and scene understanding, as this allows us to delegate some of the visual functions to nonattentional subsystems.

## Discussion

We have reviewed some of the key aspects of selective visual attention, and how these contribute more broadly to our visual experience and unique ability to rapidly comprehend complex visual scenes.

Looking at the evidence on the brain areas involved in the control of attention has revealed a complex interconnected network, shared with other subsystems, that includes the guidance of eye movements, the computation of early visual features, the recognition of objects, and the planning of actions.

Attention is guided toward particular locations in our visual world under a combination of competing constraints, including bottom up from the visual input and top down from task priorities and scene understanding. Bottom-up control is evidenced by visual search experiments, in which attention is automatically drawn toward targets that pop out from surrounding distractors. It is the best understood component of attention, and computational models exist that replicate some of the human search performance. Most models have embraced the idea that a single topographic saliency map efficiently guides attention. An important theoretical result is the critical role of cortical interactions in pruning the massive sensory input, to isolate conspicuous elements from the scene.

Attention implements an information processing bottleneck, which allows only select elements in the scene to reach higher levels of processing. But not all vision is attentional, and even though we may easily appear blind to unattended image details, there is still substantial residual vision outside the focus of attention. That is, the attentional bottleneck is not strict. In addition, it is a two-way process, such that not only are selected stimuli propagated up the visual hierarchy, they are also enhanced through top-down feedback. Computationally, a proposed unifying mechanism is the activation by attention of a winner-take-all competition among visual neurons representing different aspects of stimulus, making its dominant characteristics more explicit. Top-down attentional modulation appears both location and feature specific.

Introspection evidences how attention is not exclusively controlled bottom up. Improved performance when subjects know in advance where or what to look for provides further support for top-down attentional guidance. The exact mechanisms by which volitional attention shifts remain rather elusive. Nevertheless, high-level task specifications, e.g., a question asked about a visual scene, dramatically influence the deployment of attention and gaze.

Finally, it is important to consider attention not as an autonomous visual subsystem concerned only with stimulus selection. Indeed, it is highly unlikely, or impossible under conditions of very brief presentation, to analyze complex scenes only through attention. Rather, attention, object recognition, and rapid evaluation of scene gist and layout cooperate in a remarkable multithreaded analysis that exploits multiple time scales and levels of details within interacting processing streams. Despite tremendous recent progress, many of the key components of this complex interacting system remain poorly understood and elusive, thus renewing the challenges for future neuroscience research.

# Visual Cortex: Anatomical Structure and Models of Function

*Jennifer S. Lund and Klaus Obermayer*

## Introduction

Given a wealth of descriptive detail concerning the anatomical and physiological organization of the mammalian visual cortex, computational approaches have become an important tool with which to explore how its elements of organization interact in analyzing the visual world. Computational approaches are essential to our understanding of cortical function, since it is not easily apparent how anatomical circuitry and functional attributes of single neurons combine to determine activity patterns in large populations of neurons. Also, the anatomist needs indicators as to what connectional features are important for certain visual cortex functions, in order to guide further studies in this most complex of neuropils.

## Overview of the Anatomy of Area V1

The anatomy of the mammalian visual cortex has been studied extensively in a variety of species, but here we will discuss primarily the visual cortex of the macaque monkey as a model for the primate including humans (Levitt, Lund, and Yoshioka, 1996). It might be asked to what degree the primate visual cortex is particularly specialized in comparison with other areas of its cortex or in comparison with visual cortex of other mammals. In fact, it appears that most of its cellular components are common to other nonvisual cortical areas in its own brain as well as to the visual cortex of different mammalian species, some of which are long separated from primates in evolutionary history. Moreover, the elaborate patterning of intrinsic intra-areal connections within the primate visual cortex occurs across other cortical areas and across cortex of many other mammalian groups (Tyler et al., 1998; Lund, Yoshioka, and Levitt, 1993). These anatomical commonalities suggests that the mammalian cerebral cortex is a highly conserved neuropil in its evolution. Hence, it is likely that we will find common modes of function in areas of cortex devoted to very different sensory or motor skills within the same brain and in cortical areas of many different species.

Approximately 80% of the neurons in cerebral cortex are excitatory in their influence on other cells and are characterized morphologically by having small spines on their dendrites that act as specialized sites for synaptic contact. These spiny neurons either have dendritic processes that are all of much the same length and are called spiny stellate neurons or have one dendrite on the pial aspect of the cell that is greatly extended compared to the others and are called pyramidal neurons. The extended apical dendrite of the pyramidal neuron allows it to sample different inputs than those to the neuron's soma and basal dendrites. The other 20% of cortical neurons largely lack dendritic spines, are generally stellate in morphology, and usually contain gamma aminobutyric acid (GABA) as their principal neurotransmitter substance. These neurons are called local circuit neurons or interneurons, and they are viewed as being generally inhibitory. A variety of these inhibitory neurons exists and each variety is highly specialized in terms of their choice of postsynaptic cell and the region of the cell on which their axon terminates (see, for example, Tamas, Buhl, and Somogyi, 1997). This leads to marked anatomical specificities in their axon morphologies that serve as key features in their classification (Lund and Wu, 1997; Lund et al., 1993). The excitatory cells have longer axon relays than the inhibitory neurons in terms of lateral projections across the cortical sheet within a cortical area. They terminate on both excitatory and inhibitory neurons, and their axons also make the majority of connections between cortical areas and to subcortical regions.

The cerebral cortex is a sheetlike structure, and in the primate visual area V1, information from the thalamus is first presented across the sheet in a maplike representation of the retina. Relays coming from the right and left eyes do not mix and terminate in interleaved, segregated stripes. In addition, the macaque primary visual cortex receives a unique combination of thalamic inputs, each of which relays a different type, or channel, of visual information from the retina (reviewed by Levitt et al., 1996) and terminates in a different cortical layer. However, the postsynaptic cells' intrinsic lateral connections begin to restructure this information as well as linking different types of information (owing to differential convergence of the different streams onto common postsynaptic cells). Because of this cross-talk, new functional ("receptive field") properties are generated in cortex, and the postsynaptic neuron's properties depend on where the neuron is spatially located. Outputs from area V1 to a variety of surrounding cortical areas, emphasizing different properties, originate from V1 cell groups segregated in depth and laterally from one another, as if they express a high degree of functional specificity, akin to cortical "modules." It seems important that models should reflect this high degree of anatomical order in attempting to determine what is accomplished by the visual cortical neuropil.

There are three major channels of information entering the primate visual thalamus from the retina, and they relay on to primary visual cortex. The best-explored of these pathways are referred to as P and M channels, which originate at the $\beta$- and $\alpha$-retinal ganglion cells and project via the lateral geniculate nucleus (LGN) P and M divisions, respectively, to area V1. The channels differ in chromatic and achromatic sensitivity as well as in spatial and temporal frequency tuning. In area V1 of macaque, thalamic axons from the P and M divisions of the LGN terminate mainly in the lower half ($\beta$ division) and upper half ($\alpha$ division), respectively, of layer 4C. The third (I) channel of information relays through the LGN, via interlaminar territories inserted between its M and P layers, and terminates primarily in regularly spaced blob-shaped regions in layers 2–3 of area V1 (Yoshioka, Levitt, and Lund, 1994).

In layer 4C of area V1, the excitatory neurons postsynaptic to M and P input are almost all spiny stellate neurons rather than pyramids. These cells have staggered dendritic overlap through the depth of the layer. They send short, rising intrinsic axon projections to three different regions of the overlying layers, the target depending on their depth in layer 4C. Cells in lower 4C$\beta$ project to layer 4A, cells in mid 4C project to the interblob regions of layers 2 and 3, and cells in upper 4C$\alpha$ project to layer 4B. Their axons also contribute lateral projections to layer 4C, and the extent of these lateral projections is widest at the pial side of the layer. The interneurons within layer 4C can also receive thalamic input, but little is known of their specific relationships with the spiny cells except that one class (the so-called clutch cells) provides input to the spiny stellate cell bodies. The patterns of the inhibitory neuron axon projections relate in part to the projection patterns of the excitatory cells, but they also provide unique patterns of projections between the divisions of layer 4C. Given that the population of GABA cells is about 20% of the total cell population in all layers, any one variety of interneuron is likely to have a fairly economical distribution. This sparse distribution is interesting in that the geometry of the mosaic of inhibitory neuron dendritic surface and axon distribution may itself determine specific response characteristics in the larger population of excitatory spiny neurons with heavily overlapped dendrites. The different patterns of axon projections made by each of the interneuron classes within layer 4C suggest that a different function is fulfilled by each type in the context of processing thalamic inputs to the layer (Lund, 1987).

## Anatomical Substrates for Cortical Cell Contrast Sensitivity and Receptive Field Size

Since layer 4C of area V1 receives the bulk of the thalamic input and is the major substrate for the first stage of cortical processing of visual input, it seems very important in terms of understanding cortical function to try to model how the anatomical circuitry of layer 4C and biophysical properties of single neurons might determine the output of the layer. This output must form the substrate for models of further stages of information processing within cortical depth. We know from physiological recording experiments that very important new response properties appear in the depth of layer 4C compared to properties of the LGN neurons. These properties include orientation specificity, binocularity, and direction specificity, and the substrates for determining these properties must lie within layer 4C.

To try to simplify the first stages of modeling, we first considered (Bauer et al., 1999) what might be called basic properties: receptive field size and contrast sensitivity. These properties must be derived by the neurons of layer 4C from input from heavily overlapped thalamic axons synapsing on their surfaces. As was mentioned above, layer 4C can be considered as tripartite in output while only bipartite in input. It would seem very important to determine why this should be and what properties the three outward projections might carry. Physiological measurements of field size and contrast sensitivity are distinctly different in the M and P inputs from the LGN, but in the thalamic input zone of layer 4C, these measures show a continuum of change as cells are recorded sequentially down through the depth of layer 4C, despite the fact that the M and P inputs are segregated into upper and lower halves of the layer, respectively. The answer to how this functional gradient is achieved may lie in the way in which the spiny stellate neurons sample the M and P inputs. As the position of spiny stellate neurons in layer 4C shifts from top to bottom of the layer, the relative degree to which their dendritic fields intrude into M and P termination zones changes. Since the mature synaptic loading of each spiny stellate neuron is a constant, the cells may compute a response characteristic based on the simple weight of M versus P inputs, and their position in depth may be the sole determinant of the ratio of synapses they receive and perhaps the region to which they project.

A connectionist-type neural network model (Bauer et al., 1999) using realistic input properties to a model of layer 4C comprising eight layers in depth demonstrated that the gradient of change in properties could indeed be replicated by using dendritic overlap through the lower two thirds of the 4C layer. However, it was insufficient to explain the continuous and sharply increasing field size and contrast sensitivity observable near the top of the layer. This led us back to consider the anatomy and physiology of the region. There have been reports of very large incoming axons layering along the top half of layer 4C$\alpha$ and that input conduction velocity is at its highest at the top of layer 4C. There is then the possibility that the M input may have two subpopulations of fibers that terminate at different depths in layer 4C$\alpha$. We explored this in our model, giving the inputs properties in the range reported for M LGN cells but giving the largest reported field size and greatest contrast sensitivity to M axons terminating only in the upper half of layer 4C$\alpha$. This resulted in a good replication of the actual physiological data and required only feedforward excitation.

However, there is another feature of the anatomy of upper layer 4C$\alpha$ that could generate the observed increase in field size and contrast sensitivity at that depth. The spiny stellate neurons in upper 4C$\alpha$ make long lateral connections within the layer that might act to pool the properties of the thalamic recipient neurons and lead to the observed change in properties compared to the deeper neurons. However, in modeling the contributions of lateral connectivity providing recurrent excitation (Bauer et al., 1998), inhibition was necessary to stop runaway excitation. In exploring the parameters for inhibition, it became apparent that inhibition must have higher threshold and gain in upper 4C$\alpha$ compared to other depths in the layer to replicate the observed change in properties with depth. Returning to our anatomy, we had much earlier reported that there is a change in inhibitory cell type in upper layer 4C compared to deeper regions (the so-called clutch cell provides somatic inhibition to the spiny stellate cells in the lower two thirds of the layer, and this is replaced in the upper one third by the basket neuron type $\alpha$-6 with long, laterally spreading axon trunks). This anatomical change in the source of inhibition might provide a substrate for a change in the inhibitory properties with depth.

These modeling efforts have greatly helped to crystallize our ideas about the types of anatomical features that are of importance to the issues we have addressed. Further, the modeling has suggested which features are important to address in the next generation of physiological and anatomical studies.

## Anatomical Substrates for Orientation Specificity

In the course of physiological explorations of layer 4C, it became apparent that some cells have clear orientation specificity, even though they may not be as sharply tuned as cells in other layers. It is also apparent that the proportion of cells with preferential response to particular orientations of external visual stimuli rises as the recording position rises toward the pial side of the layer. For those cells without orientation specificity, at all levels in layer 4C but most evident in layer 4C$\beta$, where the majority of cells are not orientation selective, it is clear that with lateral movement of the recording electrode, there is a perfect retinotopic map, interrupted only by the repeat of retinotopy for the segregated interleaved territories of right and left eye inputs. This precise retinotopic mapping in the macaque thalamic input layer appears to argue against Hubel and Wiesel's (1977) model for generation of orientation specificity where direct convergence of thalamic axons arising from spatially offset rows of LGN cells would provide an elongated combined receptive field (though there is some evidence for it in the cat).

Anatomically, the clearest change in structure with depth of primate V1 layer 4C that might accompany the emergence of orientation specificity is the scale and patterning of lateral connections. In the bottom third of layer 4C, lateral connections are very limited in spread; in the middle depth, the spiny stellate cell axons make single sidesteps to terminate in local offset territories; and in the top third of the layer, the excitatory cells make extensive laterally spreading projections with discontinuously distributed stripelike terminal fields. While inhibitory neuron axons are very local in the lower two thirds of the layer, in the upper third, basket neurons provide laterally spreading axons. We have used a computational model (Adorján et al., 1999) to demonstrate that realistic orientation-selective responses can emerge as a result of anisotropic excitatory lateral intracortical projections, with no bias in connectivity of inhibitory connections, even when their spread is limited to the size of one hypercolumn (where both eyes and all orientations are represented for one small region of space). This model study demonstrates that orientation bias and tuning can occur in the same cortical circuits. The model predicts that the first part of the neuron's response will not be orientation specific, since it will be determined by the retinotopic thalamic input, but that orientation specificity appears in the later part of the response as a consequence of the lateral recurrent connections. Recent physiological studies of layer 4C neurons have shown this dual-response characteristic to be a feature of orientation-tuned neurons of that layer. In both model and real life, the orientation tuning is independent of stimulus contrast. The model shows that iso-orientation inhibition is important for controlling runaway excitation, while cross-orientation inhibition, which may be weaker, is involved in obtaining sharply tuned orientation selective cells.

## Anatomical Substrates for Surround Modulation of Visual Responses

It is not only the neurons of upper layer 4C that make extensive lateral connections with discontinuously distributed terminal fields; the same pattern of lateral connections, with stripelike terminal fields, continues into the overlying layer 4B, which receives its main input from upper layer 4C (Asi et al., 1996). Here, orientation specificity, binocularity, and direction specificity, which began in layer 4C$\alpha$, are fully expressed. In layers 2–3, which receives input from midlayer 4C, the patterning of connections changes. Axons of pyramidal neurons make long-range intra-areal lateral connections with regularly spaced clusters of terminals along their length in a polka-dot pattern. All these lateral connections are reciprocal, with retrogradely labeled neurons clustering at the same locations as the orthograde terminals when appropriate tracers are used. Clusters include the blob zones with direct thalamic input.

Regularly patterned lateral connections, usually stripelike or patchlike, are a striking general feature of superficial layer cortical organization in all areas of mammalian cortex. The connections appear to arise from neurons at every point across the cortex, rather than being a single fixed place system, and are biased to link together cells of common function. Using optical imaging, it has been shown that functions of the same kind repeat across the cortex at a center-to-center distance similar to that between adjacent patches when labeled with small injections of anatomical tracer substances, and in macaque V1, correlations between mutual connections and similar functions have been demonstrated directly (Yoshioka et al., 1996).

Since excitatory connections in the superficial layers of primate V1 spread laterally across the representation of the visual field, it has been suggested that they may form a substrate for long-distance interactions across the cortical map. The physiologically recorded response of single neurons to stimuli in the external world can be modulated by surrounding stimuli that do not enter the region of space that forms the neuron's receptive field; that is, the surround stimuli cannot directly drive activity of the neuron. The monosynaptic reciprocal lateral connections might provide a basis for this modulation (see Stetter, Bartsch, and Obermayer, 2000, for a corresponding modeling study). However, as tested by small deposits of extracellularly deposited tracer substances (such as biocytin or cholera toxin), the range of the lateral connections in area V1 made by any small region appears to cover only the territory that contains neurons whose classical receptive fields share some part of the retinotopic cumulative classical visual field map of the group of neurons taking up the tracer; these connections are not broad enough to allow directly for the often much larger extent of the modulatory surround, unless it is by a multisynaptic pathway. If polysynaptic pathways are in use, there must be a set of active interneurons that mediate the signal transmission. This, however, has not yet been observed.

Another route suggested for surround modulation is via reciprocal connections with extrastriate cortex. In our ongoing anatomical studies (Angelucci et al., 1998) examining interrelations between the early visual cortical areas, we find that any small region of V1, as well as making intrinsic connections to neurons sharing any small part of the injection region's neurons' cumulative classical receptive field, also maps that same retinotopic field onto the visual areas surrounding it. In turn, these extrastriate areas make intrinsic connections with similar rules such that lateral connections from a small injected region reach as far as all neurons sharing a portion of the aggregate classical receptive field of the injected region as well as sending back to single points on V1 a representation of that field. The neurons in the extrastriate areas all have larger classical receptive fields than the V1 neurons at the same retinotopic eccentricity, and the feedback could well provide surround modulation of the right scale to V1. Despite the apparently longer route out to these visual association areas, there need be no more synaptic steps than in the reciprocal monosynaptic connections of the V1 intrinsic lateral connection field, since the V1 afferents can engage at least the basal dendritic fields of neurons feeding back to V1. The feedback pathways to V1 are parceled into distinct clusters of terminals superimposed on the retrogradely labeled cells projecting out to that same visual association area. This suggests that an exquisite match in property must exist between the intrinsic connections patterns of V1 and the extrinsic sources of feedback such that the feedback matches precisely those points of most kinship across the V1 cortical sheet.

## Origins of Patterned Anatomical Connections

In our anatomical investigations of these patterned connections across a number of cortical areas in the primate and in the visual cortex of other species, we noted that the size of the clusters of terminals and the intervening uninnervated gaps between them are of equal width. Moreover, this dimension is closely matched to the particular width of the dendritic tree of single pyramidal neurons, making the lattice connections in each area. Since the axons of single basket neurons in the superficial layers of cortex spread three times the diameter of the local pyramidal neuron dendritic fields and contact the cell bodies of the pyramidal neurons, their inhibition will prevent axons of colocalized, coactivated pyramidal neurons from terminating on other pyramidal neurons in the range of the local basket neuron axons (using a Hebbian learning rule). This inhibitory constraint could produce the patchlike connectional fields, even with nonspecific activity patterns. This is particularly important because there is evidence that these connections form in utero in the monkey visual cortex, and indeed the basket neuron axons are visible prenatally. Yet the patterns of connections remain malleable in the early postnatal period and can be shifted in functional allegiance under the influence of afferent drive (e.g., becoming monocular by rearing with alternating monocular input), but the repetitive geometry of the connections remains the same.

# Visual Course Control in Flies

*Alexander Borst and Michael Dickinson*

## Introduction

Motion information plays a prominent role in the visual orientation of many animals. Self-motion displaces retinal images, resulting in an optical flow that depends in a characteristic way on the trajectory described by the animal and the three-dimensional structure of the visual environment. If these are evaluated appropriately, an animal can use different types of motion patterns to initiate and control appropriate behavioral responses. For example, a large-field rotation of the visual world could signal an unintended deviation from its course and initiate a compensatory turn. Just such optomotor reflexes are quite robust in flies and are thought to play an integral role in the animal's autopilot. In contrast, an expansion of a retinal image could signal the imminent approach to an obstacle and initiate a landing or avoidance response. Commensurate with its importance in flight behavior, the fly's nervous system is highly specialized with respect to motor behaviors influenced by visual motion. Since many of the cells that are responsible for motion extraction are large and individually identifiable, the fly is quite amenable to an analysis of sensory processing. Similarly, the small number of muscles and motor neurons used to generate flight maneuvers facilitates studies of motor output. This review provides a summary of recent studies that have begun to elucidate the neural mechanisms underlying the extraction of retinal motion patterns and their transformation into the appropriate motor patterns during flight.

### *The Organization of the Visual Motion Detecting System*

In flies, retinal images are transformed by a cascade of three retinotopically organized layers of nerve cells: the lamina, the medulla, and the lobula complex. The latter is divided into the lobula and the lobula plate, both receiving in parallel input from the medulla. The layers consist of repetitive elements called columns, each column corresponding to one facet in the eye. Owing to their large size and easy access, the neurons within the lamina have been investigated quite extensively. The lamina cells appear to act as high-pass filters of their incoming retinal input and are slightly inhibited by neighboring retinal positions (Laughlin, 1987). Unfortunately, because of their small size, only a few studies have succeeded in recording from the subsequent columnar elements in the medulla and the lobula; however, the results show that at least some of the neurons in these ganglia display a selective sensitivity to moving stimuli (Douglass and Strausfeld, 1995). In contrast, the large size and external position of cells within the lobula plate have made this ganglion the best characterized region of the visual system (Hausen, 1984).

Each lobula plate contains 60 giant tangential cells (LPTCs) that integrate the output signals of presynaptic columnar inputs. The LPTCs connect either to other regions within the brain or via descending interneurons to motor control centers within the thorax. Most of the LPTCs respond to motion in a directionally selective manner and play an important role in extracting different patterns of retinal motion. Owing to their extraordinary structural constancy and invariant physiological properties, the LPTCs can be identified individually from animal to animal. Three major cell families have been studied in particular detail: the CH-cells, the HS-cells and the VS-cells. HS- and VS-cells synapse onto descending neurons and thus represent output elements of the lobula plate. In contrast, CH-cells are involved in internal signal processing within and between the lobula plates of both hemispheres (Haag and Borst, 2001). HS- and CH-cells respond preferentially to horizontal image motion, whereas VS-cells are most sensitive to vertical motion. However, local directional selectivity is not constant throughout the receptive field of the LPTCs. Rather, it changes systematically in a way that matches the optic flow that would be produced by rotation and translation during flight (Krapp and Hengstenberg, 1996). Both HS- and VS-cells typically respond to visual motion with a graded shift of membrane potential and do not appear to generate full-blown action potentials. Nevertheless, they house a variety of different voltage-activated ion channels that serve, in part, to amplify high-frequency components of their synaptic inputs (Haag and Borst, 1996).

### *The Flight Motor and Mechanosensory Input*

The muscles that control wing motion in flies are segregated into two functionally, morphologically, and physiologically distinct groups—the power muscles and the control muscles (for review, see Dickinson and Tu, 1997). Most of the fly's thorax is filled with two antagonistic sets of power muscles that provide the high levels of mechanical energy required for flight. Contractions in the dorsoventral muscles (DVMs) drive the wings up, while contractions in the antagonistic dorsolongitudinal muscles (DLMs) move the wings down. The power muscles are not attached directly to the wing; rather, they transmit their forces via strains within the thorax and a complex lever system within the wing hinge. In addition, contractions of the power muscles are activated by stretch rather than action potentials in presynaptic motor neurons. The entire thorax functions as a complex resonator whereby contractions in the DLMs initiate contractions in the DVMs and vice versa. Stretch activation relieves these high-frequency muscles from the necessity of maintaining an extensive sarcoplasmic reticulum, thereby freeing the space for contractile filaments and mitochondria, while increasing the output of mechanical power. However, the very properties that make the DLMs and DVMs effective in generating power make them unsuitable for controlling the precision changes in wing kinematics required for sophisticated flight maneuvers. This task falls on a set of 17 small control muscles that insert directly onto the sclerites of the wing hinge. Unlike the power muscles, the control muscles possess extensive sarcoplasmic reticulum and contract in response to motor neuron spikes in the conventional one-to-one fashion. The motor neurons innervating the control muscles possess large-diameter axons and extensive terminal arborizations within their targets. These characteristics are consistent with a design for rapid, neurally controlled reconfigurations of the wing hinge. With one exception, the control muscles are innervated by a single motor neuron each. Thus, understanding the motor control of flight behavior in flies reduces, in large part, to an understanding of how the nervous system regulates the firing activity of a very small population of cells.

In contrast to the motor neurons of the power muscles, the control muscle motor neurons tend to fire within specific phase bands within the stroke cycle. Important sources of the phasic input to the control muscles include a variety of mechanoreceptors at the base of the wing and haltere (Fayyazuddin and Dickinson, 1996). In flies the halteres are tiny club-shaped organs that are evolutionarily derived from hind wings. They beat in antiphase to the wings during flight and act as gyroscopes to detect angular rotations of the body during flight (Nalbach, 1993). Because they are essential organs for flight control, ablation of the halteres renders a fly catastrophically unstable. Dense fields of mechanosensory cells at the base of the haltere encode both the up and down motions as well as Coriolis force–induced deflections that act on the haltere as the body rotates during flight.

## Mechanisms for Computation of Visual Motion

The only information available to the visual system comes from the temporal and spatial variations in brightness values of the retinal images sensed by the photoreceptors. A single photoreceptor, however, cannot detect motion. To do so, the fly's nervous system must process the signals from at least two spatially displaced photoreceptors in an appropriate way. Many years ago, Reichardt and colleagues formulated the "correlation" model to explain motion

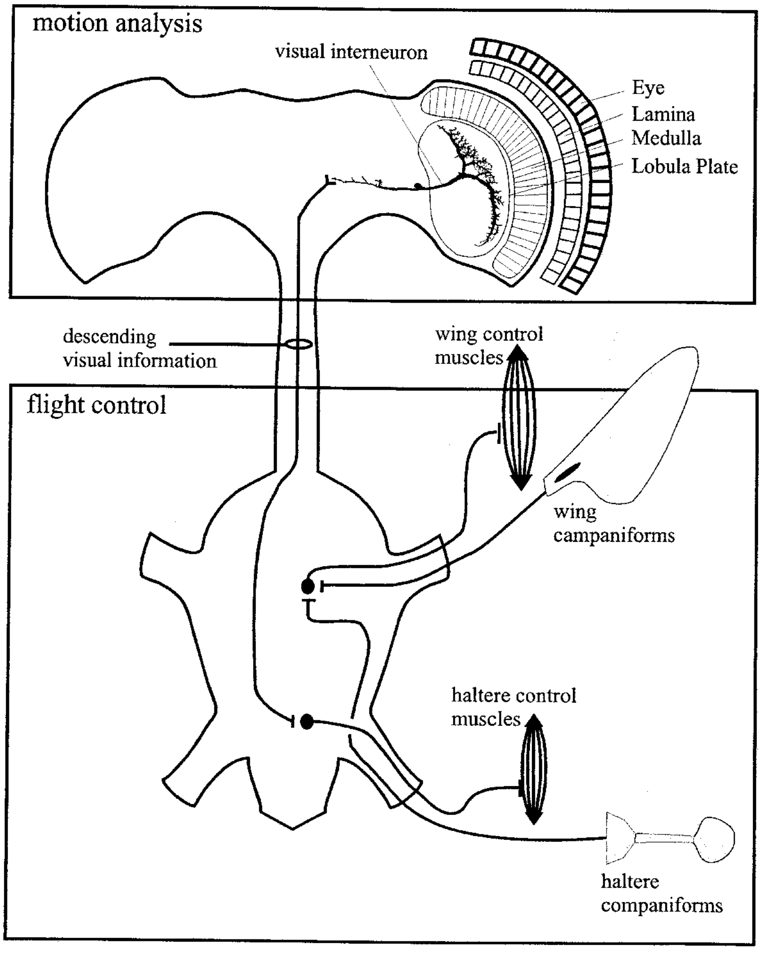

**Figure 1.** Schematic representation of the fly nervous system with the brain containing the visual ganglia (*top*) and the thoracic ganglion containing the motor control centers (*bottom*). One of the large motion-sensitive tangential cells is shown to contact a descending neuron which runs through the cervical connective. In the thorax, such descending neurons are thought to contact motor neurons controlling the wings and halteres. Haltere mechanosensory sensillae synapse on wing control muscles, thus providing a means by which visual information can directly influence mechanosensory feedback to steering muscles.

detection in the insect visual system (Reichardt, 1961). The original model, based solely on behavioral analysis, posits the existence of two mirror-symmetrical subunits, the outputs of which are subtracted from one another. Each subunit has two input channels that are multiplied after one of the signals has been delayed. Motion measurement comparable to the fly's would require two arrays of such elementary detectors, each encoding a different direction. Output signals suitable for orchestrating motor commands are generated by spatially integrating appropriately tuned movement detectors across the visual field. Unlike a speedometer, the output of a correlation detector is not proportional to image velocity throughout its dynamic range. Rather, a correlation detector has an optimal velocity at which it responds most strongly, and this optimal velocity is a function of the delay unit's time constant. In addition, its response depends on properties of the stimulus pattern such as its spatial frequency and contrast.

Since it was first proposed, Reichardt's model has been subjected to much experimental scrutiny. The first processing step consists of a nonlinear interaction between the neighboring photoreceptor inputs. In the original model, this interaction was realized mathematically as a multiplication of the two adjacent channels. A characteristic of multiplication is its sign rule: signals with the same polarity, either positive or negative, yield positive outputs, whereas input signals of opposite polarity always lead to negative output. This prediction has been tested experimentally in the blowfly using extracellular recordings from the spiking H1-cell. Flies were stimulated with step changes in luminance values in two adjacent parts of the receptive field, an experimental paradigm that creates apparent motion. The apparent motion stimulus elicited a depolarizing response in the H1-cell only when luminance changes had the same sign, i.e., both turning dark or both turning bright. In the other two possible cases, the response of the H1-cell was negative (Egelhaaf and Borst, 1992). These results are taken as confirmation that the first stage of motion detection does indeed involve a functional multiplication, although the underlying physiological mechanisms responsible for this arithmetic operation are not yet known.

Additional experiments support the second step in the Reichardt model, subtraction of adjacent channels. In this case the underlying biophysical mechanisms are better understood. In vitro pharmacological studies indicate that excitatory inputs to LPTCs are mediated by nicotinic acetylcholine receptors, while inhibitory inputs are mediated by GABA (Brotz and Borst, 1996). Blocking GABA receptors with picrotoxin leads to a strong reduction of direction selectivity in postsynaptic LPTCs. In particular, responses to motion in the preferred direction increase, while responses to motion in the null direction reverse sign (Single, Haag, and Borst, 1997). In addition, the motion-induced change of input resistance before and after picrotoxin indicates that picrotoxin application decreases the number of postsynaptic channels that open in response to visual motion, both in the preferred and the null direction. Together, these results suggest that the directional sensitivity of cells providing input to the LPTCs is not particularly strong. Thus, these input cells are activated not only by their preferred direction, but also, though to a smaller extent, by motion in the opposite direction. This antagonistic influence of adjacent inputs with opposite preferred direction appears to sharpen the directional response of the postsynaptic LPTCs.

The final processing step consists of the spatial integration of the local motion signals (Figure 2). As with the subtraction stage, this process takes place in the large dendrites of the LPTCs. Spatial integration appears to serve two quite distinct functions. First, if the optimal flow field required to elicit certain behavioral outputs has different motion vectors in different parts of the visual field, spatial integration must occur over appropriately oriented local motion detectors (Krapp and Hengstenberg, 1996). Second, even if the motion vectors have the same orientation, spatial integration is still necessary to yield reliable motion measurements because the local signals are corrupted by modulations reflecting variation in local luminance. Such local modulations could indeed be measured in the dendritic tips of LPTCs by optical recordings of cytosolic calcium (Single and Borst, 1998).

## Integrating Visual and Mechanosensory Inputs to Tune Motor Output

In order to perform complex flight maneuvers, flies must integrate visual and mechanosensory information. This integration is difficult because these two modalities operate on different time scales. Although the visual system of flies displays a temporal resolution that is unmatched in other animals, it is still sluggish compared to that of the mechanosensory neurons. For visual information to drive steering motor neurons at mechanically phases of the stroke

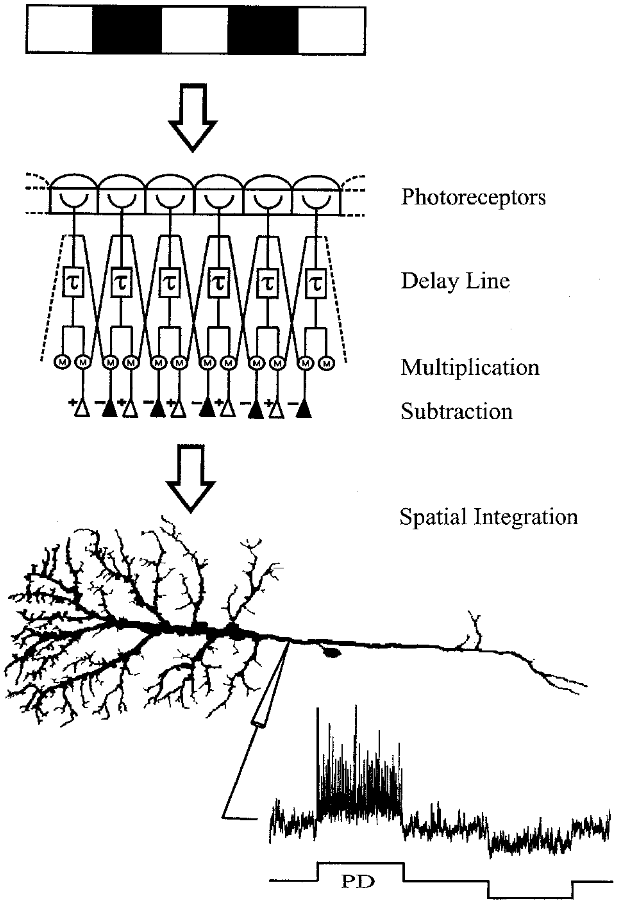

**Figure 2.** In the first step of motion analysis, motion in different parts of the visual field is computed in parallel by two-dimensional arrays of local movement detectors. A vertically striped pattern moving in the horizontal axis is shown at the top. A one-dimensional array of motion detectors, consisting of two different types, is displayed: One type, tuned to detect rightward motion, makes excitatory synapses onto the dendrite of an HS cell; the other, tuned to the opposite direction of motion, makes inhibitory synapses. In its simplest form, each motion detector measures the light intensities at two points in space. The detector input signals are multiplied by each other after one has been delayed by some sort of temporal filter. Subtraction of opponent signals and spatial integration occurs within the dendrite of the HS cell. Its directional selective response to motion in the preferred (PD) and null direction (ND) is shown at the bottom.

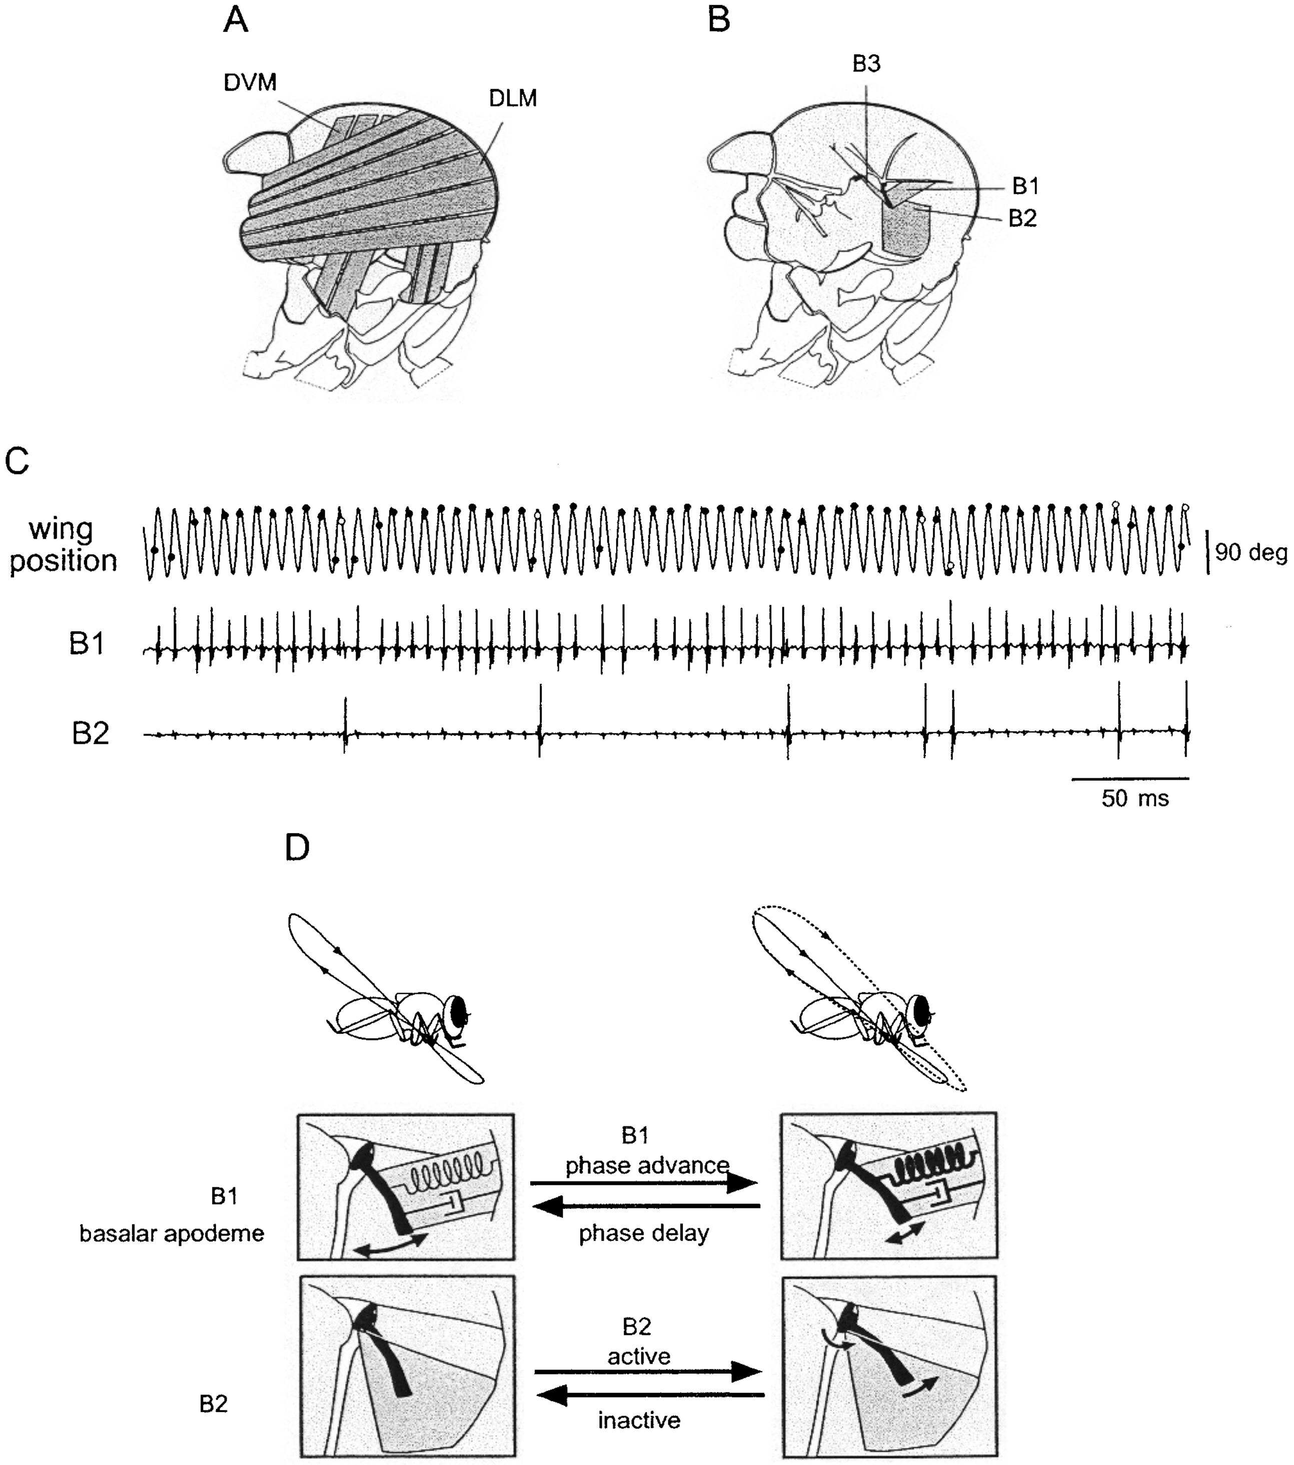

**Figure 3.** Current model for how two of the steering muscles (B1 and B2) influence wing stroke kinematics. *A*, Most of the thorax is filled with the large indirect asynchronous power muscles (DVMs and DLMs), which provide the mechanical power for flight. *B*, The position of the basalare steering muscles (B1, B2, and B3). The wing hinge contains about a dozen other control muscles, which are not shown. *C*, The firing patterns of B1 and B2 during sequence of tethered flight. The top trace shows the angular motion of the wing within the stroke plane superimposed with the firing times of B1 (solid circles) and B2 (open circles). Note the occasional phase advances of B1, which are often correlated with the presence of B2 spikes. *D*, During flight the basalar apodeme is oscillated back and forth through the action of the other flight muscles. Phase advances in the activation of B1 increase its dynamic stiffness. The increased stiffness damps the oscillation of the adodeme and pulls it forward, resulting in an increase in stroke amplitude and a rostral trajectory during the downstroke. Through its insertion on the head of the basalare, single spikes in B2 can similarly affect phase advances in B1.

cycle, it must be gated by wing beat synchronous feedback. As described below, recent experiments offer a glimpse into the mechanisms by which this integration occurs.

The importance of firing phase in the function of the steering muscles is illustrated by studies on the large basalar muscles, B1 and B2 (Figure 3; for review, see Dickinson and Tu, 1997). The basalare is a nail-shaped sclerite just anterior to the wing that acts like a clutch to reconfigure the wing hinge. Tonic firing of B1 pulls the basalar apodeme anteriorly, causing a gross configurational change in the wing hinge that greatly increases wing stroke amplitude. More subtle alterations in stroke kinematics, however, are associated with changes in firing phase. In the absence of visual input, B1 fires near the upstroke-to-downstroke transition. In response to visual motion toward the contralateral side, the muscle fires 1 to 2 ms earlier in the stroke cycle. As the phase of B1 advances, stroke amplitude increases further and the wing follows a more anterior trajectory during the downstroke. During visually induced turns, B2 is typically recruited within tonic bursts of B1 activity. Single spikes in B2 evoke large transient increases in stroke amplitude, and may underlie the rapid body saccades that some flies display in free flight. Like B1, the magnitude of B2's effect on stroke kinematics depends on the phase at which it is activated within the stroke cycle. Simply by adjusting the activation of the B1 and B2 muscles and the phase at which they fire, the fly can achieve quite complex control over stroke kinematics.

The results discussed above suggest that activation phase is an important control parameter in the flight system of flies. In the case of a tonically active B1, phase is the only variable with which the nervous system can modulate the mechanical properties of the muscle (Dickinson and Tu, 1997). When oscillated and stimulated at 150 Hz, the normal wing beat frequency of *Calliphora*, B1 does not generate positive work, but rather absorbs mechanical energy from the other muscles within the flight system. However, the work required to extend the muscle (i.e., the dynamic stiffness) varies as a function of activation phase. Thus, the flight control system can use B1 as an active spring by varying the firing phase on a cycle-by-cycle basis. From a neural perspective, the important feature of the B1 is that these biomechanical effects are controlled by precise changes in firing phase and not by firing frequency per se.

Visual motion influences stroke kinematics in two ways: by recruiting appropriate steering motor neurons and by adjusting their firing phase. In both cases, the visual input must incorporate mechanosensory feedback in some way, because the visual system does not encode wing motion and thus could not tune muscles to fire at mechanically appropriate phases of the stroke cycle. One mechanism that could explain this fusion of mechanosensory and visual channels signals is the possibility that the two modalities converge directly, either on steering motor neurons or on their premotor interneurons. In this scheme, the wing and haltere would provide phasic synaptic drive to steering motor neurons, but tonic visual input would determine whether or not the motor neurons reach threshold in any given stroke. Such simple convergence could explain how visual motion could recruit steering motor neurons to fire in phase-locked patterns. Although no clear electrophysiological evidence for such direct convergence is currently available, such negative evidence must be viewed with caution, as the appropriate connections might be physiologically gated and thus difficult to identify in the dissected preparations.

A second model of multimodal convergence is that descending visual interneurons alter firing phase and recruitment of steering motor neurons indirectly through their influence on efferent pathways controlling mechanosensory afferents. Like the wing, the haltere is equipped with a set of tiny control muscles that insert upon sclerites at its base. Motor neurons of at least two of these muscles receive input from motion-selective descending visual interneurons (Chan, Prete, and Dickinson, 1998) (Figure 4). It is not yet known what effects these steering muscles have on haltere kinematics, but one possibility is that they might influence the recruitment or firing phase of haltere mechanosensory neurons. These afferents could then relay these temporal changes to wing muscles via their strong connections with steering motor neurons, providing a means by which the visual system could manipulate mechanosensory equilibrium reflexes to cause temporally precise changes in motor output.

In addition to the haltere system, visual input may reverberate through several other sensory motor reflexes en route to the wing steering muscles. For example, descending visual interneurons provide input to muscles that control head position, while mechanoreceptors that encode head motion project to motor neurons of the wing and haltere. Changes in wing motion may alter the firing of wing mechanoreceptors, which themselves project to muscles of the neck, wings, and halteres. Far from a simple reflex arch, descending input from the targets of LPTCs thus might reverberate through this web of overlapping mechanosensory reflexes, integrating essential phasic mechanosensory information with visually controlled motor commands.

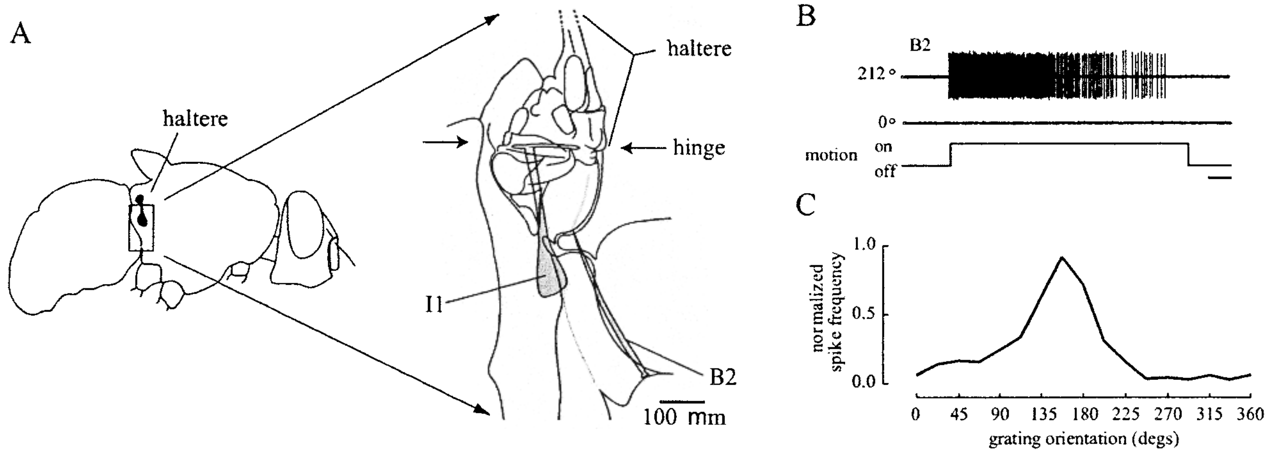

**Figure 4.** Control muscles of the haltere receive directionally sensitive input from visual interneurons. *A*, Cartoon indicating the position of the haltere and the location of two of its control muscles (I1 and B2). *B*, The motor neuron of the haltere B2 muscle is excited by downward visual motion (212°), but not by upward motion (0°). *C*, Directional tuning curve for the haltere B2 muscle. This tuning is similar to that of lobula plate VS cells.

## Conclusions

We have reviewed here our current understanding of visual course control in flies, from the changing retinal images on the fly's eyes all through the nervous system onto the control muscles of the wings. The emerging picture suggests that visual information is first processed in the visual ganglia in order to extract reliable motion information, then sent down to the thoracic ganglion for subsequent integration with mechanosensory inputs. Current research focuses on the physiological implementation of the various processing steps involved in the computation of motion information as well as its translation into precisely timed motor commands that match the biophysics of the effectors.

# Visual Scene Perception, Neurophysiology

*Edmund T. Rolls and Michael A. Arbib*

## Introduction

The task of vision is often reduced to the task of recognizing objects, but two further tasks are crucial: (1) finding the spatial disposition of objects and (2) observing features of relevance to planning our actions in the world (consider avoiding collisions when walking down a busy street). *Visual scene perception* includes visual perception of the spatial layout of objects, with properties and relationships relevant to behavior. The article Feature Analysis explores the idea that natural images can be decomposed into *objects* composed of *features* and that visual perception can thus benefit from seeing which, among all possible visual features, best reflect the statistics of natural scenes. Object Structure, Visual Processing then suggests how objects may be recognized from approximate spatial relations between fragments. Nonetheless, remarkably little recent modeling or neurophysiology has been done on raising the level from feature, fragment, and object up to scenes. This article, then, is designed to stimulate further work on visual scene perception by juxtaposing two approaches: using as a basis for action a (rather old) theoretical framework for recognizing the layout of objects in a scene and recent neurophysiology suggesting how the context of a natural scene may modify the response properties of neurons responsive to visual features.

## What, Where, and How

The vertebrate midbrain can exhibit subtle patterns of visual scene analysis; cortical mechanisms can enrich these basic capabilities. For example, the brain of a frog has basic pattern recognition routines (*perceptual schemas*; see Schema Theory) for recognizing small moving objects (prey schema) and large moving objects (predator schema). When activated, these will in turn trigger the motor schema (a control system producing action) for approach or escape, respectively. These basic perceptual schemas in the frog may be localized in the interactions of the tectum and pretectum of the midbrain, while the motor schemas rest on tectum-brainstem interactions driving motor pattern generators in the brainstem for jaw and tongue movements and in the spinal cord for limb movements. Moreover, perceptual schemas provide a parametric description that can be used to tune and calibrate behavior. Recognizing prey, the frog turns and snaps to where the prey is located; similarly, the frog will tend to jump out of the path of the predator. In addition, the frog's behavior can depend on the layout of objects in a scene. If a barrier is present, the frog may detour around it to get to prey or bias its escape from a predator to avoid bumping into the barrier. In short, multiple schemas may be coactivated to control appropriate spatially directed behaviors (Arbib and Liaw, 1995).

The role of tectum in directing whole-body movements in the frog is analogous to that of superior colliculus in directing orienting movements in mammals (see Collicular Visuomotor Transformations for Gaze Control). Moreover, a monkey (or human) without visual cortex appears blind. Humphrey (1970) argued, however, that a monkey without visual cortex should have at least as much visual ability as a frog but that such monkeys had not learned to pay attention to available visual cues. To demonstrate this, he gave two years of attention training to a monkey from which primary visual cortex had been removed. Eventually, the monkey was able to use visual cues to navigate and to grab at moving objects, but no subtlety of pattern recognition was regained. Moreover, it was discovered that humans without primary visual cortex could also "see" in this sense: They could point accurately toward small lights even though they were not aware of seeing the stimuli to which they pointed (they have *blindsight*).

Thus, midbrain visual mechanisms can determine the spatial layout relevant to basic behaviors. Our concern now is with the "added value" provided by cortex. Ungerleider and Mishkin (1982) noted that monkeys with lesions of inferotemporal cortex (IT) were profoundly impaired in visual pattern discrimination but less impaired in solving spatial tasks; the opposite results were observed in monkeys with lesions to posterior parietal cortex (PP). They thus distinguished two cortical systems in primate visual processing: a ventral "what" stream projecting from primary visual cortex, V1, to IT and a dorsal "where" stream projecting from V1 to PP. A variety of data on humans led Goodale and Milner (1992) to suggest that the dorsal system is better seen as a "how" system comprising a number of sensorimotor networks for different actions (including the "where" of object location relevant to a specific task). The "what" and "how" streams usually work together in producing useful actions, with the ventral stream serving for object identification as a precursor to planning, whereas the dorsal stream provides precise motor parameters (see Dissociations Between Visual Processing Modes). Indeed, it may have been the utility of object identification invariantly with respect to the size, position, and view of the object on the retina in identifying goals for action that provided the prime pressure for evolution of the ventral ("what") system.

## Visual Scene Perception Based on Schemas

The VISIONS system (Draper et al., 1989) is a computer vision system for recognizing outdoor visual scenes. Low-level processes take an image and extract an *intermediate representation*—an updatable set of partial representations including regions, lines, surfaces, and vertices, tagged with features such as color, texture, shape, size, and location. Perceptual schemas process different features of the intermediate representation to form confidence values for the presence of objects like houses, walls, and trees. The knowledge required for interpretation is stored in long-term memory (LTM) as a network of schemas, while the state of interpretation of the particular scene unfolds in short-term (STM) or working memory as a network of schema instances (Figure 1). The notion of STM here descends from Didday and Arbib's (1971) slide box metaphor, in which an array of "slides" were placed in retinotopic correspondence with the visual input, each slide providing data related to a given class of objects, both for object recognition and for object-related actions. This anticipates the notion of visuospatial scratchpad presented below.

When a schema instance is activated, it is linked with an associated area of the image and an associated set of local variables. Each schema instance in STM has an associated confidence level which changes on the basis of interactions with other units in STM. The STM network makes context explicit: each object represents a context for further processing. For example, activation of an instance of the roof schema might invoke an instance of the wall schema to check the region beneath the one to which it is linked in the image. If both schema instances achieve a high enough confidence level, they could jointly activate an instance of the house schema.

Miikkulainen and Leow (1995) describe VISOR, a simple schema-based neural network vision system. It has three main modules. The low-level visual module focuses attention on one component of an object at a time, extracts its shape (what) and relative position (where), and sends this information to the schema module. The schema that best matches the input suggests shifting attention to a location where another component of the object it represents is expected. The low-level visual module then shifts attention to

**Figure 1.** The VISIONS paradigm for cooperative computation in visual scene analysis. Interpretation strategies are stored in schemas that are linked in a schema network in long-term memory (LTM). Under the guidance of these schemas, the intermediate representation is modified and interpreted by a network of schema instances that label regions of the image and link them to a 3D geometry in short-term memory (STM). (From Weymouth, 1986.)

the new position, and the process repeats until VISOR has looked at all the components in the scene. Turning this model into a psychophysical model would require an attempt to analyze the tradeoff between the role of different saccadic scanpaths in answering questions about a scene and evidence that much information can be extracted in a single fixation (see Fast Visual Processing). Note that an object itself can be viewed as a small scene (see Object Structure, Visual Processing), showing that although PP may be custodian of spatial relations between distinct objects in the large, IT must track, but probably with metric imprecision, the spatial relations of fragments that constitute a familiar object or overlearned scene.

## Operation of the Temporal Cortical Visual Areas in Natural Scenes

We now turn toward a neurophysiological approach to how the visual system operates in complex natural scenes and to models at the neuronal network (rather than schema) level. IT contains a representation of objects and faces that has considerable invariance with respect to size, position, and even, for some neurons, view. The neural code (1) is sparse and distributed, with each neuron showing high firing rates to a few stimuli, the rates produced by other stimuli tailing off approximately exponentially; (2) can be read in a short time window from the spike counts of a population of neurons; and (3) has very high capacity in terms of the number of stimuli that can be represented (Rolls, 2000; Rolls and Deco, 2002—henceforth *R&D*).

Until recently, research on translation invariance considered the case in which there is only one object in the visual field. What happens in a cluttered, natural, environment? Rolls, Aggelopoulos, and Zheng (see *R&D*) analyzed the responses of IT neurons to stimuli presented in complex natural backgrounds in which the monkey had to search for one of two objects on a screen. It was found that the response magnitude and selectivity were little affected in natural scenes but that the receptive field sizes of the neurons typically became much smaller in the real scene. It is proposed that this reduced translation invariance in natural scenes helps an unambiguous representation of an object that may be the target for action to be passed to the brain regions that receive input from primate IT. It helps with the *binding problem* (linking distributed patterns of neural firing that together encode one object rather than another) by reducing in natural scenes the effective receptive field of at least some IT neurons to approximately the size of an object in the scene.

It is also found that in natural scenes, the effect of object-based attention on the response properties of IT neurons is relatively small (see *R&D*). Whereas the receptive fields were larger (51° versus 24°) for the attended object versus the nonattended stimulus with a blank background, when tested in a complex background the receptive field sizes were 26.6° (for the attended object) versus 22.8°. Trappenberg, Rolls, and Stringer (2002, see *R&D*) produced a model for this with an attractor network representing IT and a neural input layer with several retinotopically organized modules representing the visual scene in an earlier visual cortical area such as V4. The network has large receptive fields in blank scenes because a weak input in the periphery of the visual field can act as a retrieval cue for the object attractor. On the other hand, in a complex background, the object closest to the fovea acts as the retrieval cue, because the fovea is given increased weight due to the higher magnification factor of the fovea. This results in smaller receptive fields of IT neurons in complex scenes.

Attentional top-down object-based inputs can bias the competition implemented in this attractor model but have relatively minor effects (for example, in increasing receptive field size) when they are applied in a complex natural scene, as then the necessarily stronger forward inputs dominate the states reached. The results of the investigation thus suggest that object-based attention may be a much more limited phenomenon in complex, natural, scenes than in reduced displays with one or two objects present. The results also suggest that providing strong weight to whatever is close to the fovea is an important principle governing the operation of IT. This principle of operation is important in interfacing the visual system to action systems, because the effective stimulus in making IT neurons fire is in natural scenes usually on or close to the fovea. This means that the spatial coordinates of where the object is in the scene do not have to be represented in IT, nor passed from it to the action selection system, as the latter can assume that the object making IT neurons fire is close to the fovea.

## Invariant Visual Object Recognition

Such neurophysiological findings lead to the hypothesis that cortical visual processing for object (including face) recognition is organized as a set of hierarchically connected cortical regions (Figure 2; this also appears as Figure 1 in Object Recognition, Neurophysiology). There is convergence from each small part of a region to the succeeding region (or layer or stage in the hierarchy) in such a way that the receptive field sizes of neurons (e.g., 0.5° to 1° near the fovea in V1) become larger by a factor of approximately 2.5 with each succeeding stage. This connectivity would be part of the architecture by which translation-invariant representations are computed. Each stage in the hierarchy is considered to act partly as a set of local self-organizing competitive neuronal networks with overlapping inputs. Increasing complexity of representations could also be built in such a multiple-layer hierarchy by similar competitive learning mechanisms. To avoid a combinatorial explosion, low-order combinations of inputs would be learned by each neuron. (See Object Recognition for further data and models on invariant object recognition.)

Although hierarchical processing schemes have been investigated before (see Neocognitron: A Model for Visual Pattern Recognition), Rolls (1992, see *R&D*) suggested that translation, size, and view invariance could be computed in such a system by utilizing competitive learning that operates across short time scales to detect regularities in inputs when real objects are transforming in the physical world. The idea is that because objects have continuous properties in space and time in the world, an object at one place on the retina might activate feature analyzers at the next stage of cortical processing, and when the object is translated to a nearby position, because this would occur in a short period (e.g., 0.5 s), the membrane of the postsynaptic neuron would still be in its associatively modifiable state, and the presynaptic afferents activated with the object in its new position would thus become strengthened on the still-activated postsynaptic neuron.

The VisNet model was developed to test and clarify these hypotheses. The network can perform object (including face) recognition in a biologically plausible way and after training shows, for example, translation and view invariance. The network can identify objects shown in a cluttered environment (for example, a natural scene) and can identify partially occluded objects. Elliffe, Rolls, and Stringer (2002, see *R&D*) showed how, by forming high spatial precision feature combination neurons early in processing, it is possible for later layers to maintain high precision for the relative spatial position of features within an object yet achieve invariance for the spatial position of the whole object.

To incorporate top-down processing effects such as attention, associatively modifiable backprojections (*not* backpropagation!) have recently been introduced into the model. They enable the VisNet architecture to show in addition the biased competition effects that characterize attentional modulation of processing in sensory systems. By introducing into the model a dorsal visual stream

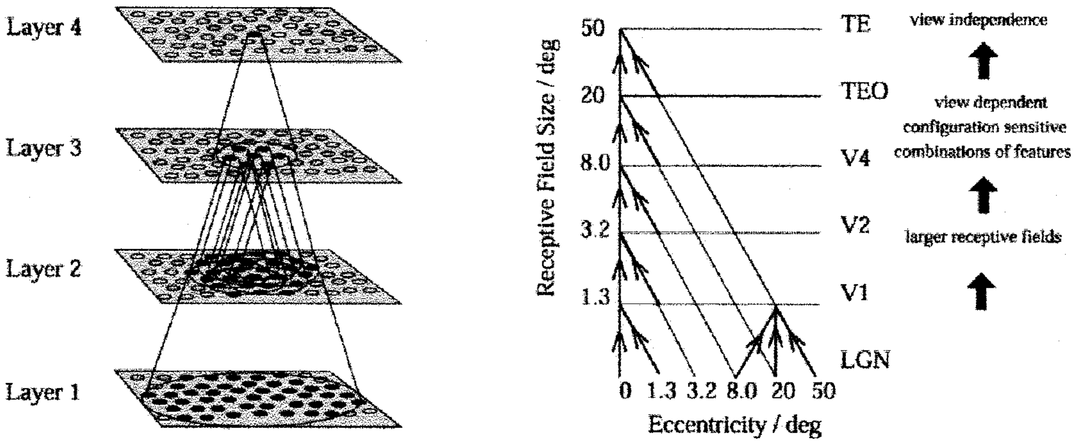

**Figure 2.** *Right*, Schematic diagram showing convergence achieved by the forward projections in the visual system, and the types of representation that may be built by competitive networks operating at each stage of the system from the primary visual cortex (V1) to the inferior temporal visual cortex (area TE) (see text). LGN = lateral geniculate nucleus. Area TEO forms the posterior inferior temporal cortex. The receptive fields in the inferior temporal visual cortex (e.g., in the TE areas) cross the vertical midline (not shown). *Left*, As implemented in VisNet, Rolls's hierarchical model of invariant visual object recognition (see *R&D*).

module (parietal cortex) that can interact with the ventral stream modules through the topologically mapped V1 and V2 modules, it is possible in a full dynamical model implemented with mean field equations to account quantitatively for many aspects of object search and spatial search in complex scenes.

## The Visuospatial Scratchpad and Change Blindness

Given the fact that the responses of IT neurons are quite locked to the stimulus being foveated, it is unlikely that IT provides the representation of the visual world that we think we see, with objects at their correct places in a visual scene. In fact, we do not really see the whole visual scene, as most of it is a memory reflecting what was seen when the eyes were last looking at a particular part of the scene. The evidence for this statement comes from change blindness experiments, which show that humans rather remarkably do not notice if, while they are moving their eyes and cannot respond to changes in the visual scene, a part of the scene changes (Rensink, 2000). Given then that much of the apparent richness of our visual world is actually based on what was seen at previously fixated positions in the scene (this being what IT represents), we may ask where this "visuospatial scratchpad"—another name for the short-term spatial scene memory modeled in terms of schema instances in the VISIONS system—is located in the brain. One possibility is in the right parieto-occipital area, since patients with lesions in this region have (dorsal) *simultanagnosia*, in which they can recognize objects but cannot see more than one object at a time (Farah, 1990).

The neural basis of this is not yet known, but Rolls has suggested that it might consist of a number of separate—that is, local—attractors, each representing part of the space and capable of being loaded by inputs from the IT (see *R&D*). The attractors would be local because they are implemented by the predominantly short-range associatively modifiable excitatory collaterals between cortical pyramidal cells (see Rolls and Treves, 1998, chap. 10). Each attractor network in the visuospatial scratchpad memory would be addressed by information based on the position of the eyes, of covert attention, and probably of the head (see Figure 3). Every module receives the same inputs that represent objects (O) and shapes from the inferior temporal visual cortex and a different position (P) input representing the current place in the environment, probably in egocentric visual field-of-view coordinates and based on the current eye position, covert attention, and perhaps head direction. The network state is cued into a new attractor, which represents the currently foveated object in a scene as indicated by the IT neurons that are firing, when it receives a position input that corresponds to the location of that attractor in the map of the visual scene. The position input must be sufficiently strong that when it is applied to a particular module in combination with the IT input, it forces the attractor to go from a state in which the recurrent collaterals dominate the activity in a stable memory mode to the new state represented by the IT input (see Renart et al., 2001; *R&D*, chap. 12). Each attractor network would be capable of holding active in its short-term memory one of something in the order of 10,000 objects stored in the recurrent collaterals (given the large number of recurrent collaterals on each neuron and the storage capacity equation of attractors storing sparse patterns; see *R&D*).

This schematic architecture would enable the objects present at different locations in a viewed spatial scene to be maintained in a set of spatially separate attractors. Information could be read out from the system from a point in space not currently being foveated by moving a weak, covert, attentional position (P) input to increase the gain in a particular module so that the firing of that module dominates a network receiving from all the attractor modules. If idiothetic (self-motion) inputs reflecting, for example, head direction need to be postulated to dynamically update the position of the object information in the different attractors, then this might be performed in the ways described by Stringer et al. (2002) for performing path integration in spatial continuous attractor neural networks (see also Rodent Head Direction System and Dynamic Remapping).

## Scene Perception and the Emergence of Planning

Moving beyond visual STM for objects in retinotopic location, note that in action-oriented perception, current sensory stimulation is always interpreted within the ongoing state of the organism; the representation is dynamic and task oriented, linking instances of perceptual schemas to motor schemas, providing parameters, and changing confidence levels. As their activity levels reach threshold, certain motor schemas create patterns of overt behavior. To see this, consider a driver instructed to "turn right at the red barn." At

p

**Figure 3.** Schematic diagram of a set of attractor networks that it is hypothesized might implement a visuospatial scratchpad in the brain (see text). Each attractor network receives the same input from the IT that represents the object (O) that is being foveated. Each network also receives a position (P) input that enables the attractor currently active in the network to be replaced with a new attractor corresponding to the object at the fovea. The number of attractor networks in the diagram is for illustration only.

first, the person drives along looking for something large and red, after which the perceptual schema for barns is brought to bear. Once a barn is identified, the emphasis shifts to recognition of spatial relations appropriate to executing a right turn "at" the barn but determined rather by the placement of the roadway, and so on. All this is "planning" in a flexible representation strongly conditioned by current goals.

Arbib and Liaw (1995) therefore suggested extending VISIONS by the inclusion of motor as well as perceptual schemas and the dynamic interaction of working memory with changing sensory input. The data reviewed above suggest that activity in IT accentuates perceptual schemas for the current focus of attention. In this case, only a few intermediate schemas may be active, with STM being updated as new results come in from this focal processing. This leads us to reverse the view of activity/passivity of schemas and instances in the VISIONS system. There, the schema in LTM is the passive code for processes (the program for deciding whether a region is a roof, for example), while the schema instance is an active copy of that process (the execution of that program to test a particular region for "roofness"). By contrast, it may be that in the brain, the active circuitry is the *schema*, so that only one or a few instances can apply data-driven updating at a time. This is somewhat reminiscent of the visuospatial scratchpad described above, which stores an object code at each location, while IT processing determines the appropriate schema for the foveal region. However, a possible weakness of that model, demanding further research, is that it requires the IT code for each object to be learned by the attractor network at each position of the scratchpad, rather than dynamically binding, let us say, IT and PP representations of the object to its current location (see DYNAMIC LINK ARCHITECTURE), which would obviate having to repeatedly determine action-relevant properties of the object as it moves. In any case, the post-VISIONS architecture integrates the "what" system (IT) and the various "how" systems (PP) (see, e.g., GRASPING MOVEMENTS: VISUOMOTOR TRANSFORMATIONS) as follows:

1. In a complex situation, we must recognize which object it is appropriate to interact with, and for what purpose, before the "how" system (PP) can generate appropriate motor parameters. If, then, object recognition is mediated by the ventral system, the question of how to act must be mediated through information from the ventral stream influencing the dorsal stream. For example, if one sees two plums on a plate, the dorsal stream can guide arm and hand in picking up one of the plums, but it may be the task of the ventral stream (and its links to orbitofrontal cortex) to recognize which plum is the riper and thus help to determine the "focus of attention" of the dorsal system.

2. We postulate that PP can be influenced by STM information about goals, etc., maintained in prefrontal cortex. Action is often determined by goals and prior input as much as, if not more than, by current sensory input. Indeed, Fuster (see CORTICAL MEMORY) has reviewed the role of the prefrontal cortex in processes that elaborate, store, and—during the course of behavior—update a plan of action. We hypothesize that at each stage of action, prefrontal cortex, through its extensive system of reciprocal interconnections with parietal cortex, "focuses the attention" of the dorsal stream so that it may elaborate visually based parameters for action. (This raises a question for further research: Is the "visuospatial scratchpad" in the right parieto-occipital area as suggested earlier, or is it part of a larger prefrontal system?) Again, through these reciprocal connections, parietal cortex can apprise the prefrontal system of the progress of motor execution as controlled by premotor cortex, as well as reporting any obstacles to execution of the current plan. This allows the prefrontal system to update the plan, through a mixture of off-line and reactive planning, as the task unfolds.

## Discussion

We have sought to show the promise for both theory and experiment of broadening the study of object recognition to encompass visual scene perception. The slide box metaphor, STM in the VISIONS system, and the visuospatial scratchpad provide three perspectives for creating a theory of how the visual perception of objects may be integrated with the perception of spatial layout. The first two stress a schema-theoretic approach, while the latter is strongly tied to visual neurophysiology and modeling in terms of quasi-neural attractor networks. In particular, we have seen that neurophysiological findings made on visual stimuli presented in isolation fail to illuminate crucial aspects of the neural processing of the view of objects embedded in natural scenes. By sandwiching our discussion of neurophysiology between a discussion the "what" and "how" systems and a prospectus for extending the VISIONS methodology to model the dynamic role of vision in the control of action, we have opened the way to future research that will embed the study of visual scene perception in an action-oriented integration of inferotemporal and parietal visual systems.

# Visual Scene Segmentation

*DeLiang Wang*

## Introduction

Visual scene analysis, a remarkable achievement of the visual system, involves two basic perceptual processes: segmentation of a visual scene into a set of coherent patterns (objects) and recognition of memorized patterns. In this article, I focus on scene segmentation, which is closely related to figure-ground segregation, whereby one object is segmented from the rest of the scene (background), and perceptual organization.

Humans perform scene segmentation with apparent ease. However, the study of automatic scene segmentation remains a challenging problem, despite dozens of years of intensive research in computer vision and image processing, where *image segmentation* is the commonly used term.

In a natural scene, objects appear as the grouping of similar sensory features and the segregation of dissimilar ones. Studies in visual perception, particularly in gestalt psychology, have uncovered a number of principles for perceptual organization, including the following important principles (see Palmer, 1999, chap. 6):

- *Proximity*: Features nearby in space and time tend to group into the same segment.
- *Similarity*: Features having similar attributes (e.g., brightness) tend to group.
- *Connnectedness*: A uniform, connected region (e.g., a blackboard) tends to form a single segment.
- *Memory*: Features that belong to the same memory pattern tend to group.

Compared to recognition, scene segmentation in neural networks is the subject of far fewer papers. The problem is particularly challenging for neural networks because the binding problem must also be addressed. The binding problem refers to how the coherence of a pattern, generally a large collection of features, is represented in a neural network. One proposal, the grandmother-cell representation, suggests that individual neurons can become so selective as to represent individual objects. Multiple objects in a visual scene would be represented by the coactivation of multiple cells. Another proposal, known as temporal correlation (von der Malsburg, 1981), encodes the binding by the correlation of temporal activities of feature-detecting cells. A special form of temporal correlation is *oscillatory correlation*, where the basic units are neural oscillators (Terman and Wang, 1995). Oscillatory correlation is the underlying representation for a number of recent studies that have substantially advanced the capability of neural networks in scene segmentation.

I first review nonoscillatory approaches, then turn to oscillatory approaches.

## Nonoscillatory Approaches

### *Boltzmann Machine*

In an early study, Sejnowski and Hinton (1987) introduced the use of a Boltzmann machine for figure-ground segregation (see SIMULATED ANNEALING AND BOLTZMANN MACHINES). Their network consists of two types of binary units: figure units and edge units. Units in the network are locally and symmetrically connected with fixed excitatory and inhibitory weights. Such connections reflect local cooperation within a connected region and local competition between figure and background. There are two kinds of input to the network: bottom-up input, which contains the location and orientation of edges (or line segments), and top-down input, which corresponds to visual attention and provides a necessary bias for selecting a figure in an image. The desired output of the system is that the units corresponding to a figural object and its boundary be active while the rest of the network units remain silent. Their simulation results on small synthetic images produced the desired results; but, as the authors point out, the applicability of the Boltzmann machine approach to segmenting real images is uncertain.

### *FBF Model*

Grossberg and Wyse (1991) proposed the FBF model for scene segmentation, which iterates between two subsystems—a feature contour system and a boundary contour system—in the order feature-boundary-feature (hence the acronym). The feature contour system detects local features using on-center/off-surround and off-center/on-surround filters, then performs diffusion within an image region; the boundary contour system detects local edges and performs contour completion. Subsequently, a filling-in process spreads a region label until there is a boundary signal. The model has been tested using simple images, but its performance on real images is unclear given the recognized difficulty of contour completion in real images. Labeling by filling-in is rather cumbersome: too few labels may miss significant regions and too many may generate duplicate segments. This labeling process, however, can be significantly improved by introducing top-down attention for selecting one region, as described by Sejnowski and Hinton (1987), and shift of attention for selecting multiple regions sequentially.

### *Classification-Based Approach*

Neural networks are well established as pattern classifiers. Because scene segmentation may be viewed, in some sense, as a classification problem, neural networks have been used in many studies to do image segmentation as classification. A training stage precedes actual classification; in the training stage, multiple classes are formed, corresponding to multiple labels for the regions of interest. After training, the classifier is used to label each individual pixel in the image. Koh, Suk, and Bhandarkar (1995) proposed a hierarchical Kohonen map (see SELF-ORGANIZING FEATURE MAPS) for range image segmentation. At each level of the hierarchy, a Kohonen map is used to segment an image into a given number of regions. A hierarchy is used for two purposes. First, the hierarchy alleviates the requirement to know the number of segments a priori. Second, the hierarchy embodies multiple scales of the input feature space. More recently, Alirezaie, Jernigan, and Nahmias (1997) used both the Kohonen map and a multilayer perceptron for segmenting two-dimensional (2D) magnetic resonance imaging (MRI) images of the human brain. Both networks are trained to classify three kinds of tissue: white matter, gray matter, and cerebrospinal fluid. After training, the two networks are used to segment the same images. Good performance is reported for Kohonen maps and poorer performance for multilayer perceptrons.

A fundamental limitation of all classification-based approaches to segmentation, neural networks or not, is that classification is based on local information only, whereas proper segmentation of a location depends on the image context of that location. This limitation is illustrated in Figure 1, where 12 line segments are arranged in two different ways in Figure 1*A* and 1*B*. Because the same set of line segments occurs in both images, local classification produces the same segmentation result, while the two images are perceptually organized very differently. Of course, one can train a system to classify a pixel together with its neighborhood. But fixed neighborhoods cannot capture the variability of image contexts.

## Oscillatory Approaches

### *Early Simulations*

Theoretical considerations and the discovery of coherent oscillations in the visual cortex in the late 1980s (see SYNCHRONIZATION, BINDING AND EXPECTANCY) triggered interest in exploring oscillatory correlation as a means to address scene segmentation and figure-ground segregation. Most of the early models employ harmonic oscillators and all-to-all connections to reach synchronization. These models are fundamentally limited in addressing the scene segmentation problem because critical information about the topology of sensory features is lost.

Recognizing the limitation of all-to-all connectivity, Sporns, Tononi, and Edelman (1991) constructed a locally connected network for modeling perceptual organization. To achieve proper synchronization, they used reentrant connections and dynamic weights, which quickly adapt to presynaptic and postsynaptic stimulation. Schillen and König (1994) proposed a network that performs synchronization and desynchronization in multiple feature domains. Their network uses Wilson-Cowan oscillators, which model oscillations from an interacting population of excitatory and inhibitory neurons, and time delays between elements of neighboring oscillators to achieve both synchronization and desynchronization. To deal with multiple-feature domains, the network is extended to include multiple modules and cross-module connections. Both of these studies have been tested using only synthetic stimuli.

### *LEGION Networks*

Terman and Wang (1995) proposed and analyzed a class of locally excitatory globally inhibitory oscillator networks, called LEGION. Each oscillator *i* in a LEGION network is a relaxation oscillator:

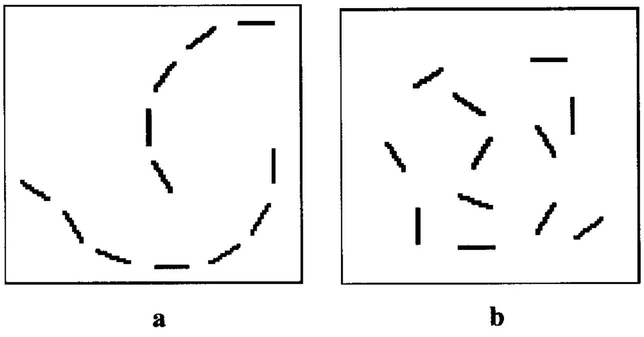

**Figure 1.** Perceptual organization of line segments. *a*, A spatial arrangement of 12 line segments. *b*, A different arrangement.

$$x_i' = f(x_i) - y_i + I_i + S_i + \rho \qquad (1a)$$

$$y_i' = \varepsilon(g(x_i) - y_i) \qquad (1b)$$

Here, $f(x) = 3x - x^3 + 2$ is a cubic and $g(x) = \alpha[1 + \tanh(x/\beta)]$ is a sigmoid ($\alpha$ and $\beta$ are parameters). $I_i$ denotes external input, and $\rho$ is intrinsic noise. The parameter $\epsilon$ is a small positive number, which yields two time scales that are the defining property of relaxation oscillations. When $I_i > 0$, (1) gives rise to a stable limit cycle, which alternates between a silent phase (small $x$ values) and an active phrase (large $x$ values). Due to $\epsilon$, the oscillator activity changes slowly within either of the two phases, but the alternation between the two phases takes place rapidly; this phenomenon is known as jumping. $S_i$ denotes the overall input from the network; it contains a local excitatory term and a global inhibitory term. The excitatory term represents the excitatory input from a set of adjacent oscillators that connect to *i*. In a 2D LEGION network, the set in the simplest case contains four immediate neighbors. This architecture is shown in Figure 2*A*. The inhibitory term specifies the inhibition from a global inhibitor.

Terman and Wang (1995) conducted an extensive analysis on LEGION networks based on an earlier analysis by Somers and Kopell (1993) on two coupled relaxation oscillators. They showed that LEGION exhibits the mechanism of *selective gating* as follows. When an oscillator jumps to the active phase, its activity spreads to its neighboring oscillators, which further spread the activity to their neighbors, and so on. This leads to synchronization in LEGION. In addition, oscillating groups inhibit each other through global inhibition so that at most one group can be in the active phase at a time. This leads to desynchronization. They proved the following theorem: LEGION networks achieve both synchronization and desynchronization in no greater than *m* cycles of oscillations, where *m* is the number of patterns in an input scene, so long as *m* does not exceed the segmentation capacity. The segmentation capacity refers to the maximum number of patterns that can be segmented by LEGION, corresponding to the ratio of the oscillation period to the duration of the active phase. The capacity is about 5 to 7 for typical parameter values.

The following simulation illustrates the selective gating mechanism. An input image with three caricature patterns—a rabbit, a duck, and a flower—is simultaneously presented to a 30 × 30 LEGION network, as shown in Figure 2*B*. The oscillators under stimulation become oscillatory, while those without stimulation

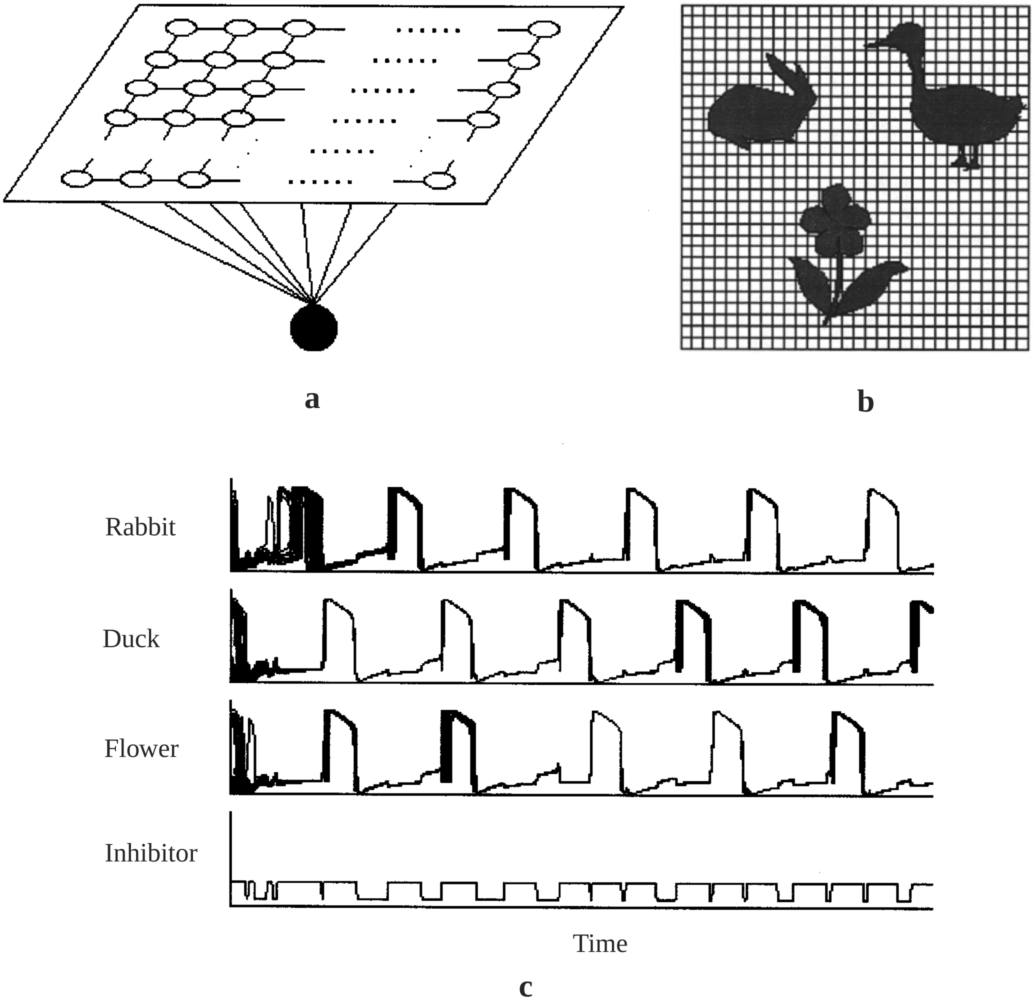

**Figure 2.** LEGION network. *a*, Architecture of 2D LEGION, where white circles indicate oscillators and the black circle indicates the global inhibitor. *b*, An input image as sampled by a 30 × 30 LEGION network. *c*, Temporal activity of the network (adapted from D. L. Wang, *Cognitive Science*, vol. 20, p. 425, 1996), where the upper three traces show the combined temporal activities of the oscillator groups corresponding to the indicated patterns. The bottom trace shows the activity of the global inhibitor.

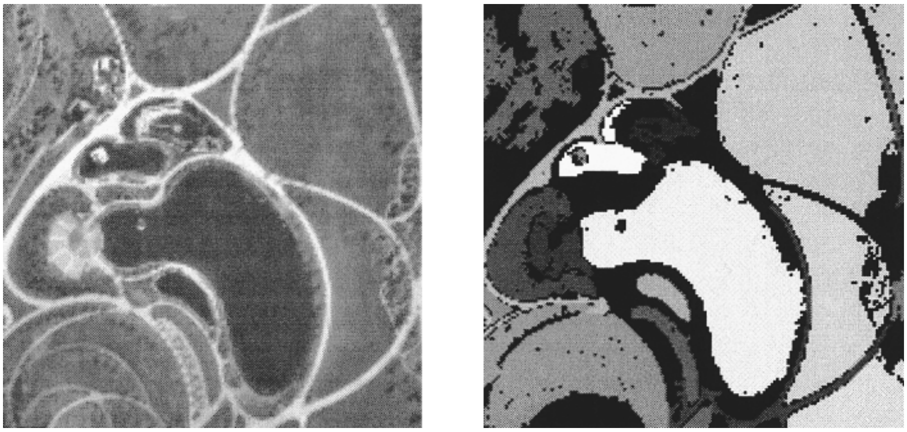

**Figure 3.** Image segmentation (from Wang and Terman, 1997). *A*, A gray-level image with 160 × 160 pixels. *B*, Segmentation result for panel *A*, where each segment is indicated by a distinct gray level.

cannot oscillate. Figure 2*C* shows the temporal evolution of every stimulated oscillator. The activities of the oscillators representing each object are combined in Figure 2*C*. Although the oscillators in the network start with random phases, the synchronization within each pattern and the desynchronization between different patterns are clearly attained in just two oscillation periods.

### *Image Segmentation Using LEGION*

Wang and Terman (1997) extended LEGION to distinguish between major image regions and noisy fragments; the latter are collected into the background. For gray-level images, each oscillator corresponds to one pixel, and two neighboring oscillators are connected with a weight proportional to pixel similarity. To speed up simulation with the large number of oscillators needed for processing real images, Wang and Terman also abstracted an algorithm that follows LEGION dynamics. To illustrate typical segmentation results, Figure 3*A* shows a gray-level aerial image. Figure 3*B* shows the result of segmentation by the algorithm. The image is segmented into 23 regions, each of which corresponds to a different intensity level in Figure 3*B*, which indicates a distinct phase of oscillators. Note that the segmentation capacity is removed in the algorithm for computational efficiency. In the simulation, different segments pop out from the network sequentially, as similarly shown in Figure 2*C*. As displayed in Figure 3*B*, almost all major regions are successfully segmented. The black scattered areas in the figure represent the background.

A variety of real imagery has been successfully segmented by LEGION networks and their variants, including intensity images such as medical (Shareef, Wang, and Yagel, 1999) and satellite images, texture images, and image sequences (motion). Oscillatory correlation provides a unique way to scene labeling. As illustrated in Figure 2*C*, segmentation is performed in *time*; each segment pops out at a distinct time from the network and different segments alternate in time. Once a segment is in the active phase, all of its features, but none of the ones from competing segments, are simultaneously available for later visual processing such as attention and recognition (Wang and Liu, 2002).

### *Contour Extraction*

Yen and Finkel (1998) used laterally coupled phase oscillators to extract salient contours. Excitatory and inhibitory connections in their network encode orientation relations between edge filters. The salience of a contour is embodied by the total activity of a synchronized oscillator group that corresponds to the contour. Using integrate-and-fire oscillators, Horn and Opher (1999) studied the detection of borders between regions. Their network uses difference-of-Gaussian coupling, and their simulations suggest that, at local minima of total network activity, firing oscillators tend to correspond to edges that separate different regions.

## Discussion

The field of neural networks has seen major advances in visual scene segmentation in recent years. The temporal correlation hypothesis is a biologically plausible representation to deal with the binding problem. The selective gating mechanism provides a computational foundation for oscillatory correlation. These advances have finally enabled neural networks to analyze real scenes. I conclude with two issues for future research.

1. *Multi-cue interaction*. There are many grouping cues responsible for perceptual organization. It is important to build systems capable of synergistically integrating multiple cues, not just breaking them into independent modules. Is there, or should there be, a common segmentation mechanism at a deeper level?
2. *Top-down analysis*. Studies in human visual psychophysics demonstrate strong top-down influence on scene analysis. Sources of top-down information include recognition, goal and expectation, short-term memory, and attention. Few studies have seriously addressed these issues in the context of analyzing real scenes. Given their importance, they deserve much more attention.

# Visuomotor Coordination in Frog and Toad

*Francisco Cervantes-Pérez*

## Introduction

Frogs and toads (anurans) live within complex, and uncertain, three-dimensional (3D) environments rich in multiple modes of sensory signals (e.g., visual, tactile, olfactory). However, their behavior is guided primarily by visual information. Therefore, they have been widely studied under visuomotor coordination paradigms, where the integration of visual signals with the animal's motor response implies a complex transformation of sensory data. The same locus of retinal activation might release different types of behavior, some directed toward the stimulus (e.g., prey catching) and others directed toward an opposite part of the visual field (e.g., predator avoidance). Furthermore, the efficacy of visual stimuli to release an animal's response is determined by a variety of factors: (1) the stimulus characteristics (e.g., form, size, velocity, geometric configuration with respect to the direction of motion, its location in space, its own current behavior); (2) the current state of internal variables of the anuran's organism, especially those related to motivational changes (e.g., season of the year, time of day, food deprivation); (3) the animal's previous experience with the stimulus (e.g., learning, conditioning, habituation); and (4) the physical condition of the animal's central nervous system (CNS) (e.g., brain lesions). In addition, other types of sensory signals can modulate frogs' and toads' responses to certain moving visual stimuli. For example, the efficacy of a prey-like dummy may be greatly enhanced by the presence of prey odor.

In this article we emphasize how the study of visually guided behaviors in anurans has become significant for scientists working in a variety of fields. In neuroscience (Llinás and Precht, 1976; Vanegas, 1984; Ewert et al., 2001) and in computational neuroscience (see articles by Arbib, Betts, Cervantes-Pérez, an der Heiden, and Lara in Ewert and Arbib, 1989; Corbacho and Weitzenfeld, 2001), people have tried to understand how these animals' CNS integrates sensory information to control motor behavior; whereas in robotics and distributed artificial intelligence, behavioral models generated from the study of amphibians have inspired the development of computer-based action selection algorithms embedded in robots displaying complex sensorimotor behaviors (Arkin in Ewert and Arbib, 1989; Arkin et al., 2000; see also Neuroethology, Computational and Reactive Robotic Systems).

## Visually Guided Behaviors in Amphibians

Ethological experiments have shown that frogs and toads are capable of interacting with a wide variety of moving and nonmoving visual stimuli. Even though they have a limited behavioral repertoire, they may display motor actions belonging to different behavioral patterns, and their survival chances depend on their ability to produce the most appropriate action to cope with diverse environmental situations.

### *Response to Nonmoving Stimuli*

A variety of stationary objects may influence the animal's next action. In general, when exploring their surroundings, frogs move toward zones in the visual field where blue is preponderant, probably because this situation might be associated to a pond (a proper habitat) location and to other stimuli whose presence is important for their survival, such as prey to eat, water to maintain their body humidity, and so on (Grüsser and Grüsser-Cornhels in Llinás and Precht, 1976). On the other hand, schema-theoretic models have been used to study those neuronal processes that occur when an obstacle (e.g., a barrier or a chasm) appears between an amphibian and a potential prey. These processes underlie an action selection mechanism that allows the animal to display a *detour behavior*, following predictable routes to avoid the obstacle in order to catch the prey (Arbib in Ewert and Arbib, 1989). Furthermore, these animals *learn to detour* a novel barrier to which they have not been yet exposed. Initially they approach the barrier, trying to go through the gaps of the fence in order to get to the prey. Then they back up and reorient toward one of the neighboring gaps; eventually, they reach the barrier edge and are able to approach the prey. After two or three trials, the dynamical changes in the processing of information allow the *trained frog* to detour without the initial bumping into the barrier (Corbacho and Weitzenfeld, 2001).

### *Predator Avoidance*

Large stimuli at close distances may yield one of several avoidance behaviors, depending on its parametric composition. When a frog is confronted with a large flying stimulus at a close distance, it exhibits a *ducking* behavior, but when the stimulus is far afield, it *orients* toward the opposite direction and *jumps* or *runs away*. In the presence of a ground predator, toads display a *stiff-legged* posture, *puffing up*, orienting toward the predator, and *tilting* the body; then they *sidestep* or *jump away* from the predator's location (see articles by Ingle and Ewert in Llinás and Precht, 1976; Ewert in Vanegas, 1984; Cobas and Arbib in Arbib and Ewert, 1991; Liaw and Arbib, 1993; Roche King and Comer, 1996).

### *Prey Acquisition*

When hunting, amphibians explore the immediate surroundings until a potential prey appears in the visual field; then they might present an action from their prey-catching repertoire: (1) Amphibians *orient* the head and body toward the prey if it appears in the peripheral part of the visual field, aiming to bring the stimulus into the binocular zone. (2) They *stalk* (toad) or *jump toward* (frog) potential prey located far afield in the frontal part of the visual field, *approaching* the prey to bring it closer. (3) Once the prey is within reaching distance, *binocular fixation* occurs to estimate its location in space. (4) If the prey is within the snapping zone, then amphibians *flick* their tongue to catch it. (5) The mechanical stimulation produced by the prey inside the mouth triggers a *gulping reflex*, and amphibians *wipe* the snout with their forelimbs (Ewert in Vanegas, 1984). This ethogram, like the ones described earlier, does not represent a fixed sequence of actions. Rather, all prey-catching responses are episodic and occur on a time scale of hundreds of milliseconds, and their outcome generates new situations with a high probability of activating one of the other prey-catching motor actions. That is, they comprise a sequence of temporally extended actions that leads toward the completion of overall goals (e.g., being fed, avoiding a dangerous situation).

### *Multisensory Guided Behaviors*

Visual information is important not only for releasing well-known visually guided behaviors, it also plays a prominent role in eliciting behaviors requiring the integration of multiple modes of sensory signals. Innate prey recognition processes can be modified when visual prey stimuli are associated with olfactory and gustatory cues. After having a negative experience with distasteful preys (e.g., the red earthworm *Eisenia foetida*, hive bees), frogs and toads avoid attacking these types of prey in future situations (for details see Ewert et al., 2001). In the case of dart-poison male frogs, vocalizations serve, among other things, to regulate male distribution within a given territory. In the field, these animals display fighting behavior against other males, producing the aggression call when in the same territory. However, with the use of dummies and a speaker to play back the call, male frogs hopped toward the sound source but did not attack. That is, acoustic cues alone are not enough to yield frog's fighting behavior. Narins, Holdl, and Grabul (2001) built what they call Roborana, an electromechanical dummy frog sitting on something that looks like a plain old log housing a loudspeaker and an air pump connected to a rubber sac, simulating the dummy's throat sac. By inflating and deflating Roborana's throat sac in synchrony with the playback of the call, these authors showed that, in territorial male frogs, agonistic behavior could be evoked only when both acoustic and visual signals were presented simultaneously.

## Neural Basis for Visuomotor Integration

### *Structural Organization*

Neuroanatomical and lesion studies have been used to delineate the structural organization of the visuomotor system in anuran amphibia, which involves both serial and highly parallel interconnections. A direct visuomotor pathway mediating between visual stimulus presentation and the elicitation of prey-catching or predator avoidance behaviors has been identified. Visual signals impinge on visual receptors, producing electrical changes that modify the level of activity displayed by the retina's neuronal elements (i.e., bipolar, amacrine, horizontal, and ganglion cells). The efferent fibers of retinal ganglion cells distribute neural signals, encoding the presence of moving and nonmoving stimuli, to different structures in the animal's CNS. These structures include the optic tectum, the pretectum, the anterior thalamus, and the basal optic nucleus, all of which receive retinotopic mappings. Various types of ganglion cells (i.e., R2, with small receptive fields, and R3 and R4, with larger receptive fields) project to the optic tectum, which in turn projects to the mesencephalic tegmentum and to the reticular formation. These latter structures are reciprocally connected and have been postulated to be involved in generating motor patterns, which are subsequently sent to motor neuron nuclei in the medulla oblongata and the spinal cord. Elements of these motor neuron nuclei exert spatiotemporal control over the activation of specific sets of muscles during the elicitation of a given motor action.

This direct pathway has many modulatory connections with forebrain structures. Pretectal thalamus receives retinotopic projections from retinal ganglion cells with large receptive fields (i.e., R3 and R4) and has reciprocal topographic connections with tectum. These retino-tectal-pretectal interactions have been posited as the basis for prey-predator discrimination, through a dynamical pretectal inhibitory effect on tectum (Cervantes-Pérez, Lara, and Arbib, 1985). Other neural loops involving neuronal elements from the direct processing pathway and from forebrain structures have been identified. Some have been postulated as the basis for motivational effects on prey-catching behaviors (tectum—lateral thalamus—striatum—pretectum—tectum) or for stimulus-specific habituation of visually elicited prey-catching orienting (tectum—anterior thalamus—ventral medial pallium—preoptic/hypothalamus—tectum). For a detailed review of all morphological connections found through anatomical techniques between 1969 and 1999, see Ewert et al. (2001) (see also articles by Grusser-Cornehls and Lázár in Vanegas, 1984, and by Lázár and Weerasuriya in Ewert and Arbib, 1989).

### *Functional Complexity*

Neurophysiological studies reinforce the anatomical hypothesis that visuomotor integration is subserved by a parallel distributed neural information processing system (for a review, see Ewert in Ewert and Arbib, 1989). The retina distributes visual information to different structures and has a great deal of parallelism within itself. Retinal ganglion cells are organized into different classes according to the size of their receptive field; that is, each class extracts information from the complete animal's visual field, but with different resolution. Class R2 cells have an excitatory receptive field (ERF) of 4°, whereas class R3 cells have an ERF of 8° and the ERF of class R4 cells ranges between 12° and 16°. In the same fashion, tectal and pretectal neurons have been grouped into different classes, according to various physiological criteria. Ewert and co-workers offered a classification of ten pretectal cell types (named TH1 to TH10) and nine types in tectum (named T1 to T9). In addition, taking into account their different sensitivities to changes in stimulus configural features, Ewert and colleagues identified several subclasses in some of these tectal cells. T5 cells were divided into four subclasses, T5.1 to T5.4, depending on the way they are activated by visual dummies: *wormlike* objects (i.e., a black rectangle moving against a white background, with its longest axis parallel to the direction of motion), *anti-wormlike* objects (the same object, but with its longest axis moving perpendicular to the direction of movement), and *square* moving objects. It has been postulated that these different types of tectal and pretectal neurons form a *command-releasing system* (see COMMAND NEURONS AND COMMAND SYSTEMS); that is, the activation of a motor pattern generator requires the simultaneous activation of appropriate combinations of specialized neurons. For example, a prey-catching orienting response is elicited only when both T5.2 (prey-feature-selecting unit) and T4 (arousal unit) cells are activated.

In addition, neuroethological data on fixed action patterns point to retino-tectal-pretectal interconnections as the basis for an amphibian's ability to interact with a variety of moving visual stimuli. First, it was suggested that in frogs, retinal ganglion cells with small receptive fields (class R2) were tuned as *bug detectors* (Lettvin et al., 1959). Then, in a more distributed view, the *integrative properties* found in the optic tectum were emphasized as the basis for detecting prey (Grüsser and Grüsser-Cornehls in Llinás and Precht, 1976). Later, prey-predator discrimination was described as the outcome of an *interactive process* among the projection of retinal ganglion cells to tectum (classes R2, R3, and R4) and pretectum (classes R3 and R4), in combination with an inhibitory pretectal effect on tectum (see articles by Arbib, Ewert, Betts, and Cervantes-Pérez in Ewert and Arbib, 1989; Cobas and Arbib in Arbib and Ewert, 1991).

## A Tricyclic Approach

The study of anurans' visuomotor coordination has followed a tricyclic approach in which interconnected cycles have been developed to generate scientific and technological contributions. The aim of the theory-experiment cycle between neuroscience and brain theory is to develop an in-depth understanding of the neurobiological basis of behavior through the interplay between experimental and theoretical studies. Theoretical models are used to integrate hypotheses generated by different experimental disciplines (e.g., anatomy, ethology, physiology, pharmacology). By means of computer simulations, theoretical models serve as test bed for studying how these hypotheses yield the appropriate behaviors, and what the critical parametric combinations may be under which these behaviors are displayed (see articles by Arbib, Ewert, and Cervantes-Pérez in Ewert and Arbib, 1989). Formal models of animal behavior, in turn, can provide effective methods for generating biologically inspired *robotic intelligence* (Arkin et al., 2000; see also the article by Arkin in Ewert and Arbib, 1989). Physical experimentation with computer-based machines can also serve to test those hypotheses embedded in the models, which may lead to new ideas, new hypotheses, or the identification of gaps in our current understanding of how these animals' brain works. Thus, a new cycle has been established between the theory-experiment cycle and the fields of robotics and artificial intelligence. Within the reach of this cycle, models can be refined to better represent the phenomenon under study, the next generation of *intelligent* machines may be designed, and future stages in animal experimentation are stimulated.

Within this experimental-theoretical framework, the study of retino-tectal-pretectal interactions as the neural basis for frogs' and toads' visuomotor coordination has been useful in identifying neurobiological operational (computational) principles. Some examples are discussed in the following subsections.

### *Cooperation and Competition in Neuronal Networks*

Ingle (1968) studied a *prey-selection phenomenon*: the snapping behavior of frogs confronted with two fly-like stimuli, each with enough prey-like characteristics (i.e., size, form, type of motion, and distance at which the fly is located in the frontal visual field) to elicit a snapping response. Frogs exhibited one of three reactions: (1) they snapped at one of the flies, (2) they did not snap at all, or (3) they snapped at the *average* fly. Didday (1976) developed a distributed network model of the optic tectum that explains this choice behavior in terms of a cooperation-competition process between two or more input signals. This model permits the network to act as a dynamic filter whose outcome is to transmit only the information encoded in the strongest signal. This process is one of the earliest examples of the *winner-take-all* algorithm (see Winner-Take-All Networks). Didday's model offered an architecture whereby different layers in tectum, organized in retinotopic correspondence, compete in such a way that the most active region in the *foodness and newness* cell layers, receiving direct retinal input, eventually suppresses all other inputs and yields an above-threshold response in the *relative foodness* layer. This process is accomplished through the integration of foodness and newness cell layer activity with a lateral inhibition effect provided by the *sameness* cell layer. It was hypothesized that the level of activation in the foodness layer represented the input to the motor circuitry and encoded information to elicit a snapping response at the corresponding point in space. That is, tectal circuitry has the structural and functional properties to process information about multiple prey-like objects, and to direct animal's actions toward one of them. Amari and Arbib (1977) placed this model in a general theoretical perspective that has been widely used in the field of computer science.

### *Pattern Representation in the Spatiotemporal Dynamics of Neuronal Networks*

Some hypotheses raised by experimental data in frogs and toads address the questions of what information may be stored in the retino-tectal-pretectal interactions, how it is retrieved, and what dynamic processes are activated by the presence of specific stimuli. These questions have also been analyzed by using different kinds of theoretical models.

Ewert and von Seelen (1974) analyzed prey-predator discrimination by considering the retina, the optic tectum, and the pretectum as *filters* working in a serial-parallel configuration (Figure 1). They postulated that within tectum there is a first filter sensitive to wormlike objects, whereas pretectum is modeled as a filter sensitive to anti-wormlike objects. Both filters receive excitatory inputs from the retina and project in turn to a second filter in tectum, which integrates an excitatory effect from the first tectal filter, with an inhibition effect coming from the pretectal filter. The signal processing built into this filter-type model allowed the authors to reproduce Ewert's physiological data: a wormlike object produced a stronger tectal response than a square object, while the antiwormlike object produced little or no response. However, this model is lumped in both space and time, and it describes neither the locus to which the toad directs its response nor the time at which the response is activated.

An der Heiden and Roth (in Ewert and Arbib, 1989) studied the same phenomenon by proposing an alternative model with no pretectal influence. Here, the activation dynamics of tectal cells (i.e., T5.1 and T5.2) are explained as the result of the spatiotemporal summation of retinal signals (i.e., ganglion cells R2 and R3), integrated with recurrent lateral inhibition among tectal elements. This model allowed the authors to reproduce important properties of the worm-antiworm discrimination, but it does not work well for bigger stimuli and does not address the issues of tectal response facilitation after a pretectal lesion or of the intrinsic tectal geometry.

Our group has developed a family of models *(Rana computatrix)* to analyze issues of the possible role played by retino-tectal-pretectal interactions in the processing of sensory signals and their translation into commands for controlling prey-catching and predator-avoidance behaviors. Cervantes-Pérez and Arbib (1990) conducted stability and parameter dependency analyses of the retino-tectal-pretectal neural circuits as organized by functional units (i.e., a layered neural network model), defined as *facilitation tectal columns* (FTCs). It was postulated that short-term memory processes underlying prey-catching facilitation are encoded in the reverberatory activity of tectal self-exciting neural loops rather than in synaptic strengthening. Cervantes-Pérez et al. (1985) presented an extended model consisting of an array of 8 × 8 FTC units, in which the effects of pretectal cell TH3 and ganglion cells R3 and R4 were added (Figure 2). The optic tectum is organized into col-

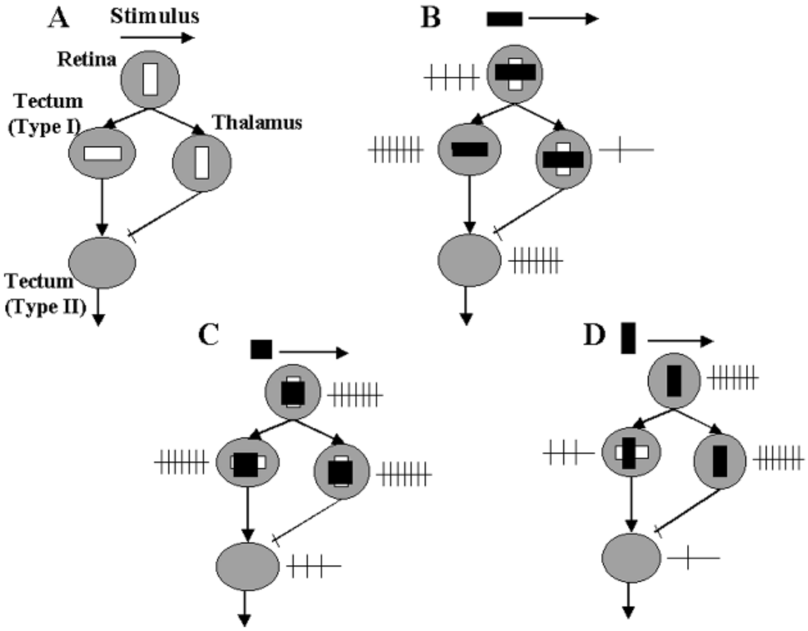

**Figure 1.** Ewert and von Seelen's filter-type model for prey-predator discrimination. The spike traces show different levels of response intensity. The higher the tectal frequencies, the better the activation of the associated prey-catching response. *A*, The tectal filter is tuned to wormlike stimuli, while the one in the thalamic pretectal area is more sensitive to large and anti-wormlike objects. *B*, During the presentation of a wormlike stimulus, the efferent tectal element presents a strong response, whereas the square produces an intermediate level of activation (part *C*), and the anti-worm elicits little or no response (part *D*). (Adapted with permission from Ewert in Ewert and Arbib, 1989.)

umns composed of different types of processing elements: the large pear-shaped cell (LP), the small pear-shaped cell (SP), the stellate neuron (SN), the pyramidal cell (PY, the only one having projecting axons outside the tectal circuit), and, finally, the glomerulus (GL), representing the convergence in the superficial tectal layers of axon terminals coming from the retina and other brain structures, and dendrite arborizations of tectal cells (see Székely and Lázár in Llinás and Precht, 1976; Lázár in Ewert and Arbib, 1989). GL receives signals from ganglion cells R2 and activates LP and SP cells, which in turn receive inputs from ganglion cells R2 and send axons back to GL, forming positive feedback loops that tend to recruit tectal activity when a prey-like stimulus is present in the animal's visual field. The LP cell also excites the SN cell, postulated to be the only inhibitory tectal cell, which forms negative feedback loops with LP and SP cells to keep tectal activation in control, especially when the stimulus disappears from the animal's visual field. Finally, the efferent PY cell integrates the overall tectal activity with the inputs it receives from ganglion cells R2, R3, and R4. The PY cell is equivalent to Ewert's T5.2 cells, whose level of activation correlates quite well with the probability of a toad displaying a prey-catching response to a visual stimulus in its visual field.

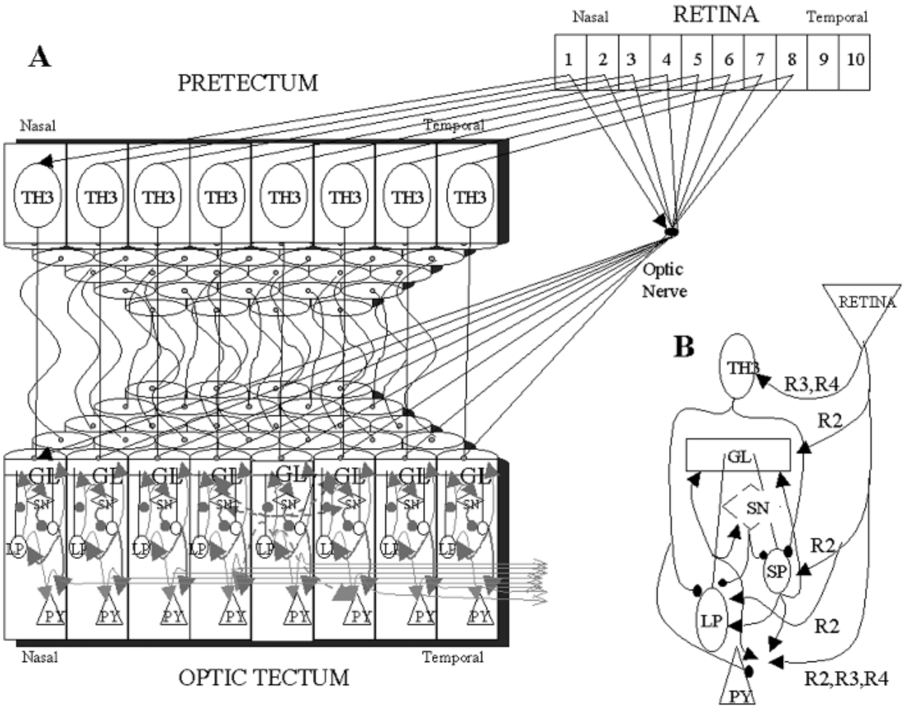

**Figure 2.** Neuronal network interactions among retina, tectum, and pretectum. *A*, The retina sends efferent fibers retinotopically to both tectum (R2, R3, and R4 ganglion cells) and pretectum (R3 and R4 ganglion cells). There is also a retinotopic projection from pretectal TH3 neurons to different tectal cells. *B*, Structural organization of a facilitation tectal column model; arrows indicate excitatory influences and dark circles inhibitory ones. (From Cervantes-Pérez in Ewert and Arbib, 1989. Reprinted with permission.)

Based on computer simulations, we analyzed how the movement direction invariance of the efficacy of a visual stimulus to elicit prey-catching behavior is a consequence of the tectal architecture. We argued that in the amphibians' visuomotor system, information about prey and predators is distributed among different structures (e.g., retina, tectum, and pretectum), and that its processing is carried out in a serial-parallel fashion. We also posited that the *knowledge* used during prey-predator recognition is *represented* within these neuronal circuits in a *spatiotemporal* way. That is, to signal whether the visual stimulus fits into the prey or the predator categories, it is important not only what neurons get activated, but also their temporal course of activation. In addition, we studied the hypothesis that the pretectal level of activation could be modulated by changes in motivational factors, so that tectum would act as a *dynamic filter* where, depending on the amount of pretectal inhibition, the same stimulus could yield different levels of tectal activation. Although the FTC model was abstracted somewhat crudely from anatomical data (Székely and Lázár in Llinás and Precht, 1976), it has been useful for analyzing how tectal circuitry involving *cooperation-competition* among positive and negative feedback loops works as a dynamic filter. The reverberatory circuits serve as mechanisms for short-term memory processes (prey-catching facilitation) and also as a *content-addressable memory* that stores information related to the probability of a stimulus fitting the prey category. This information is *retrieved* in the presence of a stimulus in the visual field (Cervantes-Pérez et al., 1985; Cervantes-Pérez and Arbib, 1990).

A wide range of those behavioral models (i.e., anurans' prey-catching, predator avoidance, and obstacle avoidance behaviors), in combination with a schema-theoretic model of the behavior of the praying mantis, *Chantlitaxia*, were implemented by Arkin et al. (2000) on a hexapod robot Hermes II equipped with a real-time color vision system. Michael, the robot, was able to properly interact with a 3D environment containing several preys and predators as well as fixed objects. These authors' work demonstrated the feasibility of importing models from the neurosciences community into robotics, and showed that species-specific behaviors can lead to interesting robotic performance.

## *Command-Releasing System*

Experimental and theoretical studies have been conducted to address the question of how are the tectal-pretectal levels of activation used by motor pattern generators to produce the proper behavior. (see articles by Ewert, Grobstein, Matsurnoto, Weerasuriya, and Lázár in Ewert and Arbib, 1989; by Grobstein and by Cobas and Arbib in Arbib and Ewert, 1991; Roche King and Comer, 1996; see also COMMAND NEURONS AND COMMAND SYSTEMS). Tectum and pretectum send efferent fibers to motor pattern–generating networks (i.e., reticular formation, mesencephalic tegmentum) and contain neurons whose level of activation form a *command-releasing system*. The simultaneous activation of appropriate combinations of tectal and pretectal cell populations may be closely correlated with the efficacy of a visual target in producing a given motor response. For example, proper levels of activation in tectal cells T1.3, T3, T4, and T5.2 yield a response to a prey, whereas if tectal cell T5.1 and pretectal cells TH3 and TH4 are activated, then a response to a predator is produced. Additionally, some neuronal elements might participate in releasing behavior toward different types of behavior; for example, in the spring, a response to a *mate* is elicited when tectal cells T4 and T5.1 reach certain levels of activation (see Ewert in Ewert and Arbib, 1989). Furthermore, Cervantes-Pérez et al. (1985) proposed that the locus of activity within tectum and pretectum defines the spatial location of visual stimuli, and that the target location of prey-catching and predator avoidance behaviors is determined by the average of their target loci as weighted by their level of activation. They also assumed a hierarchical relationship between pretectum and tectum; high pretectal activity, closely correlated with the appearance of potential predators in the visual field, should shut off the prey recognition system.

Analyzing experimental data on *direction-selective avoidance behavior*, Liaw and Arbib (1993) offered a neural network model of the retino-tectal-pretectal interactions to account for the anuran's ability to avoid looming objects (potential predators). A visual stimulus activates ganglion cells R3 and R4, which project to tectal cells T3 and T6, which are activated by moving looming objects and also by the presence of a stimulus in the upper part of the corresponding visual field. These authors suggested that the population of T3 neurons gives a spatial map of the stimulus location. The stimulus position is determined by localizing its center, encoded in the peak of activation produced by the stimulus on the T3 neuron population, and the looming stimulus direction of motion is determined by monitoring the shift of the peak of neuronal activity within this population. In addition, the signals generated by these cells are integrated, along with depth information, by pretectal neuron TH6 to indicate whether the stimulus is a looming threat. Their model includes other tectal (T2, postulated to respond to stimuli with temporonasal movement) and pretectal (TH3, sensitive to larger stimuli) neurons. On one hand, the tegmentum integrates and transforms the spatial signals conveyed by T2 and T3 cells to generate a motor heading map that specifies the escape direction. On the other hand, the appropriate motor response selection (e.g., jumping away, ducking) depends on the stimulus size and elevation, which are determined by including TH3 and TH6, and T6 signals, correspondingly.

## *Different Time-Scale Neuronal Networks as the Basis for Visuomotor Integration*

Anurans' prey-catching response can be influenced by changes in motivation (Cervantes-Pérez et al. in Arbib and Ewert, 1991; Merkel-Harff and Ewert in Arbib and Ewert, 1991) or by conditioning or learning processes (see Finkestädt in Ewert and Arbib, 1989; Cervantes-Pérez et al. in Ewert and Arbib, 1989). Through neuroanatomical, neurophysiological, and lesion studies, it has been postulated that those closed loops, formed by tectum and pretectum with telencephalic and diencephalic structures, may be the underlying mechanisms of these modulatory processes (Ewert et al., 2001).

The optic tectum projects to the anterior thalamus, which also receives input from the retina and connects to medial pallium, which in turn sends efferent fibers, directly and through the preoptic area, to dorsal hypothalamus, a structure with direct connection to tectum. This loop has been postulated to subserve *stimulus-specific habituation*, a simple form of learning in which the tendency to respond to a prey-like stimulus declines and eventually disappears when the stimulus remains in the toad's visual field, despite its efforts to catch it. Prey-catching habituation is a stimulus-specific process with almost no analogical generalization, and it shows spontaneous recovery (see Lara in Ewert and Arbib, 1989; Cervantes-Pérez et al. and Wang et al. in Arbib and Ewert, 1991; Ewert et al., 2001). The habituation process does not occur within a single failure trial; rather, it requires that the toad attempt several times to catch the prey without being successful. Thus, we postulated that the *acquisition phase* of habituation is carried out within the telencephalic modulatory path on a much slower time scale (minutes to hours) than that associated to the FTC activation dynamics (hundreds of milliseconds). We also proposed that the build-up of habituation results in an increased inhibition of tectal activity, which reduces the probability of the current stimulus fitting the prey category. That is, the *modulatory path* activity causes a change in the FTC neuronal network *activation dynamics* produced by the visual stimulus rather than changes in the *weight dynamics* related to its structural organization. This phenomenon shows spontaneous recovery, a *forgetting phase*, which may take from minutes to days. Finally, stimulus-specific habituation is a *learning-from-interactions* phenomenon whose characteristics seem to be universal (they appear in studies with different species, e.g., mollusks, rats, and humans).

The complexity of anurans' visuomotor behaviors is also enhanced by changes in factors affecting animal's motivation to display a given behavior. For example, the daytime effect on the efficacy of visual prey like *dummies* to yield prey-catching behavior depends on the time of the day (frogs and toads have a peak of prey-catching activity at dusk). Furthermore, there are also seasonal effects on anurans' prey-catching behavior, which gives the *motivational dynamics* a slow time-varying scale that may go from several hours to several days (Ewert in Ewert and Arbib, 1989).

## Discussion

Experimental and theoretical studies have been used to establish how the underlying neural mechanisms of visuomotor integration in amphibians developed into a parallel distributed neural processing system in which tectal circuitry represents more than a visual sensory map. Instead, tectal circuitry can be regarded as the *site of integration* of signals coming from retina and pretectum, as well as from thelencephalic brain regions associated with changes in motivational factors or learning processes that modulate these animals' behavior. There is a wide range of neuronal processes occurring at multiple levels of temporal abstraction. First, on the scale of hundreds of milliseconds, are changes in neuronal activity caused by the stimulus (prey or predator) characteristics and its current spatiotemporal relationship with the toad (or frog); second are signals generated during learning events happening on a temporal scale of minutes to hours; and third are signals generated by changes in motivational factors (e.g., hunger, daily and yearly cycles), which occur on a much slower time scale.

The study of anurans' visuomotor coordination system is an excellent example of how scientists from a range of disciplines (i.e., brain theory, neurosciences, robotics) can work together using theoretical models as an interlingua. This kind of study contributes to neuroscience by analyzing formal models in the quest of testing hypotheses posed by experimental studies and by generating new hypotheses that may stimulate new experimental and theoretical work. In turn, these modeling studies may contribute to building automata that process sensory information "in the manner of the brain" to carry out complex tasks when interacting with a given environmental situation. A good example is provided by the work of Arkin et al. (2000), who implemented a schema-theoretic model of the agent-environment interaction of amphibians and insects in the action-selection control algorithm of a robotic hexapod. This machine is capable of displaying visually guided behaviors equivalent to prey catching, predator avoidance, and obstacle avoidance, and to the praying mantis behavior named "Chantlitaxia" (i.e., in searching for a safe place).

Many mysteries remain to be solved before it can be said that we understand the workings of the anuran brain. However, the results obtained so far are encouraging, and the quest goes on. For the last few years, research attention has focused on the study of behavior modulation, and this trend will likely continue for years to come. People would like to understand how neuronal processes occurring on fast time scales (a few hundreds of milliseconds) can be associated (synchronized) in such a way as to underlie behavioral responses elicited on a time scale of few seconds, or learning processes requiring up to an hour and a half to be consolidated, or motivational changes occurring on a time scale of several hours to days or months.

# Visuomotor Coordination in Salamander

*Richard Woesler and Gerhard Roth*

## Introduction

For most salamanders, vision is the most important sense (Roth, 1987). To analyze a visual scene, objects have to be segmented from a background. Furthermore, in the context of prey catching, an object has to be selected and identified as prey. Finally, correct motor patterns have to be generated; for example, snapping has to occur only when prey is within reach of the tongue. On the one hand, these computational steps are difficult tasks, especially when self-motion of the salamander is also taken into account. On the other hand, the brains of salamanders are anatomically the simplest among vertebrates, containing only about 1 million neurons (frogs have up to ten times more neurons and humans one million times more). Despite these differences, the salamander (as well as the frog) and the human brain exhibit the same fundamental bauplan, or blueprint, and it is therefore interesting to study the neurobiology and the visually guided behavior of these animals (see VISUOMOTOR COORDINATION IN FROG AND TOAD).

## Behavior

Probably the most sophisticated visually guided behavior in salamanders is prey catching (Figure 1). Terrestrial prey catching generally consists of a sequence of the following reactions: First, there is an orienting movement of the head to bring the prey into the binocular visual area. Then, sometimes, differing from species to species, the prey object is approached by walking. Afterwards, an olfactory test may occur. Many salamanders, however, exhibit an "ambush" strategy, that is, they are motionless until a prey object comes within reach of the tongue. A fixation period can usually be observed. Finally, the prey is captured with the tongue and taken into the mouth. These actions may vary in their temporal sequence, depending on the motivation of the animal.

While among frogs there is a larger variety of feeding mechanisms and kinematics (cf. Nishikawa, 1997), salamanders uniformly use their tongues by a forward movement of the hyobranchial apparatus (Roth, 1987). Most species of the large family Plethodontidae have developed projectile tongues that enable them to feed on fast-moving prey such as flying insects. The longest tongue is found in the plethodontid genus *Hydromantes*. This group of salamanders is also capable of catching prey with its tongue up to 45°, or more, laterally.

## Neurobiological Results

### Retina

The retinal network consists of photoreceptors, a variety of interneurons and retinal ganglion cells (RGCs), which project to further brain areas. In *Hydromantes*, there are about 60,000 photoreceptors and about 50,000 RGCs (Roth, 1987). Most of the RGCs are movement sensitive, that is, they respond with action potentials when a contrast edge moves over receptors within their receptive fields. Three main classes of RGCs can be distinguished: RGC 1 is edge or contrast sensitive, RGC 2 is movement sensitive, and RGC 3 is sensitive for motion of large objects. The RGCs project to the tegmentum, which is thought to provide a self-motion signal to the tectum and to provide various premotor functions (Manteuffel and Naujoks-Manteuffel, 1990), to the thalamus (corpus geniculatum thalamicum, neuropil Bellonci, pars lateralis, and medialis), the pretectum (pretectal neuropil, area uncinata), and the upper layers of the tectum (Roth, Dicke, and Wiggers, 1998). The thalamus is involved in prey/predator distinction and figure/ground separation; for further results concerning thalamic neurons, see Roth and Grunwald (2000). The majority of retinal input runs to the contralateral side. Tongue-projecting salamanders, however, exhibit a substantial proportion of ipsilateral retinal input; this is supposed to be important for catching fast-moving prey with high accuracy in three-dimensional space.

### Tectum

The tectum mesencephali (often, but incorrectly, called "optic tectum") is the most important visual brain center regarding prey catching. It receives retinotopic afferents from the retina, ipsilateral lateral amygdala, striatum, thalamus and pretectum, ipsilateral and contralateral nucleus isthmi, and from the medulla oblongata/spinalis (Roth et al., 1998); the latter has premotor functions (see Lo-

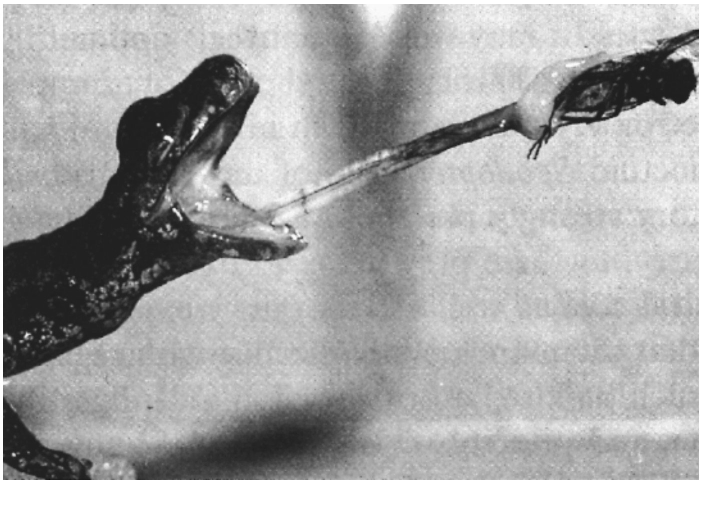

**Figure 1.** Prey-catching behavior of *Hydromantes italicus*. Protraction and retraction of the tongue takes place within less than 100 ms. (Photo by G. Roth.)

COMOTION, VERTEBRATE). The retinal input originates from RGCs mostly with small excitatory receptive fields in the range of 3°–20°. The tectum of *Hydromantes italicus* contains about 100,000 neurons, about 95% of which are local interneurons (TO-IN); the rest are projection neurons. Five major types of projection neurons can be distinguished (TO1 to TO5). TO1 and TO5 are likely to receive predominantly input from RGC 1, TO2 and TO4 mostly from RGC 2, and TO3 mostly from RGC 3 as well as somatosensory and vestibular input. TO1 to TO3 have large dendritic fields; TO4 and TO5 have smaller ones. Together, these types of neurons constitute a system of parallel ascending (to pretectum, thalamus) and descending (to tegmentum, medulla oblongata/spinalis) pathways mediating information about size, velocity, shape, and movement pattern of prey objects to different brain regions.

Data from freely moving toads demonstrate that certain tectal neurons involved in prey recognition show two different types of reactions (Schürg-Pfeiffer, 1989), which may be called low- and high-firing-rate states. Usually, these neurons show relatively low firing rates depending on the stimulus. Before an action such as an orienting movement takes place, the neurons change to a high-firing-rate state, firing with about 100–150 spikes/s. Further, during this state, the neurons produce double spikes, with interspike intervals of about 6 ms. Possibly, these double spikes are recognized in the motor and premotor areas so that only neurons in the high-firing-rate state can contribute to motor activation. Further, certain tectal neurons respond vigorously only to objects of about prey size (Spreckelsen, Schürg-Pfeiffer, and Ewert, 1995). This differs from the situation found in anesthesized animals in which corresponding tectal neurons do not show absolute size constancy.

### *Pretectum*

The pretectum receives retinal input from ganglion cells with large excitatory receptive fields (30°–90°); it also receives a considerable amount of ipsilateral retinal input (Manteuffel, 1989). Most pretectal cells were found to be sensitive to stimuli moving with about 1°–10°/s in the horizontal plane, and many of them exhibit direction sensitivity, responding best to temporonasal stimulus movement. About half of the neurons studied projected to the tectum; arborization was highly variable, ranging from a single fiber to massive arborization covering almost the entire tectal hemisphere (Luksch et al., 1998). Most neurons (87%) projected to the medulla oblongata and rostral spinal cord. The function of the pretectum is the control of the optokinetic response; it is also assumed to be involved in the prey-enemy distinction (Ewert, 1984).

## Models

### *Compensation of Visual Background Movement*

The amphibian nystagmus of the head reaches a maximum gain up to 0.8 at stimulus frequencies of about 0.03 Hz, whereas the gain of the vestibulocollic reflex reaches its maximum at about 0.5 Hz (Manteuffel, 1989). These features can be reproduced in a computer model (Manteuffel, 1989) under both constant velocity and sinusoidal input conditions, taking into account the bell-shaped velocity tuning curves of pretectal neurons and assuming that these signals are fed to the ipsilateral neck motor neurons through a salamander-specific velocity storage system and a linear velocity-to-position integrator. The results suggest that in salamanders, this system is simpler than that found in higher vertebrates and especially that it lacks an effective velocity storage element that serves a more continuous output.

### *Encoding the Place of a Single Object with High Accuracy*

From snapping responses of *Hydromantes*, for example, a high accuracy is known. However, the mean value of the width of receptive fields of recorded tectal neurons was surprisingly large (36°). Within a model called SIMULANDER, Eurich et al. (1995) could show how to encode the place of a single prey with high accuracy using a relatively small number of tectal neurons (100 neurons in the model were sufficient), the fields of which were chosen according to experimental data for tectal neurons. Only one already segmented stimulus was assumed. A neuron was defined to be active in case a part of the object was inside the neuron's receptive field. Binary tectal neurons were sufficient to solve this task. This kind of encoding is called *coarse coding*. The main idea is that a rather small displacement of the object causes it to enter or leave one of the large overlapping fields and therefore yields a change of the neuronal activity pattern. Note that this would not be the case for small fields, because their boundaries are smaller within the snapping region; therefore, the rather large fields in the model are efficient to provide high accuracy.

### *Segmentation of Objects from Background and Selection of an Object*

As has been mentioned, the model of Eurich et al. (1995) does not include segmentation of an object from the background, and no selection of one out of several objects is considered. These questions are addressed in further models (Woesler, 2001). A simplified retinal neural network model is considered, consisting of photoreceptors, interneurons, and RGCs. Anatomical receptor resolution (about 0.2°) and a time constant of the model RGCs (about 0.2 s) are chosen according to data from *Hydromantes*. This network provides segmentation of moving contrast edges from the background. The information is projected to model tectal neurons that integrate the information in a certain binocular receptive field. The center and width distributions of the fields are chosen according to experimental data. A winner-take-all model selects for each tectal hemisphere the neuron with the largest output. Simulation results show that, generally, the winner neurons' fields contain a complete object. For a simplified model (Woesler, 2001), analytical results could be obtained that are in accordance with behavioral findings, for example, concerning optimal prey velocities for prey-catching behavior and "head preference" known from toads. The width distribution of receptive fields in the simplified model arises from a plausible scaling construction within the winner-take-all networks. Comparing the distribution with that found in *Hydromantes* yields a rough correspondence: no or few neurons with small receptive fields, many neurons with relatively small fields, and only very few neurons with very large fields (Figure 2).

The winner-take-all networks exhibit a comparatively low coding accuracy for the place of an object. In the models (Woesler, 2001), the high coding accuracy known from *Hydromantes* is obtained as follows: Roughly speaking, via multiplicative synapses, the winner neurons activate the retinal input within their receptive fields to postsynaptic tectal model neurons, which one may call multiplicative neurons. By this, the multiplicative neurons only "see" the winner object. Via coarse coding, the multiplicative neurons encode the place of the winner object with high accuracy. The multiplicative neurons can be chosen to have binary output values. Note that one may propose that neurons in a state of high firing rate mentioned above correspond to such binary model neurons that are active. Using only 300 neurons in the winner-take-all networks for each hemisphere and 400 multiplicative neurons per hemisphere, the model yields an accuracy of about 1°, which is in good agreement with data from *Hydromantes* (<3°). Note that in *Hydromantes*, there are about 3,000 tectal neurons that project to motor and premotor areas.

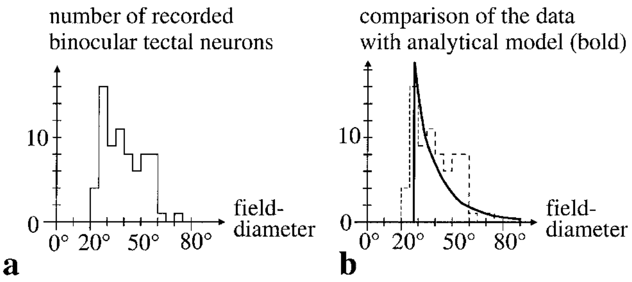

**Figure 2.** *A*, Distribution of receptive field diameters of binocular tectal neurons in *Hydromantes italicus*. Data from extracellular recordings of 72 neurons (Roth et al., 1998). *B*, Comparison of the data of part *A* (dashed line) with the corresponding function (curve) of an analytic model (Woesler, 2001). The latter is zero for fields smaller than a threshold value (here fitted to data: 28°), and for larger fields, it is inversely proportional to the field diameter to the third power.

### *Saccade Generation*

As shown in a model of Manteuffel and Roth (1993) based on anatomical and electrophysiological data from tectum and brainstem, the metric properties of salamander saccades are largely the result of visual and motor maps of the tectum. In that model, head movements toward prey were investigated by applying a continuous mapping from the retina to premotor layers of the tectum. Using the coarse coding scheme described above, Eurich et al. (1995) showed that a model with 100 discrete, binary tectal model neurons, 100 interneurons, and 100 motor neurons can exhibit the behavioral accuracy of prey localization.

### *Approach Behavior, Walking, and Swimming*

A corresponding detailed model is described by Ijspeert (see LOCOMOTION, VERTEBRATE).

### *Snapping*

Snapping at prey was modeled for *Hydromantes italicus* (Eurich, Schwegler, and Woesler, 1997). The model was restricted to frontal snapping. It demonstrates that a high distance accuracy of the snapping reaction can be obtained by using 144 tectal neurons, 12 motor neurons, and 12 inhibitory interneurons. Models of the tongue apparatus muscles rectus cervicis profundus and subarcualis rectus 1 were simulated. The snapping distance accuracy was about 0.2 cm, but it was somewhat lower for very close prey. Successful captures of prey usually occurred in more than 90% of the cases.

## Discussion

The coarse coding models (Eurich et al., 1995, 1997) have demonstrated how to encode with only a few neurons with large, overlapping receptive fields the place of an object with the high accuracy that is known from the prey-catching behavior of tongue-projecting salamanders. This is in nice relation to the fact mentioned in the introduction that the salamander brain contains so few neurons.

The models have been extended for the case in which several objects are presented to the animal by linking a segmentation network and a winner-take-all-like object selection to a coarse coding network in a biologically plausible way (Woesler, 2001).

Compensation of background movement (Manteuffel, 1989), segmentation of objects, selection of an object, saccade generation, approaching (see LOCOMOTION, VERTEBRATE), and snapping behavior have been modeled successfully as separate tasks in line with behavioral and neurobiological findings in salamanders. The models remain to be integrated into a more complete model, especially integrating the compensation of background and ego motion with object selection/segmentation (cf. VISUAL ATTENTION).

Models have to be developed for the recent data mentioned concerning thalamus and tegmentum and, finally, for the telencephalon, the largest salamander brain center, for which there are results from lesion studies (Finkenstädt and Ewert, 1983) and detailed findings concerning its connectivity (Roth and Grunwald, unpublished data). It is involved in motivation, learning, and control of "voluntary actions." These functions are challenging with respect to both experiments and modeling, considering that available computer power comes closer to that of a whole salamander brain network, and considering the roughly similar bauplan to that of human brain.

# Winner-Take-All Networks

*Alan L. Yuille and Davi Geiger*

## Introduction

A winner-take-all mechanism is a device that determines the identity, and sometimes the amplitude, of its largest input. Such mechanisms are necessary in network models for enforcing competition between different possible outputs of the network (Amari and Arbib, 1977). Classic examples include (1) associative memory models (Hertz, Krogh, and Palmer, 1991), where different stored memories compete to explain the input data, (2) cooperative models of binocular stereo, where competition is required to ensure that each feature has a unique match (Dev, 1975; Marr and Poggio, 1977), and (3) Fukushima's neocognitron for feature extraction (see NEOCOGNITRON: A MODEL FOR VISUAL PATTERN RECOGNITION). In addition, such mechanisms are often required for combinatorial optimization problems (see OPTIMIZATION, NEURAL).

There are two important variants of winner-take-all procedures. The first is *k*-winner-take-all, where the *k* largest inputs are identified. The second is a softened version, known as *softmax*, that consists of assigning each input a weight so that all weights sum to one and the largest input receives the biggest weight. In what follows, when "winner-take-all" appears without a noun, it refers to "1-winner-take-all." Winner-take-all can be considered a limiting case of softmax when the biggest weight is set equal to 1. Softmax has been applied to problems in speech recognition (Bridle, 1989) and learning by mixtures of experts (Jordan and Jacobs, 1992). Softmax also appears from a statistical physics analysis of the winner-take-all problem.

It has recently been shown (Maass, 2000) that both these variants are computationally very powerful compared with standard neural network models with threshold gates. The standard models require two layers of nonlinear units in order to represent most functions. By contrast, it can be shown (Maass, 2000) that arbitrary continuous functions can be approximated by circuits employing a single soft winner-take-all gate as their only nonlinear operation. In addition, any boolean function can be computed by a single *k*-winner-take-all unit applied to weighted sums of input variables. Moreover, both approaches require only positive weights. This may be relevant to neuroscience, because positive weights can be implemented by excitatory neural connections but there is no direct way to implement negative weights.

In this article we will concentrate on describing winner-take-all and softmax. We first describe softmax and show how winner-take-all can be derived as a limiting case. We will then describe how they can be both be derived from probabilistic, or energy function, formulations. This leads naturally to several algorithms for calculating them, and their generalization to more complicated systems. Some of these algorithms include the concept of self-annealing (Rangarajan, 2000). We then discuss VLSI and biological mechanisms for implementing these algorithms.

## Softmax

The basic idea of softmax is very simple. Suppose we have inputs $I = \{I_a : a = 1, \ldots, N\}$, and let $\beta$ be a positive parameter. We define a weight $w_a(I; \beta)$ for each input $I_a$ by

$$w_a(I; \beta) = \frac{e^{\beta I_a}}{\sum_b e^{\beta I_b}} \tag{1}$$

Clearly, because the exponential function is monotically increasing, the largest weight corresponds to the largest input. Moreover, the size ordering of the weights corresponds to the size ordering of the inputs. The weights sum up to 1, $\Sigma_a w_a(I; \beta) = 1$. In the limit, as $\beta \to \infty$, the weight of the largest input tends to 1, all other weights tending to 0, and we obtain the classic winner-take-all situation. At the other extreme, as $\beta \to 0$, the weights all tend to $1/N$. Thus the parameter $\beta$ controls the sharpness of the softmax.

The variables $w_a(I; \beta)$ in Equation 1 will preferentially weigh the largest inputs. They can also be used to calculate a weighted average of the inputs to yield

$$O(I; \beta) = \sum_a w_a(I; \beta) I_a \tag{2}$$

As $\beta \to \infty$, the output $O(I; \beta)$ will become equal to the largest input value.

We cannot make $\beta$ arbitrarily large in Equation 1. How large must it be to ensure that we are close to the true winner-take-all solution? If we require that the largest weight differ from 1 by at most $\varepsilon$, then it can be shown that we need to have $\beta \geq (1/|\Delta I|) \log\{(N - 1)(1 - \varepsilon)/\varepsilon\}$, where $|\Delta I|$ is the difference between the largest and second largest inputs.

### *Statistical Derivation of Softmax*

The winner-take-all problem can be posed as follows: Given a set of $N$ inputs $\{I_a : a = 1, \ldots, N\}$, how can we associate each input $I_a$ with a binary variable $V_a$, such that $V_{a^*} = 1$ for the largest input $I_{a^*}$, and $V_a = 0$ otherwise? We can transform the winner-take-all problem into an optimization problem by introducing the energy function

$$E[V] = -\sum_a V_a I_a \tag{3}$$

Minimizing Equation 3 with the constraint that $\Sigma_a V_a = 1$ will select the largest input.

The associated Gibbs distribution (for justification of this distribution, see OPTIMIZATION, NEURAL) is

$$P[V; \beta] = \frac{e^{-\beta E[V]}}{Z} \tag{4}$$

where the constant $\beta = 1/T$, with $T$ being the "temperature" of the system. $Z$ is a normalization factor, also known as the *partition function*. Hence, $Z = \Sigma_V e^{-\beta E[V]}$, where we sum over all allowable configurations of $V$. Because of the global constraint, these configurations are of form $V_a = 1$, $V_b = 0$, for all $b \neq a$. We calculate

$$Z = \sum_b e^{\beta I_b} \tag{5}$$

We can now directly evaluate the probabilities of the allowable configurations.

These are

$$P[V_a = 1; V_b = 0, b \neq a] = \frac{e^{\beta I_a}}{\sum_b e^{\beta I_b}}, \quad \text{for all } a \tag{6}$$

This is exactly the softmax formula. So we can interpret the weights given by softmax as the probabilities given by the Gibbs distribution. It is straightforward to design a physical system whose states are specified by the Gibbs distribution so that the probability of unit $a$ firing (i.e., $V_a = 1$) is given by Equation 6.

Alternatively, we can reinterpret the softmax weights as the mean values of the output units (for a binary variable, the means are the same as the probabilities of firing). The means can be calculated by minimizing an effective energy:

$$E_{eff}[w, P; \beta] = -\sum_a w_a I_a + (1/\beta) \sum_a w_a \log w_a + P\left(\sum_a w_a - 1\right) \tag{7}$$

where $P$ is a Lagrange multiplier to impose the constraint $\Sigma_a w_a = 1$. The second term can be interpreted as an entropy term. It is straightforward to verify that $E_{eff}$ is a convex energy function that is bounded below, and hence has a unique minimum. This minimum can be obtained by extremizing $E_{eff}$ with respect to $w$ and $P$, yielding

$$\frac{\partial E_{eff}}{\partial w_a} - I_a + (1/\beta)\{\log w_a + 1\} + P = 0$$

$$\frac{\partial E_{eff}}{\partial P_a} = \sum_a w_a = 1 \tag{8}$$

We can solve these equations, eliminating $P$, to obtain the softmax formula in Equation 1. Moreover, the effective energy can be used (see the next section) to design algorithms for calculating softmax.

### *Dynamical Systems for Computing Softmax*

There are many dynamical systems that converge to the softmax solution. One possibility is to do a variant of steepest descent that is modified to ensure that the constraint $\Sigma_a w_a = 1$ is satisfied. This corresponds to removing the component of the gradient in the direction that violates the constraints. This yields

$$\frac{dw_a}{dt} = -\frac{\partial E_{eff}}{\partial w_a} + \frac{1}{N}\sum_b \frac{\partial E_{eff}}{\partial w_b} \tag{9}$$

Substituting from Equation 7 gives

$$\frac{dw_a}{dt} = I_a - (1/\beta)\log w_a - (1/N)\sum_b I_b + (1/N\beta)\sum_b \log w_b \tag{10}$$

This update equation ensures that $d/dt(\Sigma_a w_a) = 0$, so the constraints will always be satisfied (provided the initial conditions are chosen to satisfy them). It can be shown that this equation causes the energy to monotonically increase to the minimum of the effective energy, and hence yield softmax as a solution.

Two other dynamical systems can be adapted from Waugh and Westervelt (1993). Their formulation applies to more general networks such as systems of competitive memories (see the next section). Both systems will converge to the softmax solution. Winner-take-all can be achieved by making $\beta$ sufficiently large, or by thresholding the softmax solution.

The first is a discrete-time dynamical system:

$$w_a(t + 1) = \exp\{\beta I_a + P(t)\} \tag{11}$$

where $P(t)$ is chosen to ensure that at any time $\Sigma_a w_a(t + 1) = 1$. This requires that $P(t) = -\log\{\Sigma_a e^{\beta I_a}\}$. Thus the algorithm converges to the softmax solution $w_a(1) = e^{\beta I_a}/\{\Sigma_b e^{\beta I_b}\}$ in a single iteration. The simplicity of this algorithm, and its rapid convergence, reflects the simplicity of the winner-take-all/softmax problem. (As discussed later, the algorithm is usually applied to more complex problems.)

The second is a continuous-time dynamical system:

$$\frac{dw_a(t)}{dt} = -w_a(t) + \exp\{\beta I_a + P(t)\} \tag{12}$$

where, as before, $P(t)$ is chosen to ensure that $\Sigma_a w_a = 1$. It is straightforward to verify that $\lim_{t\to\infty} w_a(t) = e^{\beta I_a}/\Sigma_k e^{\beta I_k}$, recalling that $E_{\text{eff}}$ has a unique minimum and observing that it acts as a *Lyaponov* function for this system (Waugh and Westervelt, 1993). Note that this is only a special case of Waugh and Westervelt's formalism. In the general case, the exponential functions in Equations 11 and 12 could be replaced by other monotonic differentiable functions.

For additional algorithms for this problem and detailed descriptions of the relationship of winner-take-all to effective energies, we recommend Elfadel (1995).

### *Self-Annealing to Compute Winner-Take-All*

A disadvantage of softmax is that it has an unknown parameter $\beta$ and does not converge to the winner-take-all solution unless we perform annealing on parameter $\beta$.

Rangarajan (2000) has suggested an alternative, called "self-annealing." This gives convergence to the winner-take-all solution without requiring a separate annealing schedule.

To perform self-annealing, we rewrite the energy function as

$$E[w] = -\sum_a w_a I_a + \lambda\left(\sum_a w_a - 1\right) \tag{13}$$

The update rule is defined by

$$w_a^{t+1} = \frac{w_a^t e^{-I_a/\alpha}}{\sum_b w_b^t e^{-I_b/\alpha}} \tag{14}$$

It can be proved (Rangarajan, 2000) that this converges to the winner-take-all solution.

Moreover, there is a related continuous-time dynamical system that also converges to the winner-take-all solution:

$$\frac{dw_a}{\partial t} = -w_a + \frac{w_a e^{-I_a/\alpha}}{\sum_b w_b e^{-I_b/\alpha}} \tag{15}$$

## Generalizations

Winner-take-all mechanisms are usually part of more complicated systems. In this section we show how they can be generalized to systems of competitive memories. The system converges to the "best" memory rather than to the "best" input. This applies both to softmax and winner-take-all (using self-annealing).

Following Waugh and Westervelt (1993), we now generalize the previous system to more complicated models consisting of neurons grouped into clusters. The variables are $\{w_{ia}\}$, where the index $i$ labels the cluster and $a$ labels the element in the cluster. We impose the constraint $\Sigma_a w_{ia} = R_i$, for all $i$ to ensure that in the $i$th cluster, only $R_i$ neurons are firing. The input to the $ia$th neuron is $h_{ia} = \Sigma_{jb} T_{ijab} w_{jb} + I_{ia}$, where $I_{ia}$ are the external inputs and $T_{ijab}$ are connection strengths. Then the two equations, 11 and 12, are generalized to

$$w_{ia}(t + 1) = \exp\{\beta(h_{ia}(t) + B_i(t))\}, \quad \text{for all } a, i \tag{16}$$

and

$$\frac{dw_{ia}(t)}{dt} - w_{ia}(t) + \exp\{\beta(h_{ia}(t) + B_i(t))\}, \quad \text{for all } a, i \tag{17}$$

where the $B_i(t)$ are chosen to enforce the constraints $\Sigma_a w_{ia} = R_i$, for all $i$.

These dynamical systems are guaranteed to converge (Waugh and Westervelt, 1993). Indeed, they will converge (Elfadel, 1995) to a local minimum of an effective energy, generalized from Equation 7, that is given by

$$\begin{aligned} E_{eff}[w, P; \beta] = & -\tfrac{1}{2} \sum_{ijab} T_{ijab} w_{ia} w_{jb} - \sum_{ia} w_{ia} I_{ia} \\ & + (1/\beta) \sum_{ia} w_{ia} \log w_{ia} \\ & + \sum_{i} P_i \left( \sum_{a} w_{ia} - R_i \right) \end{aligned} \tag{18}$$

where the $\{P_i\}$ are Lagrange multipliers.

Waugh and Westervelt's formulation is more general than this. It can be obtained by replacing the exponentials in Equations 16 and 17 with monotonic differential functions $F_{ia}$ and replacing the term $(1/\beta)\Sigma_{ia} w_{ia} \log w_{ia}$ in Equation 18 with $(1/\beta)\Sigma_{ia} \int_{w_0}^{w_{ia}} F_{ia}^{-1}(w)dw$.

Networks with dynamics similar to Equations 16 and 17, and effective energies similar to Equation 18, can also be used to solve optimization problems. They can also be related to the Potts models in statistical physics (see Elfadel, 1995).

The situation is similar for self-annealing (Rangarajan, 2000). We restrict ourselves to $R_i = 1, \forall\ i$. Then a discrete iterative algorithm is

$$w_{ia}(t + 1) = \frac{w_{ia}(t) e^{\alpha h_{ia}(t)}}{\sum_{b} w_{ib}(t) e^{\alpha h_{ib}(t)}} \tag{19}$$

and a continuous-time algorithm is

$$\frac{dw_{ia}}{dt} = -w_{ia} + \frac{w_{ia} e^{\alpha h_{ia}}}{\sum_{b} w_{ib} e^{\alpha h_{ib}}} \tag{20}$$

## VLSI Analog Implementations

There have been several attempts to design analog very large-scale integrated (VLSI) circuits to compute winner-take-all.

Lazzaro et al. (1989) developed a winner-take-all circuit that was used for applications to auditory localization and visual stereopsis. This network was demonstrated to work effectively, and perturbation analysis was performed to demonstrate local stability. Yet, to our knowledge, no global analysis of the network has been performed, and convergence to the optimal solution has not been proved. The circuit takes current as input and outputs voltage.

A second circuit, from Waugh and Westervelt (1993), implements Equation 12. It is guaranteed to converge to the correct solution, provided the components of the circuit correctly implement the equations. In contrast to Lazzaro et al. (1989), the input is gate voltage and the output is current.

More recently, there have been a series of VLSI circuits with biological motivations. These include circuits based on neuronal spikes (Indiveri, 1999) and circuits that emulate visual attention (Horiuchi et al., 1997).

Care must be taken when drawing conclusions from the circuit equations describing these networks. Such equations are idealizations and assume that the networks are built of perfect components. This is unrealistic, and so the design of the network must be robust to imperfections in the components. Analog networks of this type are somewhat fragile and not as robust as simple discrete methods for winner-take-all using analog comparators and digital latches. It seems, however, that latch circuits are only capable of implementing pure winner-take-all and, unlike the analog circuits, cannot perform softmax.

## Biological Models

Biological considerations have motivated some winner-take-all models (Elias and Grossberg, 1975). Here we discuss a model presented by Yuille and Grzywacz (1989). The network is updated by the following equation:

$$\tau \frac{dx_i}{dt} = -x_i + I_i K(x_1, x_2, \ldots, x_{i-1}, x_{i+1}, \ldots, x_N) \tag{21}$$

where $x_i(t)$ is the state of the $i$th network element, $\tau$ is a constant, and the function $K$ is symmetric in all its variables, decreases (or remains constant) as they increase, and tends to zero when any of them goes to infinity. The initial values of the $x_i$ are set to the inputs $I_i$, which are constrained to be positive.

The first term on the right-hand side of Equation 21 corresponds to a time decay and the second contains inhibition between the network elements (Figure 1).

Lateral inhibition is a biologically plausible mechanism that is often used in winner-take-all networks to ensure that only one neuron is firing (Amari and Arbib, 1977). An usual aspect of this model is that the output of each element feeds back to inhibit the inputs to other elements (see Figure 1). We consider a special choice of $K$, which is motivated by a biological mechanism called shunting inhibition (Yuille and Grzywacz, 1989). Let

$$K(x_1, x_2, \ldots, x_{i-1}, x_{i+1}, \ldots, x_N) = e^{-\lambda \Sigma_{j \neq i} x_j} \tag{22}$$

where $\lambda$ is a constant that plays a similar role as the parameter $\beta$ in softmax.

By using the coordinate transformation $z_i = e^{-\lambda x_i}$, Equation 21 can be transformed into

$$\frac{dz_i}{dt} = -\frac{\lambda I_i z_i}{\tau} \frac{\partial E[z]}{\partial z_i} \tag{23}$$

where

$$E[z] = \frac{1}{\lambda} \sum_{j} \left( \frac{z_j \log z_j - z}{I_j} \right) + \prod_{j} z_j \tag{24}$$

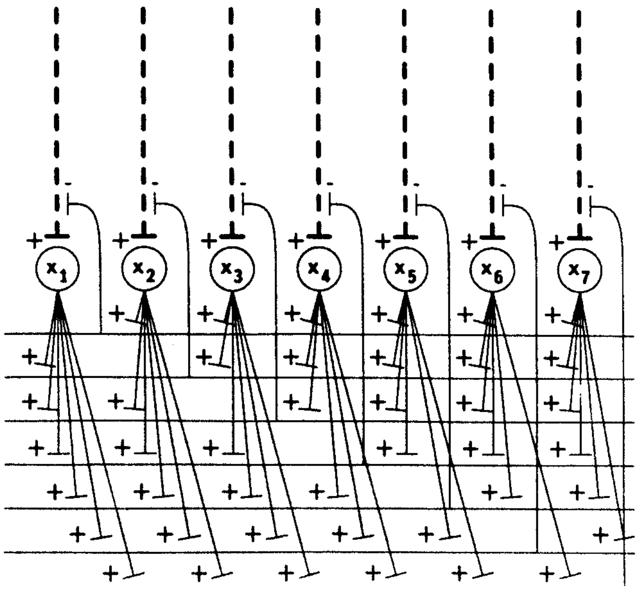

**Figure 1.** A biologically plausible circuit for winner-take-all. The dashed lines represent the inputs to the individual network elements. Each element excites inhibitory elements (similar to interneurons), which act on the presynaptic inputs of the other elements. Excitatory and inhibitory synapses are labeled with + and − signs, respectively. (From Yuille, A. L., and Grzywacz, N. M., 1989, A winner-take-all mechanism based on presynaptic inhibition, *Neural Computat.*, 1:334–347. © 1989, MIT Press; reprinted with permission.)

satisfies the properties of a Lyaponov function; it is bounded from below and always decreases with time when using the dynamics specified by Equation 23. This can be seen by observing that $dE/dt = -\Sigma_i(\lambda I_i z_i/\tau)(\partial E/\partial z_i)^2$ and recalling that the $z$s are constrained to be positive by definition. Hence the system converges to a minimum of $E$.

To understand the global convergence of the system, we examine the Hessian of $E$, the matrix with components $H_{\mathrm{ij}} = \partial^2 E/(\partial z_{\mathrm{i}} \partial z_{\mathrm{j}})$. We see that on the diagonal we have $H_{ii} = 1/(\lambda I_i z_i)$ and off the diagonal $H_{jk} = \prod_{i \neq j,k} z_i$. From Equation 21 we see that the $x_i$ are always positive, and so the $z_i$ lie in the range [0, 1]. Thus the diagonal elements are all greater than $1/(\lambda I_{max})$ and the off-diagonal elements are all less than 1. By making $\lambda \geq (N - 1)/I_{max}$ we can ensure that the Hessian is positive definite; hence $E$ is convex, and so there is a single solution that the system converges to. It was shown, in the large $\lambda$ limit, that this corresponds to the winner-take-all solution (Yuille and Grzywacz, 1989).

## Discussion

Winner-take-all is a special case of softmax. Both problems can be formulated in terms of energy minimization, and both can be solved by a number of continuous-time and discrete-time dynamical systems. Some of these systems can be implemented by VLSI circuits or by biologically plausible mechanisms.

These systems can be generalized in a straightforward way to systems of competitive memories or optimization problems. In these cases only convergence to locally optimal solutions is guaranteed.

Finally, recent results on the large computational power of winner-take-all networks, and their need for only positive weights, are very exciting. They ensure that winner-take-all networks will continue to be a major research topic for computation, biology, and VLSI.

## Introduction

This article addresses the issue of simultaneously building (1) a bottom-up pathway for encoding a pattern in the observation space into its representation in a representation space and (2) a top-down pathway for decoding or reconstructing a pattern from an inner representation back to a pattern in the observation space. This approach has been widely adopted in the literature of modeling a perception system for decades. A typical example is the Adaptive Resonance Theory (q.v.), developed by Grossberg and Carpenter starting in the 1970s. In the past decade, this approach has been widely adopted in various studies of brain theory and neural networks. Typical examples include Mumford's integrated theory for the corticothalamic and the corticocortical feedback (see Thalamus), Kawato's theory on the Cerebellum and Motor Control (q.v.), and Hinton and colleagues' Helmholtz Machines and Sleep-Wake Learning (q.v.). Moreover, the LMSER self-organizing rule proposed by Xu in 1991 (reference in Xu, 2001a) also uses a bidirectional architecture for statistical unsupervised learning.

The basic spirit of LMSER self-organizing was further developed into the Bayesian ying-yang (BYY) harmony learning in the mid-1990s. BYY harmony learning formulates the two pathways in a general statistical framework. First, a so-called BYY system is proposed for modeling the two pathways in a coordinated fashion via two complementary Bayesian representations of the joint distribution on the observation space and representation space. As a result, a number of existing major learning problems and learning methods are revisited as special cases from a unified perspective. Second, after further developments in the past several years, a harmony learning theory has been developed from which not only new regularization techniques (see Generalization and Regularization in Nonlinear Learning Systems) are obtained from a systematic perspective, but also using this theory on the BYY system results in an easily implemented approach for model selection that is made either automatically during parameter learning or sequentially after parameter learning via a new class of criteria. Third, application of the first two achievements to various specific BYY systems with typical structures led to three major learning paradigms, namely unsupervised learning, supervised learning, and temporal modeling, with new insights and a number of new results.

This article provides an introduction to the fundamentals of BYY harmony learning and outlines the major results. Further details are given in Xu (2001a, 2001b, 2002a, 2002b). Moreover, the ability of BYY harmony learning for regularization and model selection is explained from an information-theoretic perspective. A comparative discussion is made to clarify how it differs not only from the minimum message length (MML) and minimum description length (MDL) (Wallace and Dowe, 1999; Rissanen, 1999; also see MINIMUM DESCRIPTION LENGTH ANALYSIS), as well as Bayesian approach (Mackey, 1992), but also from information geometry theory (Csiszar and Tusnady, 1984; see NEUROMANIFOLDS AND INFORMATION GEOMETRY) and from HELMHOLTZ MACHINES AND SLEEP-WAKE LEARNING (q.v.).

## The Bayesian Ying-Yang System

We consider a world **X** with each object in an observation represented by an $\mathbf{x} \in \mathbf{X}$. Corresponding to each **x**, there is an inner representation $\mathbf{y} \in \mathbf{Y}$ in the representation domain **Y** of a learning system. We consider the joint distribution of **x**, **y**, which can be understood from two complementary perspectives.

On the one hand, we can interpret each **x** as generated from an invisible inner representation **y** via a backward path distribution $q(\mathbf{x}|\mathbf{y})$, called *a generative model* $q(\mathbf{x}) = \int q(\mathbf{x}|\mathbf{y})q(\mathbf{y})d\mathbf{y}$, that maps from an inner distribution $q(\mathbf{y})$. On the other hand, we can interpret each **x** as being mapped into an invisible inner representation **y** via a forward path distribution $p(\mathbf{y}|\mathbf{x})$, called a *representative model* $p(\mathbf{y}) = \int p(\mathbf{y}|\mathbf{x})p(\mathbf{x})d\mathbf{x}$, that matches the inner density $q(\mathbf{y})$.

The two perspectives reflect the two types of Bayesian decomposition of the joint density $q(\mathbf{x}|\mathbf{y})q(\mathbf{y}) = q(\mathbf{x}, \mathbf{y}) = p(\mathbf{x}, \mathbf{y}) = p(\mathbf{x})p(\mathbf{y}|\mathbf{x})$ on $\mathbf{X} \times \mathbf{Y}$. Without any constraints, the two decompositions should be theoretically identical. However, in a real consideration, the four components $p(\mathbf{y}|\mathbf{x})$, $p(\mathbf{x})$, $q(\mathbf{x}|\mathbf{y})$, $q(\mathbf{y})$ should all be subject to certain structural constraints according to the nature of the learning task. Thus, we usually have two different but complementary Bayesian representations:

$$p(\mathbf{x}, \mathbf{y}) = p(\mathbf{y}|\mathbf{x})p(\mathbf{x}), \quad q(\mathbf{x}, \mathbf{y}) = q(\mathbf{x}|\mathbf{y})q(\mathbf{y}) \tag{1}$$

where (with compliments to the ancient Chinese ying-yang philosophy) $p(\mathbf{x}, \mathbf{y})$ is called the *yang machine*, which consists of the observation space (*yang space*) $p(\mathbf{x})$ and the forward pathway (*yang pathway*) $p(\mathbf{y}|\mathbf{x})$; and $q(\mathbf{x}, \mathbf{y})$ is called the *ying machine*, which consists of the invisible state space (*ying space*) $q(\mathbf{y})$ and the *ying* (or backward) *pathway* $q(\mathbf{x}|\mathbf{y})$. Such a pair of ying-yang models is called a *Bayesian ying-yang (BYY) system*.

From a set $\chi$ of samples from the observed world **X**, the distribution $p(\mathbf{x})$ is given either by an empirical density $p(\mathbf{x}|\chi)$ or a nonparametric estimate $p(\mathbf{x}|\chi, h^2)$ with a unknown smoothing parameter $h$, as will be further specified later by Equations 8 and 11. The task of learning on a BYY system consists of specifying all the aspects of $p(\mathbf{y}|\mathbf{x})$, $q(\mathbf{x}|\mathbf{y})$, $q(\mathbf{y})$ as well as $h$ (if any).

First, we need to design the structure of $q(\mathbf{y})$, which depends on learning tasks that are closely related to the complexity of the world **X** that we observe. One typical example is a world $\mathbf{X} = \{X, L\}$ that consists of a number of individual objects to observe, with $L$ denoting a set of labels and each $\ell \in L$ denoting an object. In this case, each $\mathbf{x} = \{x, \ell\}$ contains a feature vector $x = [x^{(1)}, \ldots, x^{(d)}]^T$ observed from the object $\ell$, subject to a joint underlying distribution $p(\mathbf{x}) = p(x, \ell)$. Correspondingly, we consider a representation domain $\mathbf{Y} = \{Y, L\}$, subject to a parametric structure of $q(\mathbf{y}) = q(y, \ell)$ that describes the vector **y** and the label $\ell$ jointly. This $q(\mathbf{y})$ is specified by three ingredients. The first consists of a set $\mathbf{k} = \{k, \{m_\ell\}\}$, with $k$ denoting the number of labels in $L$ and $m_\ell$ being the dimension of either a binary or a real vector **y** that corresponds to $\ell \in L$. We call both $k$, $m_\ell$ the scales of the representation domain **Y**. The second ingredient is the functional form of $q(\mathbf{y})$, which is usually prespecified according to the nature of learning task. The third consists of a set $\theta_y$ of parameters in this given function form.

Second, we need to design the structures of $p(\mathbf{y}|\mathbf{x})$, $q(\mathbf{x}|\mathbf{y})$ that specify the mapping capacity of $x \rightarrow y$ and $y \rightarrow x$, respectively. Each of the two can be either parametric or structure free. We say $p(u|v)$ is structure free if $p(u|v)$ can be any function that satisfies $\int p(u|v) = 1$, $p(u|v) \geq 0$. A structure-free distribution is actually specified in learning. Given its functional form, a parametric $p(u|v, \theta_{u|v})$ is structured by a set $\theta_{u|v}$ of unknown parameters.

Putting this all together, the nature of a BYY system depends on the structure of $q(\mathbf{y})$ for describing the representation domain **Y**, and the architecture of a BYY system is featured by a combination of the specific structures of $p(\mathbf{y}|\mathbf{x})$, $q(\mathbf{x}|\mathbf{y})$. Discarding a useless architecture where both $p(\mathbf{y}|\mathbf{x})$, $q(\mathbf{x}|\mathbf{y})$ are structure free, there remain three choices for a meaningful BYY architecture:

- *Backward architecture* (*B-architecture*): $p(\mathbf{y}|\mathbf{x})$ is structure-free and $q(\mathbf{x}|\mathbf{y})$ is parametric.
- *Forward architecture* (*F-architecture*): $q(\mathbf{x}|\mathbf{y})$ is structure-free and $p(\mathbf{y}|\mathbf{x})$ is parametric.
- *Bidirectional architecture* (*BI-architecture*): Both $p(\mathbf{y}|\mathbf{x})$, $q(\mathbf{x}|\mathbf{y})$ are parametric.

Generally speaking, a learning task includes two subtasks. One is called *parameter learning* and is for determining a value of the set $\theta$ that consists of all the unknown parameters in $p(\mathbf{y}|\mathbf{x})$, $q(\mathbf{x}|\mathbf{y})$, $q(\mathbf{y})$ as well as $h$ (if any). The other subtask is called *model selection* and is for selecting the scales of representation, since a collection of specific BYY systems with different scales in **k** corresponds to a family of specific models that share the same system configuration but with different scales.

## Harmony Learning

We consider learning in a broad sense that starts from two $p(u)$, $q(u)$, with each of them having certain unknown parts, in either or both scales and parameters. The task of learning is to specify all the unknowns from the known parts. Our *fundamental learning principle* is to make $p(u)$, $g(u)$ have the *best harmony in* a twofold sense:

- The difference between the resulting $p(u)$, $g(u)$ should be minimized.
- The resulting $p(u)$, $g(u)$ should be of the least complexity.

Mathematically, we use a functional $H(p\|q)$ to measure the *degree of harmony* between $p(u)$ and $q(u)$. When both $p(u)$, $q(u)$ are discrete densities in the following form:

$$q(u) = \sum_{t=1}^{N} q_t \delta(u - u_t), \quad \sum_{t=1}^{N} q_t = 1 \tag{2}$$

with $\delta(u)$ being a $\delta$-function, we can simply use the following cross entropy

$$H(p\|q) = \sum_{t=1}^{N} p_t \ln q_t \tag{3}$$

as a typical example of such a measure. The maximization of $H(p\|q)$ has two interesting natures:

- *Matching nature*: With $p$ fixed, $\max_q H(p\|q)$ pushes $q$ toward

$$q_t = p_t, \text{ for all } t \tag{4}$$

- *Least complexity nature*: $\max_p H(p\|q)$ with $q$ fixed pushes $p$ toward its simplest form

$$p(u) = \delta(u - u_\tau), \textit{ with } \tau = \textit{arg } \underset{t}{\textit{max}}\ g_t \tag{5}$$

or equivalently $p_\tau = 1$, and $p_t = 0$ for other $t$, which is of least complexity from the statistical perspective (Xu, 2001a).

Thus, the maximization of this functional indeed implements the above harmony purpose mathematically. As shown by Xu (2001a), we can further represent either a discrete or continuous density $q(u)$ in the form of Equation 2 by considering its sample points $\{u_t\}_{t=1}^N$ via the following normalization:

$$\hat{q}_t = q(u_t)/z_q,\ z_q = \sum_{t=1}^N q(u_t) \tag{6}$$

Putting this into Equation 3, we can get a general form of the harmony measure:

$$H(p\|q) = \int p(u) \ln q(u)du - \ln z_q \tag{7}$$

which reduces to Equation 3 when $q(u)$, $p(u)$ are discrete (as in Equation 2), with $u$ enumerated from $u_1, \ldots, u_N$ deterministically.

Moreover, when $p(u)$ is given by its empirical density (Devroye et al., 1996),

$$p_0(u) = \frac{1}{N}\sum_{t=1}^N \delta(u - u_t) \tag{8}$$

a crude approximation $z_q = 1$ will make $H(p\|q)$ in Equation 7 become the likelihood

$$L(\theta) = \sum_{t=1}^N \ln q(u_t) \tag{9}$$

Thus, finding $\max_q H(p\|q)$ becomes equivalent to conventional maximum likelihood (ML) learning.

Generally, the term $\ln z_q$ imposes a regularization on ML learning. Two typical examples are given as follows:

1. *Normalization learning*: With $p(u)$ given by Equation 8, we approximate either a discrete or continuous $q(u)$ by Equation 6 and get Equation 7 in the form

$$H(p\|q) = L(\theta) - \ln z_q,\ z_q = \sum_{t=1}^N q(u_t) \tag{10}$$

with $\ln z_q$ imposing a de-learning on the ML learning, which avoids $q(u)$ overfitting a finite size data set (Xu, 2001a).

2. *Data smoothing learning*: Consider $p(u)$ given by a Parzen window estimate (Devroye et al., 1996)

$$p(u) = p_h(u) = \frac{1}{N}\sum_{t=1}^N G(u|u_t, h^2 I) \tag{11}$$

where, as hereafter in this article, $G(u|\mu, \Sigma)$ denotes a Gaussian density with mean vector $\mu$ and covariance matrix $\Sigma$. Under a weak constraint $\Sigma_{t=1}^N p(u_t) \approx \Sigma_{t=1}^N q(u_t) = z_q$, we can approximately get (Xu, 2001a)

$$z_q \approx \frac{z_q^N(h, k)}{N(2\pi h^2)^{k/2}},\ z_q^N(h, k) = \sum_{\tau=1}^N \sum_{t=1}^N e^{-0.5(\|u_t - u_\tau\|^2/h^2)} \tag{12}$$

where $k$ is the dimension of $u$. Thus, Equation 7 becomes

$$H(p\|q) = \int p_h(u) \ln q(u)du + 0.5k \ln (2\pi h^2) + \ln N - \ln z_q^N(h, k) \tag{13}$$

The first term regularizes ML learning by smoothing each likelihood $\ln q(u_t)$ in the near-neighborhood of $u_t$, and thus is referred to as *data smoothing*. The role of $h^2$ is equivalent to the hyperparameter in Tikhonov-type regularization (Bishop, 1995), but with a new feature that the other terms balance the first term such that an appropriate $h$ is learned together with $\theta$ (Xu, 2001a).

## BYY Harmony Learning

The fact that $\max_\theta \int p_0(u) \ln q(u|\theta)du$ leads to ML learning is well known in the literature. Moreover, $\max_\theta \int p^*(u) \ln q(u|\theta)du$, with $p^*(u)$ being the true distribution of samples, has also been studied in developing the Akaike information criterion (AIC) for model selection (Akaike, 1974). However, the least complexity nature of Equation 5 has rarely been studied because it is regarded as useless in a conventional sense. In contrast, least complexity plays an essential role that enables the harmony learning on a BYY system to implement model selection.

To be specific, we put $p(u) = p(\mathbf{x}, \mathbf{y}) = p(\mathbf{y}|\mathbf{x})p(\mathbf{x})$, $q(u) = q(\mathbf{x}, \mathbf{y}) = q(\mathbf{x}|\mathbf{y})q(\mathbf{y})$ into Equation 7, and get

$$H(p\|q) = \int p(\mathbf{y}|\mathbf{x})p(\mathbf{x}) \ln [q(\mathbf{x}|\mathbf{y})q(\mathbf{y})]d\mathbf{x}d\mathbf{y} - \ln z_q \tag{14}$$

Again, the term $-\ln z_q$ imposes regularization on learning either by normalization similar to Equation 10 or by data smoothing similar to Equation 12. This regularization may be simply ignored by setting $z_q = 1$. The details are given in Xu (2000, 2001a). For example, similar to Equation 10, we can simply get

$$z_q = \sum_{t=1}^N q(\mathbf{x}_t|\mathbf{y}_t)q(\mathbf{y}_t) \tag{15}$$

on a set of samples $\chi = \{\mathbf{x}_t\}_{t=1}^N$, where $\mathbf{y}_t$ is estimated during learning as an inner representation of $\mathbf{x}_t$.

Mathematically, harmony learning is implemented by

$$\max_{\theta, \mathbf{k}} H(\theta, \mathbf{k}), \text{ where } H(\theta, \mathbf{k}) = H(p\|q) \tag{16}$$

Unlike the case of Equation 7, the least complexity nature of a BYY system makes selecting $\mathbf{k}$ possible, because now only $p(\mathbf{x})$ is fixed as a nonparametric estimate, while $p(\mathbf{y}|\mathbf{x})$ is not fixed but able to be pushed into its least complexity form during learning. In a B-architecture, $p(\mathbf{y}|\mathbf{x})$ is free and thus will be determined by $\max_{p(\mathbf{y}|\mathbf{x})} H(p\|q)$, resulting in

$$p(\mathbf{y}|\mathbf{x}) = \delta(\mathbf{y} - \hat{\mathbf{y}}),\ \hat{\mathbf{y}} = \arg \max_{\mathbf{y}} [q(\mathbf{x}|\mathbf{y})q(\mathbf{y})] \tag{17}$$

In turn, the matching nature of harmony learning will further push $q(\mathbf{x}|\mathbf{y})$ and $q(\mathbf{y})$ toward their corresponding least complexity forms. In a BI-architecture, the learning will similarly push $p(\mathbf{y}|\mathbf{x})$ into its least complexity form, e.g., $p(\mathbf{y}|\mathbf{x}) = \delta(\mathbf{y} - f_j(\mathbf{x}, W_{y|x}))$ (Xu, 2001a).

As for $q(\mathbf{y}) = q(y, \ell) = q(y|\ell)q(\ell)$, it is not difficult to observe that letting $p(\ell)$ be zero is equivalent to reducing $k$ by one, and that letting the variance of every $q(y^{(j)}|\ell)$, for all $\ell \in L$, be zero is equivalent to removing the $j$th dimension (i.e., reducing the dimension $m$ by one). In other words, making $\theta$ take a specific value is equivalent to forcing $k$, $m_\ell$ to be reduced effectively to appropriate scales. So, model selection may come into effect either in parallel with parameter learning or sequentially after making parameter learning via enumerating $k$ on an appropriate range. That is, we have the following two types of learning implementation:

- *Parameter learning with automated model selection*: We set $k$, $\{m_\ell\}$ in $\mathbf{k}$ large enough and then implement harmony learning by

$$\max_{\theta} H(\theta),\ H(\theta) = H(\theta, \mathbf{k}) \tag{18}$$

  The least complexity nature Equation 5 will let $\theta$ take a specific value such that $\mathbf{k} = \{k, \{m_\ell\}\}$ are effectively reduced to appropriate scales, i.e., model selection is made automatically in parallel with parameter learning.
- *Parameter learning followed by model selection*: Alternatively, we can make parameter learning and model selection sequentially in two steps. In the first step, we enumerate $k$, $m_\ell$ from small values incrementally, and at each specific $k$, $m_\ell$ we perform parameter learning Equation 18, to get the best parameter value $\theta^*$. Moreover, to simplify the implementation, we can even assume $q(\ell) = 1/k$ and $q(y|\ell)$ comes from a family that satisfies certain constraint (Xu, 2002a). Then in the second step, we select a best $k^*$, $m_\ell^*$ by

$$\min_{k,m_\ell} J(k, m_\ell), \text{ where } J(k, m_\ell) = -H(\theta^*, \mathbf{k}) \tag{19}$$

  If there is more than one solution for which $J(k, m_\ell)$ gets the same minimum, we take one with the smallest values on $k$, $\{m_\ell\}$.

This, two-step implementation can be modified with the first step replaced by alternatives. One is to replace Equation 18 by minimizing the Kullback divergence (see Learning and Statistical Inference)

$$\min_{\theta} KL(\theta) = \int p(\mathbf{y}|\mathbf{x})p(\mathbf{x}) \ln \frac{p(\mathbf{y}|\mathbf{x})p(\mathbf{x})}{q(\mathbf{x}|\mathbf{y})q(\mathbf{y})}\, d\mathbf{x}d\mathbf{y} \tag{20}$$

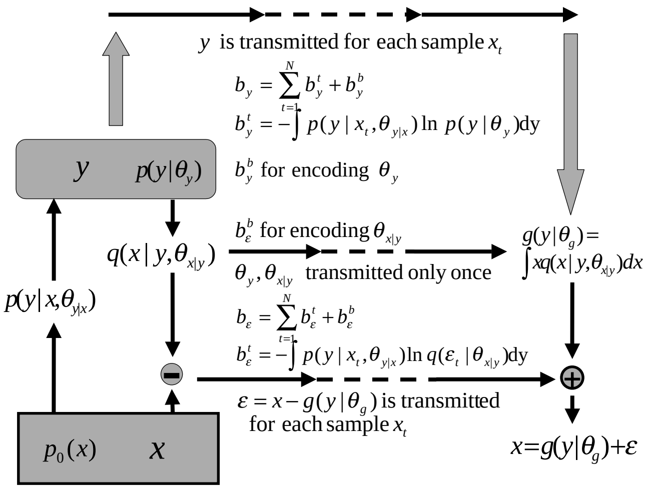
as in the initial work of the BYY learning made in 1995 (reference in Xu, 2002a) and other early studies. In this situation, the first step leads us to a number of existing learning models that are based on the maximum likelihood principle or its equivalents. Another alternative is to replace $H(\theta)$ in Equation 18 by $H(\theta) - \lambda KL(\theta)$ with $\lambda > 0$ gradually reducing toward zero from a given value. Both alternatives can reduce the local minimum effect caused by the winner-take-all mechanism of Equation 17, but at the cost of greater difficulty in handling the integral of $\mathbf{y}$ in Equation 20.

## Information-Theoretic Perspective, MML/MDL, and the Bayesian Approach

Alternatively, we can understand harmony learning from an information-theoretic perspective. We consider the transfer of the information in $\mathbf{x}$ from a sender via a communication line to a receiver. Instead of directly encoding $\mathbf{x}$ for transmission, $\mathbf{x}$ is mapped to its inner representation $\mathbf{y}$, and then $\mathbf{y}$ is encoded and sent to the receiver. The receiver then decodes $\mathbf{y}$ to reconstruct $\mathbf{x}$.

Without losing generality, we consider the BYY system with $p(y|x) = p(y|x, \theta_{y|x})$, $q(\mathbf{x}|\mathbf{y}) = p(x|y, \theta_{x|y})$, and $q(\mathbf{y}) = q(y|\theta_y)$, as shown in Figure 1. On the sender side, $x$ is mapped into its code $y$ via the yang passage $p(\mathbf{y}|\mathbf{x}) = p(y|x, \theta_{y|x})$ and then $y$ is encoded and sent to the receiver side. On the receiver side, a parametric regression function $\hat{x} = g(y, \theta_g)$ is used to construct $x$ with an error $\varepsilon = x - \hat{x}$. Assuming the functional form of $g(y, \cdot)$ is known at the receiver end, in order to get the original $x$ we need to know not only $y$ but also $\varepsilon$ and $\theta_g$, which should be decided at the sender end and then transferred via the communication line, too.

For this purpose, the reconstruction process at the receiver end is simulated by the ying machine at the sender end. First, the yang passage $p(y|x, \theta_{y|x})$ is assumed to come from a known parametric family but with an unknown set of parameters $\theta_{y|x}$. Second, the mapped $y$ is assumed to be exactly described by a distribution of a known parametric family $q(y|\theta_y)$ but with an unknown set of parameters $\theta_y$. Third, we attempt to reconstruct $x$ by the regression $g(y, \theta_g)$ with the residual $\varepsilon = x - g(y, \theta_g)$ that comes from a known parametric family $q(\varepsilon|\theta_\varepsilon)$ but with an unknown set of parameters $\theta_\varepsilon$. That is, we have $p(x|y, \theta_{x|y}) = q(x - g(y|\theta_g)|\theta_\varepsilon)$ with $\theta_{x|y} = \{\theta_g, \theta_\varepsilon\}$ and $g(y|\theta_g) = \int xp(x|y, \theta_{x|y})dx$.



$y$ is transmitted for each sample $x_t$
$b_y = \sum_{t=1}^{N} b_y^t + b_y^b$
$b_y^t = -\int p(y\,|\,x_t, \theta_{y|x}) \ln p(y\,|\,\theta_y)dy$
$b_y^b$ for encoding $\theta_y$
$y$ $p(y|\theta_y)$
$q(x\,|\,y, \theta_{x|y})$
$p(y|x, \theta_{y|x})$
$b_\varepsilon^b$ for encoding $\theta_{x|y}$
$\theta_y, \theta_{x|y}$ transmitted only once
$g(y|\theta_g) = \int xq(x|y, \theta_{x|y})dx$
$b_\varepsilon = \sum_{t=1}^{N} b_\varepsilon^t + b_\varepsilon^b$
$b_\varepsilon^t = -\int p(y\,|\,x_t, \theta_{y|x}) \ln q(\varepsilon_t\,|\,\theta_{x|y})dy$
$\varepsilon = x - g(y\,|\,\theta_g)$ is transmitted for each sample $x_t$
$p_0(x)$ $x$
$x = g(y|\theta_g) + \varepsilon$

**Figure 1.** Bayesian ying-yang harmony learning from an information-theoretic perspective.

We consider the building of the above BYY system from the perspective that the transmission of $y$, $\varepsilon$, and $\theta_g$ is made most efficiently, comparing this approach with the minimum message length (MML) and minimum description length (MDL) approached (Wallace and Dowe, 1999; Rissanen, 1986, 1999), which can be regarded as specific implementations of the more general algorithmic complexity exemplified by the celebrated Kolmogorov complexity (Gammerman and Vovk, 1999).

If we know the true distribution $q(y|\theta_y^*)$ with an exact value of $\theta_y^*$, it follows that the number of bits for encoding $y$ is $b_y^s = \Sigma_{t=1}^{N} b_y^t$, with $b_y^t$ being the bits that are needed to encode $y$ for each sample $x_t$. Since the probability of using a particular $y$ as a code of $x_t$ is $p(y|x_t, \theta_{y|x})dy$, this $b_y^t$ should be the expected number of bits to be used at $x_t$, i.e., $b_y^t = -\int p(y|x_t, \theta_{y|x}) \ln q(y|\theta_y^*)dy - c_y$, where $c_y = 0$ when $q(y|\theta_y^*)$ is a discrete probability distribution and $c_y = \ln \delta_y$ when $q(y|\theta_y^*)$ is a continuous density, with $\delta_y$ being a quantization resolution. Usually $c_y$ is omitted in the MML/MDL literature, since it is regarded as a constant.

However, on a set of finite samples $\{x_t\}_{t=1}^{N}$, instead of getting exactly $\theta_y^*$ we can obtain only an estimate $\theta_y$ that is itself a random variable. Thus, the bits for encoding $y$ consist of the above $b_y^s$ plus $b_y^b$, i.e., $b_y = b_y^s + b_y^b$, where $b_y^b$ is the number of bits for encoding an estimate $\theta_y$, which does not depend on each individual sample but on the entire data set $\{x_t\}_{t=1}^{N}$, or equivalently the distribution of $\theta_y$.

Similarly, the number of bits for encoding $\varepsilon$ also consist of two parts $b_\varepsilon = \Sigma_{t=1}^{N} b_\varepsilon^t + b_\varepsilon^b$, where $b_\varepsilon^t = -\int p(y|x_t, \theta_{y|x}) \ln q(\varepsilon|\theta_\varepsilon)dy = -\int p(y|x_t, \theta_{y|x}) \ln q(x_t|y, \theta_{x|y})dy$ for each sample $x_t$, and $b_\varepsilon^b$ for encoding $\theta_\varepsilon$. Moreover, we use $b_g$ to count the bits for encoding $\theta_g$, and then use $b_{x|y}^b = b_\varepsilon^b + b_g$ to denote the total bits for encoding $\theta_{x|y} = \{\theta_g, \theta_\varepsilon\}$, which again does not depend on each individual sample but on the entire batch of data.

Summing up, the total description length is $L_T = Nb_s + b_\theta$ with $b_s = (1/N)\Sigma_{t=1}^N(b_y^t + b_\varepsilon^t)$ being the average number of bits that is needed for each sample $x_t$ and $b_\theta = b_y^b + b_{x|y}^b = b_y^b + b_\varepsilon^b + b_g$ being the total number of bits for encoding $\theta_{x|y}$, $\theta_y$. Thus, the average unit length for each sample $x_t$ is $L_U = b_s + (b_\theta/N)$. Since $b_\theta$ does not depend on the size $N$, $(b_\theta/N)$ decreases toward zero as $N$ increases.

It further follows that $b_y^t + b_\varepsilon^t = -\int p(y|x_t, \theta_{y|x}) \ln [q(x_t|y, \theta_{x|y})q(y|\theta_y)]dy$ and thus that

$$b_s = -\int p(y|x_t, \theta_{y|x})p_0(x) \ln [q(x_t|y, \theta_{x|y})q(y|\theta_y)]dxdy$$

$$p_0(x) = \frac{1}{N}\sum_{t=1}^{N} \delta(x - x_t) \tag{21}$$

Comparing this with Equation 14, we have exactly $H(p\|q) = -b_s - \ln z_q^{-1}$, where the second term depends on the specific value of parameters $\theta_{x|y}$, $\theta_y$ and the complexity of $y$, but does not depend on each individual sample $x_t$. Also, it tends to zero as $N \to \infty$, which is consistent with the role of $b_\theta/N$ that tends to zero as $N \to \infty$. So, BYY harmony learning relates closely to the MML/MDL spirit in that both have in common minimizing $b_s$, i.e., the part of the description length for each sample. For this reason, as well as shown experimentally (Xu, 2001a), BYY harmony learning has model selection ability qualitatively similar to that of MML/MDL. This ability can be understood from the interaction between the two parts in $b_y^t + b_\varepsilon^t$. As the representation scale increases, $b_y^t$ increases while $b_\varepsilon^t$ decreases. The minimization of the two parts trades off an appropriate scale for representing $y$.

However, BYY harmony learning differs from MML/MDL on the specific form for encoding $\theta$. One obvious advantage of BYY harmony learning is that using $\ln z_q^{-1}$ instead of $b_\theta/N$ is easy in implementation. Usually, $b_\theta$ is difficult to compute and has to be replaced by some rough approximation or bound, with consequent poor actual performance. Further studies are warranted to explore the quantitative relation between $\ln z_q^{-1}$ and $b_\theta/N$ to see whether the features of the two can be combined.

In the literature on neural networks learning, it has been widely regarded that the Bayesian approach is equivalent to the MDL approach. However, the situation is not so simple, but depends on how the MDL and the Bayesian approaches are implemented.

One typical Bayesian implementation is for parameter regularization, i.e., a priori density on parameters is assumed such that parameters are determined based on the joint distribution of the parameters and the observed sample data. When MDL was first proposed (Rissanen, 1986), it was implemented basically in equivalence to the MML approach (Wallace and Dowe, 1999), which shares the same spirit of Bayesian regularization in that its first part encodes the fitting residuals and its second part corresponds to the a priori density on parameters. According to the original authors of MML, however, MML actually uses an improper prior density if we insist on relating it to the Bayesian perspective.

Another typical Bayesian implementation is the so-called evidence-based Bayesian approach (Mackey, 1992; see also Bayesian Methods and Neural Networks) using what is called the BIC model selection criterion in the literature of statistics. This one has in principle the closet agreement with the MDL principle that considers an average of all the MML code lengths for all distributions in a family instead of a single MML code length (Rissanen, 1999). In various actual implementations, however, it usually degenerates to be identical to MML after selecting a noninformative uniform prior and approximating the integral of the marginal density via considerable simplification. Interestingly, the latest implementation of MDL uses a so-called normalized maximum likelihood model as the universal model (Rissanen, 1999), which leads to improved code length and becomes different from both MML and the evidence-based Bayesian approach.

BYY harmony learning shares the common spirit of MML as well as Bayesian regularization in the general sense that $z_q^{-1}$ can be regarded as another type of improper prior density on parameters in the BYY system such that the term $-\ln z_q^{-1}$ imposes further regularization on parameter learning, while the interaction between the two parts $b_y^t + b_\varepsilon^t$ in $b_s$ makes model selection implemented either automatically during parameter learning or subsequently after parameter learning via a new class of model selection criteria. It is also possible to further extend BYY harmony learning to share the sprit of MDL and the evidence-based Bayesian approach by normalizing $z_q^{-1}$ into an a priori density $p(\theta)$ and then maximizing an average harmony measure $\int H(\theta)p(\theta)d\theta$. However, this has as extra cost the difficulty in implementing the integral.

## Examples of Applications

Applying Equations 18 and 19 to specific BYY systems for various learning tasks, we have obtained not only new insights but also a number of new results. The details are given in Xu (2001a, 2001b, 2002a, 2002b). In the following, we briefly introduce several examples of unsupervised learning.

- *The MSE clustering, number of clusters, and RPCL learning*: Considering a simple B-architecture with $p(\mathbf{y}) = p(y, \ell) = \delta(y - \mu_\ell)/k$ and $p(\mathbf{x}|\mathbf{y}) = p(x|y, \ell) = G(x|y, \sigma^2 I)$, it follows that Equation 18 with the term $-\ln z_q^{-1}$ ignored (i.e., with $z_q = 1$) becomes equivalent to

  $$\hat{\ell} = \arg\min_{\ell} \|x_t - \mu_\ell\|^2, \min_{all\ \ell} E_2, E_2 = \sum_{t=1}^{N} \|x_t - \mu_{\hat{\ell}}\|^2 \tag{22}$$

  This is exactly conventional least square clustering or vector quantization, which leads to the well-known $k$-means algorithm and classical Competitive Learning (q.v.). Moreover, we can get several new results. First obtained by Xu in 1997 (reference in Xu, 2002a), it follows that Equation 19 becomes the following criterion for the best number of clusters

  $$k^* = \arg\min_{k} J(k), \text{ with } J(k) = 0.5d \ln E_2 + \ln k \tag{23}$$

  Second, with $z_q$ given by the normalization Equation 15 and $p(\mathbf{y}) = p(y, \ell) = \delta(y - m_\ell)p(\ell)$, not only can we get a modified version of Equation 23 from Equation 19, but it also follows that Equation 18 in parallel implementation becomes equivalent to rival penalized competitive learning (RPCL), proposed by Xu, Krzyzak, and Oja in 1993 (reference in Xu, 2002a), that is able to find the correct number of clusters automatically during learning. Third, these results can also be extended to regularized versions (Xu, 2001b).
- *PCA and Gaussian factor analysis (FA)*: For a B-architecture with $p(\mathbf{y}) = G(y|0, I)$ and $p(\mathbf{x}|\mathbf{y}) = G(x|Ay, \sigma^2 I)$, it follows that Equation 18 with $z_q = 1$ becomes equivalent to Principal Component Analysis (PCA) (q.v.) and Equation 19 becomes

  $$m^* = \arg\min_{m} J(m),$$
  $$J(m) = 0.5d \ln \sigma^{*2} + 0.5m(\ln 2\pi + 1) \tag{24}$$

  for the principal subspace dimension $m$. Moreover, Equation 18 with $z_q = 1$ becomes equivalent to Gaussian FA when $p(\mathbf{x}|\mathbf{y}) = G(x|Ay, \Sigma)$, with an adaptive EM algorithm developed for its implementation. Also, Equation 18 with $z_q$ given by the normalization Equation 15 will lead to RPCL-type learning that is able to automatically determine the dimension $m$.
- *Elliptic RPCL, Gaussian mixture, and local PCA*: For a B-architecture with $p(\mathbf{y}) = p(\ell)\ G(y|\mu_\ell, I)$ and $p(\mathbf{x}|\mathbf{y}) = G(x|A_\ell y,$

$\sigma_\ell^2 I$), from Equation 18 we can obtain (1) both the batch and adaptive EM-type algorithms for either elliptic clustering or ML learning on Gaussian mixtures, (2) an elliptic RPCL algorithm with automated selection on cluster number during learning, (3) extensions to local PCA, and (4) other extensions. Moreover, we can use Equation 19 for selecting both $k$ and the dimensions $\{m_\ell\}$ of local subspaces, which simplifies to

$$\begin{aligned}[k^*, \{m_\ell^*\}] &= \arg\min_{k,\{m_\ell\}} J(k, \{m_\ell\}) \\ J(k, \{m_\ell\}) &= 0.5 \sum_{\ell=1}^{k} p(\ell)[\ln |\Sigma_\ell| \\ &\quad + m_\ell(\ln 2\pi + 1)] - \sum_{\ell=1}^{k} p(\ell) \ln p(\ell), \\ \Sigma_\ell &= A_\ell A_\ell^T + \sigma_\ell^2 I \end{aligned} \tag{25}$$

- *Binary FA, non-Gaussian FA, and local extensions*: For a B-architecture with $p(\mathbf{y}) = \Pi_{j=1}^{m} p(y_j)$ where each $p(y_j)$ is a scalar finite mixture (e.g., Gaussian mixture) and $p(\mathbf{x}|\mathbf{y}) = G(x|Ay, \sigma^2 I)$, from Equation 18 we have obtained both the adaptive EM-type and RPCL-type algorithms for implementing either binary FA when each $y_j$ is binary or non-Gaussian real FA when each $y_j$ is real which was previously studied under the name of Bayesian Ying Yang Kullback dependence reduction in 1998 (reference in Xu, 2000) and further developed with the name changed into the current one. Moreover, from Equation 19 we get criteria for selecting the number $m$ of factors. Furthermore, these results can also be extended to localized versions by considering $p(\mathbf{y}) = p(\ell)\Pi_{j=1}^{m_\ell} p_\ell(y_j)$ and $p(\mathbf{x}|\mathbf{y}) = G(x|A_\ell y, \sigma_\ell^2 I)$.
- *ICA and competitive ICA*: For an F-architecture with $p(\mathbf{y}) = \Pi_{j=1}^{m} p(y_j)$ as above and $p(\mathbf{y}|\mathbf{x}) = \delta(y - Wy)$, from Equation 18 we can revisit (1) the *learned parametric mixture—based ICA* algorithm, first proposed by Xu, Yang, and Amari in 1996 (reference in Xu, 2001a), that works not only on cases where some components of $y$ are super-Gaussian and others are sub-Gaussian, but also on cases where $W$ is not invertible but $|WW^T| \neq 0$. Moreover, it has been further extended to a localized version via competition by considering $p(\mathbf{y}) = p(\ell)\ \Pi_{j=1}^{m_\ell} p_\ell(y_j)$ and $p(\mathbf{y}|\mathbf{x}) = p(\ell|x)\delta(y - W_\ell x)$ (Xu, 2002a).
- *LMSER learning, principal ICA, and local extensions*: For a BI-architecture with $p(\mathbf{y}) = \Pi_{j=1}^{m} p(y_j)$, $p(\mathbf{x}|\mathbf{y}) = G(x|Ay, \sigma^2 I)$, and $p(\mathbf{y}|\mathbf{x}) = \delta(y - s(Wx))$, Equation 18 leads us not only to revisit LMSER learning that was first proposed by Xu in 1991 and then directly adopted by Karhunen and Joutsensalo (1994) to implement ICA under the name of nonlinear PCA, but also various extensions, including a so-called principal ICA that corresponds to the direct extension of PCA to ICA. Moreover, from Equation 19 we get criteria for selecting the dimension $m$. Furthermore, these results have also been extended to localized versions (Xu, 2001b, 2002a).

A number of new results have also obtained on supervised learning and temporal modeling.

For supervised learning, new understandings are obtained on three-layer feedforward nets with backpropagation learning, on the popular mixture-of-experts (ME) model with the corresponding EM algorithm (see Modular and Hierarchical Learning Systems), and on the alternative ME model (Xu, Jordan, and Hinton in Xu, 2002a) as well as the normalized radial basis function (NRBF) network and its extensions. Moreover, various adaptive EM-type learning algorithms are developed from both Equation 18 and Equation 20 since 1998. New criteria have been derived from Equation 19 for deciding the number of hidden units, the number of experts, and the number of basis functions. Also, we get an alternative approach for deciding the set of supporting vectors in Support Vector Machines (q.v.). For further details see (Xu, 2001b, 2002b).

Temporal BYY harmony learning has been developed as a general state space approach for modeling data that has temporal relationship among samples, and provides not only a unified point of view on Kalman filter (see Kalman Filtering: Neural Implications) and Hidden Markov Models (q.v.), but also several new results, such as higher-order HMMs, independent HMMs, temporal ICA, temporal factor analysis, temporal extension of competitive ICA and LMSER learning, and more, with adaptive algorithms for implementation and criteria for selecting the number of states or sources. Further details are supplied in (Xu, 2000, 2001a).

## Discussion

Conventional ML learning, as in maximizing $L(\theta)$ in Equation 9, is widely used for estimating $\theta$ for a parametric density $q(u|\theta)$ directly on a set $\{u_t\}_{t=1}^N$ of samples. For many practical problems, such as perception, $u$ consists of two parts, $u = (x, y)$, with $y$ invisible. What can be observed is a sample set $\{x_t\}_{t=1}^N$, and thus ML learning is not directly applicable to $q(u|\theta)$. In such cases, ML learning is usually implemented on the marginal density

$$q(x|\theta) = \int q(u|\theta)dy = \int q(x_t|y, \theta_{x|y})q(y|\theta_y)dy \tag{26}$$

which is usually called the factor model or latent variable model or *generative model* in the literature.

However, a direct implementation of ML learning on $q(x|\theta)$ is usually not computationally effective. The problem is solved by two closely related approaches. One is the popular EM algorithm, developed under incomplete data theory (IDT) (Dempster, Laird, and Rubin, 1977). The other is the well-known alternative minimization (Csiszar and Tusnady, 1984), also called the *em* algorithm, developed under information geometry theory (IGT) (see Neuromanifolds and Information Geometry). The approaches work on a class of problems where $y$ takes finite discrete values such that either Equation 26 is a finite mixture or the integral in Equation 26 can be analytically solved. However, in the implementation, we have to compute

$$\begin{aligned} p(y|x) &= \frac{q(x|y, \theta_{x|y})q(y|\theta_y)}{\int q(x|y, \theta_{x|y})q(y|\theta_y)dy}, \text{ and } \max_\theta Q(\theta) \ \textit{with} \\ Q(\theta) &= \int p(y|x)p_0(x) \ln [q(x|y, \theta_{x|y})q(y|\theta_y)]dxdy \end{aligned} \tag{27}$$

When $y$ is a binary vector of many bits or a non-Gaussian real vector, Equation 27 must be computed either by an exhaustive enumeration or by Monte Carlo approximation, and both those are computationally very expensive. The well-known Helmholtz machine tackles this problem by using a parametric $p(y|x, \theta_{y|x})$ in Equation 20 to avoid the computation on $p(y|x)$, and then minimizes the Helmholtz energy in place of maximizing $Q(\theta)$.

As discussed in the initial work by Xu in 1995 (reference in Xu, 2002a), the BYY system together with implementing Equation 20 provides a unified perspective on understanding not only the above ML learning-related approaches but also a class of information-theoretic approaches. First, $\min_{p(y|x)} KL(\theta)$ in Equation 20 with a free Yang pathway $p(y|x)$ and the empirical density $p_0(x)$ will lead to Equation 27, as well as the equivalence of Equation 20 to ML learning on Equation 26. In other words, the above IDT-and IGT-based approaches are revisited from this new perspective. Second, given a parametric $p(y|x, \theta_{y|x})$, Equation 20 becomes equivalent to minimizing the Helmholtz energy, and a specific design of $p(y|x,$

$\theta_{y|x}$), $q(x|y, \theta_{x|y})$, $q(y|\theta_y)$ will lead us to revisit Helmholtz machine learning. Third, given a parametric $p(y|x, \theta_{y|x})$ but with $q(x|y, \theta_{x|y})$ free, Equation 20 becomes equivalent to minimizing

$$KL_y(\theta_{y|x}, \theta_y) = \int p(y|\theta_{y|x}) \ln \frac{p(y|\theta_{y|x})}{q(y|\theta_y)} dy$$
$$p(y|\theta_{y|x}) = \int p(y|x, \theta_{y|x}) p_0(x) dx \qquad (28)$$

which consists of a class of information-theoretic approaches, including both the minimum mutual information approach and the INFOMAX approach for Independent Component Analysis (q.v.).

Moreover, BYY harmony learning goes beyond the approaches discussed above. First, in addition to using Equation 20 for parameter learning, the second step in the two-step implementation of BYY harmony learning provides model selection via a new class of criteria given by Equation 19, sharing a feature similar to the MML/MDL/AC and Bayeisian approaches. Second, the parallel implementation of BYY harmony learning as discussed for Equation 18 provides an easily implementable approach for model selection that is made automatically during parameter learning. Third, the architecture of the BYY system and the term $-\ln z_q^{-1}$ in the harmony function provide new regularization techniques from a systematic perspective. In contrast, learning parameters via minimizing the Kullback divergence is the sole target of the approaches discussed above, while the issues of regularization and model selection are outside the scope of their studies. Even focusing on parameter learning via minimizing Kullback divergence alone, the studies are made from different perspectives with different purposes.
